MINUTES OF THE 48th GENERAL ASSEMBLY OF THE EUROPEAN ASSOCIATION FOR THE STUDY OF DIABETES

held in Berlin Messe, Germany, Thursday 4 October 2012 at 18:00

Present:	**Dr. Andrew J.M. Boulton**	**(President)**
	Dr. Fatima Bosch	**(Vice President)**
	Dr. Michael Roden	**(Honorary Treasurer)**
	Dr. Mark Walker	**(Honorary Secretary)**
	Dr. Cees J. Tack	**(Chair, PGEC)**
	Dr.Viktor Jörgens	**(Executive Director)**
	Dr. Monika Grüsser	**(Vice Director)**
	and 49 members	

The President, Dr. Boulton, welcomed everyone to the 48th General Assembly. He asked those present to stand in memory of the following members, who had passed away: Drs. Angelika Bierhaus, Artur Czyzyk, Keith Taylor and Ulrich Vischer.

1. MINUTES 47th GENERAL ASSEMBLY 2011

Since there were no comments, the minutes were approved unanimously and officially signed as a correct record.

2. REPORTS

a) President

The President's report to the members on the activities of EASD was given in the President's Address before the Minkowski Lecture. It is available under:
http://www.easdvirtualmeeting.org/resources/2694

The President reported on the various activities and expressed his thanks to all partners. Dr. Boulton reported that as expected the EASD Annual Meeting this year in Berlin was doing very well and the number of delegates attending had slightly increased. Dr. Boulton thanked all members of the EASD Office and the Executive Committee for their commitment and hard work.

b) Honorary Treasurer

Dr. Roden reported that the income from membership fees had decreased in 2011 and income from registration fees had increased slightly. There was a decrease in donations which was due to the fact that Merck had paid for two Final Programmes (2009 and 2010) in the year 2010. In 2011 only the Final Programme for 2011 was paid for. Donations for courses increased substantially. The total income of the Association was in the same frame as in 2010.

Regarding expenditure, Dr. Roden reported that Travel/ Meeting Expenses included expenses for more than one Meeting. EASD transferred more than 3 million Euro to the Foundation.

Dr. Roden summed up by saying the accounts of EASD remained healthy.

c) Honorary Auditors

The President asked the Honorary Auditor, Dr. Peter Diem for his report. Dr. Diem confirmed that the accounts had been checked carefully by Dr. Luis Gardete-Correia and were in perfect order. Dr. Boulton asked for the vote to accept the accounts.

The Honorary Treasurer was unanimously discharged (38 votes for and 1 abstention).

d) Honorary Secretary

Dr. Walker reported that the Programme Committee for 2013 had been appointed and had met during the Annual Meeting in Berlin. He stated that 2307 abstracts had been received in 2012. The main countries submitting abstracts are the United States, Germany and Japan. He explained that the questionnaire to rate the 47th AM in Lisbon had produced mostly positive feedback, with 15% of those taking part giving a top score of 5 for venue facilities, scientific programme, prize lectures and EASD symposia. The Rising Star Symposia continue to identify promising and innovative young researchers in Europe. He brought his report to a conclusion by mentioning that he was working closely with the EASD Study Groups to develop ideas for future symposia.

Dr. Walker closed his report by thanking all those who had forwarded ideas for the scientific programme and all members of the EASD staff, in particular Ms. H. Goliberzuch and Mrs. M. Toledo, for their outstanding help and support with the organisation of the EASD Annual Meetings.

Dr. Boulton thanked Dr. Walker for his diligence and asked if there were any questions. There were no further comments.

e) Editor-in-Chief, Diabetologia

In the absence of Dr. Juleen Zierath, Editor-in-Chief, Diabetologia, the President reported the following information:
In total, 2,047 articles were submitted to Diabetologia in 2011, compared with 1,971 in 2010. The proportion of papers triaged had increased to 55%. Such a high level of triage was essential given the increased number of submissions. The Impact Factor fell very slightly from 6.973 in 2010 to 6.814 in 2011. He reported that the initiative 'Then and Now', in which historical articles were highlighted to determine what impact they had on the present day, was proving very successful. Another project, 'Up front', which included 5 short articles (access free of charge) of particular interest chosen by the Editor, was started in 2012. He stated that a panel to advise on cases of scientific misconduct had been convened.

Dr. Boulton expressed his thanks to Dr. Zierath in her absence for her co-operation and hard work. Thanks were also expressed to the team in Bristol, especially to Dr. Judy Naylor, and the outgoing associate editors.

f) Chair, Postgraduate Education Committee

Dr. Tack reported on the courses that had taken place in 2011 and early 2012: Baku/Azerbaijan, Jena/Germany, Kiev/Ukraine, Wroclaw/Poland and Kaunas/Lithuania. He added that all courses in 2011 had been very successful and had attracted delegates from many of the countries neighbouring the one where the course was held. Dr. Tack said courses were being planned in Almaty/Kazakhstan in October 2012 and in Lviv/Ukraine in April 2013.

Dr. Tack stated that with an unrestricted educational grant from Lilly EASD would produce a series of educational films aimed at a wider and less focussed audience than the previous series of lectures.

Dr. Boulton thanked Dr. Tack for his co-operation and hard work.

g) Chair, Extra-European Postgraduate Activities

Dr. Czupryniak reported on the joint postgraduate courses with ADA and IDF: Addis Ababa/Ethiopia in November 2011 and Spier/South Africa in August 2012. He stated that the 8th EASD/ADA/IDF course would be held in Sri Lanka in November 2013. He continued to report that the 5th EASD/CDS/Lilly Course had been held in Beijing in May 2012 and that the 6th was already being planned. He added that an agreement had been signed with the Chinese medical education company EMD to organise a series of webcast lectures to be delivered every two months to up to ten hospitals in Southern China and to arrange for one regular conference with EASD experts taking part. He explained that a three-year (2012-2014) partnership with the Gulf Group for the Study of Diabetes had been agreed on. The first course will take place in November 2012. He stated that future plans included another Best of EASD India course and he stated that negotiations were already underway with a new sponsor.

Dr. Czupryniak brought his report to an end by thanking Dr. Boulton for his support and the EASD team for their help in organising the courses.

Dr. Boulton thanked Dr. Czupryniak for his co-operation and hard work.

3. ELECTIONS

Vice President (2012 – 2015)
The election of Dr. Bernard Thorens was unanimously approved with 42 votes.

Council Members (2013 - 2016)
The election of Drs. Amanda Adler, Hans Hauner, Valeriya Lyssenko, Vilma Urbancic-Rovan
was unanimously approved with 42 votes each.

4. STUDY GROUPS

i) Metabolic imaging – proposal from Dr. Roden
The General Assembly was informed of the decision by the Executive Committee and Council to endorse the initiation of this EASD Study Group.
ii) Diabetes and Cancer – proposal from Dr. Andrew Renehan
The General Assembly was informed of the decision by the Executive Committee and Council to endorse the initiation of this EASD Study Group.
iii) NAFLD – proposal from Dr. Amalia Gastaldelli
The General Assembly was informed of the decision by the Executive Committee and Council to endorse the initiation of this EASD Study Group.

5. HONORARY MEMBERSHIP

The nomination of Drs. Peter Bennett, Johnny Ludvigsson and Isabel Valverde was unanimously approved. Dr. Boulton thanked them for their outstanding contribution to diabetes research.

6. ANY OTHER BUSINESS

A request was made for a reduced registration fee for senior EASD members. Dr. Boulton said this would be discussed at the next Executive Committee meeting in January 2013.

The President thanked Dr. Bosch, retiring Vice President, for her friendly collaboration and diligence during her term of office. He also expressed his sincere gratitude to the Local Organising Committee for their outstanding contribution to the organisation of the 48th EASD Annual Meeting. He warmly thanked Dr. Jörgens, Dr. Grüsser and the EASD team in Düsseldorf for their dedicated work.

Dr. Boulton brought the General Assembly to a close at 18:50.

Agenda for the 49th General Assembly of the European Association for the Study of Diabetes

to be held in the Pi i Sunyer Hall, Fira de Barcelona, Barcelona, Spain on Thursday 26 September, 2013 at 18:00

1. Minutes of the 48th General Assembly, Berlin, Germany 2012

2. Reports

a) President	A.J.M. Boulton
b) Honorary Treasurer	M. Roden
c) Honorary Auditors	P. Diem
	L. M. Gardete-Correia
d) Honorary Secretary	M. Walker
e) Editor-in-Chief, Diabetologia	J. Zierath
f) Chair, Postgraduate Education Committee	C. Tack
g) Chair, Extra-European Postgraduate Activities and Secretary PGEC	L. Czupryniak

3. Elections

To be nominated for retiring member(s):

a) Honorary Secretary 2013-2016	Mark Walker
b) Editor-in Chief, Diabetologia 2013-2015	Juleen Zierath
c) Chair, PGEC 2013-2016	Cornelis (Cees) Tack
d) Chair, Extra-European PGEC 2013-2016	Leszek Czupryniak
e) Council Members 2014-2017	Kare Birkeland
	Jonathan Bodansky
	Claire Levy-Marchal
	Peter Nawroth

4. Study Groups

5. Honorary Membership

6. Any other business

49th EASD Annual Meeting of the European Association for the Study of Diabetes

Barcelona, Spain, 23 – 27 September 2013

Abstracts

Index of Oral Presentations

Index of Poster Sessions

PS 029 Quantification of beta cell mass
PS 030 Beta cell mass expansion and survival
PS 031 ER stress and apoptosis
PS 032 Islet cell toxicity and survival
PS 033 Experimental immunology
PS 034 Clinical immunology
PS 035 Islet transplantation
PS 036 Insulin is not the only islet player
PS 037 Clinical hypoglycaemia
PS 038 Hypoglycaemia mechanism and prevention
PS 039 Insulin resistance improvement
PS 040 Muscle metabolism
PS 041 Insulin resistance biomarkers
PS 042 Weight loss and caloric modulation
PS 043 Beta cell function in man
PS 044 Incretins: secretions and action
PS 045 Insulin secretion and action: using animal models
PS 046 Gut and gut hormones
PS 047 Exercise: physiology and clinical benefits
PS 048 Liver metabolism
PS 049 Mitochondria, ROS and metabolism
PS 050 Gender: difference and sex hormones in metabolism
PS 051 Bariatric surgery
PS 052 Brain metabolism
PS 053 Inflammation in obesity and type 2 diabetes
PS 054 Fatty acids and triglyceride storage: impact on inflammation and glucose metabolism
PS 055 Exercise, muscle and lipid metabolism
PS 056 Adipose tissue: expandability
PS 057 Autophagy, endoplasmic reticulum and oxidative stresses
PS 058 Adipose tissue distribution
PS 059 Cancer and metabolism
PS 060 Fatty liver: human studies
PS 061 Fatty liver: rodent studies
PS 062 Signalling in adipocyte metabolism
PS 063 Lipoproteins
PS 064 Adipokines and secreted proteins in obesity and diabetes
PS 065 Myeloid cells and type 2 diabetes
PS 066 Nutrition and weight loss
PS 067 Preventing and treating diabetes: the nutrition impact
PS 068 Mechanistic insights: GLP-1-based medications and GPR40 agonists
PS 069 Incretin-based drugs: predictors of clinical outcomes
PS 070 Incretin-based drugs: treatment strategies
PS 071 Incretin-based drugs: potential risk and use in special populations
PS 072 Incretin-based agents: assessing the risk-benefit ratio
PS 073 SGLT-2 clinical trials
PS 074 SGLT-2 inhibitors: influence on cardiovascular risk factors
PS 075 SGLT-2 inhibitors: side effects, special populations
PS 076 Metformin: old agent - novel perspectives
PS 077 Oral antidiabetic agents
PS 078 Effects of glucose-lowering therapy on cardiovascular risks
PS 079 Novel approaches to treat type 1 and type 2 diabetes
PS 080 Novel agents: novel mechanisms
PS 081 Innovative treatments of type 2 diabetes
PS 082 Treatment intensification in type 2 diabetes
PS 083 Novel insulin preparations: pharmakinetics and pharmacodynamics
PS 084 Insulin therapies: basal and novel combination
PS 085 Hypoglycaemia in type 1 and type 2 diabetes
PS 086 Insulin adjustment and self-management
PS 087 Diabetes self care and adherence
PS 088 Self blood glucose monitoring: utility and metrics
PS 089 New devices for glucose monitoring and insulin delivery
PS 090 Closed looPS and CGMS
PS 091 Insulin pumPS in clinical practice
PS 092 Delivering diabetes care
PS 093 Type 1 diabetes education
PS 094 Education and motivation in type 2 diabetes
PS 095 Psychosocial aspects of diabetes
PS 096 Good news for depression in diabetes?
PS 097 Health economics: living better? at what cost?
PS 098 Inflammation and immunity: links to clinical practice
PS 099 Nephropathy: epidemiology and clinical correlates
PS 100 Nephropathy: clinical risk factors, markers and outcomes
PS 101 Nephropathy basic science: from profiling to targets
PS 102 Hypertension: from experimental evidence to bedside
PS 103 Basic science retinopathy: novel in vitro and in vivo findings
PS 104 Clinical retinopathy
PS 105 Autonomic neuropathy
PS 106 Neuropathy I: correlates and treatments
PS 107 Neuropathy II: large fibres, small fibres, peripheral and central
PS 108 Diabetic foot: epidemiology, risk factors and outcomes
PS 109 Pregnancy: treatment, efficacy and safety
PS 110 Pregnancy outcomes in GDM
PS 111 Pregnancy - GDM: risk factors and delivery outcomes
PS 112 Pregnancy in diabetes
PS 113 Mechanisms of vascular disease
PS 114 Sleep apnoea, cognitive function and musculoskeletal complications
PS 115 Other diabetic complications
PS 116 Cerebrovascular and peripheral artery disease
PS 117 Risk factors for cardiovascular disease
PS 118 Non-invasive characterisation of cardiovascular disease
PS 119 Diabetes in childhood

OP 01 Individualising the choice among GLP-1 receptor agonists

1

Glycaemic control and hypoglycaemia in metformin-treated T2DM patients with exenatide BID vs insulin lispro TID added to titrated insulin glargine QD: the 4B trial

B.H.R. Wolffenbuttel[1], M.A. Nauck[2], R. Shaginian[3], J. Malone[4], S. Cleall[5], D. de Vries[3], B. Hoogwerf[3], L. MacConell[6], M. Diamant[7];
[1]Univ of Groningen, Netherlands, [2]Diabeteszentrum Bad Lauterberg, Germany, [3]Eli Lilly & Co, Netherlands, [4]Eli Lilly & Co, Indianapolis, USA, [5]Eli Lilly & Co, Windlesham, UK, [6]Bristol-Myers Squibb, San Diego, USA, [7]VU University Medical Center, Amsterdam, Netherlands.

Background and aims: Addition of prandial to basal insulin is the current strategy when HbA_{1c} remains elevated in pts with T2DM, but is accompanied by weight gain and increased episodes of hypoglycaemia (hypo). Exenatide twice daily (BID), administered with the largest meals of the day, may improve glycaemic control with a lower risk of hypo than prandial insulin. The 4B Trial prospectively compared glycaemic control of Basal insulin glargine (IG) + Exenatide BID Treatment (BET) to Basal IG + Bolus insulin lispro (IL) 3 times daily (TID) Treatment (BBT) in patients (pts) with uncontrolled hyperglycaemia after 12 wks of intensified IG.
Materials and methods: After a 2-wk screening period and 12-wk basal insulin optimization (BIO) phase to titrate IG dose (INITIATE algorithm) to achieve the lowest possible FBG (target 5.6 mmol/L) without hypo, pts unable to achieve HbA_{1c} ≤7% (53 mmol/mol) enrolled in the 30-wk intervention phase comparing BET to BBT. The BET regimen: titrated Basal IG at bedtime plus Exenatide Treatment 5 mcg BID for 4 wks followed by 10 mcg BID. The BBT regimen: titrated Basal IG at bedtime plus Bolus IL Treatment TID titrated based on 4-point self-monitored blood glucose (SMBG) according to a protocol-specified titration rule (pre-meal glucose of <6.1 mmol/L with no hypo). Primary outcome was non-inferiority of ΔHbA_{1c} for BET vs BBT from baseline to 30 wks in the per protocol population (PP). Secondary outcomes compared the BBT and BET regimens on FG, PPG from SMBG profiles, weight, insulin dose, and hypo in the PP population.
Results: 1036 pts were screened and 917 pts (mean: age 60 y, BMI 32 kg/m^2, T2DM duration 12.6 y, HbA_{1c} 8.5% (69 mmol/mol), serum FG 8.3 mmol/L, IG dose 0.45 IU/kg/d, metformin dose 1993 mg/d) entered the BIO phase. 637 pts had $HbA1_c$ >7% (53 mmol/mol) and were randomised 1:1 to BET (n=316, PP n=247) or BBT (n=321, PP n=263) for 30 wk. HbA_{1c} reduction with BET was non-inferior to BBT for mean change in HbA_{1c} from randomisation to wk 30. LS mean HbA_{1c} decreases at wk 30 were similar in both groups. BET was associated with significant weight reduction, -2.4±0.3 kg, compared to BBT, +2.1±0.2 kg (BET vs BBT tx difference -4.6 kg [95% CI, -5.2 to -3.9], *P*<.0001). IL dose at 30 wks in BBT was 0.5±0.4 IU/kg/d. More gastrointestinal events (which were transient) were noted for BET vs BBT: nausea (32% vs 2%), vomiting (12% vs 1%), and diarrhoea (11% vs 5%). BET pts experienced less hypo overall compared to BBT pts except for nocturnal events (events/100-y: minor: 206 vs 522; major: 2 vs 7; non-nocturnal: 64 vs 350; nocturnal: 144 vs 178).
Conclusion: In this 44-wk study, the 4B Trial results support BET as an alternative to BBT in pts with T2DM not at target after intensified basal IG.

Measure	BET	BBT	BET vs BBT	95% CI
IG at randomisation (IU/kg/d)	0.7 (0.3)	0.7 (0.3)	--	--
IG at 30 wk	0.6 (0.3)	0.6 (0.3)	--	--
HbA_{1c} at randomisation (%)	8.3 (1.0)	8.2 (0.9)	--	--
HbA_{1c} at 30 wk	7.2 (0.9)	7.1 (0.8)	0.03 (0.07)	-0.11, 0.18
ΔHbA_{1c}	-1.1 (0.05)[a]	-1.1 (0.05)[a]	-0.04 (0.07)[a]	-0.18, 0.11
FG at randomisation (mmol/L)	7.1 (2.3)	7.0 (2.5)	--	--
FG at 30 wk	6.5 (2.0)	7.2 (2.8)	--	--
Δ FG	-0.46 (0.16)[a]	0.18 (0.15)[a]	-0.64 (0.20)**	-1.05, -0.24
Δ PPG (mmol/L)				
Δ Morning 2h post-meal[b]	-2.6 (0.14)[a]	-2.3 (0.14)[a]	-0.27 (0.18)[a]	-0.63, 0.09
Δ Midday 2h post-meal[b]	-2.2 (0.16)[a]	-3.1 (0.16)[a]	0.93 (0.21)***	0.52, 1.34
Δ Evening 2h post-meal[b]	-2.9 (0.17)[a]	-3.2 (0.17)[a]	0.28 (0.22)[a]	-0.16, 0.72

Values are mean (SD) except as indicated. Shaded: LS mean Δ by MMRM. [a](SE) *P = .002 for BET vs BBT; **P< .0001 for BET vs BBT. [b]From SMBG profiles. Endpoint data is 30 wk, PP.

Clinical Trial Registration Number: NCT00960661
Supported by: Eli Lilly, Amylin Pharmaceuticals

Sustaining HbA_{1c} control over three years during treatment with exenatide once weekly compared with insulin glargine

J. Malloy[1], B. Guerci[2], M. Trautmann[3], W. Huang[1], J. Han[1], M. Diamant[4];
[1]Bristol-Myers Squibb, San Diego, USA, [2]Hopital Brabois, Nancy, France, [3]Internist/Diabetology, Hamburg, Germany, [4]VU University Medical Centre, Amsterdam, Netherlands.

Background and aims: The DURATION 3 study was an open-label, randomised, controlled trial of patients with T2DM comparing the once-weekly fixed-dose formulation of the GLP-1 receptor agonist exenatide (EQW) with titrated insulin glargine (IG) over 3 years. Sustained glucose control is difficult to achieve due to the progressive deterioration of insulin secretion over time requiring therapy escalation. These additional analyses assessed the comparative abilities of EQW vs IG to sustain HbA_{1c} control as defined below.
Materials and methods: Patients were followed through a 26-week core study with an option to continue treatment up to 156 weeks. Dosage for the IG group was determined by the Initiate Insulin by Aggressive Titration and Education (INITIATE) algorithm. HbA_{1c} control was defined as achieving and maintaining an HbA_{1c} ≤7% (53 mmol/mol) after 26 weeks of treatment. Loss of, or failure to achieve, HbA_{1c} control was defined as an HbA_{1c} >7% at two consecutive visits (10 to 12 weeks apart) or an HbA_{1c} >9% at one visit after 26 weeks of treatment.
Results: The intent-to-treat (ITT) population comprised 233 EQW and 223 IG patients. Baseline characteristics (EQW vs IG) included mean age (57 vs 58 years), % male (52 vs 55), mean duration of diabetes (both 8 years), and mean HbA_{1c} (both 8.3%). Within both treatment groups 70% of patients were taking metformin (MET) alone and 30% were taking MET and a sulfonylurea. Mean daily insulin dose increased from baseline 10 IU to 31 IU at Week 26 and 39 IU at Year 3. Of the enrolled participants, 140 EQW and 147 IG patients completed 3 years in their original treatment groups. Within the ITT population, a greater percentage of EQW patients achieved and sustained HbA_{1c} control until last visit (50%) compared with IG patients (43%). Similarly, a higher percentage of EQW 3-year completers (43%) demonstrated HbA_{1c} control through 3 years compared with IG patients (33%). EQW ITT patients had a longer period of HbA_{1c} control. The median time of control was 25.0 months for EQW patients and 16.7 months for IG patients (Kaplan-Meier estimates *P*=0.03 from Wilcoxon test). The ITT population hazard ratio of failure in control over 3 years was 1.4 (IG/EQW, *P*=0.006 from Cox proportional hazard model). Among ITT patients with HbA_{1c} control until last visit the following results were observed. Greater HbA1c reduction was observed in EQW (LS mean = -1.32%) compared with IG (-1.17%; 95% CI difference = -0.34, 0.04, *P*=0.12). EQW patients exhibited less reduction (LS mean = -2.28 mmol/l) in fasting serum glucose compared with IG patients (-3.07; 95% CI difference = 0.03, 1.54, *P*=0.04) and greater weight loss than IG patients (LS mean = -3.44 kg vs +0.70, respectively (95% CI difference = -5.71, -2.56, *P*<.0001). EQW patients demonstrated less hypoglycaemia (event rate per year 1.1) than IG (3.1). EQW patients reported greater nausea and diarrhoea than IG patients with EQW patients reporting 18% nausea and 15% diarrhoea and IG patients reporting 2% nausea and 4% diarrhoea.
Conclusion: Throughout the 3-year trial of EQW vs IG a greater number of EQW patients achieved and sustained HbA_{1c} control with greater weight reduction and less hypoglycaemia compared with IG patients, despite continued insulin up titration.
Clinical Trial Registration Number: NCT00641056

3

Positive effects of liraglutide as adjunct to insulin in type 1 diabetes: glycaemic control and safety in a randomised, double blind, placebo controlled crossover trial

S.R. Heller[1], S. Korsatko[2], J. Gurban[3], L. Jensen[4], E. Christiansen[4], F. Kiyomi[5], T.R. Pieber[3];
[1]Endocrinology, University of Sheffield Medical School, UK, [2]Medicine, Medical University of Graz, Austria, [3]Endocrinology, Medical University of Graz, Austria, [4]Novo Nordisk A/S, Søborg, Denmark, [5]Novo Nordisk Pharma Ltd, Tokyo, Japan.

Background and aims: Treatment with a GLP-1 analogue as adjunct to insulin may positively impact glycaemic control and other parameters in type 1 diabetes (T1D). In a placebo controlled trial investigating effects of liraglutide as adjunct to insulin on counter regulatory hormone responses to hypogly-

caemia, we also assessed short term effects on glycaemic control, body weight (BW), hypoglycaemia and overall safety.
Materials and methods: 45 adults with T1D were allocated to 1 of 3 dose groups of liraglutide (0.6, 1.2 and 1.8 mg/day) and placebo as add on to insulin for 4 weeks in a crossover design with a washout period of 2 to 3 weeks. Starting dose of liraglutide was 0.6 mg/day, with weekly dose escalation of 0.6 mg until target dose was reached. Subjects received target dose for a minimum of 2 weeks. Daily insulin dose, change in HbA_{1c} and mean 9 point self measured plasma glucose (SMPG) were measured for the efficacy assessment. Number of hypoglycaemic episodes, adverse events (AEs), vital signs (pulse, blood pressure [BP]) and BW were measured for the safety assessment.
Results: Baseline characteristics were similar between groups: age 34.5±11.2 years, BW 74.1±11.4 kg, BMI 23.9±2.4 kg/m^2, HbA_{1c} 7.6±0.8%, T1D duration 16.6±9.4 years [mean±SD]. There was no difference in daily insulin dose at baseline between groups. At end of treatment, liraglutide at 1.2 and 1.8 mg significantly lowered daily insulin dose (by 27% for 1.2 mg vs placebo and 24% for 1.8 mg vs placebo). No systematic differences in mean SMPG 9 point profile or change in HbA_{1c} were observed. Frequency of hypoglycaemic events was unaffected; no severe events were reported. A small increase in pulse was seen with liraglutide treatment compared to placebo; however this was not statistically significant. No significant treatment differences in systolic and diastolic BP were seen. No AEs were reported as serious. As expected, gastrointestinal (GI) AEs were more frequent with liraglutide, with nausea the main contributor, and few cases of diarrhoea, vomiting or other; no cases were reported as severe. 1 withdrawal (of 3) was due to a treatment related AE (vomiting). Liraglutide induced weight loss of up to 3.3 kg, which was not considered a safety issue.
Conclusion: This trial supports a pharmacological effect of liraglutide in T1D that may contribute to glycaemic control. Besides the known GI side effects, no liraglutide related safety or tolerability issues were identified in this short term trial in T1D. The observed weight loss is of potential clinical benefit. Long term controlled trials are needed to establish the overall clinical benefit of liraglutide and its potential utility in the treatment of T1D.

	Liraglutide 0.6 mg / placebo	ETD or R [95% CI] p-value	Liraglutide 1.2 mg / placebo	ETD [95% CI] p-value	Liraglutide 1.8 mg / placebo	ETD [95% CI] p-value

Efficacy and safety of dulaglutide vs metformin in type 2 diabetes (AWARD-3)

S. Tofé Povedano[1], G. Umpierrez[2], F. Perez Manghi[3], L. Shurzinske[4], V. Pechtner[5];
[1]Endocrinologia, Clinica Juaneda, Palma de Mallorca, Spain, [2]Division of Endocrinology, Emory University School of Medicine, Atlanta, USA, [3]Centro de Investigaciones Metabólicas (CINME), Buenos Aires, Argentina, [4]Eli Lilly and Company, Indianapolis, USA, [5]Eli Lilly and Company, Neuilly sur Seine, France.

Background and aims: This Phase 3, randomised, double-blind, parallel-arm, monotherapy study compared the efficacy and safety of 2 doses of dulaglutide (DU), a long-acting glucagon-like peptide-1 (GLP-1) receptor agonist, to metformin (MET) in patients with early type 2 diabetes (mean 2.6 years) treated with diet and exercise alone or in combination with 1 oral antidiabetic medication (low dose for ≥3 months before screening).
Materials and methods: Patients (N=807; mean baseline [BL] age, 55.6 years; HbA_{1c}, 7.6%; weight, 92.3 kg) were randomised to once-weekly DU 1.5 or 0.75 mg or MET 1000 mg twice-daily. Primary hypothesis was DU 1.5 mg is noninferior to MET on HbA_{1c} change from BL to 26 weeks (wks). Key secondary hypotheses were DU 1.5 mg is superior to MET, and DU 0.75 mg is noninferior and/or superior to MET.
Results: Both DU doses were superior to MET at 26 wks and DU 1.5 mg was superior to MET at 52 wks as measured by HbA_{1c} change from BL. Incidence of serious adverse events was 5.2% for DU 1.5 mg, 7.4% for DU 0.75 mg, and 6.0% for MET. The rank order of incidence of gastrointestinal-related adverse events among groups was: DU 1.5 mg >MET >DU 0.75 mg. At 52 wks, documented symptomatic hypoglycaemia (≤3.9 mmol/L) incidence was 6.3%, 5.9%, and 4.9% for DU 1.5 mg, DU 0.75 mg, and MET, respectively (overall p=0.756).
Conclusion: In conclusion, both once-weekly DU doses at 26 wks and DU 1.5 mg at 52 wks demonstrated superior glycaemic control compared to MET and were well tolerated.

Summary of efficacy results at primary and final time points

Primary Time Point (26 Weeks, ITT, LOCF)	**DU 1.5 mg (n=269)**	**DU 0.75 mg (n=270)**	**MET 2000 mg (n=268)**
HbA_{1c} change (%), LS Mean (SE)	-0.78 (0.06)††	-0.71 (0.06)††	-0.56 (0.06)
% of patients with HbA_{1c} <7%	61.5#	62.6#	53.6
Weight change (kg), LS Mean (SE)	-2.29 (0.24)	-1.36 (0.24)#	-2.22 (0.24)
Final Time Point (52 Weeks, ITT, LOCF)			
HbA_{1c} change (%), LS Mean (SE)	-0.70 (0.07)††	-0.55 (0.07)†	-0.51 (0.07)
% of patients with HbA_{1c} <7%	60.0#	53.2	48.3
Weight change (kg), LS Mean (SE)	-1.93 (0.29)	-1.09 (0.29)#	-2.20 (0.29)

HARMONY 3: 104 week efficacy of albiglutide compared to sitagliptin and glimepiride in patients with type 2 diabetes mellitus on metformin

S. Johnson[1], B. Ahrén[2], M. Stewart[3], D. Cirkel[4], F. Yang[3], C. Perry[3];
[1]GlaxoSmithKline, Research Triangle Park, USA, [2]Lund University, Sweden, [3]GlaxoSmithKline, Upper Merion, USA, [4]GlaxoSmithKline, Stevenage, UK.

Background and aims: To evaluate the efficacy, tolerability, and safety of once-weekly albiglutide (Albi) compared to placebo (Pbo), sitagliptin (Sita), or glimepiride (Glim) in patients with type 2 diabetes mellitus who had inadequately controlled haemoglobin A_{1c} (HbA_{1c}: 7–10%) on metformin (Met).
Materials and methods: The 3-year trial was designed as a randomised, double-blind, Pbo- and active-controlled, Phase III study. Subjects taking stable Met were randomised to Albi (30 mg), Pbo, Sita (100 mg), or Glim (2 mg). Pa-

tients meeting predefined hyperglycaemia criteria qualified for blinded dose titration (Glim 2 to 4 mg; Albi 30 to 50 mg). Patients were allowed to continue in the study if rescue for persistent hyperglycaemic rescue was required. The primary objective was to evaluate HbA_{1c} change from baseline at Week 104, using an analysis of covariance model adjusting for baseline HbA_{1c},region, prior myocardial infarction history, and age.

Results: Baseline age was 54.5 years (mean, SD 10.0), BMI 32.6 kg/m^2 (5.5), weight 90.7 kg (19.3), HbA_{1c} 8.1% (0.8), duration of diabetes 6.0 years (4.8). A reduction in HbA_{1c} was seen in all active treatment groups. For the change in HbA_{1c}, Albi was statistically superior compared to Pbo (−0.91%; 95% CI: −1.16, −0.65, p <0.0001), Sita (−0.35%; 95% CI: −0.53, −0.17, p = 0.0001), and Glim (−0.27%; 95% CI: −0.45, −0.09, p = 0.0033). Albi had superior reduction in fasting plasma glucose (FPG) (mmol/l) compared to Pbo (−1.53; 95% CI: −2.16, −0.90 p <0.0001), Sita (−0.86; 95% CI −1.30, −0.41, p = 0.0002) and Glim (−0.56; 95% CI −1.01, −0.12, p = 0.0133). All treatment groups (except for Glim) had modest mean weight loss at 104 weeks (Pbo: −1.00 kg, Sita: −0.86 kg, Glim: 1.17 kg, Albi: −1.21 kg). Weight change (kg) compared to Albi was similar for Pbo (−0.2; 95% CI −1.14, 0.73, p = 0.7) and Sita (−0.4; 95% CI −1.01, 0.31, p = 0.3). Albi weight loss was superior to Glim (−2.4 kg; 95% CI −3.03, −1.71, p <0.0001). Gastrointestinal adverse events through Week 104 with Pbo/Sita/Glim/Albi were nausea, 11%/7%/6%/10%; diarrhoea, 11%/9%/9%/13%; and vomiting, 1%/4%/4%/6%. Injection site reactions occurred in 5% of patients randomised to Pbo, 6% for Sita, 8% for Glim, and 17% for Albi. The incidence of pre-rescue documented (≤3.9 mmol/l) symptomatic hypoglycaemia events was 4% for Pbo, 2% for Sita, 18% for Glim, and 3% for Albi; no severe hypoglycaemia events were reported.

Conclusion: Albiglutide treatment for type 2 diabetes mellitus as add on to Met therapy was durable and superior to Sita and Glim in HbA_{1c} and FPG reduction, superior in weight loss to Glim, and well tolerated up to Week 104.

Therapeutic efficacy of lixisenatide added to basal insulin is greater when FPG is well-controlled

J. Vidal[1], R. Aronson[2], F. Giorgino[3], M. Fisher[4], P. Miossec[5], W. Stager[6], D. Raccah[7], L.E. Litwak[8], M. Riddle[9];
[1]Endocrinology and Nutrition, University of Barcelona, Spain, [2]LMC Diabetes & Endocrinology, Toronto, Canada, [3]University of Bari, Italy, [4]Glasgow Royal Infirmary, UK, [5]Sanofi-Aventis, Paris, France, [6]Sanofi-Aventis, Bridgeport, USA, [7]University Hospital Sainte-Marguerite, Marseille, France, [8]Servicio de Endocrinología, Hospital Italiano, Buenos Aires, Argentina, [9]Oregon Health & Science University, Portland, USA.

Background and aims: Lixisenatide is a novel once-daily prandial glucagon-like peptide-1 receptor agonist recently approved in Europe for treatment of type 2 diabetes (T2DM) in adults. In the GetGoal-L study, treatment with lixisenatide added to stable basal insulin caused significant reductions in HbA_{1c} levels, postprandial glucose, and body weight compared with placebo. The present *post hoc* analysis of data from this study examined whether the fasting plasma glucose (FPG) level at baseline was related to the ability of added lixisenatide to control hyperglycaemia.

Materials and methods: GetGoal-L was a double-blind, placebo-controlled study with a mean treatment period of 24 weeks, in which 496 patients with T2DM and inadequate glucose control on a stable dose of basal insulin ± metformin were randomised to lixisenatide 20 µg once daily or placebo. The current analysis was based on patients who were included in the HbA_{1c} change from baseline analysis at Week 24. Patients were subdivided according to baseline levels of FPG as group 1 (G1): FPG ≤6.7 mmol/L (120 mg/dL); group 2 (G2): FPG >6.7 to ≤ 8.9 mmol/L (160 mg/dL); and group 3 (G3): FPG >8.9 mmol/L. Efficacy parameters included HbA_{1c}, weight, 7-point self-measured blood glucose (SMBG) profiles and basal insulin dose.

Results: Clinical characteristics at baseline were similar between lixisenatide and placebo within each group. Mean duration of diabetes (years) with lixisenatide vs placebo was, respectively, G1=13.9 vs 14.8, G2=11.6 vs 11.8 and G3=12.1 vs 10.8. Mean duration of basal insulin treatment (years) with lixisenatide vs placebo was, respectively, G1=4.0 vs. 4.4; G2=2.4 vs 2.8 and G3=2.7 vs 2.5 years. Mean BMI (kg/m^2) in the lixisenatide group vs placebo was, respectively, G1=31.5 vs 31.8; G2=32.1 vs 33.0 and G3=32.6 vs 32.8. Mean HbA_{1c} (%) for lixisenatide vs placebo was G1=8.1 vs 8.1, G2=8.4 vs 8.4 and G3=8.7 vs 8.7. Adding lixisenatide reduced HbA_{1c}, weight, and SMBG post-breakfast in all subgroups, but participants with baseline FPG <6.7 mmol/L showed greater placebo-adjusted reductions than those in the two other groups (Figure 1). The placebo-corrected mean dose change in basal insulin (± standard error) from baseline to endpoint was G1=-4.8 (2.5), G2=-6.0 (2.5) and G3=-0.7 (2.6), respectively.

Conclusion: Adding lixisenatide to basal insulin improved glycaemic control and the effect was most pronounced in patients with controlled FPG. These findings are consistent with lixisenatide's known effect on prandial glycaemic control.

Risk factors for stroke and subtypes of stroke in patients with type 1 diabetes

S. Hägg[1,2], L.M. Thorn[1,2], C.M. Forsblom[1,2], D. Gordin[1,2], M. Saraheimo[1,2], J. Wadén[1,2], R. Liebkind[3], J. Putaala[3], T. Tatlisumak[3], P.-H. Groop[1,2], FinnDiane Study Group;
[1]Folkhälsan Institute of Genetics, Folkhälsan Research Center, Biomedicum, Helsinki, [2]Division of Nephrology, Department of Medicine, Helsinki University Central Hospital, [3]Department of Neurology, Helsinki University Central Hospital, Finland.

Background and aims: Type 1 diabetes is associated with a markedly increased risk of stroke. Risk factors for stroke and different subtypes of stroke in type 1 diabetes are, however, poorly studied. Thus, the aim was to determine the risk factors for stroke and its subtypes cerebral infarction, lacunar infarction, and cerebral hemorrhage in a large study population of patients with type 1 diabetes.
Materials and methods: A total of 4,083 patients with type 1 diabetes from the nationwide multicenter FinnDiane (Finnish Diabetic Nephropathy) Study, without a history of stroke at baseline, and available follow-up data on stroke were included. Strokes during follow-up were identified from FinnDiane follow-up visit questionnaires, medical files, death certificates, and national hospital discharge records. All strokes were classified by stroke neurologists based on medical files and brain imaging. At baseline, mean age of the patients was 37.4 ± 11.8 years, duration of diabetes 21.3 ± 12.1 years, 51% were males, 20% had diabetic nephropathy (DN), 32% had severe diabetic retinopathy (SDR), 46% had a history of smoking, and 36% had anti-hypertensive treatment (AHT). Cox proportional hazards analyses with forward stepwise variable entry and removal were performed in order to determine the risk factors for the different end-points.
Results: During 9.0 ± 2.7 years (36,680 person-years) of follow-up, 149 (3.6%) patients suffered an incident stroke. The independent risk factors for all strokes, cerebral infarction, lacunar infarction, and cerebral hemorrhage are presented in the table below. Sex, age at onset of diabetes, insulin dose per kg body weight, coronary heart disease, current smoking, diastolic blood pressure, waist circumference, high sensitive C-reactive protein, LDL-cholesterol, HDL-cholesterol, triglycerides, and anticoagulative medication were not independent risk factors for any of the end-points studied.
Conclusion: In this largest study so far on risk factors for stroke in type 1 diabetes, we were able to show that in patients with type 1 diabetes, the microvascular diabetic complications, as well as poor glycemic control and insulin resistance, are associated with an increased risk for stroke. The traditional risk factors for stroke (smoking, hypertension, and age/duration of diabetes) were also risk factors in type 1 diabetes. For the different subtypes of stroke, the risk factors were similar, except lower BMI that was associated with an increased risk of cerebral hemorrhage.

ProBNP strongly predicts future macrovascular events independently from the baseline coronary artery disease state in patients with and without type 2 diabetes

C.H. Saely[1,2], P. Rein[1], A. Vonbank[1,2], H. Drexel[1,3];
[1]Academic Teaching Hospital Feldkirch, Austria, [2]Private University of the Principality of Liechtenstein, Triesen, Liechtenstein, [3]Drexel University College of Medicine, Philadelphia, USA.

Background and aims: The power of pro-B-type natriuretic peptide (proBNP) to predict cardiovascular events is unclear, in particular in patients with type 2 diabetes (T2DM).
Materials and methods: We therefore aimed at investigating whether proBNP predicts major cardiovascular events in patients with T2DM as well as in subjects without diabetes in a large cohort of patients characterized by coronary angiography at baseline. We prospectively recorded major cardiovascular events in a cohort of 718 consecutive patients undergoing coronary angiography for the evaluation of established or suspected stable CAD over 3.2±1.2 years.
Results: Overall, the incidence of cardiovascular events was higher among patients with T2DM than among subjects who did not have diabetes. Cardiovascular risk increased significantly over tertiles of proBNP both among patients with diabetes (6.3%, 24.1%, and 32.4%,; p = 0.004) and among non-diabetic subjects (11.5%, 11.4%, and 21.1%; p = 0.012). Also as a continuous variable, baseline proBNP proved strongly predictive of major cardiovascular events both among patients with T2DM and among non-diabetic subjects (standardized adjusted HRs = 1.40 [1.12 - 1.74], p = 0.003 and 1.19 [1.06 - 1.33], p = 0.003, respectively) after adjustment for age, gender, BMI, LDL cholesterol, HDL cholesterol, hypertension, and smoking. Additional adjustment for the angiographically determined baseline presence of CAD did not significantly attenuate these results.
Conclusion: We conclude that proBNP both among patients with type 2 diabetes and among non-diabetic subjects strongly predicts future macrovascular events independently from the baseline coronary artery disease state.

Biomarkers for prediction of CVD in type 2 diabetes

I. Brady[1], H.C. Looker[1], M. Colombo[2], T. Zeller[3], B. Thorand[4], L. Groop[5], C.N.A. Palmer[1], A. Hamsten[6], U. de Faire[6], E. Nogoceke[7], N. Barbarini[8], F.V. Agakov[2], P.M. McKeigue[2], H.M. Colhoun[1], on behalf of the SUMMIT Investigators;
[1]University of Dundee, UK, [2]University of Edinburgh, UK, [3]University Heart Center Hamburg, Germany, [4]Helmholtz Zentrum München (GmbH), Neuherberg, Germany, [5]Lund University, Malmö, Sweden, [6]Karolinska Institutet, Solna, Sweden, [7]Hoffman-La Roche, Basle, Switzerland, [8]Università degli Studi di Pavia, Italy.

Background and aims: Improving prediction of cardiovascular disease (CVD) in type 2 diabetes (T2D) is important for tailoring therapy and also for risk stratification into clinical trials. Here we examined a wide range of 42 potential serum biomarkers for incident CVD in a combined analysis of data from five European cohorts.
Materials and methods: The study included T2D patients from 5 cohorts: Go-DARTS (n=1204), the Scania Diabetes Registry (n=666), MONICA/KORA (n=308), IMPROVE (n=94) and 60-year Old Stockholm Study (n=46). Baseline samples from incident cases of major CVD (MI or stroke) and an equal number of age and diabetes duration stratum-matched controls free of CVD at end of follow up were analysed. 9 markers were analysed by standard ELISAs or on automated Roche systems (Elecsys 2010 and Cobas Integra) and 33 were measured on a Luminex platform. Candidate biomarkers were chosen based on a literature mining search tool, previous reports of association with CVD in diabetic or non-diabetic cohorts or based on pathways reported as implicated in CVD. Data analysis was by logistic regression using 50-fold cross validation with forward selection and by 50-fold cross validated backward selection with LASSO penalty. Clinical covariates measured at baseline included in models were age, sex, diabetes duration, BMI, height, blood pressure, smoking, LDL, HDL, Triglycerides, HbA1c, eGFR, study centre, and medication (including antihypertensive, aspirin, lipid-lowering agent and insulin use).
Results: Of 42 biomarkers analysed 16 were retained as improving the prediction of CVD beyond the clinical covariates. N-terminal pro B-type Natriuretic Peptide (NT-proBNP), Apolipoprotein CIII (ApoCIII), soluble RAGE

(sRAGE), high sensitivity Troponin T (hsTnT), IL-6 and IL-15 were the most strongly associated with CVD (see table for ORs). However the increment in the area under the ROC curve was slight; from 0.67 for a model with clinical covariates only to 0.73 for a model including all clinical covariates and 16 associated biomarkers.
Conclusion: We confirm the association of NT-proBNP and hsTnT with incident CVD in T2D. IL-6 is known to be associated with incident CVD in general populations and we confirm that finding now in T2D. We also report a novel association of IL-15 with incident CVD in T2D. The inverse associations between ApoCIII and sRAGE with incident CVD are unexpected and need further investigation. The improvement in prediction of CVD with these 16 biomarkers in this cross validation study indicates that validation of these markers is now warranted.

Logistic regression model adjusted for all clinical covariates and all selected biomarkers		
Normalised Biomarker	Odds Ratio per standard deviation of normalised biomarker (95% CI)	Wald p-value

Metabolic profiles improve the prediction of cardiovascular events in elderly patients
S. Rizza[1], M. Copetti[2], M. Cianfarani[1], A. Luzi[1], C. Pecchioli[1], A. Urbani[3], C. Rossi[3], G. Di Cola[1], F. Pellegrini[2], M. Federici[1];
[1]Tor Vergata University, Rome, [2]IRCCS - "Casa Sollievo della Sofferenza", San Giovanni Rotondo (FG), [3]"G. D'Annunzio" University, Chieti-Pescara, Italy.

Background and aims: One of the most important determinants of cardiovascular health is the age's person, therefore the management of cardiovascular diseases (CVD) in elderly people entails great challenge. However, why age is such a critical component of CVD etiology remains unclear. A possible explanation of vascular senescence process is the mitochondrial damage and dysfunction. We hypothesized that metabolomic profiling would identify biomarkers predicting major cardiovascular events (MACEs) in elderly people, improving the clinical standard cardiovascular risk factors.
Materials and methods: Targeted mass spectrometry-based profiling of 49 metabolites was performed in a group of very old participants (n=67, mean age=78±3 years) with a high rate of previous CVD (68%). Principal component analysis and Cox proportional hazards regression modeling were used to evaluate the relation between the metabolite factors and recurring MACEs. We tested discrimination ability and reclassification of clinical and metabolomic models
Results: At follow-up (median=3.5 years), 17 MACEs occurred (5 cardiovascular deaths, 1 nonfatal myocardial infarction, 7 nonfatal strokes and 4 peripheral artery surgeries) (incidence=7.3% person-years). Metabolite factor 1, composed by medium- and long-chain acylcarnitines, and factor 7 (alanine) were independently associated with MACEs, after adjustment for clinical CV covariates [HR=1.77 (95%CI=1.11-2.81, p=0.016) and HR=2.18 (95%CI=1.17-4.07, p=0.014), respectively]. However, only factor 1 significantly increases the prediction accuracy of the Framingham Recurring-Coronary-Heart-Disease-Score, with a significant improvement in discrimination (integrated discrimination improvement=7%, p=0.01) and correctly reclassifying 41% of events and 37% of non-events resulting in a cNRI=0.79 (p=0.005)
Conclusion: Ageing mitochondrial dysfunction evaluated by metabolomic profiling is associated with MACEs, independently of standard predictors.

Background and aims: Low testosterone concentrations in men have been associated to diabetes, hypertension and CVD-mortality and all cause mortality. We aimed to investigate the associations between endogenous testosterone and acute myocardial infarction (AMI) in men with type 2 diabetes mellitus (T2DM).
Materials and methods: The study was conducted in 1109 subjects ≥40 years of age who participated in a population survey conducted in a rural area of southern Sweden with baseline examinations in 1993-94. Information about smoking habits and physical activities was assembled using validated questionnaires. BMI, waist hip ratio (WHR) and blood pressure measured with a sphygmomanometer in the supine position after 5 min rest were obtained. Total-, LDL-and HDL-cholesterol and triglycerides were measured after overnight fasting. Total testosterone, estradiol and sex hormone-binding globulin (SHBG) analyses were obtained in 99% of cases. A diagnosis of T2DM was based on one of three criteria: a) A known history of T2DM, b) Two consecutive fasting blood glucose ≥ 6,6 mmol/L and c) Subjects with fasting blood glucose >5,5 had an OGTT test and T2DM was defined if two consecutive 2h blood glucose were >11.0mmol/L. Individual patient information on the AMI events in this observational cohort study was ascertained by record linkage with national inpatient and mortality registers from baseline through 2012. IBM-SPSS Statistics version 20 was used for the analyses. Hazard ratios (95% Confidence Intervals) were examined, with adjustment for risk factors in Cox proportional hazard models stratified on sex and T2DM (present or not).
Results: The prevalence of T2DM at baseline was 10% in men and 7,5% in women. During follow-up of 13,8y±5,5y, there were 89 AMI events in men (74 in diabetics and 15 in non diabetics) and 72 in women (61 in non diabetics and 11 in diabetics). In the age adjusted Cox models there was a significant inverse association between AMI morbidity and testosterone in men with T2DM (HR=0,86 CI(0,75-0,98)). There was no significant association in men without diabetes or in women regardless of T2DM. The association remained significant with adjustment for SHBG and oestradiol (HR=0,84 CI(0,72-0,99)). Finally, in the model including WHR, systolic blood pressure, total cholesterol and active smoking the association remained significant (HR=0,83 CI(0,7-0,99)). There was no significant association between AMI and SHBG or estradiol in men or in women, with or without T2DM.
Conclusion: Low concentrations of testosterone predicted AMI in diabetic men in this cohort independent of other risk factors. Whether testosterone replacement therapy could reduce the risk of AMI in men with T2DM remains to be investigated.

Soluble C5b-9, a marker for terminal complement activation, is not associated with markers of atherosclerosis or prevalent cardiovascular disease: The CODAM study
E. Hertle[1,2], M.M.J. van Greevenbroek[1,2], I.C.W. Arts[1,3], C.J. van der Kallen[1,2], I. Ferreira[1,4], E.J. Feskens[5], C.G. Schalkwijk[1,2], C.D.A. Stehouwer[1,2];
[1]CARIM School for Cardiovascular Diseases, Maastricht University, [2]Dept. of Internal Medicine, Maastricht University, [3]Dept. of Epidemiology and School for Public Health and Primary Care (CAPHRI), Maastricht University, [4]Dept. of Internal Medicine, Dept. of Clinical Epidemiology and Medical Technology Assessment, Maastricht University, [5]Section Nutrition and Epidemiology, Wageningen University, Netherlands.

Background and aims: The complement system has been implicated in the development of both type 2 diabetes (DM2) and cardiovascular disease (CVD). Complement is a complex protein network that can be activated via different enzymatic pathways, which all converge on the terminal pathway. Soluble C5b-9 (sC5b-9) is a product of terminal complement activation and the most downstream factor in the cascade. In DM2 patients with acute myocardial infarction, sC5b-9 at admission predicted a poor outcome. However, there are no studies on the role of sC5b-9 in the development of cardiometabolic disease. Therefore, we investigated the associations of sC5b-9 with

markers of atherosclerosis [carotid intima-media thickness (cIMT), ankle-arm blood pressure index (AAIx)] and prevalent CVD in a cohort with a high prevalence of DM2.
Materials and methods: We conducted cross-sectional analyses among 548 individuals (61% men, mean±SD age 59.4±6.9 years, 22% with impaired glucose metabolism (IGM) and 26% with DM2) from the Cohort on Diabetes and Atherosclerosis Maastricht (CODAM) Study. Prevalent CVD was defined on the basis of self-reports, signs of myocardial infarction on an ECG and/or an AAIx<0.9; cIMT was measured by ultrasonography and AAIx by Doppler ultrasound. SC5b-9 was measured with a commercial ELISA (intra-assay CV 5.1%, inter-assay CV 11.8%). Associations between sC5b-9 and study outcomes were analysed with multiple logistic (for prevalent CVD) or linear regression (for cIMT and AAIx) analyses. All analyses were adjusted first for age, sex and glucose metabolism status (minimal model), and furthermore for BMI, waist, blood lipids, blood pressure, eGFR, physical activity, smoking and use of medication.
Results: The prevalence of CVD was 28%, cIMT was 0.77±0.16 mm, AAIx was 1.09±0.12 and sC5b-9 was 113±34 ng/ml. Plasma sC5b-9 (per 1 SD increase, 1SD=34 ng/ml) was not associated with markers of atherosclerosis or CVD, neither in the minimal model [cIMT: β=-0.004, (95%CI: -0.017; 0.009); AAIx: β=0.002 (-0.008; 0.012); CVD: OR=0.99 (0.82; 1.21)] nor in the fully adjusted model [cIMT: β=-0.009, (95%CI: -0.021; 0.004); AAIx: β=0.004 (-0.006; 0.014); CVD: OR=0.97 [0.78; 1.20)].
Conclusion: In the CODAM study population, activation of the terminal complement pathway, as represented by systemic concentrations of sC5b-9, was not associated with markers of atherosclerosis or prevalent CVD. It remains to be determined whether other aspects of terminal complement activation may be involved in the aetiology of CVD.

Calcium concentration predicts future development of diabetes and impaired glucose tolerance: the Insulin Resistance Atherosclerosis study
C. Lorenzo[1], A.J.G. Hanley[2,3], S.M. Haffner[1];
[1]Medicine, University of Texas Health Science Center, San Antonio, USA, [2]Departments of Nutritional Sciences and Medicine and the Dalla Lana School of Public Health, University of Toronto, [3]Leadership Sinai Centre for Diabetes, Mt. Sinai Hospital, Toronto, Canada.

Background and aims: Serum calcium concentration and calcium supplementation have been associated with cardiovascular mortality. Calcium concentration has also been associated with impaired glucose tolerance (IGT) independently of the confounding effect of age, obesity, or vitamin D concentration. Accordingly, we aimed to examine the relationship between total calcium concentration and risk of future development of IGT and diabetes.
Materials and methods: Incident diabetes and incident IGT were ascertained in 863 and 723 participants in the Insulin Resistance Atherosclerosis Study after a 5-year follow-up period using the 2003 American Diabetes Association criteria. Insulin sensitivity index (S_I) and acute insulin response (AIR) were directly measured and glomerular filtration rate was estimated (eGFR) using the Modification of Diet in Renal Disease. Logistic regression analysis was used to assess the relationship between calcium concentration and incident diabetes (or incident IGT).
Results: The relationship between incident diabetes and calcium concentration modeled by a smooth function was statistically significant (p = 0.020), but was not linear (Wald test, p = 0.040). Therefore, risk of developing diabetes and IGT were assessed by categories of calcium concentration (Table). Calcium concentration ≥2.5 mmol/L was associated with increased risk of incident diabetes and incident IGT. As a continuous variable, calcium concentration was an independent predictor of incident diabetes (OR x 1 SD, 1.34 [95% CI: 1.07 - 1.68]) after adjusting for age, sex, race/ethnicity, family history of diabetes, BMI, plasma glucose levels, S_I, AIR, eGFR, and diuretic drugs.
Conclusion: Calcium concentration predicts the development of type 2 diabetes. Calcium concentration may play a role in the diabetes disease process independent of measured glucose, insulin secretion, and insulin resistance.

Odds of developing diabetes or IGT by categories of calcium concentration

Visceral adiposity predicts incident diabetes more strongly in South Asians than in Europeans or African Caribbeans, independent of insulin resistance and other fat depots

S.V. Eastwood[1], T. Tillin[1], A. Wright[2], J. Heasman[3], A. Hughes[1], N. Chaturvedi[1];
[1]National Heart and Lung Institute, Imperial College London, [2]Faculty of Medicine, Imperial College London, [3]Radiology, Imperial NHS Healthcare Trust, London, UK.

Background and aims: South Asians and African Caribbeans have higher risks of diabetes than Europeans, and different distributions of ectopic fat. The role of individual fat depots in determining diabetes and whether this differs by ethnicity is unclear.
Materials and methods: We used data from a UK cohort, the Southall And Brent Revisited (SABRE) study, comprising 2197 Europeans, 1355 South Asians and 650 African Caribbeans at baseline. Baseline (1988-1991, mean age 52±7) and follow-up (2008-2011, mean age 70±6) measurements included fasting blood and anthropometry. Incident diabetes was identified from primary care record review, self-report (plus anti-diabetic medication), glycaemia exceeding 1999 WHO diagnostic thresholds, hospital statistics and death certificates.Surface anthropometry cannot distinguish between abdominal visceral (VAT) and subcutaneous (SAT) adipose tissue. We therefore used CT to derive ethnic specific equations for VAT and SAT and applied these to baseline measures. We summed subscapular and suprailiac skinfolds to assess truncal adiposity, and triceps, thigh and suprapatellar skinfolds for peripheral subcutaneous fat. Predictive models for incident diabetes by ethnicity were fitted with each ectopic depot, and each measure of glycaemia/insulin resistance, individually and in combination.
Results: There were ethnic differences in baseline VAT, which was greatest in South Asians, then Europeans, then African Caribbeans (means 149 ±70 cm^2, p<0.001, 120±76cm^2 and 100 ±64 cm^2, p=0.0006). Diabetes was more prevalent at follow-up in South Asians (33%) and African Caribbeans (30%), compared to Europeans (14%). Baseline VAT, of all the fat measures, was one of the strongest predictors of incident diabetes in all ethnicities. After adjustment for other baseline fat measures, the association between VAT and diabetes remained in South Asians and Europeans but not African Caribbeans. Adjustment for any measure of glycaemia/insulin resistance did not wholly account for the association between VAT and diabetes in any ethnic group. When fasting insulin was added to a model including all ectopic fat depots, the association between VAT and incident diabetes remained only in South Asians (standardised OR 2.09, vs. 1.28 in Europeans, and 1.05 in African Caribbeans).
Conclusion: VAT was one of the strongest predictors of diabetes in all ethnicities. This association remained independent of other fat depots and of measures of glycaemia/insulin resistance in South Asians, but not in Europeans or African Caribbeans. Our findings suggest that underlying mechanisms governing the association between VAT and diabetes differ by ethnicity, and VAT plays a particularly important role in the aetiology of diabetes in South Asians.

A simple self-assessment score for predicting the risk of non-alcoholic fatty liver disease

Y.-H. Lee[1], H. Bang[2], Y. Park[3], E. Kang[1], B.-W. Lee[1], K.J. Kim[4], B. Cha[1], H. Lee[1], J. Bae[5], W. Lee5, D. Kim[6];
[1]Yonsei University College of Medicine, Seoul, Republic of Korea, [2]University of California at Davis, Davis, USA, [3]National Health Insurance Corporation Ilsan Hospital, Goyang, [4]Yixing-Severance VIP Health Promotion Centre TFT, Severance Hospital Executive Healthcare Clinic, Seoul, [5]Sungkyunkwan University School of Medicine, Seoul, 6Ajou University School of Medicine, Suwon, Republic of Korea.

Background and aims: Although non-alcoholic fatty liver disease (NAFLD) is a prevalent and rapidly increasing disease worldwide associated with the escalated risk of morbidity and mortality, few screening models are available to evaluate the risk of NAFLD. Considering the clinical impact of NAFLD on public health, we developed and validated a self-assessment score for presence of NAFLD in the general populations and compared it to other screening methods.
Materials and methods: The development cohort included 15676 subjects (8313 men and 7363 women) who visited National Health Insurance Service Ilsan Hospital in year 2008-2010. Abdominal ultrasound and biochemical analyses were performed for the regular health check-up. After excluding patients with excessive alcohol consumption (>140g/week for men and 70g/week for women) or existing liver diseases and thyroid disorders, logistic regression analysis was conducted to determine predictors of NAFLD and derive risk score models. We validated our models and compared with other existing methods using an external dataset (n = 66868).
Results: In the self-assessment simple models, age, sex, waist circumference, BMI, history of diabetes and dyslipidemia, alcohol intake, physical activity and menopausal status were independently associated with NAFLD. We calculated a NAFLD self-assessment score (range, 0-15), and a cut-point of 8 or higher defined 58% or 45% of men or women as high-risk for NAFLD and yielded a sensitivity of 80% or 87%, specificity of 67% or 72%, positive predictive value of 72% or 56%, and negative predictive value of 76% or 93% (area under the curve [AUC]=0.82 or 0.87) in men or women, respectively. Comparable results were obtained in the validation dataset.
Conclusion: This self-assessment score may be useful for identifying individuals at high-risk for NAFLD. Further studies are needed to evaluate the utility and feasibility of this score in various settings.

16

Investigating the validity of the UKPDS outcomes equations in current clinical practice

T. Ward[1], P. McEwan[1,2], K. Bergenheim[3];
[1]HEOR Ltd, Monmouth, [2]Centre for Health Economics, Swansea University, UK, [3]AstraZeneca, Molndal, Sweden.

Background and aims: The UKPDS outcomes equations are routinely used to assess the benefits associated with glucose control in contemporary type 2 diabetes mellitus (T2DM) cohorts escalating to 2nd or 3rd line therapy. Their validity has been questioned because they were derived from a cohort of newly diagnosed T2DM subjects and diabetes management practices have evolved considerably since the UKPDS reported. The objective of this study was to re-calibrate the equations to contemporary healthcare data to better understand their continued relevance to assess the benefits of glucose control in T2DM.
Materials and methods: We utilized data from The Health Improvement Network (THIN) database over the period 1/1/2004 to 31/12/2009. In contrast to the UKPDS newly diagnosed population we selected patients either aged > 64 years with HbA1c >7.5% and diabetes duration >10 years or aged >55 years with at least 1 established cardiovascular risk factor. Weibull survival equations were fitted to the following endpoints; myocardial infarction (MI), stroke, congestive heart failure (CHF), ischemic heart disease (IHD), amputation, blindness and end-stage renal disease (ESRD) using R. Missing data was modelled using multiple imputation.
Results: Data were available on 68,990 T2DM subjects meeting the inclusion criteria with mean age 66.1 years, 46% female, 8.8 years duration of diabetes; with mean body mass index (29.7m/kg^2), HbA1c (8.0%), systolic blood pressure (147.5mmHg), total cholesterol (5.1mmol/l) and HDL cholesterol (1.3mmol/l). Log hazards (standard error) associated with unit changes HbA1c were 0.097(0.011) for MI, 0.084 (0.008) for CHF, 0.051 (0.009) for

stroke, 0.112(0.02) for blindness, 0.043 (0.007) for ESRD and 0.225 (0.017) for amputation. These estimates were statistically consistent (at the 95% level) with the original UKPDS log hazards except for IHD (non-significant in the THIN database) and ESRD (non-significant in UKPDS).
Conclusion: This study demonstrates that, in general, the UKPDS outcomes equations retain their validity for assessing the relationship between HbA1c and macrovascular and microvascular complications in current T2DM subjects. It is likely that use of UKPDS equations will overestimate the incidence of IHD and underestimate the incidence of ESRD.

Skin collagen advanced glycation endproducts (AGEs) as prospective markers of sub-clinical cardiovascular disease (CVD) outcomes in type 1 diabetes
V.M. Monnier[1], W. Sun[2], D.R. Sell[3], P.A. Cleary[2], J.M. Lachin[2], S.M. Genuth[3], DCCT/EDIC Research Group;
[1]Departments of Pathology & Biochemistry and Medicine, Cleveland, [2]The George Washington University, Rockville, [3]Case Western Reserve University, Cleveland, USA.

The DCCT/EDIC previously reported that skin collagen intrinsic fluorescence and AGEs had long-term associations with the incidence of microvascular diseases in type 1 diabetes. However, the association between AGE and CVD events has not been explored in EDIC. Other studies have reported cross-sectional but not prospective associations between noninvasive skin auto/intrinsic fluorescence and CVD outcomes in diabetes. In this report we investigated the long-term association of collagen-linked fluorescence at 370/440nm (CLF) in collagen digest, a novel acid-labile fluorescent AGE named LW-1, and a panel of 9 other AGEs measured in skin collagen digest from skin biopsies (n=216) obtained near DCCT closeout (1993), on subclinical CVD outcomes. CLF was associated with the mean coronary artery calcium (CAC) at EDIC Yr 7-9 (n=187), and risk of CAC>0 and CAC>100 (each P<0.002). These associations remained significant even after false discovery rate (FDR) adjustment for multiple tests (each P<0.03). Adjustment for mean DCCT A1c weakened the association with CAC>0 but not with CAC >100 or mean CAC. Change of Intimal-Media Thickness (IMT) from EDIC Year 1 to 6 (n=127) was predicted by higher methylglyoxal hydroimidazolones (MG-H1), LW-1, and pentosidine even after adjustment for A1c (each P<0.022). Likewise, cardiac MRI left ventricular (LV) mass at EDIC Yr 15-16 (n=142) was associated with higher LW-1 and CLF with or without adjustment for A1c (each P<0.035). In contrast, DCCT mean A1c was positively associated with risk of CAC, but nullified after adjustment for CLF or furosine. IMT and MRI endpoints were not associated with DCCT or EDIC mean A1c in this sub-cohort. These results point to the unique ability of CLF and selected tissue AGEs to predict future risk of subclinical CVD, and a likely role for glucose-mediated matrix crosslinking in LV mass and IMT. They also suggest that tissue AGEs might more reliably predict subclinical CVD risk than HbA1c.

Assessment of serum ghrelin as a biomarker of HNF1A-MODY
N. Nowak[1,2], J. Skupien[1], M. Szopa[1], I. Solecka[1], M. Malecki[1];
[1]Department of Metabolic Diseases, Jagiellonian University, Krakow, Poland, [2]Section on Genetics and Epidemiology, Joslin Diabetes Center, Boston, USA.

Background and aims: Ghrelin is a non-glycosylated hormone composed of 28 amino acids. It is present in the serum in two major molecular forms - desacyl and acylated ones. Ghrelin expression by the digestive tract epithelium is regulated by the hepatocyte nuclear factor 1A (HNF1A), a transcription factor whose mutations cause one of the forms of maturity onset diabetes of the young (MODY). As shown in an animal model, ghrelin expression is increased by approximately five-fold in homozygous HNF1A knock-out mice (Hnf-/-) as compared to a wild type. Furthermore, this is followed by its five-fold higher concentration in serum with a subsequent reduction in insulin secretion. The relationship between ghrelin and HNF1A gene mutations in humans has not yet been evaluated. In this study, we assessed ghrelin level in various forms of diabetes and evaluated it as a potential biomarker for HNF1A MODY.
Materials and methods: We examined 47 diabetic HNF1A gene mutation carriers, 55 type 2 diabetes (T2DM) subjects, 42 type 1 diabetes (T1DM) patients and 31 glucokinase (GCK) gene mutation carriers with diabetes. Blood specimens for the ghrelin measurement were taken in the fasting state. Ghrelin was measured using a commercially available EIA kit with polyclonal antibodies against the C-terminal fragment of its both forms (total ghrelin). Samples were diluted prior the analysis. Comparisons of ghrelin concentrations were performed with the t-test and linear regression. Ghrelin concentration was used as a dependent variable and group, BMI, HbA1c, age at examination were covariates in the multiple analysis. To control the extent of degradation of the analyte, we also included length of storage, defined as the time between blood collection and assay determination, as a covariate.
Results: Mean ghrelin concentration in HNF1A-MODY subjects was 0.77 ng/ml (SD=0.33 ng/ml). It was twofold higher than in T2DM group (0.39±1.6 ng/ml; p<0.001) and by 50% higher than in the T1DM group (0.49±0.19 ng/ml; p<0.001). No significant differences were found between HNF1A and GCK MODY (0.7±0.2 ng/ml; p=0.32). The difference between HNF1A-MODY and T1DM remained significant (p<0.001) after adjusting for the relevant confounders and HNF1A mutation carrier status was the only independent variable associated with ghrelin in the multivariate model. The discriminative accuracy as expressed by the area under the curve (AUC) of serum ghrelin between T1DM and HNF1A-MODY was 0.74 (95%CI: 0.63; 0.84; p<0.001) with the corresponding sensitivity and specificity of 74% and 66.7%. The difference between HNF1A-MODY and T2DM was not significant (p=0.18) after adjusting for age and BMI.
Conclusion: Serum ghrelin level is lower in HNF1A-MODY than in both common polygenic forms of diabetes. It may be a valuable complementary marker for clinical differential diagnosis between HNF1A-MODY subjects and T1DM patients although, its discriminative accuracy is too low to allow use as a sole screening test. For T2DM, it appears that differences in clinical characteristics contributed to the observed difference against HNF1A-MODY in ghrelin levels.

OP 04 Beta cell genes and type 2 diabetes

19

The P300/CBP-associated factor (PCAF) is a histone acetyl transferase that controls beta cell function

J.-S. Annicotte[1], N. Rabhi[1], C. De Bettignies[1], P.-D. Denechaud[2], A. Bonnefond[3], P. Froguel[3];
[1]Molecular physiopathology of diabetes and obesity, European Genomic Institutes for Diabetes, Lille, France, [2]Departement de physiologie, Université de Lausanne, Lausanne, Switzerland, [3]European Genomic Institutes for Diabetes, Lille, France.

Background and aims: Pancreatic β-cells control insulin secretion through a fine-tuned process. Dysfunctions of this particular cell type are at the origin of pathological conditions, such as Diabetes Mellitus and cancer. A common component of the two type of diabetes, i.e. immune type 1 and non-immune type 2 (T2D), is a decrease of β-cell mass, finally resulting in hyperglycemia and its subsequent deleterious consequences. Therefore, a complete understanding of the factors and mechanisms responsible for β-cell maintenance is of high importance and could be of interest for the treatment of diabetes. We and others have demonstrated that cell cycle regulators, in particular E2F1, CDK4 (and its repressor INK4) and pRb are key regulators of glucose and lipid metabolism through their role in white adipose tissue, muscle and β-cells. The histone acetyl transferase PCAF has been shown to physically interact and up-regulate E2F1 activity through acetylation. Moreover, PCAF has been associated to the regulation of a metabolic gene program in response to insulin, suggesting potential functions for this transcriptional coregulator in the control of metabolic pathways.
Materials and methods: In this project, we used global PCAF KO mice, as well as isolated Pcaf +/+ and -/- islets. Islet structure was analyzed by classical histochemistry, and immunofluorescence. Ultra-structural analysis was performed by electron microscopy. Gene expression analysis was performed by qRT-PCR, and global gene expression by illumina DNA chips. Analysis was performed using the Ingenuity Pathway analysis software.
Results: We show here that Pcaf-/- mice are hyperglycemic in fed conditions and are resistant to diet-induced obesity. Moreover, these mice are glucose-intolerant under chow or high-fat diet due to decreased insulin secretion after a glucose load. Using isolated islets, we further demonstrated by static incubation experiments that Pcaf-/- β-cells were unable to secrete insulin in response to glucose. Electron microscopy analysis of isolated islets from Pcaf+/+ and -/- mice showed defects in insulin maturation and/or crystalization process, suggesting that PCAF could play a role in both maturation and secretion of insulin. Key genes involved in insulin crystalization/maturation processes were shown to be down-regulated upon Pcaf genetic inactivation, reinforcing the key role for this lysine acetyltransferase in the control of β-cell functions. Interestingly, GCN5 and P300, which are closely related to PCAF, could not compensate for PCAF deficiency, suggesting a β-cell specific function for PCAF. Moreover, Ingenuity pathway analysis of global gene expression from Pcaf +/+ and -/- isolated islets revealed a PDX-1 and HNF1a gene regulatory network dependent on PCAF. Finally, genetic analysis (using the dataset of DIAGRAM) revealed that two frequent single nucleotide polymorphisms (rs12639214 and rs12639078) were associated with T2D risk ($P < 5 \times 10\text{-}3$) in the Kat2b gene, encoding PCAF.
Conclusion: In summary we provide evidence that the PCAF acetyl transferase is involved in glucose homeostasis and could play a key role in type 2 diabetes physiopathology. The molecular mechanisms linking PCAF to β-cell functions are under investigations.

Exploration of novel genes contributing to pathogenesis of type 2 diabetes in human pancreatic islets

J. Taneera[1], M. Zhang[1], J. Fadista[1], U. Krus[1], E. Renström[2], L. Groop[1];
[1]Diabetes and Endocrinology, Lund University, [2]Islets pathophysiology, Lund University, Malmö, Sweden.

Background and aims: Normal glucose homeostasis is characterized by low HbA1c level and appropriate insulin secretion. Hence, gene expression signatures associated with these two phenotypes could be essential for islet function. To address this question, we have identified genes whose expression in human islets correlate with normal/high insulin secretion and low HbA1c level, followed by functional studies could be an interesting approach to uncover novel genes involve in the pathophysiology of T2D.
Materials and methods: Global a spearman's correlation test was used to correlate microarray gene expression data from human pancreatic islets (90 donors) with HbA1c level and insulin secretion from the same donors. The correlated genes were prioritized based on their correlation p-value and genes showing the strongest correlation were selected for further studies. This included silencing of their expression using siRNA in clonal rat β-cell line (INS-1 831/13). Transfection efficiency was determined by qRT-PCR and secreted insulin with the Coat-A-Count Insulin radioimmunoassay kit.
Results: Expression of 518 genes showed strong positive correlation with insulin secretion and inverse correlation with HbA1C ($p < 0.5$). Among the top 10 ranked genes (GLR1A, ATP2A3, MCF2L2, PTEN, PPP1R1A, SYT13, PLXCD3, ENO2, FAM105A, PFKFB2) several genes (ATP2A3, PTEN, SYT13 and PFKFB2) were previously shown to be involved in insulin secretion and islet function. Also, expression of these 10 genes was down-regulated in diabetic compared to non-diabetic islets. siRNA silencing of GLRA1, PPP1R1A, PLXCD3 and FAM105 in INS-1 cells showed high knockdown efficiency (70-90%). Insulin secretion in response to 2.8 mM and 16.7 mM glucose 72 hr after siRNA transfection showed a significant reduction ($p < 0.5$) for PPP1R1A, FAM105A and PLCDX3 compared to the negative control, whereas, silencing of GLRA1 had no influence on insulin secretion (Fig 1). Analysis of the insulin content in transfected cells did not show any difference compared to the siRNA negative control suggesting a defect in the secretory machinery rather than in insulin production.
Conclusion: By searching for genes whose expression in human islets was associated with low HbA1c and normal insulin secretion we identified and functionally confirmed PPP1R1A, FAM105A and PLCDX3 as potential regulators of islet function in man.

Figure 1: Gene knockdown of PPP1R1A, FAM105A and PLCXD3 in INS-1 cells resulted in reduced insulin secretion compared to negative control, whereas, silencing of GLRA1 showed no effect.

Paternal allelic mutation at the Kcnq1 locus reduces pancreatic beta cell mass via epigenetic modification of Cdkn1c

H. Inoue[1], S.-I. Asahara[2], H. Etoh[1], K. Teruyama[1], Y. Ihara[1], T. Matsuda[2], M. Koyanagi-Kimura[2], A. Kanno[2], K. Nagashima[3], W. Nishimura[4], K. Yasuda[4], N. Inagaki[3], S. Seino[2], M. Kasuga[4], Y. Kido[1,2];
[1]Department of Biophysics, Kobe University Graduate School of Health Sciences, [2]Division of Diabetes and Endocrinology, Kobe University Graduate School of Medicine, [3]Department of Diabetes and Clinical Nutrition, Kyoto University Graduate School of Medicine, [4]National Center for Global Health and Medicine, Tokyo, Japan.

Background and aims: In a large-scale SNP analysis of Japanese type 2 diabetes patients, a SNP in the *Kcnq1* gene on chromosome 11 was reported as a significant risk factor associated with the development of type 2 diabetes. The

Kcnq1 gene is known as an imprinting gene, and non-coding RNA *Kcnq1ot1* is expressed from the *Kcnq1* genomic region and regulates the expression of neighboring genes located adjacent to the *Kcnq1* gene via epigenetic modification. However, the association of *Kcnq1* mutation with the development of type 2 diabetes mellitus has not been shown yet. Then, we analyzed the effect of a mutation at the *Kcnq1* locus on the pancreatic β-cells to clarify the development mechanism of type 2 diabetes mellitus.
Materials and methods: We generated *Kcnq1* heterozygous knockout mice in which exon 2 of *Kcnq1* on chromosome 7 has been replaced by a neomycin resistance gene.To analyze the effect of imprinting, *Kcnq1* heterozygous mice were classified into 3 groups: wild-type mice group (WT); mice with mutations in the alleles inherited from one's mother (MH); and mice with mutations in the alleles inherited from one's father (PH).
Results: An analysis of unclassified *Kcnq1* heterozygous mice showed that the mutation did not affect insulin secretion and glucose tolerance. However, pancreatic β cell mass both at birth and at 24 weeks of age was significantly reduced in PH mice compared with WT or MH mice. Further, the expression level of *Kcnq1ot1* was significantly decreased and the expression level of *Cdkn1c* was significantly increased in the islets of PH. Then, we examined the extent of H3K27 trimethylation at the *Cdkn1c* promoter region in islets of PH, MH, and WT mice by chromatin immunoprecipitation (ChIP) analysis. The level of H3K27 trimethylation was significantly reduced in only PH mice.
Conclusion: These results suggest that disruption of *Kcnq1* results in reduced *Kcnq1ot1* expression as well as increased expression of *Cdkn1c* only when the mutation is on the paternal allele. Furthermore, histone modification at the *Cdkn1c* promoter region in pancreatic islets was found to contribute to this phenomenon. We have now shown that the regulation of gene imprinting at the *Kcnq1* locus was strongly associated with the modulation of pancreatic β-cell mass in the development of type 2 diabetes mellitus.

22

Hypoxia alters the expression of the type 2 diabetes-associated Zn^{2+} transporter Slc30a8/ZnT8 and cytosolic Zn^{2+} levels in human and rodent islets

P.A. Gerber[1], E.A. Bellomo[1], G. Meur[1], D.J. Hodson[1], A. Solomou[1], M. Hollinshead[2], F. Chimienti[3], V.J. Lavallard[4], D. Bosco[4], S.J. Hughes[5], P.R. Johnson[5], G.A. Rutter[1];
[1]Cell Biology, Department of Medicine, Imperial College, London, [2]Microscopy, Department of Medicine, Imperial College, London, UK, [3]Mellitech SAS, St Martin D'Heres, France, [4]Department of Surgery, Geneva University Hospitals, Switzerland, [5]Nuffield Department of Surgical Sciences, University of Oxford, UK.

Background and aims: Hypoxic damage often leads to the loss of functional islets during islet isolation and transplantation, and may also contribute to beta cell failure in Type 2 Diabetes (T2DM). It is not known whether susceptibility of beta cells to hypoxia might be genetically modulated. A single nucleotide polymorphism, rs13266634 in the SLC30A8 gene, is associated with an increased T2DM risk and reduced activity of the pancreatic beta cell-enriched granular zinc transporter ZnT8. We have previously observed decreased expression of *slc30a8* and reduced cytosolic free zinc $\{(Zn^{2+})_{cyt}\}$ in hypoxic mouse islets. We asked whether such changes can also be seen in rat and human islets and what the consequences of this reduced activity may be.
Materials and methods: Isolated murine, rat, and human islets as well as dispersed cells were exposed to hypoxia or normoxia (1% vs. 21% O_2) for 24 hours. For expression analysis, mRNA was isolated and quantified by qRT-PCR. $(Zn^{2+})_{cyt}$ in dispersed islet cells was measured using the FRET-based Zn^{2+} probe eCALWY-4, which was delivered to cells by adenoviral transfection. Cell death was measured by calcein / propidium iodide staining.
Results: Levels of *SLC30A8* mRNA were sharply (>50%) reduced after exposure to hypoxia of human (0.45 ± 0.06 (SE) vs. 1.00 ± 0.15, p<0.01) and rat (0.48 ± 0.05 (SE) vs 1.00 ± 0.02, p<0.001) pancreatic islets. $(Zn^{2+})_{cyt}$ was reduced in human islet cells (0.67 ± 0.13 vs. 1.00 ± 0.14, p<0.05). Likewise ZnT8 protein levels were lowered in dispersed murine pancreatic islets following hypoxia exposure as demonstrated by quantitative immunofluorescence imaging (0.63 ± 0.08 vs. 1.00 ± 0.08, p<0.01). Since we also observed a clear up-regulation of mRNAs encoding the zinc binding metallothioneins 1 and 2 in all species after hypoxia (for human islets: 6.87 ± 1.55 vs. 1.00 ± 0.17 for *MT-1*, 7.47 ± 1.02 vs. 1.00 ± 0.21 for *MT-2,* p<0.05), we asked whether altered metalloprotein abundance might be responsible for the changes in *SLC30A8* expression. Arguing against this view, there was no difference in the expression of the transporter in islets of mice lacking Mt-1 and Mt-2 (129S7/SvEvBrd/$Mt1^{tm1Bri}Mt2^{tm1Bri}$/J). On the other hand, islets from global ZnT8 null mice displayed significantly reduced expression of *MT-1* (0.47 ± 0.04 vs. 1.00 ± 0.02, p<0.01) and *MT-2* (0.44 ± 0.05 vs. 1.00 ± 0.10, p<0.01) in hypoxia, pointing to an impaired response to hypoxia of these islets. The importance of altered metallothionein regulation in hypoxic responses was also demonstrated by the fact that islets from mice null for Mt-1 and Mt-2 exhibited significantly increased cell death after hypoxia (12.7 ± 0.4 % vs. 5.7 ± 0.9 % cell death, p<0.01).
Conclusion: The present study demonstrates that ZnT8, variants of which are strongly associated with T2DM across human populations, is an important modulator of the response of pancreatic beta cells from different species to hypoxia. Lowered cytosolic Zn^{2+} levels and impaired MT1/2 induction at low oxygen tensions may thus contribute to the deleterious effects of *SLC30A8* risk alleles on insulin secretion.

IGF-2 expression in beta cells induces susceptibility to develop diabetes

A. Casellas[1,2], C. Mallol[1,2], A. Salavert[1], V. Jimenez[1,2], M. Obach[1], M. Garcia[1,2], J. Agudo[1], M. Molas[1,2], R. Lage[1], L. Vilà[1,2], M. Morró[1,2], J. Ruberte[1,3], F. Bosch[1,2];
[1]Center of Animal Biotechnology and Gene Therapy (CBATEG), Universitat Autònoma de Barcelona, Bellaterra, [2]CIBER of Diabetes and Associated Metabolic disease (CIBERDEM), Barcelona, [3]Department of Animal Health and Anatomy, School of Veterinary Medecine, Universitat Autònoma de Barcelona, Bellaterra, Spain.

Background and aims: The human insulin like growth factor-II (IGF-2) is located in the insulin (INS) gene region, and this locus is associated with type 1 diabetes (IDDM2). Genome-wide association (GWA) studies have reported an association between IGF-2 mRNA-binding protein 2 (IGF2BP2) with type 2 diabetes. Moreover, we have shown that local expression of IGF-2 specifically in β cells of transgenic mice (Tg-IGF2), leads to a pre-diabetes state with mild hyperglycemia, increased β-cell mass, hyperinsulinemia and altered glucose and insulin tolerance tests. Here, we use Tg-IGF2 mice to study the effect of IGF-2 and insulin signaling pathway on pancreatic islets and its implication in β cell functionality.
Materials and methods: Gene expression profile analysis in islets from IGF-2 transgenic mice was performed using GeneChip™ Affimetrix™ Technology. Islets and INS-1 cells were treated with adenoviral vectors expressing IGF-2 or recombinant IGF-2 protein. IFN-β/IGF-2 double transgenic mice were obtained and phenotyped. Treatment with streptozotocin was performed in Tg-IGF2 mice.
Results: In this work, we report that expression of IGF-2 in β-cells of transgenic mice led to β cell dysfunction and reticulum endoplasmic (ER) stress causing islet dysfunction. Data from gene expression profile of islets from Tg-IGF2 mice showed a reduction in Glut2, GcK and insulin gene expression in β cells, probably due to a reduction in the transcription factors that regulate their expression, such as Pdx1 and HNF3β. These alterations could explain the impaired insulin secretion in Tg-IGF2 mice. In addition, transgenic islets presented expression changes in genes involved in β-cell ER stress, such as SERCA, Xbp1, CHOP, and ER dilatations. In vitro studies, using adenovirus-mediated IGF-2 expression in wild type islets and islets treated with recombinant IGF2 protein, proved the direct effect of IGF-2 in β cell this functionality. IGF-2 effects were in part mediated via the insulin/IGF1 receptor pathway. Furthermore, transgenic islets showed hyperexpression of molecules involved in the immune response, such as MHC class I and II. Thus, local expression of IGF-2 in Tg-IGF2 islets might lead islets to be more sensitive to immune attack and β-cell damage. To determine whether IGF-2 overexpression in β cells could predispose transgenic mice to develop overt diabetes, we treated Tg-IGF2 mice with very low doses of streptozotocin (STZ) that do not affect control mice. After treatment, only transgenic mice became diabetic. Tg-IGF2 mice were also crossed with IFN-β transgenic mice, a mouse model that shows important lymphocytic infiltration in islets. IFN-β/IGF-2 double transgenic mice developed diabetes spontaneously during the first two months of age, whereas the single Tg-IFNβ and Tg-IGF2 mice remained normoglycemic. Therefore, Tg-IGF2 islets were more sensitive to immune attack and β-cell death.
Conclusion: These results indicate that local IGF-2 expression in islets might lead to β cell dysfunction. As a consequence, IGF-2 expressing islets are more sensitive to the immune attack and β-cell damage and trigger onset of diabetes.

Carriers of loss-of-function mutations in EXT display impaired pancreatic beta cell reserve due to smaller pancreas volume

S.J. Bernelot Moens[1], H.L. Mooij[1], H.C. Hassing[1], J.K. Kruit[2], J.J. Witjes[1], M.A.J. van de Sande[3], A.J. Nederveen[4], G.M. Dallinga-Thie[1], E.S.G. Stroes[1], M. Nieuwdorp[1];
[1]Vascular Medicine, Academic Medical Center, [2]Pediatrics, UMCG, [3]Orthopedics, LUMC, [4]Radiology, Academic Medical Center, Amsterdam, Netherlands.

Background and aims: A genome wide association study identified exostosin 2 (EXT2) as a novel risk factor for the development of type 2 diabetes mellitus. As EXT genes, involved in the chain elongation step of heparan sulfate (or HSPG) biosynthesis, are intricately involved in organ development, we hypothesized that mutations in these genes might affect pancreatic islet mass and insulin secretion capacity. Here we used a translational approach to study the effect of EXT mutations on pancreatic development, insulin secretion and glucose metabolism in mice and humans with heterozygous EXT mutations causing hereditary multiple exostoses (HME).
Materials and methods: In HME subjects and family-based non-carriers (similar age, sex, and BMI) we performed oral glucose tolerance tests (OGTTs) for insulin resistance, hyperglycemic clamps for insulin secretion capacity and abdominal MRI to assess pancreas volume. In heterozygous EXT1 or EXT2 mice we also performed OGTTs, insulin tolerance tests and harvested each mouse pancreas for extraction of islets (insulin secretion) and immunohistochemistry (beta cell mass).
Results: No differences in oral glucose tolerance and insulin resistance were found in mice and humans with EXT mutations compared to controls. No effects on insulin signalling were found in isolated islets challenged with hyperglycaemia. However, glucose stimulated insulin secretion (hyperglycaemic clamp) showed that HME subjects had a significantly altered glucose induced first-phase insulin secretion (GSIS) (IAUC carriers vs controls: 0.72 [0.46-1.16] vs. 1.53 [0.69-3.36] nmol•l-1•min-1, P=0.046) as well as an impaired beta cell reserve (upon arginine bolus)(IAUC carriers vs controls: 7,14 [4,22-10,95] vs. 10,32 [7,91-12,70] nmol•l-1•min-1 p=0.041). In line with these finding, Magnetic Resonance Imaging showed a significantly smaller pancreas volume in HME subjects compared to controls (74 [63-86] vs.87 [82-105] cm3 p=0,016).
Conclusion: Carriers of loss-of-function mutations in EXT showed impaired GSIS without insulin resistance due to reduced functional beta cell mass and decreased anatomic pancreas volume. Our data provide evidence that heparansulfates are important for normal beta-cell function in humans.

OP 05 New frontiers in autoantibody epidemiology

N-terminally truncated GAD discriminates progression in GAD antibody positive relatives of patients with type 1 diabetes

A.J.K. Williams[1], V. Lampasona[2], M. Schlosser[3], P.W. Mueller[4], D. Pittman[5], W.E. Winter[5], R. Wyatt[1], B. Akolkar[6], P.J. Bingley[1], P. Achenbach[7];
[1]School of Clinical Sciences, University of Bristol, UK, [2]Center for Translational Genomics and Bioinformatics, San Raffaele Scientific Institute, Milan, Italy, [3]Department of Medical Biochemistry and Molecular Biology, University of Greifswald, Karlsburg, Germany, [4]Molecular Risk Assessment Laboratory, Centers for Disease Control and Prevention, Atlanta, [5]Department of Pathology, University of Florida, Gainesville, [6]Division of Diabetes, Endocrinology, and Metabolic, National Institute of Diabetes and Digestive and Kidney Diseases, Bethesda, USA, [7]Institute of Diabetes Research, Helmholtz Center Munich, Neuherberg, Germany.

Background and aims: Autoantibodies to glutamate decarboxylase (GADA) are sensitive markers of type 1 diabetes (T1D), but diabetes antibody and islet autoantibody standardization program (DASP/IASP) workshops have shown that GADA assay specificity varies with assay format. IASP-2012 included a comparison between GADA assays using radiolabelled full-length human GAD65 (1-585) or N-terminally truncated GAD65 (96-585), which suggested that removal of the first 95 amino acids improved assay specificity. We aimed to determine whether a GAD65 (96-585) based assay could discriminate risk of progression in GADA positive first-degree relatives of patients with T1D (FDRs).
Materials and methods: Samples from 278 FDRs (134 male) participating in the Bart's-Oxford family study of T1D previously identified as GADA positive with a local radiobinding assay were re-assayed with the harmonized standard GADA assay using 35S-methionine labelled GAD generated by in vitro transcription/translation with plasmids encoding (1) full-length GAD65 (1-585) or (2) N-terminally truncated GAD65 (96-585). Median age at first sample was 31 years (range 1 to 57 years) and median follow-up from first sample was 13.2 years (range 0.2 to 27 years). Diabetes was ascertained by annual questionnaire. Assay thresholds were set at the 97.5th percentile of 222 healthy schoolchildren.
Results: Of 278 FDRs previously found positive for GADA, 255 were positive on re-assay using 35S-GAD65 (1-585), 204 with 35S-GAD65 (96-585) and 193 with both labels. Of 66 FDRs who progressed to diabetes, 63 were positive for GADA (1-585) and 61 positive for GADA (96-585). Kaplan-Meier survival analysis showed that because of their higher specificity, GADA (96-585) stratified risk of progression to diabetes in FDRs positive for GADA (1-585) (Figure 1, p<0.001).
Conclusion: Assays using N-terminally truncated GAD65 (96-585) offer improved specificity for diabetes with minimal loss of sensitivity. These findings confirm the lack of association between diabetes and GADA epitopes in the N-terminal region and suggest that GADA assays using GAD65 (96-585) should be adopted for diabetes screening.

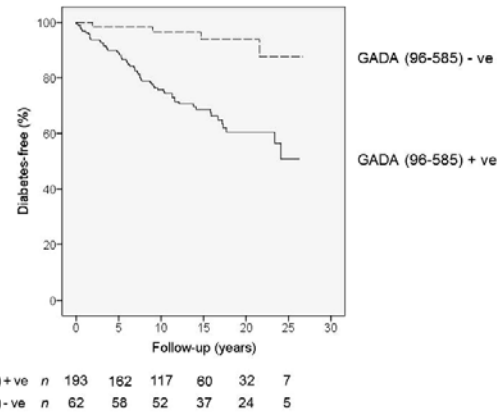

Figure 1. Kaplan–Meier survival analysis; progression to diabetes in 255 relatives of patients with type 1 diabetes found GAD autoantibody (GADA) positive using 35S-labelled full-length GAD65 (1-585), according to positivity with an assay using GAD65 (96-585) ($P < 0{\cdot}001$). The number of diabetes-free relatives remaining at each time-point is given below the axis.

PTPN2 rs45450798 polymorphism is associated with accelerated progression of beta cell autoimmunity to clinical type 1 diabetes

J. Lempainen[1,2], A.-P. Laine[1], A. Hammais[1], R. Veijola[3], O. Simell[2], M. Knip[4,5], J. Ilonen[1,6];
[1]Immunogenetics Laboratory, University of Turku, [2]Department of Pediatrics, University of Turku, [3]Department of Pediatrics, University of Oulu, [4]Children's Hospital, University of Helsinki and Helsinki University Central Hospital, [5]Department of Pediatrics, Tampere University Hospital, [6]Department of Clinical Microbiology, University of Eastern Finland, Kuopio, Finland.

Background and aims: Natural history studies on type 1 diabetes (T1D) associated autoimmunity provide an opportunity to identify the phase where each genetic and/or environmental factor exerts its effect in follow-up cohorts of infants at increased risk for T1D. PTPN2 is one of the recently identified non-HLA genes affecting disease susceptibility and the encoded molecule has been observed to modulate beta cell apoptosis. We now set out to characterize the role of a T1D-risk associated polymorphism rs45450798 in the PTPN2 gene in various phases of the autoimmune process leading to T1D.
Materials and methods: The study subjects were participants in the prospective DIPP study and carried T1D-risk associated HLA II genotypes. The study cohort included 521 case subjects who during the follow-up turned positive for at least one biochemically-defined autoantibody (insulin autoantibodies, antibodies against glutamic acid decarboxylase -65 and/or antibodies against islet antigen -2) and 989 control subjects who remained autoantibody negative. The median follow-up time for the appearance of beta cell autoimmunity was 10.0 years (range 0.85-17.5 years) and median follow-up time for the development of T1D after the appearance of beta cell autoimmunity was 4.4 years (range 0.0-15.7 years). During the follow-up 269 case subjects were diagnosed with T1D. PTPN2 rs45450798 polymorphism was genotyped using the Sequenom platform.
Results: The PTPN2 rs45450798 polymorphism showed a borderline association with progression to T1D in the current cohort (p=0.055 comparing the CC, CG and GG genotypes, Cox regression analysis). No effect of the polymorphism was observed on the appearance of the first beta cell autoantibody (p=0.151). In contrast, a strong effect of the polymorphism on the progression rate of already-established beta cell autoimmunity was detected (p=0.001 comparing the CC, CG and GG genotypes, adjusted for seroconversion age and the presence of the high-risk HLA DR3/DR4 genotype). Among subjects homozygous for the minor C allele associated with T1D risk, 13 of 16 (81.2%) progressed to clinical T1D during the follow-up compared to 253 of 498 (50.8%) of subjects with the CG or GG genotype (p=0.000319, HR 2.820, 95% CI 1.603-4.959).
Conclusion: The PTPN2 rs45450798 polymorphism seems to affect the rate of beta cell destruction after the initiation of beta cell autoimmunity but not the initiation of beta cell autoimmunity. PTPN2 has previously been shown to modulate the activation of a specific pro-apoptotic pathway in beta cells. This is in line with the apoptosis of beta cells induced by CD8+ cytotoxic T cells dominating the insulitis in the late phase of the disease process. These findings provide new insights into the factors controlling the destruction rate of beta cells and provide one tool to identify rapid progressors in trials aimed at halting the ongoing beta cell destruction leading to clinical T1D.

27

Relation between beta cell autoimmunity and levels of allergen-specific IgEs in young Finnish and Estonian children

H. Siljander[1,2], A. Peet[3], V. Tillmann[3], T. Härkönen[1], O. Niemelä[4], J. Ilonen[5,6], L. von Hertzen[7], T. Haahtela[7], E. von Mutius[8], M. Knip[1,2];
[1]Research Laboratory, Hospital for Children and Adolescents, University of Helsinki and Helsinki University Hospital, [2]Folkhälsan Research Center, Helsinki, Finland, [3]Department of Pediatrics, University of Tartu and Tartu University Hospital, Estonia, [4]Department of Laboratory Medicine and Medical Research Unit, University of Tampere and Seinäjoki Central Hospital, [5]Immunogenetics Laboratory, University of Turku, [6]Department of Clinical Microbiology, University of Eastern Finland, Kuopio, [7]Skin and Allergy Hospital, Helsinki University Hospital, Finland, [8]Dr von Hauner Children's Hospital, Ludwig Maximilian University of Munich, Germany.

Background and aims: The Th1/Th2 paradigm assumes that an active autoimmune process prevents or suppresses allergen-specific IgE responses and vice versa. We set out to test this assumption in young Finnish and Estonian children.
Materials and methods: Population based cohorts of 3-year old children (52.4% males) in Finland (n=1530) and Estonia (n=1642) were tested for signs of type 1 diabetes (T1D) associated autoimmunity (autoantibodies against insulin [IAA], glutamate decarboxylase [GADA], islet antigen 2 [IA-2A], and zinc transporter 8 [ZnT8A]) and IgE-mediated allergic sensitization (total IgE and allergen-specific IgEs to cat, dog, egg, cow's milk, peanut, timothy, birch, and dust mite [D. pteronyssinus]). These children were also genotyped for HLA-conferred T1D-susceptibility.
Results: Although Finnish children carried high and moderate HLA risk genotypes more frequently than Estonian children (14.0% vs. 7.6%, p<0.001), the proportion of seroconverted children (2.6% vs. 3.0%, p=0.53) and the distributions of combinations and numbers of positive autoantibodies were comparable (p=0.55 and p=0.18, respectively) in these populations. Total IgE level was higher in Estonian children (median 33.1 vs. 24.7 kU/l, p<0.001), while allergen-specific sensitization (sIgE≥0.35 kU/l) was more common in Finnish children (35.2% vs. 27.2%, p<0.001). Levels of total and allergen-specific IgEs were similar in children with and without autoantibodies, except for timothy, which was higher in IAA-negative children (p=0.02). IAA levels were lower in children positive for cow's milk IgE (p<0.001), whereas the levels of other autoantibodies were comparable in children with and without other positive sIgEs. In the whole cohort we observed weak inverse correlations between IA-2A levels and several allergen-specific IgEs (cat [rS= -0.05, p=0.01], dog [rS= -0.06, p=0.001], peanut [rS= -0.06, p<0.001], birch [rS= -0.04, p=0.01], timothy [rS= -0.07, p<0.001], and dust mite [rS= -0.11, p<0.001].
Conclusion: Positivity for diabetes-associated autoantibodies does not prevent allergen-specific IgE-sensitizations or the other way around. The inverse associations between allergen-specific IgEs and IA-2A titers, IA2A being a marker of an advanced autoimmune process, suggest that advanced beta-cell autoimmunity may reduce allergic sensitization to certain extent.

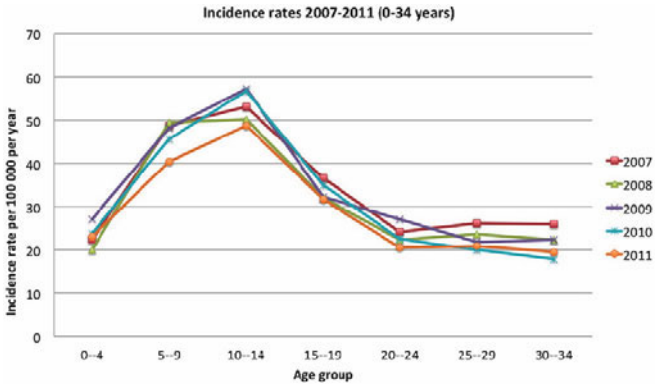
Incidence of type 1 diabetes in Sweden 2007-2011: reassessing the spring harvest theory

A. Rawshani[1], M. Landin-Olsson[2], A.-M. Svensson[1], H.J. Arnqvist[3], L. Nyström[4], J. Bolinder[5], S. Gudbjörnsdottir[1];
[1]Department of Medicine, Sahlgrenska Academy, University of Gothenburg, [2]Dept of Clinical Science, Lund University, [3]Department of Clinical and Experimental Medicine, Linköping University, [4]Department of Clinical Science, Umeå University, [5]Department of Endocrinology, Metabolism and Diabetes, Karolinska Institutet, Sweden.

Background and aims: International multicentre studies report an annual 2.5-3.5 % increase in the incidence of type 1 diabetes (T1DM) among individuals aged 0-14 years. The steepest increase has been noted in the age group 0-4 years and it appears that onset of T1DM has shifted to younger ages. It has been postulated that the increasing incidence in the age-group 0-14 years is due to onset at a younger age and thus mirrored by a reciprocal decrease among individuals older than 14 years (i.e. spring harvest theory). Studies investigating the latter age group have been less standardized and results have been contradictory. It is unknown whether overall cumulative incidence has increased or whether disease onset has merely shifted to younger ages. Previous reports from Sweden, based on two different incidence registers, are in accordance with the spring harvest theory. We aimed to assess the reliability of these reports and attempt to estimate the incidence by other procedures.
Materials and methods: Capture-recapture methodology was used to assess level of ascertainment in the Diabetes Incidence Study in Sweden (DISS) register, which has been used to calculate incidence trends for individuals aged 15-34 years. New estimations of the incidence was done by using the Drug Prescription Register started in 2005. All subjects who collect prescribed insulin for the first time (no insulin collected the previous year), with exclusion of individuals who also obtained oral antidiabetics and females with <3 prescriptions, were counted from 2005 to 2012.
Results: DISS had 55 % level of ascertainment. For the same age-group we calculated, via our proxy for diagnosis, a three times higher incidence than previously reported with no temporal trend during 2007-2011. We recaptured 97 % of the individuals from the Drug Prescription Register in the National Diabetes Register, where 93% had a clinical classification of T1DM. Males showed consistently higher incidence rates than females. The highest incidence rate was noted for males 10-14 years which reached 64.2 per 100 000

per year in 2009. The average age-specific rates per 100 000 per year were 23.3, 46.5, 53.1, 33.5, 23.4, 22.5 and 21.7 at ages 0-4, 5-9, 10-14, 15-19, 20-24, 25-29 and 30-34 years, respectively (2007-2011; graph). Our incidence rates were comparable with figures from the Swedish Childhood Diabetes Register (individuals 0-14 years), which has outstanding level of ascertainment. We did not observe any significant temporal trend regarding age at onset (0-34 years).

Conclusion: This study questions previous reports from Sweden and contradict the postulated spring harvest theory.



29

Enterovirus RNA in longitudinal blood samples from children at the highest genetic risk of type 1 diabetes, and the development of islet autoimmunity: the MIDIA study

O. Cinek[1], L.C. Stene[2], L. Kramná[1], G. Tapia[2], S. Oikarinen[3], E. Witsø[2], K. Holkova[1], T. Rasmussen[2], H. Hyöty[3], K.S. Rønningen[4];
[1]Department of Pediatrics, Charles University in Prague, Czech Republic, [2]Division of Epidemiology, Norwegian Institute of Public Health, Oslo, Norway, [3]Department of Virology, University of Tampere, Finland, [4]Pediatric Research, Oslo University Hospital, Norway.

Background and aims: Enterovirus is suspected to participate in the pathogenesis of islet autoimmunity leading to type 1 diabetes, but only a few longitudinal molecular studies are available, and their results are conflicting. There is a considerable heterogeneity among case-control studies nested within large prospective cohorts as to the association of enterovirus RNA in blood to islet autoimmunity, and positive findings seem to be limited to the Finnish population. Our aim was to investigate such an association in a Norwegian high-risk cohort study, which represents another Nordic population that largely shares the climate, socioeconomic conditions, and lifestyle with the Finns.

Materials and methods: Children with a single HLA-DQ-DR genotype, conferring the highest genetic risk for type 1 diabetes, formed the Norwegian birth cohort MIDIA ("Environmental Triggers of Type 1 Diabetes"). Their blood samples taken at 3, 6, 9, 12 months, and then annually, were tested for autoantibodies to insulin, GAD65, and IA-2 as markers of islet autoimmunity. Among 911 children at risk, 48 cases developed positivity for two or more autoantibodies confirmed in subsequent samples by October 2011, and were included into the present analysis. Two controls from the cohort were matched to each case by the follow-up time, date of birth and county of residence. Enterovirus was tested in RNA obtained from frozen cell packs after removal of plasma, using a meticulously controlled reverse transcriptase TaqMan real-time PCR. The assay was similar to the previous works from Finland, whereas the RNA came from cells rather than serum.

Results: Enterovirus RNA was observed in 15% of the 778 tested blood samples. Positivity for enterovirus in blood was not associated with the appearance of islet autoantibodies, as demonstrated in a logistic regression model with random intercept: OR = 1.01, 95%CI 0.58 - 1.79, p=0.96 for the enterovirus positivity in the sample with first islet autoantibodies or in preceding samples. Similarly, no significant association was found in the time window just prior to developing autoantibodies, or in samples with high levels of enterovirus RNA.

Conclusion: We observed no link between enterovirus RNA in blood and the development of islet autoimmunity in a large Norwegian cohort with homogeneously high genetic risk. Of note, the detection method and the RNA source yielded high enterovirus positivity rates, rendering our study higher power than some of other works. Our negative finding does not exclude an existence of a diabetogenic virus genotype responsible for only a small proportion of infections - genotyping of enteroviruses in blood is therefore warranted, although it is technically extremely difficult.

NPY minor autoantibodies in newly diagnosed type 1 diabetes patients

H. Skärstrand, F. Vaziri-Sani, C. Andersson, H. Elding-Larsson, S. Ivarsson, Å. Lernmark, Skåne Study Group;
Lund University, Department of Clinical Sciences, Skåne University Hospital, Malmö, Sweden.

Background and aims: Neuropeptide Y (NPY) was suggested as a minor autoantigen in a selective screening of new autoantigens targeted in Type 1 Diabetes (T1D). Nearly 9% of newly diagnosed T1D patients were found to have autoantibodies against NPY (NPYA). NPY is a neurotransmitter expressed in the central and peripheral nervous system implicated in vasoconstriction, insulin secretion and in regulation of food intake. A single nucleotide polymorphism (SNP) at rs16139 (T1128C) identified an amino acid substitution from Leucine (L) to Proline (P) (L7P) associated with atherosclerosis, impaired glucose tolerance and a three- to four-fold increased risk for Type 2 diabetes (T2D). We aimed to determine 1) the influence of NPY-L (Leucine) and NPY-P (Proline) autoantibodies on the diagnostic sensitivity of T1D, 2) the association of NPY-LA and NPY-PA with other islet autoantibodies such as GADA, IAA, IA-2A and the ZnT8A variants, and 3) the association of NPY-LA and NPY-PA to HLA-DQ genotypes in newly diagnosed T1D patients in the Skåne study.

Materials and methods: Newly diagnosed T1D patients (n=675; median age 10.2 years) from six pediatric clinical centers in Skåne, South of Sweden, were recruited between 1996 and 2005. Serum samples at diagnosis were analyzed for autoantibodies against NPY-L and NPY-P in a Radiobinding assay as well as against insulin, GAD65, IA-2 and ZnT8. The patients were genotyped for HLA-DQ genotypes. Control samples were obtained from 398 healthy blood donors in Skåne during 2004.

Results: The frequency of positive T1D patients was 17% (n=115) for NPY-LA ($p<0.001$) and 24% (n=161) for NPY-PA ($p<0.001$) as compared to 1% (n=4) of the controls. Our results showed that 2.1% (n=14) of the T1D patients were positive only for the NPY-LA compared to 0.5% (n=2) of controls while 9% (n=61) of the T1D patients were single positive for the NPY-PA variant compared to the controls who were negative for this variant. By including the NPY-LA and NPY-PA to the other major autoantibodies the autoantibody negative T1D patients were reduced from 5.5% (n=37) to 4.8% (n=32). The median levels of the NPY-LA were higher in both T1D patients (31 U/mL; $p<0.001$) and the controls (23 U/mL; $p<0.001$) compared to the levels of NPY-PA (26 U/mL; $p<0.001$) in T1D patients and the controls (16 U/mL; $p<0.001$). The levels of the two NPYA variants were strongly correlated ($R2=0.631$; $p<0.001$). The majority of the T1D patients with NPY-LA (49.6%; $p=0.005$) and NPY-PA (52.8%; $p<0.001$) were diagnosed between the age of 10 and 14 years. Neither of the NPYA variants appeared with any of the GADA, IAA, IA-2A nor the ZnT8A, although the NPY-PA variant showed a slight agreement with ZnT8W (kappa 0.07, $p=0.030$) and GADA (kappa 0.06, $p=0.040$). There were no associations observed between the NPYA positive patients and the HLA-DQ genotypes in the patients.

Conclusion: We conclude that NPY is a minor autoantigen in newly diagnosed T1D patients and therefore, autoantibodies against NPY should be further investigated in the autoimmune disease of T1D. By including the NPYA the diagnostic sensitivity of T1D was increased from 94.5% to 95.2% which may suggest that NPYA could be important at T1D diagnosis.

The novel adipokine WISP2 regulates adipogenesis and is a canonical Wnt ligand

J.R. Grünberg, A. Hammarstedt, S. Hedjazifar, U. Smith;
Molecular and Clinical Medicine/Diabetes, Medicine, Göteborg, Sweden.

Background and aims: Adipose precursor cell commitment and differentiation are regulated by the canonical WNT and BMP4 signalling pathways. We have recently shown that these pathways cross-talk via WISP2 (WNT1-inducible signalling pathway protein 2), a novel adipokine which regulates PPARγ activation as an intracellular protein by inhibiting the effect of BMP4 to promote the nuclear targeting of the PPARγ transcriptional activator ZNF423. However, WISP2 is also a secreted protein and we here focus on its mechanisms of action as an extracellular protein.
Materials and methods: The experimental studies were performed with 3T3-L1 cells and NIH-3T3 cells. The cells were treated with recombinant WISP2 or Wnt3a; transfected with siRNA or full-length or truncated WISP2. The latter plasmid had a deleted N-terminal signal peptide sequence to prevent WISP2 secretion. mRNA, protein expression levels and different markers of adipogenesis were measured.
Results: We have previously shown that intracellular/cytosolic WISP2 regulates adipogenic commitment of precursor cells in response to BMP4. We here compared the effect of full-length vs secreted WISP2 and expressed both a full-length and a truncated molecule lacking the signal sequence and which, thus, was not secreted. We also compared the effects of adding rWISP2 to the cells to those of Wnt3a, a well-established canonical WNT activator. Wnt3a is able to de-differentiate mature adipose cells by inhibiting PPARγ and, remarkably, we also found that WISP2 did the same measured as significant inhibition of both C/EBPα and PPARγ as well as several PPARγ-regulated genes including GLUT4, adiponectin, aP2 and LPL. These results suggest that WISP2 may also activate canonical WNT. To further examine this, we measured expression and phosphorylation of down-stream molecules for WNT activation and found that both Wnt3a and WISP2 increased pS-LRP 5/6 as well as β-catenin serine phosphorylation, a marker for nuclear targeting, as well as total β-catenin expression. Axin, the rate-limiting protein for β-catenin degradation in the degradation complex, was also significantly down-regulated by both ligands. In line with this, we also found increased nuclear β-catenin levels in the presence of rWISP2 as well as activation of the nuclear receptor for β-catenin in a Tcf/Lef reporter assay (234%, $p< 0.05$) in NIH-3T3 cells. Importantly, we found that full-length, but not intracellular (truncated and not secreted), WISP2 increases β-catenin serine phosphorylation.
Conclusion: These results show that the secreted adipokine WISP2, which is highly expressed in mesenchymal stem cells and early precursor cells, is a regulator of adipogenesis and PPARγ activation as a canonical WNT ligand, thereby keeping the cells in an undifferentiated state. Our previous studies have shown that it also retains the PPARγ transcriptional activator ZNF423 in the cytosol and that this complex is dissociated by BMP4 thereby initiating the first steps of adipogenic commitment and PPARγ activation. However, full differentiation also requires inhibition of secreted WISP2. Thus, WISP2 plays a key role in the regulation of adipogenesis by both regulating precursor cell commitment in response to BMP4 as well as the subsequent differentiation and PPARγ activation as a WNT ligand.

32

BMPs regulate glucose uptake in 3T3L1 adipocytes in an insulin independent manner

K. Ruschke, G. Doerpholz, P. Knaus;
Dept. for Chemistry and Biochemistry, Freie Universität Berlin, Germany.

Background and aims: With the increasing number of patients with pronounced insulin resistance and type 2 diabetes, the identification of insulin-independent mechanisms regulating glucose uptake is of great interest. Bone morphogenetic proteins (BMPs) are cytokines of the transforming growth factor beta superfamily. They are involved in several cellular processes like proliferation and migration of precursor cells but also in differentiation, maintenance and apoptosis. Furthermore, recent studies suggested an impact of BMPs during adipogenesis. To unravel a putative regulatory role of BMPs during glucose homeostasis in adipose tissue we investigated if stimulation with BMP-2 or BMP-6 influences the glucose uptake in 3T3L1 adipocytes and which related factors are regulated by an activated BMP-signaling cascade.
Materials and methods: Fully differentiated 3T3-L1 adipocytes where short/long term stimulated either with Insulin, BMP-2, BMP-6, or combinations thereof. Afterwards, H3-2-deoxyglucose uptake was compared to unstimulated cells. For immunofluorescence based visualization of BMP-mediated GLUT-4 translocation we used a stable 3T3L1 cell line expressing a cMYC-GLUT4-GFP fusion protein. Alterations in the expression of factors related to GLUT-4 translocation and BMP-signaling after stimulation for 2 to 24 hours where measured by Real Time PCR and Western Blot.
Results: Activation of the BMP-signaling cascade by BMP-2 but particularly by BMP-6 leads to an up to 4-fold increase of glucose uptake in 3T3L1 adipocytes compared to controls ($p<0.005$). A combined long term BMP-6/short term insulin treatment had a synergistic effect with up to 6-fold and 2-fold higher uptake rates compared to controls ($p<0.01$) and BMP-6 or insulin treated cells ($p<0.05$), respectively. The increase in glucose uptake was mediated by translocation of GLUT-4 vesicles to the cell surface. On mRNA level PPAR gamma expression was significantly increased already after 2 hours of BMP-6 stimulation, which suggests direct BMP-mediated transcriptional control by binding of Smad-complexes to the PPAR gamma 2 promoter. The mRNA expression of insulin receptor and leptin decreased continuously in long term BMP-6 stimulated cells. Expressions of BMP-6 bound BMP receptors ALK 3, BMPRII and ActRIIa decreased under BMP-6 stimulation after 8 and 18 hours suggesting a negative feedback mechanism after activation of these receptors.
Conclusion: Glucose uptake in 3T3L1 adipocytes is increased by BMP-stimulation especially after long term BMP-6 treatment. The effect is mediated by GLUT-4 vesicle translocation to the cell surface. Combined BMP-6/Insulin treatment acts synergistically to increase glucose uptake rates to a maximum level compared to BMP-6 or insulin treatment alone, which suggest distinct mechanisms of action during regulation of glucose uptake. We hypothesize a BMP-dependent functional interaction of the BMP- and Insulin-signaling pathways during regulation of glucose homeostasis, in which BMP-6 acts as insulin sensitizer.

SHORT syndrome with partial lipodystrophy due to impaired PI 3-kinase signalling

P.R. Njolstad[1], K.K. Chudasama[2], J. Winney[3], S. Johansson[2], T. Claudi[4], R. Koenig[5], I. Haldorsen[6], B. Johansson[2], J.R. Woo[3], D. Aarskog[2], J.V. Sagen[6], C. Kahn[3], A. Molven[6];
[1]Medical and Population Genetics, Broad Institute of Harvard and MIT, Cambridge, USA, [2]Department of Clinical Science, University of Bergen, Norway, [3]Joslin Diabetes Center, Harvard Medical School, Boston, USA, [4]Department of Medicine, Nordlandssykehuset, Bodø, Norway, [5]Department of Human Genetics, University of Frankfurt, Germany, [6]Department of Clinical Medicine, University of Bergen, Norway.

Background and aims: Phosphatidylinositol (PI) 3-kinase signaling regulates fundamental cellular processes such as metabolism, proliferation and survival. A central component in this pathway is the p85α regulatory subunit, encoded by PIK3R1.
Materials and methods: We studied two independent families with autosomal dominantly inherited short stature, facial dysmorphism, low body mass index (BMI), Rieger anomaly, teething delay (SHORT syndrome), diabetes and partial lipodystrophy. We used whole-exome sequencing, micro array genotyping, structural modeling and functional studies including insulin signaling in vitro, as well as PI kinase assays in the investigations.
Results: Using whole-exome sequencing, we identified a heterozygous PIK3R1 mutation (R649W) in the two unrelated families with SHORT syndrome and partial lipodystrophy. This mutation led to impaired interaction of p85α with IRS-1 and reduced AKT-mediated insulin signaling in patient fibroblasts and reconstituted pik3r1 knockout preadipocytes.
Conclusion: Normal PI 3-kinase activity is critical for adipose differentiation and insulin signaling, the mutated PIK3R1 therefore provides a unique link between lipodystrophy, growth and insulin signaling.

The role of microRNA 107 in the regulation of adipogenesis

D. Löffler, D. Rockstroh, W. Kiess, A. Körner;
Pediatric Research Center, Leipzig, Germany.

Background and aims: MicroRNAs (miRNAs) are a family of small, endogenously expressed, non-coding RNAs that negatively regulate gene expression at the post-transcriptional level. Several miRNAs were reported to be expressed in adipocytes and seem to play a role in the regulation of adipogenesis even with potential impact on adipogenesis dysfunctions. In this study we investigated the effect from miRNAs on human adipogenesis by inhibition of the miRNA processing. Furthermore, we searched for miRNAs that are differentially regulated during human adipocyte differentiation and their putative target genes.
Materials and methods: *In vitro* experiments were performed in human Simpson-Golabi-Behmel syndrome (SGBS) cells, a cell model for human adipogenesis. MiRNA processing was inhibited by knock down of Drosha and Dicer, key enzymes of the processing machinery. Effects on adipogenesis were measured by Oilred staining, counting of differentiated cells and expression analysis of *PPARg*. Regulated microRNAs were identified using Illumina technology based miRNA sequencing. Results were validated by real time PCR.
Results: A knock down of Drosha and/or Dicer significantly reduced fat accumulation to 42±6.8 % and *PPARg* expression by trend to 58±26 %. Sequencing experiments identified 7 miRNAs at least 2.5 fold induced and 12 miRNAs at least 0.4 fold repressed during adipogenesis. MiR107 was 2.5 induced at d12 of differentiation. We could identify Progranulin as a putative target of MiR107. Therefore, *Progranulin* is inversely regulated compared to miR107 during SGBS adipogenesis. Ectopic expression of miR107 in preadipocytes mediated a reduction of Progranulin and inhibits adipogenesis. Furthermore, a knock down of *Progranulin* leads to a significantly reduced fat accumulation to 73±11% (P=0.05), which is accompanied by a decreased *PPARg* (P<0.001) and *aP2* (P<0.001) mRNA expression.
Conclusion: Inhibition of miRNA processing reduced human adipocyte differentiation capacity. We identified 19 miRNAs differential regulated during human adipogenesis and showed that Progranulin is a target of the upregulated miR107. Our results support a regulatory function of miR107 and Progranulin during adipogenesis.

35

Regulation of PPARγ activity by a novel serine phophorylation

T. Oh[1], B.-H. Park[2], Y.-H. Lee[2];
[1]Internal Medicine, [2]Biochemistry, Chungbuk National University, Cheongju, Republic of Korea.

Background and aims: The mammalian ste20 kinase (MST) pathway, originally identified as hippo pathway in Drosophila, plays an important role in the regulation of apoptosis and cell cycle control. Previously, we showed that MST2 activates PPARγ and induces adipocyte differentiation. To further characterize this phenomenon, we sought to identify and analyze the phosphorylation of PPARγ by MST2 kinase.
Materials and methods: We performed a mass spectrometric analysis of PPARγ protein which was co-expressed with MST2. We employed various protein analysis methods and Oil red staining to analyze the effect of the phosphorylation in HEK293 cells and 3T3-L1 adipocytes.
Results: Using mass spectrometric analysis, we detected a novel Ser phosphorylation site in PPARγ protein that was co-expressed with MST2. Mutation of Ser to Ala (SA) resulted in a significant decrease in transcription activity of PPARγ compared to WT. Interaction of PPARγ with PGC1β, one of the various PPARγ coactivators, was increased by rosiglitazone. However, SA mutant showed significantly inhibited interaction with PGC1β, indicating the identified Ser phosphorylation may be important for the binding of PPARγ to its coactivators. SA mutation significantly decreased PPARγ-induced adipocyte differentiation of 3T3-L1 cells. Finally, a rabbit pSer-specific antiserum was prepared and detected a strong phosphorylation in PPARγ-WT but not in SA.
Conclusion: In this report, we present a novel Ser phosphorylation site in PPARγ and propose that this phosphorylation may be a novel regulatory mechanism of PPARγ activation by MST pathway.

The transcription factor Prep1 impairs adipose tissue differentiation

A. Liotti[1], F. Oriente[1], S. Cabaro[1], I. Cimmino[1], F. Ariemma[1], S. Ricci[1], F. Blasi[2], P. Formisano[1], F. Beguinot[1];
[1]DISMET & CNR/IEOS, Università di Napoli FEDERICO II, Napoli, [2]IFOM, Milano, Italy.

Background and aims: Adipose tissue is crucial for maintaining energy and metabolic homeostasis. Adipose tissue functionality is closely related to the adipocytes differentiation state, which is regulated by several transcriptional factors. Prep1 is an homeodomain transcription factor belonging to the TALE proteins, which plays an important role in hematopoiesis, organogenesis and development. Previous studies have indicated that Prep1 hypomorphic ($Prep1^{i/+}$) mice, which express only 55-57% of protein, have a complex metabolic phenotype with at least two relevant features. One is the presence of smaller but otherwise normally structured islets with reduced fasting and post-loading plasma insulin levels. The second is increased insulin sensitivity in skeletal muscle and in liver which is accompanied by protection from streptozotocin-induced diabetes. In this study we have focused our attention on the role of Prep1 on the regulation of adipocytes differentiation and on the adipose tissue functionality.
Methods and results: To understand the possible role of Prep1 in adipose tissue we have evaluated the expression of some markers of adipocytes differentiation, including PPARγ, C/EBPα, GLUT4 and aP2/FABP4 in Prep1 hypomorphic and WT mice. Western blot and qRT-PCR experiments show a significant increase of C/EBPα, GLUT4 and aP2/FABP4 protein and mRNA expression in adipose tissue of Prep1 hypomorphic mice, while PPARγ does not change. In addition, insulin- stimulated glucose-uptake is increased in adipocytes isolated from adipose tissue of $Prep1^{i/+}$ mice compared to the adipocytes from WT mice. To further study the function of Prep1 on adipocytes differentiation, we have analyzed Prep1 expression during different steps of adipogenesis in 3T3-L1 murine fibroblasts. Levels of Prep1 are progressively reduced during the conversion from preadipocytes to adipocytes 3T3-L1. Moreover, adipocytes 3T3-L1 stable transfected with Prep1 cDNA show reduced lipid accumulation, after Oil Red-O staining, and reduced mRNA and protein expression of the adipogenic markers C/EBPα, GLUT4 and aP2/FABP4.
Conclusion: All together these data suggest that Prep1 regulates adipocytes differentiation giving a rationale to investigate Prep1 as possible new therapeutic agents in preventing adipose tissue dysfunctions.

OP 07 Type 1 diabetes: lifetime impacts

37

A comparison of type 1 diabetes phenotype in a young multi-ethnic urban population

T. Brabarupan, S. Misra, N.S. Oliver;
Diabetes, Endocrinology and Metabolism, Imperial College London, UK.

Background and aims: Type 1 diabetes (T1DM) is a heterogenous condition, presenting with variable phenotypes. The South Asian (SA) and African Caribbean (AC) population in the UK have a higher proportion of type 2 diabetes than the White European (WE) population, but the incidence of T1DM in these groups approaches that of European populations. Whilst studies have demonstrated phenotypic differences in type 2 diabetes (T2DM) between ethnic groups, such as a lower BMI in SA individuals and higher HbA1c in AC individuals, very few studies have assessed the phenotypic differences in a multiethnic T1DM population.
Materials and methods: A cross-sectional retrospective study of subjects with T1DM diagnosed below 35 years of age, from WE, AC or SA ancestry was undertaken from an electronic database in a large multiethnic London diabetes clinic. Age at diagnosis, duration of diabetes, BMI, HbA1c, microalbuminuria, blood pressure, and lipid profiles were compared between ethnic groups. A sub-analysis of subjects diagnosed between 16-35 years was additionally undertaken to assess the same parameters in young-adults diagnosed with T1DM.
Results: 642 individuals diagnosed with T1DM before 35 years of age were identified over a 10-year period. 88% of the population was WE, with 6% each from SA and AC populations. Table 1 shows the differences in measured parameters between each ethnic group with significance. Comparing the WE group to the AC group; BMI was not significantly different, however duration of diabetes was significantly longer with associated younger age at diagnosis in the WE group, HbA1c and microalbuminuria were also lower than in the AC group. Comparing the WE group to the SA group; HDL and systolic BP were significantly higher in the WE group. On comparison of the AC group to the SA group; HbA1c and systolic BP were significantly higher in the AC group. Sub-analysis of those diagnosed 16-35 years (n=346), revealed similar differences in HbA1c, microalbuminuria and BP, but HDL levels were additionally higher in the WE group compared to the AC group and duration of diabetes was similar across all groups.
Conclusion: There are significant differences in the biochemical and clinical attributes of people with T1DM between ethnic groups, with differences in HbA1c, microalbuminuria and blood pressure for the same BMI . In this cohort the changes were most marked when comparing the WE to the AC group, the latter demonstrating poorer control with evidence of microvascular complications and higher BP despite a significantly shorter duration of diabetes and similar BMI. HDL levels were lower in the adult-onset AC group, but other differences persisted despite a similar duration of diabetes. Only some of these differences however, were observed comparing SA individuals to the WE group. These results suggest marked heterogeneity of T1DM between ethnic groups, which may reflect differing underlying pathophysiologies or variations in management. Further study is required to delineate the factors that underlie these differences.

Differences in measured parameters between ethnic groups, diagnosed <35years

Parameters median(IQR)	White European (WE)	African Caribbean (AC)	South Asian (SA)	Significant

An international collaboration to compare glycaemic control among people with type 1 diabetes

J.A. McKnight[1,2], International quality of care for type 1 diabetes group;
[1]University of Edinburgh, [2]NHS Lothian, Edinburgh, UK.

Background and aims: Optimising glycaemic control in type 1 diabetes has been shown to reduce microvascular complications. Most guidelines recommend a target HbA1c of 6.5 to 7.5% (48 to 58 mmol/mol). Our aim was to investigate whether comparison of HbA1c of populations with type 1 diabetes in different healthcare systems is feasible as a first step in informing approaches to improving glycaemic control.
Materials and methods: Through open invitation, and with appropriate permissions data were obtained for 142,260 children and/or adults with type 1 diabetes defined using the best available information for each country from 12 countries in total (Austria, Denmark, Germany, Italy, Latvia, New Zealand, Norway, Scotland, Slovenia, Sweden, Ukraine, United States with data from Australia, England, Finland, France and Northern Ireland anticipated) for the previous 12 to 24 months from both population-based registers and clinic-based databases. Data were analysed where available for more than 100 people in each age stratum (<15 years, 15-29 years, 30+ years). The sample size by country therefore varied from 340 to 27,904. Median HbA1c and interquartile range (IQR) were estimated from aggregated data within age strata. Proportions in each population with above target HbA1c (defined as HbA1c ≥7.5% (≥58mmol/mol)) were compared in the same age strata.
Results: Estimated median HbA1c was 7.75% (IQR 7.25% to 8.75%) in individuals <15 years (n=29673), 8.25% (7.25% to 9.55%) in individuals between 15 and 29 years (n=36812) and 8.25% (7.25% to 8.75%) in individuals 30+ years (n=73622). The proportion with HbA1c above target varied between countries from 53.6% to 84.3% for people <15 years of age (n = 29,727), from 50.4% to 86.7% in people of 15 to 29 years (n = 36,812) and from 45.5% to 79.1% in those 30+ years (n = 73,629).
Conclusion: Substantial variations in glycaemic control among people with type 1 diabetes exist between countries. Further work is required to investigate the roles of selection bias and HbA1c assay variation on these preliminary findings before the data can be used to influence health service development. We encourage the development of true population based registers in all health systems and welcome collaborators from other countries.

39

The impact of a childhood onset of type 1 diabetes on higher education and labour market outcomes

S. Persson[1], G. Dahlquist[2], U.G. Gerdtham[1,3], K. Steen Carlsson[1];
[1]Health Economics Unit, Department of Clinical Sciences, Lund University, Malmö, [2]Pediatrics Unit, Department of Clinical Sciences, Umeå University, [3]Department of Economics, Lund University, Sweden.

Background and aims: Childhood onset of Type 1 diabetes mellitus (DM) may place great strain on the affected individuals, their families and society. The time consuming treatment requires lifestyle changes and the complications of the disease may increase absenteeism and reduced work capacity. This study investigates the effect of a childhood onset of Type 1 diabetes on university education and labour market outcomes in early adulthood.
Materials and methods: Individuals, diagnosed <15 years and born in 1972-1978, were selected from the Swedish Childhood Diabetes Register, which was linked to national population registers including the Longitudinal integration database for health insurance and labour market studies (LISA). For each individual (n=2,485), four controls from the general population, matched for year of birth and residency at the time of the diagnosis, were selected by Statistics Sweden (n=9,940). Data concerning annual earnings was available from 1990 to 2010 which allowed the analysis to consider the time period after graduation from upper secondary school (age 19) to the age of 31. Linear, logistic and panel data (random effects) regression was used to conduct the analysis, controlling for demographics and socioeconomic background.
Results: The results indicate that individuals with diabetes were less likely to have a university degree at 31 years of age (OR 0.81, 95% CI 0.70-0.94 for both women and men) and they were also less likely to have attained higher education for 3 years or longer (OR 0.77, 95% CI 0.66-0.90 and 0.78, 95% CI 0.66-0.92 for women and men, respectively). Further, individuals with diabetes were less likely to be employed at age 31, particularly women (OR 0.64, 95% CI 0.52-0.79 and 0.70, 95% CI 0.55-0.90 for women and men, respectively).

Among those employed at age 31, the results also showed negative effects on earnings, although not significant for women (-5% women, p=0.192 and -13% men, p<0.001). The largest negative effect on earnings was found among men without higher education (-16%; p<0.001). The results using panel data analysis showed lower earnings for people in the ages 19-31 years with diabetes active on the labour market (women -9.30%; p<0.001, -5.27%; p=0.023). The negative effect was larger among those without university education, especially for women, whereas no significant difference was seen among men with university education.
Conclusion: The results showed that Type 1 diabetes with childhood onset negatively impacts the level of education and labor market outcomes among young adults. Women with diabetes were generally worse off, with the greatest impact among women with pre-university education only.

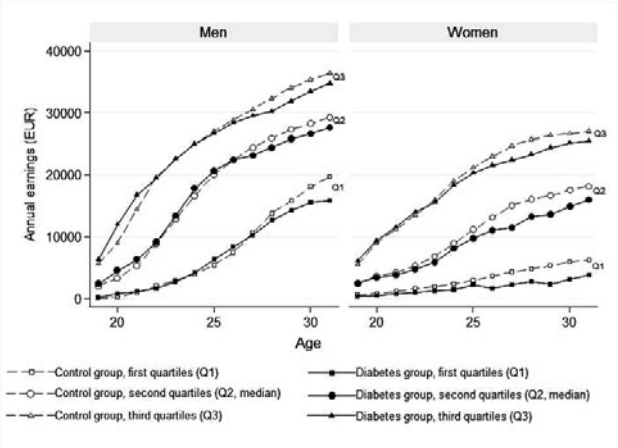

Figure 1: Development of annual earnings for the diabetes group and the control group in the age between 19 to 31 years.

Early retirement in patients with type 1 diabetes: data from a nationwide multicentre survey in Brazil
M.B. Gomes[1], C.A. Negrato[2], Brazilian Diabetes Type 1 Study Group;
[1]Internal Medicine, State University Rio De Janeiro, [2]Internal Medicine, Associação Médica De Diabéticos Bauru, Brazil.

Background and aims: Type 1 diabetes mellitus (T1D) is a chronic disease which carries a great risk of morbidity and mortality, as a result of the microvascular and macrovascular complications that reduce individual's quality of life and life expectancy. In general T1D patients had less probability to be in the workforce, had more work-loss days that could be enhanced by the presence of any diabetes-related complication. Moreover, the rate of unemployment is greater in T1D, of 5.6% in comparison to T2D, of 1.9% and non diabetic individuals, of 2.9% . This data must be interpreted with the knowledge that the majority of T1D were in a labor age and in the most productive years of their lives. Objective: To evaluate the prevalence, causes and predictors of early retirement in patients with T1D in Brazil considering the absence of national data on this topic.
Material and methods: This was a cross-sectional, multicenter study conducted between December 2008 and December 2010 in 28 public clinics in 20 Brazilian cities. Data were obtained from 3,180 patients, aged 22 ± 11.7 years, of whom 56.3% were females, and 57.4% were Caucasians. The mean time since diabetes diagnosis was 10.3 ± 8.1 years. Working status was evaluated in T1D with criteria to be employed or retired, n=2,046 (64.4%), which were subdivided according to self-reported retirement because of diabetes and employed but aged enough to be retired. Patients retired at expected age, n=22 (0.7%), T1D without criteria to be employed or retired (n=1,106, 34.8%) and patients with permanent disability due to other diseases, n=6 (0.2%) [(Down Syndrome, n=4, congenital amaurosis, n=1 and schizophrenia, n=1); were excluded from this study.
Results: The prevalence of retirement because of T1D was 4.2%, without difference between genders. The mean age of retirement in patients retired because of T1D was 35.5 ± 9.3y, resulting in more than 15 y of workforce loss in our society. Retired patients had a significantly higher prevalence of severe hypoglycemia, proliferative and non-proliferative retinopathy, foot disorders, clinical nephropathy, chronic renal disease under conservative and under dialysis treatment and had undergone renal transplantation than employed patients. Cataract, glaucoma, psychological disorders, hypertension and overweight/obesity were also significantly more frequently found in patients that retired because of diabetes in comparison to employed patients. Multivariate logistic regression model performed for retirement (yes/no) as the dependent variable showed an adjusted odds ratio,(95% confidence interval) [OR, 95%CI] of 4.81(2.66-8.69) for the presence of microvascular complications, of 3.5 (1.95-6.59) for the presence of macrovascular complications, of 1.08 (1.05-1.11) for age, of 1.06 (1.02-1.10) for duration of diabetes.
Conclusions: It is imperative in our country, to change the approach given to T1D by the diabetes care team in terms of education and follow-up to a proactive model, in order to avoid or postpone the occurrence of chronic complications and consequently early retirement, which might in many ways worsen an already compromised quality of life. Considering the great workforce loss resulting from early retirement in T1D, this fact must be considered an important issue this group of patients.

15 year follow-up of quality of life in type 1 diabetes mellitus: no impact of treatment mode (FANTA-1)
P.R. van Dijk[1], S.J.J. Logtenberg[2,1], K.H. Groenier[3,1], N. Kleefstra[1,4], H.J.G. Bilo[1,2];
[1]Diabetes centre, Isala clinics, Zwolle, [2]Internal Medicine, University Medical Center Groningen, [3]General practice, University Medical Center Groningen, Zwolle, [4]Langerhans, Zwolle, Netherlands.

Background and aims: Over the last decades intensified insulin therapy with multiple daily injections (MDI), or continuous subcutaneous insulin infusion (CSII) has become the treatment of choice for patients with type 1 diabetes mellitus (T1DM). The aim of the current study was to evaluate metabolic control and health related quality of life (HRQOL) in a T1DM population treated with different insulin regimes during a 15 year follow-up.
Materials and methods: As part of a prospective cohort study which was initiated in 1995, 283 patients with T1DM were included. To determine long term changes in HRQOL and glycaemic control data from subjects who completed baseline and follow-up measures in 2002 and 2010 were analysed. Linear mixed models were used to calculate estimated values and to test differences between the three moments in time and the three treatment modalities.
Results: At baseline, in subjects who completed follow-up (n=113, 63.7% male) the median age was 37.1 (IQR 29.4, 43.0) years and diabetes duration 13.4 (5.5, 21.2) years. Among these patients significant changes (mean Δ (95% confidence interval (CI)) in BMI (2.4 kg/m^2 (0.98, 3.8)), systolic blood pressure (-6.4 mmHg (-11.4, -1.3)), serum creatinine (-10.1 micromol/L (-14.8, -5.4)) and EuroQol-VAS (-7.3 (-11.4, -3.3)) were observed over time (p<0.05). Regarding mode of therapy, 33 patients switched from MDI to CSII at some point during follow-up. A total of 52 patients remained on MDI and 28 remained on CSII throughout follow-up. Among patients on MDI, HRQOL decreased significant in time: mental component summary (-9.8 (-16.3, -3.2)), physical component summary (-8.6 (-15.3, -1.8)) and EuroQol-VAS (-8.1 (-14.0, -2.3)), p<0.05 for all. The latter also decreased over time among CSII users: -9.6 (-17.5, -1.7, p<0.05). There were no significant differences between patients that remained on either therapy or patients that switched from MDI to CSII).
Conclusion: Although some parameters of HRQOL decreased among patients on MDI and CSII, it remained stable for the whole group of T1DM patients after long-term follow-up, irrespective of changes in BMI and blood pressure. There were no differences with respect to metabolic and HRQOL parameters between the various treatment modalities.

42

Explanatory factors of emotional diabetes distress and glycaemic control in type 1 diabetes
L.E. Joensen[1], T. Almdal[2], I. Willaing[1];
[1]Steno Health Promotion Center, Steno Diabetes Center, [2]Gentofte University Hospital, Denmark.

Background and aims: The majority of patients with type 1 diabetes are expected to self-manage their disease. Diabetes is a heavy burden for the pa-

tients and psychological problems are highly prevalent among patients with type 1 diabetes. Little is known about the relationship between social factors, psychological factors and glycaemic control. The objective of this study was to investigate and compare explanatory factors of the variance in diabetes distress and HbA1c respectively - in patients with type 1 diabetes. We investigated the association of low social status, living without a partner, lack of social support and poor self-management behaviours to poor glycaemic control (HbA1c) and to emotional diabetes distress. Furthermore, we investigated the association of HbA1c level to the variance in emotional diabetes distress and the association of emotional, interpersonal, regimen and physician distress to the variance of HbA1c.

Materials and methods: We used a cross-sectional survey of 2419 Danish patients with type 1 diabetes and data from an electronic patient record. Data were analysed using stepwise addition of covariates in multiple linear regression models with HbA1c and emotional diabetes distress as dependent variables. We included patient characteristics: sex, age, diabetes duration, complication status and other chronic illness as covariates in all models.

Results: Results showed that patient characteristics, social status, cohabitation status and social support accounted for 23 % (P<0.0001) of the total variance in emotional diabetes distress. Adding HbA1c and self-management behaviours raised the explained component to 25% (P<0.0001). Furthermore, patient characteristics, social status, cohabitation status and social support accounted for 8 % (P<0.0001) of the variance in HbA1c. Adding emotional, interpersonal, regimen and physician diabetes distress covariates explained 19% (P<0.0001) and adding self-management behaviours raised it to 21% (P<0.0001).

Conclusion: Our study highlights the relationship between social factors, psychological factors and glycaemic control. The study points towards a web of causes influencing psychological distress as well as glycaemic control. The large unexplained component of variance calls for further research into factors explaining the variance in glycaemic control and emotional diabetes distress

GLP-1 and the DPP-IV inhibitor saxagliptin similarly protect human beta cells from palmitate-induced toxicity: potential role of autophagy regulation

M. Bugliani, F. Syed, M. Suleiman, F. Olimpico, U. Boggi, M. Masini, P. Masiello, F. Filipponi, L. Marselli, P. Marchetti;
Dept. Clinical and Experimental Medicine, Islet Cell Laboratory, University of Pisa, Italy.

Background and aims: GLP-1 protects beta cells from lipotoxicity; moreover, the recent discovery of GLP-1 and DPP-IV in human pancreatic islets (HI) has raised interest on the possibility of a direct action of this local GLP-1 system on islet cell pathophysiology. Here we studied the role of GLP-1 and the DPP-IV inhibitor saxagliptin on isolated HI exposed to palmitate toxicity, and explored some of the possible mechanisms involved, including autophagy.

Materials and methods: HI were isolated from the pancreas of 14 multiorgan donors (age: 71±13 yrs, M/F: 8/6, BMI: 26.5±3.0 kg/m2) by enzymatic digestion and density gradient purification. Survival, functional, ultrastructural and molecular studies were performed with HI incubated for 48h at control conditions (Ctrl) or in the presence of 0.5 mM palmitate (lipotoxic condition), with or without the addition of 10 nM GLP-1 or 50 μM saxagliptin, either alone or in combination.

Results: As expected, palmitate caused increased beta cell death (7.0±1.1 vs 1.0±0.2% of Ctrl, p<0.01) and blunted glucose-stimulated insulin secretion (stimulation index: 1.6±0.5 vs 2.2±0.9, p<0.05). This was accompanied by significant reduction of insulin granules, increased ER and mitochondrial volume (all quantified by electron microscopy) and unchanged expression (by qPCR) of glut2 and glucokinase. GLP-1 or saxagliptin alone similarly decreased palmitate-induced beta cell death (-40%), improved insulin secretion (+40%) and preserved, at least in part, organelle ultrastructure. A synergic effect of GLP-1 and saxagliptin was only seen on insulin secretion, that doubled compared to that of palmitate exposed islets. Incubation with palmitate led to the accumulation of autophagosomes in beta cell cytoplasm (0.8±0.1 vs 0.2±0.1 ml% of Ctrl, p<0.01), that associated with increased expression of the autophagic genes Beclin 1, ATG5, ATG7 and LAMP2. Co-incubation with GLP-1 or saxagliptin resulted in normalization of autophagosome volume density and autophagy gene expression.

Conclusion: Since saxagliptin had protective effects on lipotoxicity similar to GLP-1, it is suggested that inhibiting DPP-IV can have direct beneficial actions on human islet cells, which was supported by saxagliptin and GLP-1 synergic potentiation of glucose-stimulated insulin release; changes at the autophagy level may play a role.

Direct enhancement of insulin secretion by dipeptidyl peptidase 4 inhibitors in pancreatic islets: studies in incretin receptor deficient mice

B. Omar[1], L. Ohlsson[1], Y. Yamada[2], Y. Seino[3], B. Ahren[1];
[1]Clinical Sciences, Lund University, Sweden, [2]Medicine, Akita University, Akita City, [3]Kyoto University, Japan.

Background and aims: Type 2 diabetes (T2D) is characterized by insulin insufficiency and insulin resistance. Successful treatments for T2D have been achieved by improving insulin secretion by targeting the incretin hormones glucose dependant insulinotropic polypeptide (GIP) and glucagon-like peptide (GLP-1). Inhibition of dipeptidyl peptidase 4 (DPP-4), the enzyme that degrades and inactivates GIP and GLP-1, has proven to be a successful strategy for treating T2D. DPP-4 inhibitors effectively lower HbA1C in type 2 diabetic individuals without increasing circulating GLP-1 and GIP to supraphysiological levels. This has led many to question whether the effects of DPP-4 inhibitors are mediated solely through preserving intact intestinally secreted GLP-1, allowing it to exert insulinotropic effects on beta cells. Recent studies have demonstrated that alpha cells express and secrete GLP-1 and GIP and that the islet secreted incretins exert their insulinotropic effect directly on adjacent beta cells. We hypothesize that DPP-4 activity is also present in mouse and human islets and that DPP-4 inhibitors exert some of their effects on insulin secretion by preserving intact GLP-1 and GIP secreted from alpha cells.

Materials and methods: Islets were isolated from female C57BL/6 (WT) mice as well as GIP receptor knockout (GIPR-/-) or double incretin receptor knockout (DIRKO) mice, which are doubly deficient in the GIP and GLP-1 receptors. Islets were incubated in media containing 2.8 or 16.7 mM glucose with or without the addition of the DPP-4 inhibitor NVP-DPP728. Insulin secretion was determined by ELISA. Dipeptidyl peptidase 4 activity was assayed in homogenates of frozen mouse and human islets.
Results: DPP-4 activity was readily detected in mouse and human islet homogenates. The enzymatic activity of DPP-4 in mouse islet homogenates was lower than that in plasma from the same animals (36.0 ± 1.8 vs. 139.8 ± 4.4 pmol/minute/mg protein in islets and plasma, respectively). In frozen human islet homogenates, DPP-4 activity was detectable but lower than that of mouse islets (36.0 ± 1.8 vs. 9.8 ± 1.0 pmol/min/mg protein in mouse and human islets respectively). Glucose stimulated insulin secretion from isolated mouse islets was potentiated by the DPP-4 inhibitor NVP-DPP728. The GLP-1 receptor antagonist Ex9-39 inhibited insulin secretion in both the presence and absence of NVP-DP728. The effect of DPP-4 inhibition on glucose stimulated insulin secretion was further determined in islets from GIPR (-/-) and DIRKO mice. Islets isolated from GIPR (-/-) mice showed robust glucose stimulated insulin secretion and this was significantly potentiated by treatment with NVP-DPP728 (855 ± 49 vs. 1143 ± 95 pmol/min/islet, p=0.03 in untreated vs. NVP-DPP728 treated, respectively). Islets from DIRKO mice showed significantly impaired basal and glucose stimulated insulin secretion and were not responsive to treatment with NVP-DPP728.
Conclusion: Human and mouse islets contain appreciable DPP-4 activity and inhibition of this activity directly potentiates insulin secretion. Islet derived GLP-1 makes a substantial contribution to basal glucose stimulated insulin secretion and the insulin secretion induced by DPP-4 inhibition in vitro. The effect of DPP-4 inhibition on insulin secretion is maintained in islets from GIPR(-/-) mice but not in DIRKO mice lacking both GIP and GLP-1 receptors.

Pulsatile secretion of glucagon-like peptide-1(GLP-1) from pancreatic alpha cells: evidence for independent mechanism from intestinal GLP-1 secretion in rodents
K. Nakashima, S. Hamamoto, Y. Kimura, M. Shimoda, K. Tawaramoto, H. Hirukawa, T. Kimura, S. Okauchi, K. Kaku;
Division of Diabetes, Endocrinology and Metabolism, Department of Internal Medicine, Kawasaki Medical School, Kurashiki, Japan.

Background and aims: It has been reported that pancreatic islet(alpha) cells in rodents have a potential to secrete glucagon-like peptide 1(GLP-1) as well as glucagon, but the secretion profile and its function are not well known. We hypothesize that GLP-1 from alpha cells has the paracrine action to maintain the beta cell function in the islet by the different mechanism from that of the intestinal GLP-1. In this study, the secretion profile of GLP-1 from pancreatic alpha cells was compared with that from the intestine.
Materials and methods: Male F344/JCL rats at the age of 11-13 weeks were fasted for 18 hrs before perfusion study. Rats were divided into 2 groups; simultaneous perfusion of pancreas and intestine (P-I perfusion) and pancreas perfusion without the intestine. Tissues were perfused with Krebs-Ringer-bicarbonate-HEPES with 30 % dextrin, 0.25% BSA, 40 nM vildagliptin and 50 μg/ml aprotinin continuously gassed with 95% O_2 5 %CO_2 mixture at 37 ℃, through the celiac and superior mesenteric artery via a catheter inserted into the abdominal aorta. The perfusate from the portal vein was collected sequentially in 1 min intervals, and then subjected for the measurements of GLP-1, insulin and glucagon. The perifusion study using isolated mouse islets was also performed to directly examine a secretion profile of the pancreatic GLP-1.
Results: In P-I perfusion, 12 mM glucose, 2 mM isobutyl-methylxanthine (IBMX), or 20 nM glucose-dependent insulinotroic peptide (GIP) stimulated significantly both insulin and GLP-1 secretion with the peak of 2 min and 6 min, respectively. In pancreas perfusion, the similar effects of these secretagogues were also observed on insulin secretion, but not on GLP-1 secretion. Instead, the pulsatile secretion of GLP-1 was observed in the pancreas perfusion. Continuously repeated 5-7 cycles with peak and bottom in 60 min perfusion were selected from each experiment. Peak to peak intervals were 8.05±0.09 min (mean±SE, n=39 from total 6 rats). The peak and bottom GLP-1 concentrations were 2.50±0.15 pM and 1.59±0.09 pM, respectively (n=39, p<0.0001 with t-test). Pulsatile GLP-1 secretion was not affected by glucose, IBMX, GIP or IL-6. On the other hand, the secretion of pancreatic GLP-1 as well as the intestinal GLP-1 was suppressed by addition of 20 nM somatostatin (SST). The unique profile of pancreatic GLP-1 secretion was confirmed in the perifusion study using isolated mouse islets.
Conclusion: In the present study, we demonstrated the pulsatile secretion of GLP-1 from pancreatic islet (alpha) cells probably through an independent mechanism of the intestinal GLP-1 secretion. The physiological role of pancreatic GLP-1 remains to be further elucidated.

46

Novel glucagon receptor antagonist peptides help alleviate streptozotocin induced diabetes and preserve beta cell function in mice
F.P.M. O'Harte, L.M. McShane, N. Irwin;
School of Biomedical Sciences, University of Ulster, Coleraine, UK.

Background and aims: Studies on glucagon receptor KO mice have shown that they are resistant to streptozotocin (STZ) induced diabetes and retain normal glycaemic control and glucose tolerance. In this study, the effects of chronic administration of two novel glucagon receptor antagonist (GRA) peptides was assessed in STZ-induced type 1 diabetic mice.
Materials and methods: Male NIH Swiss mice (8 weeks old) were fed a high fat diet (45% fat) for 10 days. Groups of mice (n=8) were treated with either a single intraperitoneal (i.p.) injection of STZ (125 mg/kg body weight) or saline (controls) and maintained on the high fat diet for 6 days with daily i.p. saline injections. Once daily i.p. GRA peptide injections were then commenced for 18 days with either desHis^{1}Pro^{4}Glu^{9}glucagon or its closely related acylated analogue desHis^{1}Pro^{4}Glu^{9}Lys^{12}(glut-PAL)glucagon, or daily saline injections were given to both a STZ-treated control or a healthy control group (no STZ). Body weight, blood glucose and plasma insulin were measured at regular intervals over 18 days. After 18 days treatment, various assessments were performed including an OGTT (2 g glucose/kg bw), insulin sensitivity test (25 U insulin/kg bw), energy expenditure by indirect calorimetry using an Oxymax complete laboratory animal monitoring system, and quantification of terminal plasma glucagon and pancreatic insulin content by RIA.
Results: desHis^{1}Pro^{4}Glu^{9}glucagon and desHis^{1}Pro^{4}Glu^{9}Lys^{12}(glut-PAL) glucagon had no significant effect on STZ-induced weight loss over the course of the study (day 0-18), however, both GRA peptides transiently delayed STZ-induced hyperglycaemia on day 3 (p<0.05). Compared with STZ-treated controls (glucose $AUC_{(0\text{-}60\ min)}$ 750±153, mean±sem), desHis^{1}Pro^{4}Glu^{9}glucagon (AUC 530±189) and desHis^{1}Pro^{4}Glu^{9}Lys^{12}(glut-PAL)glucagon (AUC 513±185) treatment significantly (p<0.05) improved oral glucose tolerance. In an insulin sensitivity test, both desHis^{1}Pro^{4}Glu^{9}glucagon and desHis^{1}Pro^{4}Glu^{9}Lys^{12}(glut-PAL)glucagon significantly (p<0.05) enhanced the glucose lowering effects of insulin by 1.4-fold ($AAC_{(0\text{-}60\ min)}$ 1471±145) and 1.3-fold (AAC 1396±113), respectively when compared to STZ-treated controls (AAC 1079±166). Energy expenditure was also significantly increased (p<0.001) in both GRA treated groups compared with STZ-treated controls. Interestingly, the acylated analogue desHis^{1}Pro^{4}Glu^{9}Lys^{12}(glut-PAL)glucagon partially protected the pancreatic insulin content of STZ-treated mice producing a 40-fold increase (0.85±0.46 μg/g, p<0.001) in pancreatic insulin content compared to STZ-treated mice (0.02±0.02 μg/g, >99% insulin loss versus healthy controls 2.44±0.27 μg/g). STZ treatment resulted in a 1.9-fold (p<0.001) increase in terminal plasma glucagon concentrations compared with healthy controls (50.6±15.0 mg/ml vs 26.7±8.0 mg/ml), but both desHis^{1}Pro^{4}Glu^{9}glucagon and desHis^{1}Pro^{4}Glu^{9}Lys^{12}(glut-PAL)glucagon significantly reduced (p<0.001) the STZ-induced rise in plasma glucagon by 50% (25.5±7.0 mg/ml) and 60% (20.2±2.7 mg/ml), respectively.
Conclusion: These data show that the novel glucagon receptor antagonists desHis^{1}Pro^{4}Glu^{9}glucagon and desHis^{1}Pro^{4}Glu^{9}Lys^{12}(glut-PAL)glucagon can significantly improve glucose tolerance and insulin sensitivity and suppress hyperglucagonaemia in a model of type 1 diabetes. The acylated GRA analogue has pancreatic β-cell protective effects which could prove useful therapeutically.

Exenatide, a GLP-1 receptor agonist, activates glucose transport in L6 muscle cell by an AMPK-dependent mechanism

F. Andreozzi[1], C. Nigro[2], G.A. Raciti[2], C. Miele[2], F. Folli[3];
[1]Department of Experimental and Clinical Medicine, University of Catanzaro, [2]IEOS-CNR & DiSMeT, Federico II University of Naples, Italy, [3]Department of Medicine, Division of Diabetes University of Texas, UT Health Science Center, San Antonio, USA.

Background and aims: Exenatide (EXE) is a GLP-1 analogue which acts on pancreatic beta cells potentiating glucose-induced insulin secretion in type 2 diabetes treatment. The effects of EXE on the regulation of glucose metabolism in skeletal muscle as well as the molecular mechanisms potentially involved are unknown and a subject of active investigation. We aimed to explore the acute and chronic effects of EXE on L6 skeletal muscle myotubes as well as the existence of a cross-talk between insulin- and EXE-dependent signalling pathways.
Materials and methods: Western blot analysis and 2DG uptake were evaluated in L6 myotubes treated with 10-7 M Exenatide.
Results: Time-course experiments showed that 10-7 M EXE induced glucose uptake up to 48 h, achieving the maximum effect already after 20' (2-deoxyglucose nmol/min/mg prot: basal 1.14±0.09; EXE 20' 2.32±0.18; EXE 2h 2.12±0.27; EXE 4h 1.92±0.14; EXE 24h 2.22±0.15; EXE 48h 2.09±0.37; $p<0.01$) to an extent similar to insulin (2-deoxyglucose nmol/min/mg prot: basal 1.14±0.09; Insulin 100nM 30' 2.84±0.17; $p<0.001$). In order to identify the molecular mechanism through which EXE exerts its effect on glucose uptake, we evaluated the activation state of intracellular signaling pathways. EXE treatment, differently from insulin, was not able to induce IR beta subunit and IRS1 tyrosine phosphorylation, activation of AKT and GSK3beta defined by the phosphorylation at Ser473 and Ser21/9 respectively, as well as ERK1/2 and JNK1/2 phosphorylation. Thus, we hypothesized that an alternative pathway, such as AMPK, could be involved in EXE effect on glucose uptake. EXE acutely increased AMPKalpha and ACC phosphorylation by 2.5-fold compared to control ($p<0.01$). By contrast, insulin neither activated AMPK nor increased EXE effect on AMPK activation when cells were stimulated with both insulin and EXE. To clarify the role of AMPK in the effects of EXE on glucose uptake in L6 myotubes, cells were incubated either with LY294002 (LY), a PI 3-kinase inhibitor, or with tubercidin (Tub), widely used as AMPK inhibitor, prior to treat cells with EXE, insulin or a combination of both. LY inhibited insulin but not EXE-induced glucose uptake (basal 1.23±0.12; Insulin 100nM 30' 2.94±0.15; Insulin 100nM 30' + LY 1.26±0.08; EXE 20' 2.42±0.16; EXE 20' + LY 2.13±0.17 nmol/min/mg prot, $p<0.001$), whilst Tub pre-treatment almost abolished EXE effect on glucose uptake (EXE 20' 2.42±0.16; EXE 20' + Tub 1.45±0.07; $p<0.01$) but decreased insulin-induced glucose uptake only by 20% (Insulin 100nM 30' 2.94±0.15; Insulin 100nM 30' + Tub 2.36±0.18, nmol/min/mg prot, $p<0.05$)
Conclusion: Our results show that acute treatment with Exenatide stimulates glucose uptake by activating AMPK, in L6 myotubes.

48

Oxyntomodulin has significant acute glucoregulatory effects comparable to liraglutide in subjects with type 2 diabetes

S.S. Shankar[1], R. Shankar[2], L. Mixson[3], B. Pramanik[1], S. Stoch[1], H.O. Steinberg[2], D.E. Kelley[2];
[1]Early Stage Development, [2]Diabetes and Endocrinology, [3]Biostatistics, Merck Research Laboratories, Rahway, USA.

Background and aims: Oxyntomodulin (OXM), a gut peptide in the preproglucagon family, appears to have acute glucoregulatory effects in preclinical models, attributed in part to GLP-1 receptor activation, and to induce weight loss (WL) in non-diabetic humans at 4 weeks. However, there are no data with OXM in patients with Type 2 diabetes mellitus (T2DM).
Materials and methods: We tested the hypothesis that OXM has glucoregulatory effects in T2DM, independent of WL, by comparing acute changes in pancreatic beta cell function in response to a single dose of either OXM (continuous intravenous infusion at 3pmol/kg/min, a dose that provides exposures associated with WL) or the GLP-1 analogue, liraglutide (LIRA: 0.6 mg, subcutaneous). In the setting of a randomized, double-blind, placebo-controlled, three-period crossover trial, following an overnight fast, male T2DM (N=12, age: 30.1 ± 8.2 years, BMI: 30.9 ± 1.9 kg/m2, HbA1c:6.9 ± 0.7%, fasting glucose: 5.53 ± 0.42 mmol/L) underwent a graded glucose infusion (GGI), at glucose infusion rates (GIR) of 2, 4, 6 and 10mg/kg/min (40 minutes each), while receiving OXM or LIRA or placebo (PBO).
Results: Data over the duration of the GGI are presented as change from baseline, mean +/- SD, plasma glucose (G) and maximal glycemic excursion (Gmax) in mmol/L, and insulin secretion rates (ISR, derived by C-peptide deconvolution) in ng/min. At matched GIR, OXM and LIRA led to significant augmentation of ISR and blunting of G and Gmax ($p<0.001$ for all comparisons over PBO). Significant changes were observed in G (5.90 ± 1.28 vs.6.80 ± 1.96), Gmax (11.7 ± 3.5 vs 15.1 ± 2.8), ISR (2.78 ± 0.9 vs 1.66 ± 0.7), and slope of ISR/G (0.019 ± 0.01 vs 0.006 ± 0.003) ($p<0.001$ for all comparisons, OXM vs PBO). The effects of OXM and LIRA on blunting of glycemic excursion were comparable [p=NS, OXM vs LIRA, for G (5.90 ± 1.28 vs 6.06 ± 1.20) and Gmax (11.7 ± 3.5 vs 11.6 ± 3.7)].
Conclusion: Our findings demonstrate for the first time that OXM may have significant direct acute glucoregulatory effects in T2DM, independent of weight loss.
Clinical Trial Registration Number: NCT01373450

OP 09 Retinopathy: risk stratification and novel therapies

Pre-pubertal onset of diabetes may delay development of retinopathy: possible influence of metabolic control and blood pressure

F. Schellino[1], G. Curletto[1], E. Coppo[1], A. Raviolo[1], E. Sitia[1], S. Albani[1], P. Dalmasso[2], F. Cavallo[2], F. Cerutti[2], M. Trevisan[1], M. Trento[1], M. Porta[1]; [1]Dept. of Medical Sciences, [2]Dept. of Public Health and Paediatric Sciences, University of Turin, Italy.

Background and aims: Diabetic Retinopathy (DR) is infrequent, and hardly ever severe, before puberty. However, it is not known whether this is due to the relatively short duration of diabetes or to a real "protective" effect of the pre-pubertal milieu. We compared the cumulative prevalences of DR in relation to disease duration in patients in whom diabetes onset was before or after puberty.
Materials and methods: Data of 1473 patients with diabetes onset before age 30, on insulin treatment and duration <30 years who underwent screening for DR between 1991 and 2010 were analysed. Age at onset of diabetes was in pre-pubertal age (defined as 0-12 in males and 0-11 in females) in 644 patients (324 females) and later in the remaining 829 (414 females). DR had been assessed by 2-field retinal photography and classified as absent or mild/more severe (at least microaneurysms in one eye). The levels of HbA1c, systolic and diastolic blood pressure at the time of screening were available for 771 patients, 327 pre-pubertal and 444 post-pubertal.
Results: Mean age at first screening was 18.8±8.0 vs 32.4±10.4 in prepubertal and postpubertal onset patients (p<0.001), respectively, and diabetes duration was 11.6±7.8 vs 12.6±8.6 years (NS). The overall prevalence of DR was lower in the pre-pubertal patients, 29.1% (n=186) vs 46.1% (n=378), p=0.001, and remained significantly so between 4 and 14 years of diabetes duration, after which the curves tended to overlap. HbA1c was higher in the pre-pubertal patients (8.3±1,3 vs 8.1±1,4, p=0.03), especially in the first 15 years of disease, whereas systolic (114.9±12.5 vs 120.8±14.4, p<0.001) and diastolic blood pressure (70.5±7.4 vs 72.4±7.7, p=0.0006) were higher in the post-pubertal onset patients throughout.
Conclusion: This case series confirms that DR may appear later and develops more slowly if diabetes onset is before puberty. However, in the long term, its prevalence becomes similar to that of patients with post-pubertal onset. This can be interpreted as a combination of higher blood pressure accelerating DR when diabetes onset is after puberty, with worse overall HbA1c in the pre-pubertal patients, resulting in a "catch up" phenomenon in later years.

50

Twenty years on from UKPDS: More or less diabetic retinopathy at diagnosis of type 2 diabetes?

S.J. Aldington, I.M. Stratton, A. Sallam, M. Histed, P.H. Scanlon; Gloucestershire Diabetic Retinopathy Research Group, Gloucestershire Hospitals, Cheltenham, UK.

Background and aims: To compare retinopathy and other characteristics of patients newly diagnosed with Type 2 diabetes mellitus (T2DM) in Gloucestershire between 2005 and 2012 with those recruited to the UK Prospective Diabetes Study (UKPDS) between 1978 and 1990.
Materials and methods: Data were collected from the Gloucestershire Diabetic Eye Screening Service (GDESS) in the UK. Retinopathy status was extracted from the GDESS database and clinical information from primary care records for those newly diagnosed with T2DM between 2005 and 2012 and aged 65 or younger at diagnosis. Clinical characteristics and diabetic retinopathy (DR) grading results were analysed and compared with data from patients with newly diagnosed T2DM originally recruited to UKPDS, all of whom were 65 or younger. GDESS offers nationally-approved DR screening using two-field 45º digital retinal images (macular- and disc-centred), taken and assessed by qualified and quality assured staff. Screening is offered as soon as possible after diabetes diagnosis and annually thereafter. UKPDS four-field 30º film-based imaging (temporal-to-macula, macula, disc and nasal-to-disc), which largely equates to the current two-field screening protocol, was carried out as soon as possible after diagnosis and triennially thereafter. UKPDS images were assessed in a single reading centre by trained and quality assured staff. DR status by eye in GDESS identifies: R0M0, no DR; R1, mild non-proliferative DR (microaneurysms (MA) ± haemorrhages ± exudate ± cotton wool spots (CWS)); R2, intraretinal microvascular abnormalities (IRMA), venous beading or reduplication or multiple deep round or blot haemorrhage; R3, any proliferative feature and M1; presence of two-dimensional surrogate markers for macular-involving DR (only in conjunction with R1, R2 or R3). Grades R2, R3 or M1 are reasons for referral to hospital eye service. UKPDS utilised ETDRS-derived grading severity scales from 10 (no DR); 20 (MA only); 31 (MA and haemorrhage (HMA) ± exudate ± CWS); 41 (IRMA or beading) through to 61+ for proliferative DR. Level 41 and above is here considered a comparable reason for referral although some patients with level 31+ could also have had macular-involving DR.
Results: GDESS data were available for 2,070 men and 1,375 women first screened soon after diagnosis of T2DM. Of these 1,403 (68%) men and 990 (72%) women had no retinopathy. Retinopathy was found in 667 (32%) men of whom 415 (20%) had R1 in only one eye, 202 (10%) had bilateral R1 and 50 (2%) had any referable DR. In women the rates were 385 (28%), 258 (19%), 100 (7%) and 27 (2%) respectively (p=0.0033). In UKPDS, DR proportions at diagnosis amongst 1731 men were 61% no DR, 19% unilateral MA, 5% bilateral MA, 7% HMA and 8% more severe (level 41+) DR. In 1233 women the rates were 66%, 20%, 3.5%, 7% and 4.5%. Overall there was proportionally more DR and referable DR in UKPDS than in GDESS patients (p<0.0001). GDESS patients were of similar age to those in UKPDS but had lower HbA1c (mean difference -1.8%), higher systolic and diastolic blood pressure (+7 and+2 mmHg, respectively) and were heavier (BMI +4 kg/m^2).
Conclusion: Patients newly diagnosed with T2DM in this screening programme have lower rates of DR and of referable DR, are less hyperglycaemic but they have higher blood pressure and are substantially heavier than those recruited to UKPDS. This has implications for screening programs and risk estimation.

51

Validation of an individualised screening model for diabetic retinopathy

I. Walraven[1], A.A.W. van der Heijden[2], E. van 't Riet[3], T. Aspelund[4], S.H. Lund[4], P. Elders[2], A.C. Moll[1], B.C.P. Polak[1], J.M. Dekker[3], G. Nijpels[2]; [1]Ophthalmology, [2]General Practice, [3]Epidemiology and Biostatistics, VU University Medical Center, Amsterdam, Netherlands, [4]Medicine, University of Iceland, Reykjavik, Iceland.

Background and aims: The aim of this study was to validate a recently published risk algorithm for determination of individualised screening frequency to monitor diabetic retinopathy.
Materials and methods: An Icelandic study group developed a risk algorithm which recommends individual screening intervals ranging from 6 to 60 months depending on several risk factors (sex, HbA_{1c}, systolic blood pressure, presence of grade 1 to 3 diabetic retinopathy at baseline and diabetes duration). For validation of the risk algorithm clinical data on 2,764 type 2 diabetes patients of the Diabetes Care System (DCS) West-Friesland in the Netherlands were analysed. Two-field fundus photographs were taken every year and graded according to the EURODIAB coding system. Sight threatening retinopathy (STR) was considered EURODIAB grade 3 and 4. Patients with STR at baseline were excluded from the study. Validity of the model was assessed using the ability to predict the number of observed cases of STR during follow-up (calibration) and the ability to distinguish between those who develop STR during follow-up from those who do not (discrimination, area under the curve (AUC)). We compared the number of fundus photographs determined by the model with the actual number of annually taken fundus photographs within usual care of the DCS. Outcomes of omitted fundus photographs according to the model and potentially missed cases of STR were calculated.
Results: Assessment of discrimination of the algorithm in our cohort demonstrated a good fit (AUC 0.77 95% CI 0.71 to 0.82). Calibration showed that the model slightly overestimated the risk of developing STR. Using the model, 72.9% of the patients were appointed a screening interval longer than 12 months ranging from 22 to 60 months. Of those, 11 patients (0.6%) developed STR before the recommended screening interval. 26 patients (3.5%) developed STR before 1 year (usual care) and according to the model, screening in those patients should have been performed 6 months earlier. In the total population 53% of the fundus photographs would be safely omitted during 60 months of follow-up.
Conclusion: This study provides the first validation of the individualised screening algorithm to monitor diabetic retinopathy. We showed that, using the model, the screening interval can be prolonged while efficacy and safety were hardly compromised. Use of the individualised screening model may help to reduce screening costs for diabetic retinopathy.

Polyphenol-enriched cocoa protects the diabetic retina from glial reaction and oxidative stress through the sirtuin (SIRT-1) pathway

D.A. Duarte, M.M. Rosales, A. Papadimitriou, K.C. Silva, M. Vitelo, J.B. Lopes de Faria, J.M. Lopes de Faria;
Faculty of Medicine, State University of Campinas, Brazil.

Background and aims: Sirtuins, Class III histone deacetylases, act in response to various stressors and have currently been listed as having an important molecular function in the regulation of various diseases such as Alzheimer's, chronic obstructive pulmonary disease, and longevity. Silent information regulator 1 (SIRT1) acts in some locus removing the acetyl group from the histone chromatin, but it can also suppress other proteins by deacetylation, including the NFkB-p65 subunit protein. Studies have shown that cocoa is a rich source of polyphenols with antioxidant properties. In this study, we hypothetised that cocoa can protect the diabetic retina by reducing inflammatory citokynes, thus decreasing glial reaction (glial fibrillary acidic protein, GFAP), an early marker of diabetic retinopathy (DR). To test this hypothesis, in vivo and in vitro studies were conducted.
Materials and methods: Diabetes was induced by streptozotocin (SZT) in 12-week-old hypertensive rats (SHR).The animals were randomised to receive polyphenol-enriched cocoa (60% polyphenol, 24mg/kg/day) or water by gavage daily for 16 weeks. Similarly, non-diabetic rats were randomised to be treated with polyphenol-enriched cocoa or water by gavage. In vitro, rat Muller cells (rMCs) were exposed for 24 hours to normal (NG) or high glucose (HG), either combined with cocoa or not combined with cocoa (10μg/ml), with or without SIRT-1 inhibitor EX 527 (10μM), 1 hour pre-treatment. The cells were also treated with H_2O_2 as an oxidative stress inducer.
Results: As expected, the diabetic rats displayed high expression of GFAP and occluding (early markers of DR), as well as elevated nitrotyrosine (NT) levels and decreased SIRT-1 activation ($p<0.05$). The retinal function evaluated by electroretinogram was markedly impaired ($p<0.05$). The treatment with cocoa fully restored all the above-mentioned alterations in the diabetic animals. In vitro, rMCs exposed to HG increased ROS production, GFAP expression and lysine-310-p65-NFkB acetylation ($p<0.05$). By immunofluorescence, SIRT-1 was predominantly present in cytosol, and its protein expression and activity were markedly reduced. The treatment with cocoa prevented these abnormalities and the co-treatment with SIRT-1 inhibitor abolished the effects of cocoa on the rMCs exposed to HG. Similarly, the rMCs exposed to H_2O_2 treated with cocoa prevented the up-regulation of GFAP, p65-NFkB acetylation and decreased the SIRT-1 protein expression and activity ($p<0.05$).
Conclusion: In an animal model of DR, the early markers of DR accompanied by increased NT expression and decreased SIRT-1 activity were prevented by oral administration of polyphenol-enriched cocoa. The presence of cocoa in the rMCs exposed to HG or H_2O_2 prevented p65-NFkB acetylation by increasing SIRT-1 activity, thus reducing GFAP up-regulation. This study reveals, for the first time, the beneficial effect of the oral administration of cocoa on reducing GFAP up-regulation in the pathogenesis of DR through the SIRT-1 activation pathway.

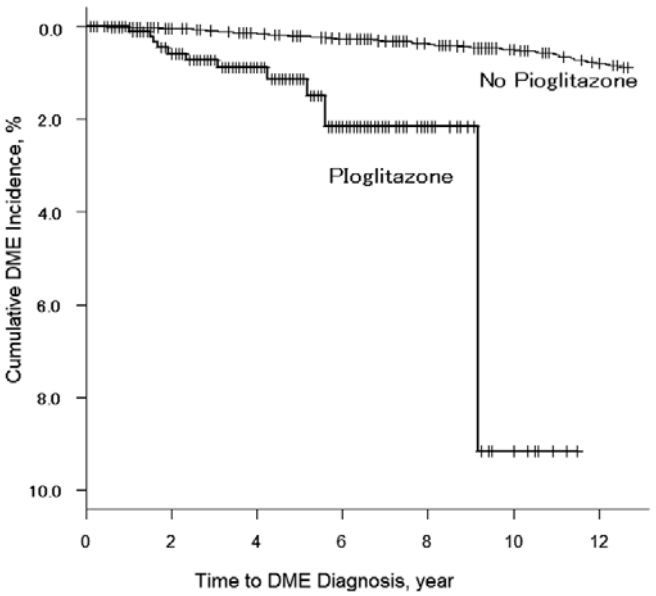
Pioglitazone increases the risk of diabetic macular oedema in patients with type 2 diabetes

K. Fujimoto[1], Y. Hamamoto[1], S. Honjo[1], H. Tatsuoka[1], A. Matsuoka[1], Y. Wada[1], H. Ikeda[1], J. Fujikawa[2], I. Saito[3], H. Koshiyama[1];
[1]Center for Diabetes and Endocrinology, [2]Department of Clinical Laboratory, [3]Department of Ophthalmology, Tazuke Kofukai Foundation Medical Research Institute Kitano Hospital, Osaka, Japan.

Background and aims: There has been a concern about the potential link of pioglitazone with adverse effects, including an increased incidence of bone fractures, edema, heart failure and bladder cancer. Recent studies have raised a possibility that pioglitazone, which generally causes fluid retention, may develop diabetic macular edema (DME). DME is one of the main causes of visual impairment in patients with diabetic retinopathy. We investigated whether the use of pioglitazone may increase the risk of DME in Japanese patients with type 2 diabetes.
Materials and methods: We retrospectively examined the incidence of DME in patients with type 2 diabetes in relation to pioglitazone administration during 12 years from 2000 to 2011 using the database in our institute. Subjects included a total of 22,115 patients with type 2 diabetes. The incidence of DME was calculated at 2 and 12 years of follow-up. Cox multiple regression analysis was used as the analysis to calculate the hazard ratio (HR). Kaplan-Meier curves were constructed to illustrate graphically the difference in DME incidence according to exposure to pioglitazone.
Results: A total of 99 subjects with type 2 diabetes were found to have DME, and the total prevalence of DME in type 2 diabetes was 0.45 % at 12 years of follow-up. Among 953 patients taking pioglitazone, 11 patients were found to have DME (1.15 %). The unadjusted HR of pioglitazone for development of DME was 7.76 [95%CI: 4.00-15.07] at 12 years of follow-up. After Cox multiple regression analysis (adjusted for age; sex; HbA1c levels; and use of insulin, antiplatelets, or renin-angiotensin system inhibitors), pioglitazone use was associated with an increased risk of DME at 2 years of follow-up (HR 4.71 [95%CI: 1.38-16.10]) and 12 years of follow-up (HR 5.12 [95%CI: 2.61-10.04]). Furthermore, combination therapy with pioglitazone plus insulin was associated with a higher risk for DME (adjusted HR 9.21 [95%CI: 4.06-20.89]) at 12 years of follow-up.
Conclusion: In this study, the association was observed between pioglitazone and DME, suggesting an increased risk of DME by pioglitazone in patients with type 2 diabetes.



54

36-month safety and efficacy of ranibizumab in diabetic macular oedema: the RESTORE extension study (final analysis)

A. Boixadera[1], J. Garcia-Arumi[1,2];
[1]Hospital Vall D'Hebron, Paseo Valle de Hebron, [2]Instituto de Microcirugía Ocular de Barcelona, C/ Josep Maria LLadó 3, Barcelona, Spain.

Background and aims: Diabetic macular edema (DME) is the most common cause of vision loss in patients (pts) with diabetes. The randomized, double-masked RESTORE core study demonstrated superior efficacy of ranibizumab monotherapy (RBZ) or combined with laser (RBZ+laser) versus laser monotherapy in patients with visual impairment due to DME. The RESTORE extension open-label study was designed to evaluate the long-term safety and efficacy of RBZ 0.5 mg intravitreal injections.
Materials and methods: 240 out of 303 pts who were treated with RBZ, RBZ+laser, or laser in the core phase and completed the 12-month (M) core study (Day [D] 1-M12) entered the 24M extension study (M12-M36). During the extension phase, all pts were eligible to receive RBZ pro re nata (PRN) according to pre-specified best-corrected visual acuity (BCVA) stability and DME progression-based retreatment criteria. Laser PRN was allowed according to Early Treatment Diabetic Retinopathy Study (ETDRS) guidelines. Here we report overall (12M core phase+ 24M extension phase [D1-M36]) results for the incidence of adverse events (AEs), treatment exposure, mean changes in BCVA, central retinal subfield thickness (CRT), and patient-reported visual functioning (assessed by Visual Functioning Questionnaire [VFQ-25]) outcomes. Last observation carried forward approach was used for BCVA, CRT, and VFQ-25 analysis.

Results: 208 (86.7%) pts completed the extension study. Ocular serious adverse events (SAE) were observed in 2.4%-4.1% of the pts with no reports of endophthalmitis, retinal tear, or retinal detachment over 36 months. Overall, the most frequent nonocular SAEs were coronary artery disease and cerebrovascular accident (1.7%, each). The most frequent ocular AEs were cataract (16.3%) and eye pain (15.4%), while the most frequent nonocular AEs were nasopharyngitis (23.3%) and hypertension (13.3%). The mean number of RBZ injections for prior-RBZ, prior-RBZ+laser, and prior-laser groups was 14.2, 13.5, and 13.9 (D1-M35); 3.9, 3.5, and 4.1 (M12-23); and 2.9, 2.5, and 2.4 (M24-35), respectively. Across all prior-treatment groups, 19% to 25% of pts did not require any RBZ injections from M12-35. The mean BCVA gain and CRT reductions at M12 were maintained over M36 in pts treated with prior-RBZ in both core and extension phase (+8.0 letters, -145.9μm [prior-RBZ], +6.7, -142.1μm [prior-RBZ+Iaser]), while a progressive BCVA improvement (+6.0 letters) and CRT reduction (-142.7μm) was observed from M12-36 in prior-laser treated pts after allowing individualized RBZ treatment during the extension phase. Mean changes in VFQ-25 scores (D1-M36) for prior-RBZ/prior-RBZ+Iaser/prior-laser groups were +12.2/+7.8/+8.4 (near activities), +2.6/+4.1/+3.5 (distance activities), and +5.0/+4.3/+3.9 points (composite score).
Conclusion: No new ocular/nonocular safety findings or increased safety concerns for intravitreal RBZ 0.5 mg PRN with or without laser used over three years in patients with DME were identified. BCVA and CRT improvements in the first year could be maintained with a decreasing frequency of RBZ treatments over time. Individualized RBZ treatment led to an overall improvement or maintenance of BCVA, CRT, and VFQ-25 outcomes.
Clinical Trial Registration Number: NCT00687804

OP 10 In-patient diabetes: rights and wrongs

Glycaemic variability is not related to postoperative complications in elective cardiac surgery patients on tight glucose control
M. Mraz[1], P. Kopecky[2], M. Lips[2], J. Lindner[3], S. Svacina[1], J. Blaha[2], M. Haluzik[1];
[1]3rd Department of Medicine, [2]Department of Anaesthesia, Resuscitation and Intensive Medicine, [3]Department of Cardiovascular Surgery, Charles University, Prague, Czech Republic.

Background and aims: Glycemic variability has been recently proposed as an independent factor associated with worsened outcomes in critically ill patients. The aim of our study was to assess the relationship between glycemic variability and postoperative complications in elective cardiac surgery patients with either perioperatively (PERI) or postoperatively (POST) initiated protocols for tight glucose control (TGC).
Materials and methods: 2383 patients (age 18-90 years, 28.1% diabetics) undergoing elective cardiac surgery were randomized into either PERI (1134 subjects, 26.9% diabetics) or POST (1151 subjects, 29.4% diabetics) group according to the time of initiation of intravenous insulin infusion therapy. Target glucose range was set at 4.4-6.1 mmol/l. Glycemic variability was calculated using selected formulas including SD (standard deviation), MAGE-Day (mean amplitude of glycemic excursions during 24 hours), LBGI and HBGI (low and high blood glucose index). Adverse events from any cause were collected during the whole postsurgical hospital stay.
Results: In the whole cohort, perioperatively initiated TGC markedly reduced the number of patients with postoperative complications (23.8 vs. 31.4%, $p<0.001$) in spite of only modest improvement of glucose control (blood glucose 6.6±0.7 vs. 6.7±0.7 mmol/l, $p<0.001$). The positive effect of TGC on postoperative complications was driven by non-diabetic patients (20.3 vs. 31.7%, $p<0.001$; blood glucose 6.6±0.7 vs. 6.5±0.6 mmol/, $p<0.05$) while no significant effect was seen in the diabetic patients subgroup (33.2 vs. 30.5%, n.s.) despite significantly better glucose control in the PERI diabetic group (blood glucose 6.6±0.7 vs. 7.1±0.8 mmol/l, $p<0.001$). In the whole PERI group glycemic variability was only slightly reduced compared to POST group (MAGEDay 2.98 ± 2.09 vs. 3.19 ± 1.36, $p<0.0001$). Similar situation could be seen in the diabetic subgroup (MAGEDay 4.01 ± 3.57 vs. 4.12 ± 1.44, $p<0.01$), while the opposite was true for non-diabetic subjects (MAGE 4.74 ± 4.54 vs. 4.63 ± 1.49, $p<0.05$). The risk of hypoglycemia was low in the whole study cohort (LBGI<2.5) with minimal differences between subgroups. No correlation between the number of postoperative complications and various glycemic variability indices was observed in the study.
Conclusion: Perioperative initiation of intensive insulin therapy during elective cardiac surgery reduces postoperative morbidity only in non-diabetic subjects. Glycemic variability does not seem to play an important role in postoperative outcomes of elective cardiac surgery patients.

Short term continuous subcutaneous insulin infusion (CSII): a boon for type 2 diabetic patients with severe hyperglycaemia undergoing urgent surgical procedures
K.P. Singh[1], H. Chohan[1], N.C. Raina[1], A. Jindal[1], M. Galhotra[2];
[1]Fortis Hospital, Mohali, [2]India Medtronic, Chandigarh, India.

Background and aims: To determine the efficacy, safety and cost effectiveness of short term Continuous Subcutaneous Insulin Infusion (CSII) therapy using Insulin Pumps Vs. conventional Continuous Intravenous Insulin Infusion (IVII) among Type-2 Diabetes Mellitus (T2D) patients with severe Hyperglycemia requiring urgent control of Blood glucose pre intervention or surgery.
Materials and methods: This is a pilot study over a period of three months on 50 T2DM patients (26- Males (M), 24-Females (F)) on MSI (Multiple subcutaneous Insulin) and/or Oral hypoglycemic agents who presented with severe hyperglycemia (Random blood glucose > 400mg/dl, fasting blood glucose > 250mg/dl). The patients were in the age group - 34 to 78 years. These patients were planned for various medical and surgical interventions and

were randomized in two treatment groups - 25 patients were put on continuous IVII (14M, 11F) while 25 patients were put on a short term(3-5 days) CSII therapy (12M, 13F) to manage severe Hyperglycemia. The target glucose level was 100-150mg/dl. One hourly capillary blood glucose level was measured in both the groups. Patients in both the groups were matched in terms of blood glucose, HbA1c, BMI, creatinine clearance, h/o diabetic complications, and h/o steroids usage. There was no episode of sepsis in either group.

Results: In the CSII group, 23/25 patients achieved the target BG. While, 25/25 patients in the IVII group achieved the target BG (p=0.26). CSII was clinically safer than IVII. 1/25 patients had an episode of mild hypoglycemia in the CSII group whereas in the IVII group, 1/25 patients had an episode of mild hypoglycemia while 3/25 patients had severe hypoglycemia which required 50% dextrose infusion for management (p=0.051). CSII therapy was more convenient and did not require hospitalization. The cost of the CSII therapy for a period of 3 days was <13.3 % of the total cost of IVII therapy in patients hospitalized for control of hyperglycemia

Conclusion:

- Short term CSII is safer than IVII therapy for treatment of urgent severe hyperglycemia in T2D. There were lesser episodes of hypoglycemia among patients in the CSII group (4%) Vs. IVII therapy (16%).
- CSII is as efficacious as IVII for treatment of severe hyperglycemia in T2D
- Total length of hospital stay was reduced in the CSII group.
- CSII proved to be highly cost effective (<13.3%) as compared to IVII.
- Large scale studies are needed to further evaluate benefits of CSII in this group of patients.

57

Comparison of inpatient glycaemic control by continuous glucose monitoring (CGM) and capillary point-of-care (POC) testing in general medicine patients with type 2 diabetes

A.M. Gomez[1], G.E. Umpierrez[2], P. Aschner[1], F. Herrera[1], O. Muñoz[1];
[1]Endocrinology, Hospital Universitario San Ignacio, Bogota, Colombia,
[2]Endocrinology, Emory University School Of Medicine, Atlanta, USA.

Background and aims: Point-of care testing with capillary glucose fingerstick tests is the universally accepted method of glucose monitoring in the hospital. No previous studies have compared the efficacy of CGM in the management of hyperglycemia in general medicine (non-ICU) patients with T2D. Accordingly, this prospective randomized study compared glycemic control by CGM (Sofsensor iPro 2, Medtronic) to bedside POC testing in non-ICU patients treated with basal bolus regimen for ≥ 3 days. Both patients and hospital staff were blinded to the CGM data. POC testing measurements were performed before meals, 2-h after meals, at bedtime and 3 AM. The primary outcomes were differences in daily BG, and number of hypoglycemia (<3.9 mmol/L) and hyperglycemia (>10 mmol/L) events between groups.

Materials and methods: A total of 40 insulin-naïve patients (age: 65.8±8 yr, DM duration 14.7±9 yr, admission BG: 13.9±1 mmol/L, A1C: 9.7±2.4%, ±SD) were treated with glargine and glulisine at a starting total dose of 0.4 U/kg/day if BG was between 140-200 mg/dl and 0.5 U/kg/day if BG was between 200-400 mg/dl, given half as glargine once daily and half as glulisine before meals.

Results: We observed no difference in daily BG after the 1st day of treatment by CGM and POC testing (9.8±2 vs 9.77±2mmol/L, p:0.828). There were 10 patients with hypoglycemia recognized by both methods, but CGM detected higher number of events (55 vs 12, p=0.0001) than POC testing, with 40% occurring between breakfast and dinner and 60% between dinner and 6 A.M. A total of 26.3% of hypoglycemia were asymptomatic and most (86.7%) were only identified by CGM. The proportion of BG >10 mmol/L was 36.8% by CGM and 42.1% by POC, p=0.828.

Conclusion: The use of CGM recognized increased number of hypoglycemic events compared to POC testing. Our study indicates potential benefit of using real-time CGM in the hospital to detect symptomatic and asymptomatic hypoglycemic events in a more timely fashion compared to POC testing.

Randomised clinical trial to assess efficacy of two insulin protocols in hospitalised subjects with type 2 diabetes mellitus receiving medium/high dose of corticosteroids: preliminary results

M.S. Ruiz de Adana[1,2], S. Valdés[1,2], N. Colomo[1,2], F. García-Torres[1,2], M.I. Fontalba[1,2], F. Linares[1,2], C. Maldonado[1,2], R. Fernández[1,2], F. Soriguer[1,2];
[1]Endocrinology and Nutrition, Hospital Regional Universitario Carlos Haya, Málaga, [2]Instituto de investigación biomédica de Málaga (IBIMA), Spain.

Background and aims: To assess efficacy and safety of two different basal-bolus insulin protocols (glargine vs. NPH insulin as basal insulin) in subjects with type 2 diabetes (T2DM) who received medium or high dose of intermediate acting corticosteroid therapy. Primary endpoint: mean blood glucose between 80 and 180 mg/dl. Secondary endpoints: number of mild or severe episodes of hypoglycaemia, glycaemic variability, and length of hospital stay.

Material and methods: Randomised clinical trial that included 51 consecutive subjects aged between 18 and 80 years admitted on the Pneumology ward and who received medium or high dose of intermediate acting corticosteroids between February 2011 and November 2012. Subjects were randomly assigned to receive glargine+glulisine (n=25) or NPH insulin+glulisine (n=26) as insulin therapy during hospitalisation. Sociodemographic, clinical data and days of hospital stay were collected. HbA_{1c} was measured. Information on insulin dose, corticosteroid dose, and capillary blood glucose measurements before and 2hour after meals during the first 6 days after admission was recorded. Continuous glucose monitoring (iPro2 Medtronic) was used for 6 six days in 26 subjects (16 in the glargine group and 10 in the NPH insulin group).

Results: Mean diabetes duration was 8.1±6.7 yrs. Mean HbA_{1c} at admission was 7.4±1.6% and was not statistically significantly different between groups. Diagnosis at admission was: chronic obstructive pulmonary disease exacerbation in 49% of subjects, pneumonia in 27.5%, asthma exacerbation in 13.7% and other causes in 9.9%. Mean length of hospitalisation was 9.0±3.2 days, and although glargine group had a shorter length of stay, it did not reach statistical significance (Glargine 8.2±2.8 days vs. NPH insulin 9.8±3.4 days, p>0.05). Table 1 shows glycaemic control between study groups. Data from continuous glucose monitoring were not significantly different between study groups.

Conclusion: Our preliminary results pointed that an insulin protocol based on the administration of glargine for hospitalised subjects with T2DM treated with medium or high dose of corticosteroids might be safe and have similar efficacy to achieve glycaemic control than a protocol with NPH insulin.

Glycemic control

Variables	Total (n=51)	Glargine (n=25)	NPH insulin (n=26)	p
Sex (men/women) (n)	31/20	19/6	12/14	0.05
Age (yrs)	68.8±7.3	70.2±6.6	67.5±7.8	ns
Daily insulin dose on first day (U/kg/day)	0.5±0.2	0.5±0.3	0.6±0.2	ns
Daily insulin dose on sixth day (U/kg/day)	0.7±0.3	0.7±0.3	0.7±0.4	ns
Mean capillary blood glucose on first day (mg/dl)	224±73	226±82	223±65	ns
Mean capillary blood glucose on sixth day (mg/dl)	189±54	180±58	196±51	ns
Subjects with mean capillary blood glucose between 80-180 mg/dl on first day (%)	37.5	45.8	29.2	ns
Subjects with mean capillary blood glucose between 80-180 mg/dl on sixth day (%)	48.6	57.1	42.9	ns

The safety and efficacy of a subcutaneous continuous glucose monitoring system compared to point of care measurement in critically ill patients: a randomised controlled trial

D.T. Boom[1], S. Rijkenberg[1], S. Kreder[1], M.K. Sechterberger[2], P.H.J. van der Voort[1];
[1]Intensive Care, Onze Lieve Vrouwe Gasthuis, Amsterdam, [2]Internal Medicine, Academic Medical Centre Amsterdam, Netherlands.

Background and aims: Hyperglycaemia, hypoglycaemia and glucose variability are associated with adverse outcome of critically ill patients. Using a continuous glucose monitoring (CGM) system might reduce these disturbances in glucose regulation. The reliability and accuracy of CGM using subcutaneous measurements has been studied in critically ill patients before. The present study aims to determine whether the clinical use of subcutaneous CGM is safe, effective and feasible in critically ill patients.
Materials and methods: In an open labeled randomized controlled trial patients were assigned to glucose regulation using a subcutaneous CGM system (FreeStyle Navigator®) or frequent point of care measurements (POCM) using Accu-Chek® (Roche) for 5 days or until ICU discharge. Blinded arterial blood glucose measurements were performed on standard times in both groups. Patients with POCM also had subcutaneous CGM but these data were blinded. Data from CGM or POCM were entered in the same computerized glucose regulation protocol which prescribed the insulin dose and the time of next data entering.
Results: 178 Patients were included. Median APACHE IV was 0.32 (IQR 0.55) and 92% were mechanically ventilated. 13% were complicated cardiac surgery patients, the others medical patients. From 15 patients CGM data were lost for technical reasons, therefore 163 were analysed. The median study duration was 70 hrs (IQR 99) in the CGM patients and 60 hrs (IQR 89) in POCM patients (p=0.91). We analyzed 2844 glucose measurements, of which 1358 were paired CGM-POCM. The median time in target range (5-9 mmol/l) was 57.5 hrs (IQR 74.4) in CGM patients and 34.9 hrs (IQR 62.7) in POCM group (p=0.043). The incidence of severe hypoglycaemia (below 2.2 mmol/l) or severe hyperglycaemia (above 25 mmol/l) was similar in both groups (p=0.54 and 0.09) as well as the glucose variability in terms of mean absolute glucose change per hour (MAG). The total number of blood samples per patient was 25 for CGMS and 41 for POCM (p=0.001). Hospital and ICU length of stay and mortality did not show any significant differences.
Conclusion: Glucose monitoring using a subcutaneous device was safe in terms of hypoglycaemia incidence and resulted in significantly more time in target range than the use of a point of care blood measurement. In addition, the number of blood samples was reduced.
Clinical Trial Registration Number: NCT01526044

Continuous glucose monitoring at the intensive care unit: nursing workload reduction and cost-benefit analysis

M.K. Sechterberger[1], J.H. DeVries[1], P.H.J. van der Voort[2];
[1]Internal Medicine, Academic Medical Centre, [2]Intensive Care, Onze Lieve Vrouwe Gasthuis, Amsterdam, Netherlands.

Background and aims: Continuous glucose monitoring (CGM) in ICUs has the potential to improve glycaemic control and thereby enhance patient safety and outcomes. Furthermore, CGM may reduce nursing workload related to glucose control. The primary objective of this study was to assess the influence of real-time CGM on nursing workload for glucose control, compared to intermittent point-of-care glucose measurements (POCM) in patients admitted to the ICU and treated with insulin. We also estimated the net financial benefit or cost of using CGM systems in a critical care setting.
Materials and methods: We used data of a recent randomized controlled trial at the ICU of a teaching hospital in the Netherlands comparing subcutaneous glucose monitoring with real-time CGM (FreeStyle Navigator®) versus conventional POCM (arterial blood sampling by use of the Accu-Chek® glucometer). The main outcome of this substudy was nursing workload defined as the time burden for glucose control per patient per day (24 hours). A time-in-motion design was used to estimate the nursing workload. We additionally performed a cost-benefit analysis in which we assessed the average difference in costs using either real-time GCM or conventional POCM. Cost parameters were nursing personnel costs, costs of the devices and materials used for blood glucose monitoring and laboratory costs. Subsequently, the incremental cost-effectiveness ratio (difference in costs divided by the percentage difference in nursing workload) was calculated.
Results: We analyzed data of 78 patients with CGM versus 77 patients with POCM. The average total time burden for glucose control in the CGM group was 49 [44-58] minutes per 24 hour, whereas in the POCM group the total time burden was 70 [64-81] minutes (p<0.001). The mean reduction in total nursing workload for glucose control was 30% or 21 minutes per patient per 24 hours. Mean total costs per patient per day were slightly less in patients randomized to CGM (EUR 64) compared to patients randomized to POCM (EUR 89, difference EUR 25; 95% CI -43 to 29). The incremental cost-effectiveness ratio was - EUR 83, indicating the superiority of real-time CGM over conventional glucose control.
Conclusion: This study shows that in ICU patients the use of continuous subcutaneous glucose monitoring significantly reduces the nursing workload for glucose control and costs were reduced compared to conventional glucose monitoring with intermittent point of care measurements.

OP 11 Exercise physiology and impact on ageing

61

Effect of chronic exercise on skeletal muscle mitochondria dynamics in older adults

C. Greggio[1], N.T. Broskey[1], M. Boutant[2], C. Canto[2], F. Amati[1];
[1]University of Lausanne, [2]Nestlé Institute of Health Sciences, Lausanne, Switzerland.

Background and aims: Aging is thought to decrease mitochondrial (Mito) content and function. Acute exercise has been shown to promote Mito remodeling. The extent to which chronic exercise (i.e. training) modifies mitochondrial content and the different transcription factors in skeletal muscle of older adults is not known. The goal of this study was to explore the effects of chronic exercise on Mito volume density (MVd), Mito proteins and transcription factors involved in Mito biogenesis and dynamics. To this aim, we compared skeletal muscle from older sedentary adults to chronically trained athletes matched by age.
Materials and methods: Seven sedentary (S) were compared to 8 master athletes (A) in a cross sectional design (Mean Age 67.3 ± S.E.M. 1.4). Skeletal muscle specimens were obtained by vastus lateralis biopsies in the fasting and resting state (at least 48 hours after the last exercise bout). VO2peak was measured by GXT, lean body mass (LBM, kg) and fat mass (FM, kg) by DXA. Mitochondrial volume density (MVd, %) was measured by transmission electron microscopy. Proteins and mRNA levels were quantified by western blotting and quantitative RT-PCR. Independent T tests were done to compare groups and correlations were analyzed by Spearman rho. To look for patterns of distribution of the transcripts, we performed a principal component analysis (PCA).
Results: S had higher BMI (S=27.55kg/m2 ± 1.34; A=21.83kg/m2 ± 0.39; p=.002) and FM than A (S=28.12kg ± 2.73; A=11.70kg ± 1.00; p=.0001). A had higher VO2peak (S=38.21ml/min/KgLBM ± 1.92; A=48.02 ± 2.41; p=.006) and MVd (S=4.41% ± .48; A=7.71% ± .67; p=.002) than S. A had higher contents of proteins from respiratory complexes (C) I, IV and V (all p≤.01). No group differences were found for CII and III. MFN 1 & 2 protein levels were higher in A (p≤.03), while OPA1 and DRP1 were not different. The following mRNAs were significantly higher in A: CS, Mfn2, ATG5g1, Nampt1 (all p<.05), but not Tfam, Nrf1, Nrf2, Drp1, Mfn1, Sirt1, Ndufa2. VO2peak correlated with CI (p=.02), CIV (p=.0009), CV (p=.03), MFN2 (p=.02). MVd correlated significantly with CIV (p=.03), CV (p=.0002), MFN2 (p=.008). We observed a strong correlation among the protein expression levels of CI, CIV, CV, MFN1&2 on one hand and DRP1, CII and CIII on the other. At the gene expression level, we identified groups of transcripts that were highly correlated. The PCA identified 4 factors that explained 96% of the variance of the mRNA data. These were: [CS, Drp1, Sirt1, Tfam, Mfn2], [Nampt1, Nrf2, Ndufa2, ATG5g1], [Mfn1] and [Nrf1].
Conclusion: In this study, chronically active older subjects had a higher content of mitochondria, electron transport chain components and mitochondrial fusion proteins as compared to their sedentary counterparts. These results highlight the effect that lifestyle has at the molecular level on mitochondria. Indeed, aging per se might not explain the mitochondrial dysfunction observed in older humans. On the contrary, our data suggests that a sedentary lifestyle decreases specific mitochondrial proteins. Furthermore, we describe patterns of gene expression that may be involved in the maintenance of mitochondrial content with age and exercise. Some but not all of the genes explored were increased at the mRNA level in the athletes. This could be explained by the lack of an acute effect as this study was built solely to observe chronic effects.

The effect of exercise training on skeletal muscle mitochondrial content in older adults correlates with exercise efficiency and fat oxidation

N.T. Broskey, E.-J. Fares, C. Greggio, F. Amati;
University of Lausanne, Switzerland.

Background and aims: Skeletal muscle mitochondrial content has been implicated in age-related metabolic dysfunction. Cross-sectional studies have shown that trained older adults have more mitochondrial content than untrained. It is known that substrate usage during exercise also changes with chronic training to rely more on fat than carbohydrates. The extent to which mitochondrial content impacts fat oxidation during exercise is not known. The purpose of this study was to examine the changes in skeletal mitochondrial content, exercise efficiency and exercise substrate use in older sedentary adults undergoing an exercise intervention.
Materials and methods: In this pre/post intervention design, 13 sedentary older (age 66.15±0.82, range 63-71) men (N=7) and women (N=6) underwent four months of an endurance exercise intervention. Volunteers trained 3 supervised sessions per week at 60-75% of their maximal heart rate. Mitochondrial volume density (MVD) was measured in vastus lateralis biopsy specimens by using transmission electron microscopy and classic stereological measures. Gross efficiency (GE, %) and proportion of energy expended from fat (EEF, %) were determined during one-hour of submaximal (55% of VO2peak) cycle ergometry exercise in tightly controlled conditions (fasting and 72 hours from last exercise bout). VO2peak was determined by a GXT. Intervention effects were measured by Paired T Test and correlations by Spearman rho. Results are presented in mean ± SEM.
Results: Mean weight, BMI, and percent fat decreased by 2.3 ± 0.9, 2.3 ± 0.9 and 8.5 ± 2.6 % respectively (all p<0.05). VO2peak, GE and MVD all increased by 16.3 ± 4.5, 5.9 ± 1.7 and 58.2 ± 18.3 % (all p<0.05). EEF increased by 36.3 ± 9.7% (p=0.002). MVD at baseline correlated with GE (r=0.73, p=0.016) but not with EEF or carbohydrate oxidation. GE correlated with VO2peak (r=0.78, p=.002) but not BMI or weight. EEF did not correlate with VO2peak. The change in EEF with intervention was related to the change in MVD (r=0.70 p=0.022) but not to the change in VO2peak or GE.
Conclusion: This data confirms that older adults are able to respond to a moderate intensity exercise training protocol in terms of improved fitness, exercise efficiency and mitochondrial content. Interestingly, improvements in mitochondrial content predicted a greater reliance on fat as an energy source during submaximal prolonged exercise.

Electrodiab study: impact of bi-quadricipital muscular electrostimulation on insulin sensitivity in type 2 diabetic subjects

M. Joubert[1], L. Metayer[1], G. Prevost[2], A. Rod[1], J. Morera[1], J. Morera[1], Y. Reznik[1];
[1]Endocrinology Unit, University Hospital of Caen, [2]Endocrinology Unit, University Hospital of Rouen, France.

Background and aims: Physical activity improves insulin sensitivity and promotes type 2 diabetes (T2D) control. However, physical activity guidelines are rarely applied due to lack of motivation or to concomitant diseases (diabetic foot, coronary artery disease···). Muscular electro-stimulation (MES) enhances both muscles strength and volume. Metabolic effect of MES on insulin sensitivity is explored in this study, as an alternative to physical activity.
Materials and methods: Prospective multicentric 4 weeks pilot study. Inclusion criterias : T2D ; 18-75 years ; BMI > 25 ; 6-9% HbA1c ; treatment with oral hypoglycemic agents (OHA) and/or GLP1 analogs > 3 months. Usual physical activity was controlled with a body monitoring system and dietary intake was controlled with dietary self reports during the study. Insulin sensitivity was evaluated with 3 euglycemic hyperinsulinemic clamps (EHC) (80mUI/m2/min) for each subject : baseline (T0), one hour after a unique MES session (T1), and after one week of ambulatory daily MES training (T2). Each MES session was a 25 minutes bi-quadricipital simultaneous stimulation with a 4 channel electrostimulator. Patients were asked to increase stimulation to maximal tolerated intensity. Indirect calorimetry energy expenditure (EE) was also evaluated at rest and during the first MES session.
Results: 15 patients T2D were included (age 60.1±9.0 years ; diabetes duration 12.3±7.0 years; BMI 32.9±5.2 ; HbA1c 7.3±0.8%). For overall population (responders and non-responders), insulin sensitivity (M-Value) increased of 11.3±40.8% (ns) and 28.3±38.4% (p<0.05) at T1 and T2 vs T0, respectively. For the 8/15 responders, M-Value increased of 36.8±37.7% (ns) and 58.3±24.9% (p<0.05) at T1 and T2 vs T0, respectively. During the first MES session, for a mean stimulation intensity of 25.8±5.6/100, energy expenditure (EE) (indirect calorimetric measure) increased of 93.6±176.8 Kcal/h (ie +5.2±9.4% from EE at rest) (ns). During the daily MES training week, patients increased stimulation intensity with a week mean of 37.1±12.9/100. Concerning tolerance, 8/15 subjects felt moderate muscle pain (n=7) and/or

skin pain (n=4) during or after MES sessions. 14/15 patients would perform regular MES sessions on the long term, 3 times/week for 10/14 patients.
Conclusion: A one week training with daily biquadricipital 25 minutes MES sessions significantly improves insulin sensitivity of ~ 30% in orally treated type 2 diabetic patients. This substantial improvement of insulin sensitivity occurs despite a weak EE increase during MES (+5,2±9,4%, p=0,055). This discrepancy suggests a specific metabolic effect of MES. Furthermore, this weak EE increase allows to consider the extent of this physical treatment in T2D patients with cardiovascular deconditioning, a usual sedentary population. All together, these data encourages further longer term research on the effect of MES on glycemic control.

Increased IGF-I bioavailability ameliorates the decline in insulin sensitivity that occurs with ageing and type 2 diabetes
P. Crossey, D.T. Jones;
Biomedical Section, University College Dublin, Dublin, Ireland.

Background and aims: Cross sectional and epidemiological studies have shown a correlation between low circulating levels of total IGF-I and the risk of developing type 2 diabetes and disease prognosis. These findings have been reinforced by data from clinical and experimental animal models which provide evidence linking reduced levels of free IGF-I and diabetes. The corollary of these data suggest that increased free IGF-I might have beneficial effects on insulin sensitivity and glucose homeostasis. The aim of this study was to investigate the effects of aging and consumption of a diabetogenic diet on insulin sensitivity and glucose homeostasis in an animal model of increased free IGF-I.
Materials and methods: These studies utilise mice deficient in IGFBP-1, a specific high affinity binding protein that sequesters IGF-I, as a model of increased free IGF-I . In this longitudinal study, we have assessed glucose and insulin tolerance, insulin secretion and endocrine profiles in IGFBP-1 knockout (BP1KO) mice that have been fed either a diabetogenic (high fat) or a normal diet.
Results: Although glucose tolerance was similar in both groups at 8 weeks of age, BP1KO mice were significantly more insulin sensitive (AUC KO v WT 376.5 ± 20.05 v 483.94 ± 21.6 $p < 0.05$). Of interest, we noted that BP1KO mice were heavier than age matched controls (KO v WT 26.4 ± 0.4 g v 25.8 ± 0.25 $p < 0.05$) and analysis of body composition showed this was mainly due to a difference in body fat (KO v WT 3.7 ± 0.42 g v 2.3 ± 0.32 $p < 0.05$). Glucose and insulin tolerance tests were repeated after 16 weeks of feeding a normal chow or high fat diet (45% kcal from fat). There was evidence of impaired glucose tolerance (AUCKO v WT 615 ± 63 v 803 ± 40.6 $p < 0.01$) and insulin resistance (AUCKO v WT 360 ± 12.4 v 517.5 ± 15.9 $p < 0.01$) in both groups on both diets but the impairment was significantly ameliorated in BP-1KO mice, particularly in the high fat fed cohort. BP1KO mice also secreted significantly less insulin than controls in response to a glucose challenge at both timepoints. Weight gain was similar in both groups of chow fed mice but high fat feeding resulted in greater weight gain in wild type mice than BP1KO mice (weight gain KO v WT 12.7 ± 0.3g v 19.5 ± 0.44g $p < 0.01$). Analysis of body composition revealed that wild type mice lost lean muscle mass and gained fat when maintained on either diet whereas BP1KO mice gained lean muscle mass and acquired less fat mass than controls regardless of diet. Endocrine profiling (table 1) indicated differences in leptin resistin and TNFα all of which were lower in BP1KO mice than controls at all timepoints. Free IGF-I is approximately 3 fold higher in BP1KO mice than controls although levels of total IGF-I are similar.
Conclusion: These data support the hypothesis that increased levels of free IGF-I are beneficial in ameliorating the deterioration in glucose homeostasis and insulin sensitivity that occurs with aging and type 2 diabetes and suggests that factors which enhance free IGF-I may have therapeutic applications in treating insulin resistance in diabetes and other states.

Effect of exercise training and resveratrol on HFD-induced changes in skeletal muscle PDHa activity: impact of PGC-1 alpha
R.S. Biensø, S. Larson, C.M. Kristensen, N. Brandt, J. Olesen, H. Pilegaard;
Department of Biology, University of Copenhagen, Denmark.

Background and aim: Obesity is associated with increased risk of dysregulated glucose metabolism and insulin resistance which potentially can lead to the development of type 2 diabetes. High fat diet (HFD) is known to impair glucose metabolism in skeletal muscle. One important protein in glucose metabolism is the pyruvate dehydrogenase (PDH) complex, which converts pyruvate into acetyl CoA in a reaction which represents the only entry of carbohydrates into mitochondria for oxidation. It is well known that exercise can improve whole body glucose homeostasis and increase oxidative capacity in skeletal muscle. Resveratrol (RSV) is a polyphenol located in the skin of dark grapes and fruits. RSV has been shown to mimic some the beneficial effects of exercise in rodents activating some of the same molecular pathways inside the cell as exercise. Peroxisome proliferator-activated receptor co-activator (PGC)-1alpha is a transcriptional co-activator involved in mitochondrial biogenesis and suggested to play a role in substrate regulation. The aim of the present study was to investigate the effect of exercise training and RSV on HFD induced changes in the activity of PDH in the active form (PDHa) in skeletal muscle.
Materials and methods: Muscle specific PGC-1alpha knockout (KO) and littermate wild type (WT) mice were put on either high fat diet or chow diet for 16 weeks. The mice on HFD were divided into 4 groups, HFD, HFD+RSV (4g/kg food), HFD+exercise training and HFD+exercise training+RSV (4g/kg food). The respiratory exchange ratio (RER) was measured during 24 hours in metabolic chambers. Mice were euthanized by cervical dislocation and Quadriceps muscles were removed. The PDHa activity was measured in homogenates from the Quadriceps.
Results: The PDHa activity in resting quadriceps muscle was in all HFD groups lower ($p<0.05$) in PGC-1alpha KO than in WT mice. The PDHa activity tended to be lower ($0.05<p<0.1$) in WT and was lower ($p<0.05$) in PGC-1alpha KO in the HFD group than in the chow group. Exercise training increased ($p<0.05$) the PDHa activity in WT, but this effect was blunted in PGC-1alpha KO mice. There were no effects of RSV or exercise training+RSV. The RER was in both genotypes lower ($p<0.05$) in all the HFD groups than in chow, and the only difference within the HFD groups was a higher ($p<0.05$) RER in HFD+exercise training than HFD in PGC-1alpha KO mice.
Conclusion: The main finding of the present study is that exercise training prevented a HFD-induced decrease in PDHa activity in mouse skeletal muscle and that muscle PGC-1alpha is required for this effect. In addition, RSV had no effect on PDHa activity and the combination of RSV+exercise even seemed to block the effect of exercise alone. Therefore it seems that exercise

training alone and not RSV can normalize the PDHa activity in mice on a HFD, properly due to increased PDH protein content.

Exercise - but not resveratrol - increases performance and oxidative proteins in elderly human skeletal muscle
J. Olesen[1], L. Gliemann[2], R.S. Biensø[1], J. Schmidt[2], Y. Hellsten[2], H. Pilegaard[1]; [1]Department of Biology, [2]Department of Nutrition, Exercise and Sports, University of Copenhagen, Denmark.

Background and aims: Aging is associated with reduced physical performance, decreased muscle mass and strength as well as reduced oxidative capacity in skeletal muscle. Altogether this may affect the overall health status and quality of life for the individual. Exercise training has been shown to increase muscle mass, mitochondrial biogenesis and oxidative capacity in skeletal muscle and thus has the potential of postponing many of the observed age-associated metabolic complications. Recently, the naturally occurring antioxidant resveratrol (RSV) has been shown to exert "exercise like" effects on mitochondrial biogenesis and oxidative capacity in skeletal muscle of high fat diet challenged rodents. However, little is known about the effect of RSV on metabolism in healthy aging. The aim of the present study was to investigate whether RSV supplementation (suppl.) alone or in combination with exercise training has beneficial effects on whole body performance as well as metabolic parameters in human skeletal muscle of elderly subjects.
Material and methods: 43 physical inactive healthy aged men (age: 64.9 0.5 years; BMI: 24.9 0.6 kg $2h^{-1}$; VO_{2max} 2605 70.2 mlO_2 min^{-1}) were randomized into 4 groups with 8 weeks of daily suppl. of 250 mg RSV or placebo with or without concomitant high-intensity exercise training. Before and after the intervention all subjects performed an incremental cycle ergometer VO_2 max test and time to exhaustion during one-leg knee-extensor exercise. Vastus lateralis muscle biopsies were obtained before and after the intervention period.
Results: Whereas RSV suppl. alone did not affect VO2 max, both exercise groups increased VO2 max, but the placebo group increased more than the RSV group (19 % and 13 % increase respectively). Time to exhaustion increased similarly in the two exercise groups (22% and 58 % increase respectively). The content of oxidative proteins cytchrome c and cytochrome c oxidase I in skeletal muscle increased equally ~1.5 fold in both exercise groups, whereas no effect of RSV suppl. alone was observed. Sirtuin 1 protein content, a potential mediator of both exercise and RSV-induced adaptations in skeletal muscle did not change with any of the interventions.
Conclusion: Exercise training increased overall physical performance and the capacity for oxidative phosphorylation in human skeletal muscle of elderly subjects, but RSV alone or in combination with exercise training had no effect in the present settings. The present findings support a potent effect of exercise training rather than RSV on metabolism in healthy aging.

OP 12 FGF21 cures it all?

67

High glucose represses fibroblast growth factor 21 (FGF21) action through peroxisome proliferator-activated receptor gamma in mouse pancreatic islets
W.Y. So[1], Q. Cheng[1], L. Chen[1], C.E. Molina[2], A. Xu[3], K.S.L. Lam[3], P.S. Leung[1]; [1]The Chinese University of Hong Kong, China, [2]Indiana University School of Medicine, Indianapolis, USA, [3]University of Hong Kong, China.

Background and aims: Fibroblast growth factor 21 (FGF21) is a distinctive member of the FGF family whose actions require the cofactor β-klotho. Restricted expression of β-klotho in liver, pancreas and adipose tissue provides the mechanistic basis for tissue-specific actions of FGF21 and thus implicates the important roles of β-klotho in these tissues. Circulating FGF21 levels are elevated in diabetic subjects and correlate with abnormal glucose metabolism, while pharmacologically administered FGF21 can ameliorate hyperglycemia. The pancreatic islet is a target of FGF21, yet the actions of FGF21 in islet under normal and diabetic conditions are not fully understood. This study aimed to investigate the role of high glucose in islet FGF21 action by using animal models of diabetic db/db mice and FGF21 knockout (KO) mice.
Materials and methods: Pancreatic islets were isolated from db/db diabetic mice and m+/db normal mice, as well as FGF21 KO mice and their wild-type littermates. FGF21 and insulin levels were assessed by a specific mouse enzyme-linked immunosorbent assay (ELISA) kit. mRNA expression was evaluated by real-time RT-PCR; protein expression and post-receptor signaling pathways were analyzed by Western blotting. Islet morphology was evaluated by immunofluorescence.
Results: Serum levels of FGF21 were increased in diabetic db/db mice at 12 wks (m+/db 12.76 ± 4.53 pg/ml; db/db 39.00 ± 6.08 pg/ml; $^{**}P < 0.01$). The expression of β-klotho at both mRNA and protein levels, but not all FGF receptors, was reduced (72% and 53% respectively; $^{***}P < 0.001$) in islets isolated from adult db/db mice in an age-dependent manner. FGF21-induced phosphorylation of FGF receptor substrate 2 (FRS2) was impaired in islets from overt diabetic mice. In corroboration, *ex vivo* studies revealed that treatment with elevated glucose concentration (28 mM) down-regulated β-klotho expression (55%; $^{**}P < 0.01$), compared to those treated with normal glucose (5.6 mM). Weakened FGF21-induced FRS2 phosphorylation was also observed after high glucose treatments. Reduced β-klotho expression and FGF21 signaling in islets from adult diabetic mice or treated with high glucose were reversed by rosiglitazone (20 μM), an anti-diabetic peroxisome proliferator-activated receptor gamma (PPARγ) ligand. Both diabetic mice islets and high glucose-treated islets showed decreased PPARγ expression and activity, which were prevented by rosiglitazone. Meanwhile, islets of FGF21 KO mice showed distorted architecture and impaired glucose-stimulated insulin secretion.
Conclusion: Hyperglycemia in type 2 diabetes mellitus (T2DM) may lead to FGF21 resistance in pancreatic islets, probably through the reduction of PPARγ expression and activity which represents a novel mechanism for glucose-mediated islet dysfunction.

Glucagon like peptide 1 (GLP1) in combination with fibroblast growth factor 21 (FGF21) enhances browning of white adipose tissue
T. Coskun, L.S. O'Farrell, A.L. Kauffman, A. Efanov, A.C. Adams;
Eli Lilly and Company, Indianapolis, USA.

Background and aims: GLP1 causes body weight loss via suppression of appetite, while FGF21 decreases body weight via a rise in energy expenditure. We have recently reported that GLP1 and FGF21 when administered in combination generate synergistic body weight loss in diet-induced obese (DIO) mice greater than that observed with either agent alone. In the present study, we aimed to investigate the molecular mechanism underlying this synergistic weight loss.
Materials and methods: DIO C57/Bl6 male mice were treated via subcutaneous osmotic pumps with either vehicle (Phosphate Buffered Saline, 12 μl/mouse/day), GLP1 (10 nmol/kg/day), FGF21 (10 nmol/kg/day) or GLP1 (10 nmol/kg/day) + FGF21 (10 nmol/kg/day) combination (COMBO) for 14 days. Body weight and food intake were monitored daily, In addition basal metabolism was also measured from Day 6 to Day 8 via indirect calorimetry.

Following sacrifice, several tissues (brown adipose tissue [BAT], white adipose tissue [WAT] and liver) were collected for analysis of mRNA expression of candidate genes by QPCR.
Results: Treatment with GLP1 or FGF21 alone led to 7% or 12% body weight loss, respectively, as compared to vehicle. However, COMBO treatment resulted in significantly greater body weight loss (27% decrease from vehicle). Even though GLP1 alone treatment had no effect on the energy expenditure, GLP1 in combination with FGF21 significantly potentiated the FGF21-induced energy expenditure increase during light photoperiod. As summarized in the table, COMBO treatment up-regulated PGC-1α and UCP-1 mRNA expression in epididymal white adipose tissue indicative of "browning" of WAT. Moreover GLP1+FGF21 combination increased leptin receptor expression in metabolically active peripheral tissues.
Conclusion: Combination of GLP1 and FGF21 produces a profound decrease in body weight via enhanced transformation of adipose tissue from a WAT to BAT-like state and the marked increase in peripheral mRNA expression suggests that leptin signaling and leptin sensitivity may be enhanced.

Table. mRNA expression of candidate genes in white adipose tissue and liver following 14 day treatment of DIO mice
(* indicates significant from control; + significant from GLP1 or FGF21).

Treatment	Tissues (fold increase from control)

FGF21 knockdown exacerbates hepatic insulin resistance via STAT3/ SOCS3 pathway
Y. Lei[1,2], L. Li[1,2], G. Yang[1];
[1]College of Laboratory Medicine, [2]the Key Laboratory of Laboratory Medical Diagnostics in Ministry of Education, Chongqing Medical University, China.

Background and aims: Insulin resistance is a metabolic disorder often associated with type 2 diabetes. Recent reports have demonstrated that FGF-21 plays an important role in the progression of insulin resistance. Nonetheless, the biochemical and molecular mechanisms by which changes in FGF-21 activation result in changes in the rates of hepatic gluconeogenesis and glycogenolysis remain to be elucidated. This study aimed to explore the effects of FGF-21 knockdown on HGP, especially the relative contribution of gluconeogenesis and glycogenolysis to HGP, and STAT3/ SOCS3 signal pathways.
Materials and methods: We have developed an adenovirus-mediated RNA interference technique in which short hairpin RNAs (shRNAs) were used to inhibit FGF-21 expression in the liver. Insulin sensitivity was examined by euglycaemic-hyperinsulinaemic clamping. Glucose rates of appearance (GRa) were determined with 3-[3H] glucose. Whole body GRa and glucose uptake (GRd) were calculated using the non-steady-state equation. mRNA and protein expressions were measured by qRT-PCR and Western blot, respectively.
Results: Liver-specific knockdown of FGF-21 in HFD-fed ApoE-/- mice produced a 39% increase in glycogenolysis and a 75% increase in gluconeogenesis and were accompanied by increases in the hepatic expression of glucose-6-phosphatase and phosphoenolpyruvate carboxykinase. FGF-21 knockdown further suppressed phosphorylation of STAT3 in HFD-fed mice. And SOCS3 mRNA and protein levels in FGF-21 knockdown plus HFD-fed mice were decreased to 10% and 50% compared to that in HFD-fed mice alone.
Conclusion: We present evidence suggesting that FGF-21 knockdown exacerbated hepatic insulin resistance in the liver is a consequence of increased gluconeogenesis and glycogenolysis in concert with activation of G6Pase and PEPCK via the STAT3/ SOCS3 pathway.

Alpha lipoic acid induces hepatic FGF21 expression via up-regulation of Nur77 and CREBH
K.-H. Bae, A.-K. Min, K.-G. Park, I.-K. Lee;
Department of Endocrine and Metabolism of Internal Medicine, Kyungpook National University School of Medicine, Taegu, Republic of Korea.

Background and aims: Fibroblast growth factor 21 (FGF21) is a potential candidate for the treatment of metabolic syndrome due to its beneficial effects on glucose and lipid metabolism. FGF21 stimulates hepatic fatty acid oxidation,ketogenesis and gluconeogenesis in the response to long-term fasting. The mechanisms underlying the transcriptional regulation of FGF21 are not fully elucidated. Nur77 is a transcription factor that belongs to a nuclear hormone receptor superfamily and implicated in hepatic gluconeogenesis during fasting. Alpha lipoic acid (ALA), naturally occurring thiol antioxidants, decreases lipogenesis and increases insulin sensitivity in liver. Previously we demonstrated that ALA induces Nur77 induction in vascular cells. The aim of this study is to determine whether ALA induces Nurr77 and increases FGF21 expression in liver.
Materials and methods: The alterations of FGF21, Nur77, cyclic AMP response element binding protein H (CREBH) and fasting-related metabolic gene expression were compared in mice under both fed and fasted conditions. The effects of ALA and adenovirus-mediated Nur77 and CREBH on hepatic FGF21 production in vitro and in vivo were investigated. We also examined whether downregulation of endogenous Nur77 by small interfering (si) RNA restores the ALA effect on hepatic FGF21 production.
Results: We found that fasting and ALA treatment induced Nur77 and CREBH production. ALA treatment and adenovirus-mediated overexpression of Nur77 and CREBH increased hepatic FGF21 expression and serum FGF21 levels. Moreover, the inhibition of endogenous Nur77 expression by siRNAs markedly abolished ALA-induced CREBH and FGF21 expression. Nur77 and CREBH synergistically increased FGF21 expression in liver cells.
Conclusion: This study suggests Nur77 as novel positive regulator of hepatic FGF21 expression during fasting state and ALA has potential metabolic benefits by upregulation of FGF21.

71

Brown adipose tissue, a sink of glucose disposal? Effects of FGF21 on glucose metabolism in brown adipose cells
F. Villarroya[1], E. Hondares[1], J. Diaz-Delfin[2], R. Iglesias[1], M. Giralt[1];
[1]University of Barcelona and CIBER Fisiopatologia de la Obesidad y Nutrición, [2]University of Barcelona, Spain.

Background and aims: Brown adipose tissue (BAT) is a site of adaptive thermogenesis in mammals. BAT is more active and abundant in adult humans than expected, and its activity is negatively correlated with obesity and type II diabetes. BAT is a sink of lipid utilization but evidence of active uptake of radiolabeled glucose, as detected in PET-scan procedures, has led to the hypothesis that BAT could be an important site of glucose utilization, and BAT activation could be useful to prevent hyperglycemia. FGF21 is a novel hormonal factor with beneficial metabolic effects on glycemia, and BAT is a potential site of FGF21 action. Here we determined the effects of FGF21 on glucose metabolism in brown adipocytes, in an attempt to evaluate the capacity of FGF21 to induce the potential of BAT as an active site glucose disposal.
Materials and methods: We evaluated brown adipocytes (mouse primary cultures) as targets of FGF21 on glucose metabolism, by determining the effects of FGF21 (5nM, or a range of 5nM to 50 nM) on: a) expression of the components of the FGF21 response machinery (FGF receptor-1 and beta-Klotho cor-receptor): b) potential intracellular responses to FGF21 (ERK1/2, p38MAP kinase, protein kinase A), by immunoblot detection of the phosphorylated forms, c)3H-2-deoxyglucose uptake in absence or presence of insulin, d) 14C-glucose oxidation to 14C-CO2; d) expression of glucose transporters GLUT1 and GLUT4 and other marker genes of oxidative (cytochrome oxidase activity, spectrophotometric) and thermogenic (UCP1 expression) activity; e) overall respiratory activity (Biosensor; f) lipolysis (glycerol in the medium, Sigma). Transcript levels were measured by standard qRT-PCR (TaqMan, Applied Biosystems) and specific protein levels by immunoblot. Statistical analysis used ANOVA.
Results: Differentiation of brown adipocytes led to a strong induction of beta-Klotho expression. FGF21 caused a strong and rapid (15 min) activation of ERK1/2 and p38 MAP kinase but did not alter protein kinase-A activity.

Exposure to FGF21(5nM) caused a induction in glucose uptake both in the presence (2.2-fold, P=0.03) and absence (2.6-fold, P=0.02) of insulin; and a 3.8-fold induction (P=0.01) of glucose oxidation in brown adipocytes. Induction of overall cellular respiration was 1.4-fold (P=0.03). In parallel, FGF21 caused a dose-response induction of GLUT4 and GLUT1 expression (overall, a range of 2-3-fold maximal induction in specific transcript and protein levels for each transporter) This was paralleled by a significant induction of cytochome oxidase activity (2.3-fold, P=0.02) and expression of the thermogenic marker UCP1 (2.9-fold, P=0.008). FGF21 caused a significant induction of lipolysis (1.8-fold, P=0.03).
Conclusion: Brown adipocytes are sensitive targets of FGF21. FGF21 induces glucose uptake and overall oxidation, and a specific strong induction of oxidation of glucose. This happened in association with a coordinate activation of the overall machinery for mitochondrial uncoupled oxidation plus a specific induction in the expression of glucose transporters. This effect appears to be independent from responsiveness to insulin. Thus, the induction of brown adipocyte amounts and/or activity appears as a foreseeable strategy to enhance glucose disposal. FGF21 is a promising tool to promote this process with potentially beneficial effects in conditions of hyperglycemia

FGF21 resistance relevant to insulin resistance in skeletal muscle of patients with type 2 diabetes
M. Lee[1], J. Jeon[1], E. Ha[1], S.-E. Choi[1], T. Kim[2], S.-Y. Ahn[1], S. Han[1], H. Kim[1], D. Kim[1], Y. Kang[3], K.-W. Lee[1];
[1]Department of Endocrinology and Metabolism, Ajou University School of Medicine, Suwon, [2]Division of Endocrinology, Department of Internal Medicine, Kwandong University, College of Medicine, Goyang, [3]Institute of Medical Science, Ajou University School of Medicine, Suwon, Republic of Korea.

Background and aims: Insulin resistance and hyperinsulinemia are the hallmark features of type 2 diabetes (T2DM) and obesity, but the detailed pathogenesis underlying the initiation of insulin resistance is still poorly understood. Recently, fibroblast growth factor 21 (FGF21), a novel member of the fibroblast growth factor family, was identified as a potent metabolic regulator with specific effects on glucose and lipid metabolism. We investigated the mechanisms involved in the induction of FGF21 resistance in human skeletal muscle of T2DM patients.
Materials and methods: We recruited 16 T2DM subjects and 12 subjects with normal glucose tolerance for this study. Whole-body insulin-mediated glucose uptake was determined using a euglycemic hyperinsulinemic clamp test. A percutaneous biopsy sample of the vastus lateralis muscle was obtained from 15 to 20 cm above the knee using a Bergstrom needle. We used western blotting to determine levels of FGF21 and active FGF receptor and FRS2α in skeletal muscles from T2DM subjects and normal glucose tolerant subjects. Differentiated human skeletal muscle myoblasts (HSMMs) were pretreated with palmitate at three different concentrations for 24 hours, and then were stimulated for 10 minutes with recombinant FGF21 (100 ng/ml). We measured levels of FGF21, FGF Receptor, FRS2, and ERK1/2 using antibodies in HSMMs treated with palmitate.
Results: Levels of FGF21 were significantly increased in skeletal muscles from T2DM subjects but levels of active FGF receptor and FRS2α were significantly decreased in skeletal muscles from T2DM subjects. Similarly, FGF21 increased levels of active FGF receptor, FRS2α and ERK1/2 in HSMMs but there were significantly decreased levels of FGF21-stimulated FGF receptor, FRS2α and ERK1/2 in HSMMs treated with palmitate.
Conclusion: In conclusion, FGF21 resistance apparently was involved in insulin resistance in skeletal muscle in type 2 diabetes.

Baseline characteristics of participants enrolled in the cardiovascular outcome study of linagliptin versus glimepiride in early type 2 diabetes (CAROLINA)
N. Marx[1], J. Rosenstock[2], S.E. Kahn[3,4], B. Zinman[5,6], J.J. Kastelein[7], J. Lachin[8], M.A. Espeland[9], E. Bluhmki[10], M. Mattheus[11], S. Patel[12], O. Johansen[11], H.-J. Woerle[11];
[1]Department of Internal Medicine I, University Hospital Aachen, Germany, [2]Dallas Diabetes and Endocrine Center, Dallas, [3]Department of Medicine, Division of Metabolism, Endocrinology and Nutrition, VA Puget Sound Health Care System, Seattle, [4]Department of Medicine, University of Washington, Seattle, USA, [5]Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, [6]Division of Endocrinology, University of Toronto, Canada, [7]Department of Vascular Medicine, Academic Medical Center, Amsterdam, Netherlands, [8]The Biostatistics Center, The George Washington University, Rockville, [9]Department of Biostatistical Sciences, Wake Forest University Health Sciences, Winston-Salem, USA, [10]Boehringer-Ingelheim, Biberach, [11]Boehringer-Ingelheim, Ingelheim, Germany, [12]Boehringer-Ingelheim, Bracknell, UK.

Background and aims: Current evidence on the cardiovascular (CV) safety of diabetes drugs remains inconclusive, in particular for sulphonylureas (SUs). There is therefore a need for properly designed, long-term, active controlled studies in type 2 diabetes (T2D) to provide solid evidence on the potential benefit or lack thereof of different glucose-lowering therapies on CV events and mortality.
Materials and methods: In CAROLINA potential differing effects on CV outcomes of linagliptin (5 mg/day) therapy versus glimepiride (up to 4 mg/day) will be determined in participants with early T2D at high CV risk or with CV complications. The study is a double-blind, double dummy, event driven (targeting 631 events [time to first event of a composite of non-fatal myocardial infarction, non-fatal stroke, CV death or hospitalisation for unstable angina pectoris]) trial powered for CV non-inferiority and superiority.
Results: Between Dec 2010 and Dec 2012, 581 clinical sites globally randomised 6103 patients. At baseline, data on clinical history, symptoms and medications along with centralised evaluations of ECGs and lab specimens were obtained. Most participants come from Europe (45.3%) or North-America (19.5%), 40.2% are women and 34.2% have previous CV complications. Diabetes duration was ≤5 years in 41% and mean HbA1c was 7.2% (HbA1c <7.5%: 73%). 67% were on 1 and 23% on 2 glucose-lowering agents, with the vast majority taking metformin (TABLE). The population was overweight/obese, with BMI ≥30 kg/m^2 in 46% of participants.
Conclusion: Baseline characteristics indicate that an appropriate target population has been recruited to address the study question of potential differing effects of linagliptin and glimepiride on CV outcomes and thus will help inform clinical decision-making when selecting second line therapy in T2D.

Table. Baseline characteristics of the study population in CAROLINA

Liraglutide effect and action in diabetes: evaluation of cardiovascular outcome and results (LEADER) trial design and methods

S.P. Marso[1], N.R. Poulter[2], S.E. Nissen[3], M.A. Nauck[4], B. Zinman[5], S. Pocock[6], R.M. Bergenstal[7], J.F.E. Mann[8], L.S. Ravn[9], A.C. Moses[10], J. Buse[11];
[1]Medicine, Saint Luke's Mid America Heart Institute, Kansas City, USA, [2]Imperial College, London, UK, [3]Cleveland Clinic Foundation, Cleveland, USA, [4]Diabeteszentrum, Bad Lauterberg, Germany, [5]Medicine, Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, Canada, [6]London School of Hygiene and Tropical Medicine, UK, [7]International Diabetes Center at Park Nicollet, Minneapolis, USA, [8]Friedrich Alexander University of Erlangen, Germany, [9]Novo Nordisk, Bagsvaerd, Denmark, [10]Novo Nordisk, Princeton, USA, [11]Medicine, University of North Carolina, Chapel Hill, USA.

Background and aims: Diabetes is independently associated with a two-fold excess risk for a broad range of cardiovascular adverse events including cardiovascular death, stroke, and non-fatal myocardial infarction. Liraglutide is a human glucagon-like peptide (GLP-1) receptor analog approved for use in patients with type 2 diabetes (T2DM). Its cardiovascular safety is being formally evaluated in the ongoing LEADER trial.
Materials and Methods: LEADER is Phase 3B, multi-center, international, double-blind, placebo-controlled clinical trial with long-term follow-up. Patients with T2DM at high risk for cardiovascular disease (CVD) who are treated with either oral antidiabetic (OAD) agents or selected insulin regimens alone or combined with OADs were eligible for inclusion. Patients with and without prior CVD were randomized to liraglutide once daily (maximum dosage of 1.8 mg) or placebo. The primary endpoint is the time from randomization to the first occurrence of cardiovascular death, non-fatal myocardial infarction, or non-fatal stroke. Estimated minimum enrollment of 8,754 randomized subjects was based on accrual of no less than 611 primary events with minimum follow-up of 42 months after last subject randomized. Consistent with United States Food & Drug Administration guidelines for demonstrating cardiovascular safety in anti-diabetes drugs, noninferiority of liraglutide will be established if the upper 2-sided 95% confidence limit for the relative risk of the primary endpoint is less than 1.3.
Results: LEADER enrolled patients from 2010-2012. Baseline demographics of the enrolled population (N=9,340) are shown in the Table. Of the 9,340 patients, 7,633 (81.7%) had prior CVD and 1,707 (18.3%) did not. There were 1,854 (19.9%) patients with estimated glomerular filtration rate (eGFR) 30-59 mL/min/1.73m²) and 177 (1.9%) with eGFR < 30 mL/min/1.73m².
Conclusions: LEADER is an ongoing phase 3B time- and event-driven randomized double blind clinical trial evaluating the cardiovascular safety of liraglutide in patients with T2DM at heightened risk for cardiovascular complications. Over 80% of the population has a history of prior CVD. It is anticipated that LEADER will provide conclusive results on the cardiovascular safety of liraglutide, with results expected in 2016.

Effects of metformin versus placebo in combination with insulin analogues in patients with type 2 diabetes mellitus: the CIMT randomised clinical trial

L. Lundby-Christensen[1,2], The CIMT Trial group;
[1]Trial Unit, Rigshospitalet, University Hospital, Copenhagen, [2]Steno Diabetes Center, Gentofte, Denmark.

Background and aims: It is unknown whether metformin versus placebo in combination with insulin analogues offer more benefits than harms in patients with T2D. In the Copenhagen Insulin Metformin Therapy (CIMT) trial we assessed the effects of 18-month metformin versus placebo in combination with one of three insulin analogue regimens in T2D patients on mean carotid intima-media thickness and adverse events.
Materials and methods: A centrally randomised, 2 x 3 factorial, treat-to-target (HbA1c ≤ 7.0%) clinical trial conducted at eight clinics assessing blindly metformin (1g twice daily) versus placebo. Inclusion criteria: T2D, HbA1c > 7.5%, BMI 25 to 40 kg/m2, oral antidiabetic agents for one year and/or insulin for at least 3 months. Insulin regimens were insulin detemir, insulin aspart biphasic, or a combination of aspart and detemir. Primary outcome: change in mean carotid intima-media thickness of the common carotid arteries. Secondary outcomes: serious adverse events, hypoglycaemia, weight, HbA1c, and dose of insulin (treatment variable). After multiple imputations for the primary outcome, intention-to-treat analyses were performed adjusted for stratification variables plus entry mean carotid intima-media thickness with two-sided significance tests (alpha 0.01) using general linear univariate model (continuous data) or Chi-square test as appropriate.
Results: Only 413 of 950 planned patients were randomised 1:1 to metformin vs. placebo. The two groups did not differ regarding insulin regimens. The 18-month ratio between the mean carotid intima-media thickness did not differ significantly (1.013, 95% CI 0.995 to 1.030, P=0.16; metformin mean 0.784 (95% CI 0.771 to 0.798) mm vs. placebo 0.774 (95% CI 0.761 to 0.787) mm). The number of patients with serious adverse events was 29.6% vs. 24.8% (P=0.27), with severe hypoglycaemia 5.8% vs. 5.3% (P=0.83), and with non-severe hypoglycaemia 76.2% vs. 75.2% (P=0.82). The 18-month insulin dose did not differ significantly between the two groups (mean difference -9.24 IE, 95% CI -24.6 to 6.16 IE; P=0.24). The 18-month HbA1c (mean ratio 0.96, 95% CI 0.93 to 0.98, P=0.0015; mean 7.65 vs. 8.00%) and weight (mean ratio 0.98, 95% CI 0.96 to 0.99, P=0.002; mean 97.5 vs. 100.0 kg) and the AUC of insulin doses during the 18 months (mean difference -7425 IE, 95% CI 2115 to 12735 IU, P=0.006) were significantly less in the metformin group.
Conclusion: We did not observe significant effects of metformin versus placebo on mean carotid intima-media thickness, serious adverse events, severe hypoglycaemia, non-severe hypoglycaemia, or 18-month insulin dose. Metformin significantly decreased the 18-month HbA1c and weight as well as the total insulin dose during the trial. However, the trial only reached 43% of the planned sample size, and our results underscore the need for large randomised clinical trials with adequate methodologies to determine the impact

of long-term combination of metformin with insulin analogues versus insulin analogues alone in T2D.

LV remodelling in patients with type 2 diabetes: determinants of the beneficial effect of olmesartan
R.E. Schmieder[1], L.M. Ruilope[2], H. Haller[3], C. Ott[1], C. Ott[1], U. Raff[1], for the ROADMAP trial investigators;
[1]Nephrology and Hypertension, University of Erlangen-Nürnberg, Germany, [2]Hypertension Unit, Complutense University, Madrid, Spain, [3]Clinic for Nephrology, Hannover Medical School, Germany.

Background and aims: Cardiac structural adaptation develops early in hypertension and diabetes and is aggravated if both conditions coexist. Blockade of the angiotensin receptors may attenuate these cardiac processes and we analyzed clinical determinants (including therapy with olmesartan) of preventing or delaying left ventricular (LV) remodeling in a large-scale prospective study.
Materials and methods: In the ROADMAP study, a double blind, placebo controlled, multicenter, phase IIIb study, comparing olmesartan 40mg (OM) vs. placebo (Pb; additional anti-hypertensive medication allowed, except RAAS inhibitors) on microalbuminuria prevention in diabetic patients, also 12-lead ECGs have been conducted at baseline and in yearly intervals over the mean study duration of 3.2 years. Patients were eligible to enter the prespecified ECG-LVH analysis if they had an evaluable ECG at baseline and one after at least 2 years. All ECGs were centrally and independently evaluated by two investigators in a blinded fashion. The primary ECG parameter of LV remodeling and hypertrophy was Cornell voltage QRS duration product, and the Cornell voltage index and Sokolow-Lyon index were secondary parameters.
Results: Of the 14.074 ECG recorded in the ROADMAP study, 9.418 have been found evaluable and 1.513 patients were identified in whom interpretable ECGs were available at baseline and at last assessment (N=736 Pb and N=777 OM patients). Dividing the study population into 4 quartiles defined by the Cornell voltage QRS duration product at baseline, the prevalence of patients in the highest quartile (i.e. >200 mV*msec) increased from 24% to 26,5% in the placebo but decreased from 25.5% to 22.3% in the olmesartan group (odds ratio 0.598 [95% CI: 0.440-0.813], p=0.0011). When adjusted for potential differences in clinical baseline parameters (incl. blood pressure), the odds ratio did not change substantially. Analysis of determinants for LV remodeling in these diabetic patients revealed that the prevalence of the Cornell voltage QRS duration product was significantly reduced in diabetic patients in the OM group with a BP either < or > 130/80 mmHg at last assessment (Risk reduction [RR] 39.2%, and 45.6 %, p=0.0081 and 0.0406, respectively). In addition, it was also significantly reduced in the OM group independently of the age (> or ≤ 58 years; RR 37.9% and 42.3%, p=0.0347 and 0.0121, respectively) or being male or female (RR 46.5% and 36.3%, p=0.0448 and 0.0136, respectively). A significant reduction for OM was also seen in patients with a duration of diabetes > 5 years (RR 37.7%, p=0.0039), with anti-diabetic medication at baseline (RR 41.5%, p=0.0008), in obese patients (BMI >28 kg/m^2; RR 44.2%, p=0.0011), in patients with an HbA1c >7,0% (RR 46.1%, p=0.0023) at baseline, as well as in patients with an increase in HbA1c during the study period (RR 52.6%, p=0.0010).
Conclusion: Olmesartan significantly decreased ECG left ventricular remodeling in type 2 diabetes independent of differences in blood pressure, age and gender. This effect was most striking in patients with longer duration of diabetes, intake of anti-diabetic medication, obesity and a high HbA1c at baseline or its increase during the study. Thus, in addition to clinical parameters, olmesartan delayed ECG signs of cardiac structural adaptation in type 2 diabetes.

Predictors of congestive heart failure after treatment with an endothelin receptor antagonist: a post-hoc analysis of the ASCEND trial
J. Hoekman[1], H.J. Lambers Heerspink[1], J. Mann[2], D. Green[3], G. Viberti[4], D. De Zeeuw[1];
[1]Clinical Pharmacology, University Medical Center Groningen, Netherlands, [2]Department of Medicine, University Erlangen, Munich, Germany, [3]Quintiles Ltd., Strasbourg, France, [4]King's College London School of Medicine, UK.

Background and aims: The Avosentan on time to doubling of Serum Creatinine, ENd stage renal disease or Death (ASCEND) trial tested the potential renoprotective effect of the endothelin receptor antagonist (ERA) avosentan versus placebo in patients with diabetic nephropathy. Yet, the trial was prematurely terminated due to high incidences congestive heart failure (CHF) in the avosentan arms likely due to fluid retention. The aim of this study was to identify risk markers associated with congestive heart failure (CHF) after treatment with the endothelin receptor antagonists (ERA) avosentan.
Materials and methods: In a post-hoc analysis of ASCEND (N=1392) we assessed whether baseline CHF risk was modified by avosentan treatment. Furthermore, post-randomisation changes between baseline and the first available measurement of the fluid retention surrogates body weight (BW) and haemoglobin (Hb) were examined for their relationship with CHF development.
Results: Relative to placebo, avosentan increased CHF risk (HR 2.72; 1.66 to 4.47; p<0.001). The avosentan induced CHF risk increased with lower baseline cholesterol levels (p=0.03) and concomitant statin use (p=0.060), while it decreased with lower eGFR (p=0.040). Patients allocated to avosentan had a median BW increase of 0.6 kg (IQR 0.0 to 2.0 kg) and a median Hb decrease of 14 g/L (IQR -21 to -7 g/L) at the first post-randomisation measurement (p<0.001 vs. placebo). Avosentan induced BW increase was a predictor of CHF (p=0.038), while Hb decrease was not (p=0.603). The increase in BW was particularly pronounced in patients with a cardiovascular disease history and in those using statins.
Conclusion: In avosentan treated patients with diabetic nephropathy, BW increase, but not Hb decrease, was an early risk marker for CHF development, indicating that close BW monitoring could be used to identify high risk subjects in future trials with ERAs. Monitoring of statin use is recommended as avosentan-exposure may increase in combination with these agents.

Effects of bariatric surgery on ectopic fat depositions and cardiovascular function in obese type 2 diabetes patients
J.W.A. Smit[1], M.A. Sleddering[2], L.D. van Schinkel[3], M.A. Lips[3], J.T. Jonker[3], A. de Roos[4], H. Pijl[3], H.J. Lamb[4], I.M. Jazet[3];
[1]General Internal Medicine, The Radboud University Nijmegen Medical Centre, [2]General Internal Medicine, LUMC, Leiden, [3]Endocrinology, LUMC, Leiden, [4]Radiology, LUMC, Leiden, Netherlands.

Background and aims: Cardiovascular disease (CVD) is the main cause of death in type 2 diabetes (T2DM) patients. Lipotoxicity, caused by ectopic fat depositions in and around the heart, is thought to play a role in the pathogenesis of CVD. Diet-induced weight loss results in a decrease in cardiac ectopic fat stores, however whether this is the same for weight loss after bariatric surgery is less clear. Therefore, we assessed myocardial TG content, pericardial fat and cardiac function in obese, insulin-dependent T2DM patients before and 16 weeks after a Roux-en-Y gastric bypass (RYGB) surgery.
Materials and methods: Nine obese patients (40% male, age 54 ± 9 years (mean ± SEM)) with insulin-dependent T2DM, without a history of cardiovascular disease, scheduled to undergo RYGB surgery were enrolled in this study. Cardiovascular function and ectopic fat accumulation were assessed with magnetic resonance (MR) imaging and myocardial TG content with MR spectroscopy before and 16 weeks after the RYGB surgery.
Results: BMI decreased from 41.6 ± 1.5 kg/m2 at baseline to 34.2 ± 1.0 kg/m2 (p<0.001) 16 weeks after RYGB surgery. Glycemic control improved as well, as shown by a decrease in HbA1c from 8.0 ± 0.4 to 6.8 ± 0.5 % (p<0.05). Total daily insulin dose decreased (-115 ± 19 units/day) and 2 patients discontinued insulin therapy completely. A significant decrease of abdominal and pericardial fat depots was seen, with a wide variation in the relative changes. There was a high relative decrease in visceral (-35.2 ± 3.4%) as compared

to subcutaneous (-25.7 ± 2.3%) fat volume and a higher relative decrease in paracardial (-16.9 ± 7.7%) as compared to epicardial (-5.8 ± 2.6) fat volume (Figure 1). We did not observe an effect of the RYGB surgery on cardiac function, pulse wave velocity or myocardial TG content.
Conclusion: This study shows that surgical-induced weight loss results in tissue-specific changes in body fat distribution.

Figure1. Relative changes in fat depots 16 weeks after RYGB.

The pharmacologic profile of rapid-acting insulin administered by jet-injection in patients with diabetes
E.E.C. Engwerda, B.E. De Galan, C.J. Tack;
General Internal Medicine, Radboud University Nijmegen Medical Centre, Netherlands.

Background and aims: We recently showed in a euglycemic clamp study among healthy subjects faster absorption and action of rapid-acting insulin when injected by a jet injector rather than by a conventional pen. To determine whether these benefits exist in patients with diabetes in a more real-life situation, we compared the pharmacologic profile of rapid-acting insulin administration by jet injection to that by conventional insulin pen prior to a standardized meal in patients with type 1 or type 2 diabetes.
Materials and methods: In a randomized, double-blind, double-dummy cross-over study, 12 patients with type 1 and 12 patients with type 2 diabetes (mean±SD age: 49.9±16.0 years, BMI: 26.4±2.1 kg/m^2, HbA1c: 7.5±0.8%) received insulin aspart either by jet injection or by conventional pen followed by a standardized high-glycemic index meal (108g carbohydrates). Blood was sampled for six hours for determination of plasma glucose and insulin levels to calculate pharmacologic parameters.
Results: Insulin administration by jet injection resulted in shorter time until peak plasma insulin levels (51.3±6.4 versus 91.9±10.2 min, P=0.003) and reduced hyperglycemic burden during the first hour (154.3±20.8 versus 196.3±18.4 mmol·min·l^{-1}, P=0.041) when compared to conventional administration. Jet injection did not significantly reduce the hyperglycemic burden during the hours thereafter. There were no differences between the jet injector and conventional pen with respect to number of patients requiring exogenous glucose to prevent hypoglycemia (17 versus 18, P=0.75) or the amount of glucose administered (21.0±5.5 g versus 23.7±5.7 g, P=0.61). Both injection methods elicited a similar experience of pain (VAS, 1.96±1.9 versus 1.40 ±1.6, P=0.14). The jet injector did not perform significantly different in patients with type 1 or type 2 diabetes, although there was a suggestion that the jet injector had a stronger effect in patients with type 2 diabetes.
Conclusion: In patients with type 1 or type 2 diabetes, insulin administration by jet injection resulted in considerably more rapid insulin absorption compared to administration by conventional pen. This translated into a significant decrease in early postprandial hyperglycemia. Beyond one hour, the benefit of jet injection on postprandial glycemic burden was no longer statistically significant. The improved postprandial glucose control may specifically benefit patients with difficulty limiting postprandial glucose excursions.2

Clinical evaluation of the Imperial College bio-inspired artificial pancreas overnight and after breakfast in adults with type 1 diabetes
M. Reddy[1], P. Herrero[2], N. Oliver[1], P. Georgiou[2], M. El-Sharkawy[2], P. Pesl[2], N. Jugnee[1], H. Thomson[1], C. Toumazou[2], D. Johnston[1];
[1]Division of Diabetes, Endocrinology and Metabolism, Imperial College London, [2]Center for Bio-Inspired Technology, Institute of Biomedical Engineering, Imperial College London, UK.

Background and aims: The aim of this study was to assess the safety and efficacy of the Imperial College Bio-inspired Artificial Pancreas in adults with type 1 diabetes mellitus (T1DM) during overnight and post-prandial conditions. The bio-inspired closed-loop control algorithm, developed by our group, is based on a mathematical model of beta-cell physiology and is implemented on a microchip within a handheld device.
Materials and methods: This was a non-randomised open label study. Each subject underwent 13-hours of closed-loop control starting at 22:00. The system comprises a Medtronic Enlite sensor, the Imperial College bio-inspired controller and a Roche Accu-Chek Combo insulin pump. A standard breakfast containing 40 grams of carbohydrates was given at 06:00 the next day with the meal announced to the controller.
Results: 10 adult subjects with T1DM (60% male, mean (SD) age 45 (11) years, duration of diabetes 19 (11) years, duration of pump therapy 3.1 (3.2)

years, HbA1c 7.6 (0.6) %, body mass index 25 (3) kg/m2) participated in the study. The percentage time (median (IQR)) in target (3.9-10.0 mmol/l) was 67.6 % (60.8-69.0) and 38.4 % (33.1 - 51.0) in euglycaemia (3.9-7.8 mmol/l). 0.0 % (0.0 - 0.0) of time was spent in hypoglycaemia (<3.9 mmol/l) or severe hyperglycaemia (<15 mmol/l). The graph below shows the mean glucose (dotted line) and sensor glucose (starred line) with standard error bars and mean insulin (bars) delivered over the 13-hours closed-loop study. No algorithm decisions were rejected by the study team and no rescue carbohydrate was given.

Conclusion: The Imperial College Bio-inspired Artificial Pancreas is safe and achieves good glycaemic control in subjects with T1DM overnight and after a meal challenge, demonstrating the safety and efficacy of a physiologically based glucose controller in a closed-loop insulin delivery system. Reassuringly, no time was spent in the hypoglycaemic or severe hyperglycaemic range.

Using CGM data to test the hypothesis that higher levels of fear of hypoglycaemia are related to poorer glycaemic control

L. Gonder-Frederick, K. Vajda, J. Shepard, C. Wakeman, M. McElwee, B. Kovatchev;
Psychiatry and NB Sciences, University of Virginia, Charlottesville, USA.

Background and aims: Fear of hypoglycemia (FoHypo) is recognized as a major potential barrier to optimal diabetes control; however, few studies have found relationships between FoHypo and measures of glycemic control such as HbA1c. Most of these studies have used the Hypoglycemia Fear Survey-II (HFS-II) to measure FoHypo. We have recently published findings showing that the Behavior Subscale of the HFS-II contains two factors, one describing behaviors to avoid hypoglycemia that involve maintaining higher BG levels (Maintain High BG Subscale), and one describing other types of behaviors aimed at avoiding hypoglycemia (Avoidance Subscale). The primary purpose of this study was to test the hypothesis that higher patient scores on the Maintain High BG subscale would be related to glucose profile variables indicating poorer glycemic control (e.g. higher average BG levels). Glucose profile variables were computed based on data from continuous glucose monitoring (CGM) devices used for a one-month period. No previous studies have used CGM data to investigate the impact of FoHypo on diabetes control. In addition, this study tested the hypothesis that a new measure of fear of hyperglycemia (FoHyper) would be related to glucose profile variables indicative of problems with hypoglycemia.
Materials and methods: A total of 60 patients (58% female) participated in the study. Mean/SD for age was 40.4 ± 13.6 years and for diabetes duration was 23.9 ± 10.8 years. All participants used continuous subcutaneous insulin infusion (CSII) therapy and, for the purposes of this study, used CGM devices for a one-month period. The mean number of glucose readings obtained from participants during this period was 7,586 ± 972. Prior to beginning CGM data collection, participants completed psychosocial questionnaires including the HFS-II and the newly-constructed FoHyper survey.
Results: As predicted, higher scores on the Maintain High BG Subscale correlated significantly with higher average BG levels (r = .29, p = .043) and higher BG variability (r = .31, p = .028). Higher scores on the Avoidance Subscale correlated with a higher number of low (<3.9mmol/L) BG readings (r = .39, p = .005) and with higher hypoglycemic risk (r = .38, p = .007). Higher scores on the FoHyper Behavior Subscale were associated with more frequent low BG levels (r = .39, p = .005), lower average BG levels (r = -.49, p < .001), and higher hypoglycemic risk (r = .31, p = .03).
Conclusion: This is the first study to investigate the relationship between FoHypo and FoHyper on glucose profiles using CGM data. These preliminary findings support the hypothesis that patient anxiety about both hypo- and hyperglycemia may influence diabetes management behaviors and control.

In type 1 diabetic patients insulin pump treatment is associated with reduced arterial stiffness

S. Rosenlund[1], S. Theilade[1], T.W. Hansen[1], P. Rossing[1,2];
[1]Steno Diabetes Center, Gentofte, [2]University of Copenhagen, Denmark.

Background and aims: Insulin pump treatment is often associated with reduced glucose variability and in small improvements in average glycemic control. This might reduce development of vascular complications. We investigated the relationship between arterial stiffness, evaluated by pulse wave velocity (PWV), and treatment with insulin pump in patients with type 1 diabetes, and examined if this association was dependent of glucose control.
Materials and methods: Cross-sectional study, from 2009-2011, including 639 Caucasian patients with type 1 diabetes. PWV measurements (SphygmoCor, AtCorMedical, Australia) were available in 58 patients with insulin pump (35 with albuminuria ≥ 30mg/d) and 542 (274 with albuminuria ≥30mg/d) treated with multiple daily insulin injections ((MDI) ≥2 injections). ANCOVA compared groups and adjusted linear regression analyses examined the association between PWV and treatment group as well as HbA_{1c}-level.
Results: Insulin pump *vs.* MDI treated patients were 52% *vs.* 57% men, 51±11 *vs.* 54±12 years of age, 34±13 *vs.* 32±16 years diabetes duration, mean arterial pressure was 93±11 *vs.* 93±11 mmHg, and HbA_{1c} 62±10 *vs.* 64±13mmol/mol (p>0.08 for all). PWV was lower in patients treated with insulin pump (9.3±2.8 *vs.* 10.4±3.4m/s; p=0.016). This difference remained significant (p=0.001) after adjustment for gender, diabetes duration, eGFR, urine albumin excretion rate, HbA_{1c}, total-cholesterol, smoking, mean arterial pressure, heart rate and BMI. In patients with albuminuria, PWV was also higher in the MDI *vs.* insulin pump treated groups (11.5±3.4 *vs.* 9.5±2.4 m/s; adjusted p<0.001). In adjusted regression analysis, treatment with insulin pump was significantly (p = 0.026) associated with lower PWV, while HbA_{1c}- level was not associated with PWV neither in patients treated with or without pump ($p \leq 0.925$).
Conclusion: Insulin pump treatment was independently associated with reduced arterial stiffness, while HbA_{1c} was not. Although glucose variability was not assessed, our results suggest that glucose variability and not HbA_{1c}-level affects arterial stiffness. This needs confirmation in randomised prospective studies.
Clinical Trial Registration Number: NCT01171248

Interim 12 month results from a post market clinical trial of DJBL treatment outcomes in subjects with type 2 diabetes and/or obesity

J. Teare[1], J. Byrne[2], J. Mason[3], J. Kelly[2], S. Read[2], D. Thornton[3], H. Ashrafian[1];
[1]Department of Surgery & Cancer, Imperial College, London, [2]Department of Surgery, Southampton University Hospital, [3]Department of Gastroenterology, Trafford Healthcare, Manchester, UK.

Background and aims: The Duodenal-Jejunal Bypass Liner (DJBL) is an endoscopically placed and removed device that creates a bypass of the proximal small intestine mimicking the Roux-en-Y and Duodenal-Jejunal Bypass without the risks associated with surgery. The DJBL is indicated for the treatment of type 2 diabetes and/or obesity and remains implanted for up to 12 months. The aim of this study was to observe the efficacy and safety of DJBL in the post market setting in the United Kingdom.
Materials and methods: 45 subjects implanted with DJBL were included in the study. Interim twelve month data are available for 32 subjects and data collection is ongoing for the remainder. Baseline mean BMI was 39.6 kg/m2 (range: 30.1-50.4 kg/m2), weight 245.5lb (range: 167.4-381.4lb). Subjects were reported to have had type 2 diabetes for a mean duration of 4.6 years (range: 1-10 years), with a baseline HbA_{1c} of 8.5% (7.2-10.5%). Adverse events were monitored continuously throughout the implant period. Data were collected at baseline and 3, 6 and 12 months post implant/removal as well as 3 and 6 months post-removal. Twelve month post-implant weight, blood pressure,

HbA_{1c}, fasting plasma glucose, insulin, total cholesterol, LDL, and TG are presented here.
Results: At twelve months post-implantation the mean BMI (35.4, -4.4kg/m2,), weight (219.1, -26.4lb), HbA_{1c} (7.5, -1.0%), fasting plasma glucose (7.8, -1.5 mmol/L), insulin (14.0, -3.8 mU/L), SBP (129.4, -8.3mmHg), DBP (76.6, -2.7mmHg), total cholesterol (3.9, -0.47mmol/L), LDL (2.15, -0.10 mmol/L) and TG (1.64, -0.24 mmol/L) were reduced from baseline/implant. The most common reported device related adverse events were reported as mild to moderate and gastrointestinal in nature. Three (6.7%) subjects had their device removed for device related reasons (abdominal pain, anchor migration, melena). Ten (22.2%) subjects had their device removed for non device related reasons.
Conclusion: Use of the DJBL is safe and leads to improved glycaemic control, body weight, and associated biomarkers at 12 months compared to baseline in subjects with type 2 diabetes and/or obesity in the post-market setting.

Clinical effectiveness and cost-effectiveness of using positive airways pressure to manage sleep apnoea in patients with type 2 diabetes in the UK
J.F. Guest, M. Panca, E. Sladkevicius;
Catalyst Health Economics Consultants, Northwood, UK.

Background and aims: To assess the clinical effectiveness and cost-effectiveness of using positive airways pressure (PAP) to manage sleep apnoea in patients with type 2 diabetes from the perspective of the UK's National Health Service (NHS).
Materials and methods: Using a case-control design, a model was constructed depicting the treatment paths and associated resource use attributable to managing a cohort of sleep apnoea patients with type 2 diabetes. The model was based on the case records of 150 PAP-treated patients and 150 matched non-PAP treated patients from the THIN database (a nationally representative database of patients registered with general practitioners in the UK). Differences between groups were tested for significance using either a Mann-Whitney U-test or Chi-Square test. Regression analyses were also performed to assess the relationship between baseline parameters and outcomes. The model estimated the total NHS cost and outcomes of patient management in each group over 5 years and the cost-effectiveness of PAP compared to no PAP treatment.
Results: Patients' mean age was 53.7 years, 82% were male and >80% of patients in both groups were obese at 5 years. The time between diagnosis of sleep apnoea and starting PAP treatment was a mean 19.6±31.2 months. Compliance with PAP ranged from 93% in year 1 to 89% in year 5. PAP-treated patients had significantly lower HbA1c levels (66.0 versus 108.4 mmol/mol (8.2% versus 12.1%); $p<0.03$), indicative of better controlled diabetes. Logistic regression showed that females were more likely than males to have lower HbA1c levels at 5 years (Odds ratio: 13.03; $p<0.01$) and patients with angina were more likely to have uncontrolled diabetes (Odds ratio: 0.033; $p<0.02$). Diabetic retinopathy was an independent predictor of patients experiencing anxiety disorder (Odds ratio: 6.79; $p<0.03$). Time from diagnosis to starting PAP was an independent predictor of increasing the relative risk of having a stroke (Odds ratio: 10.46 for each 10 months; $p<0.04$). Multiple regression showed that HbA1c values increased by 2.7 mmol/mol (2.4%) for each 10 years of age ($p<0.05$) and decreased by 24.6 mmol/mol (4.4%) among PAP-treated patients ($p<0.05$). Use of PAP significantly increased patients' health status by 0.89 quality-adjusted life years (QALYs) (from 2.11 to 3.00 QALYs; $p<0.0001$) per patient over 5 years. PAP treatment also resulted in an increased NHS cost of £5,555 (from £11,973 to £17,528) per patient. Hence, the cost per QALY gained with PAP is £6,242. PAP remained a cost-effective intervention for plausible changes in the model's inputs.
Conclusion: Initiating treatment with PAP in sleep apnoea patients with type 2 diabetes leads to significantly better controlled diabetes and affords a cost-effective use of NHS resources.

Diabetes induces neuronal loss in the rostroventromedial medulla of streptozotocin-diabetic rats: the preventive effects of antioxidant treatment
C. Morgado[1,2], A. Miranda[1,3], D. Raposo[1], J. Silva[1,3], P. Pereira-Terra[1,2], I. Tavares[1,2];
[1]Department of Experimental Biology, Faculty of Medicine of Oporto, Porto, [2]IBMC, Porto, [3]ECS, University of Minho, Braga, Portugal.

Background and aims: Diabetic neuropathy (DN) is one of the most frequent complications of diabetes, presenting repercussions at the somatossensory nervous system. Diabetes is associated with structural and functional changes at brain areas involved in ascending transmission of nociceptive input, as the spinal cord and thalamus. This is likely to concur to the exacerbated pain in patients with diabetic neuropathy. The effects of diabetes on brain areas involved in descending pain modulation are almost unknown. We previously reported a significant increase in oxidative stress damage in the rostroventromedial medulla (RVM), a key brainstem area involved in serotoninergic descending pain modulation, in the streptozotocin (STZ)-diabetic rat. Such damage may impair serotonin-mediated pain inhibition and explain the low analgesic efficacy of serotonin-selective reuptake inhibtitors (SSRIs) in diabetic neuropathic pain. In the present study we evaluated the effects of a treatment with epigalocathechin gallate (EGCG), a potent antioxidant present in green tea, in oxidative stress damage, neuronal density and number of serotoninergic neurons at the RVM of STZ- diabetic rats.
Material and methods: Diabetes was induced in male Wistar rats by intraperitoneal injection of STZ (60 mg/kg). Control animals (CTR group) received the vehicle solution. During the 10 weeks post-injection, a group of STZ rats received EGCG (2g/l) in drinking water while the other experimental groups received only water (untreated-STZ and CTR). Mechanical hyperalgesia and tactile allodynia were evaluated using the paw pressure test and the plantar aesthesiometer, respectively, before treatment onset and after its completion. Oxidative stress damage was quantified by densitometry in RVM sections immunoreacted against 8-OHdG, a marker of acid nucleic oxidative damage, and neuronal density was determined by counting the number of cells immunoreactive to Neu-N (a marker of neurons). Serotoninergic neurons were identified by immunodetection of tryptophan hydroxylase (TpH-IR; enzyme involved in serotonin synthesis).
Results: All STZ rats developed hyperglycemia, which was not affected by EGCG treatment. EGCG ameliorated the mechanical hyperalgesia and tactile allodynia detected in untreated-STZ rats. The untreated-STZ rats presented increased oxidative stress damage and decreased neuronal density at the RVM which was accompanied by a reduction in the number of serotoninergic neuron. EGCG treatment prevented those changes.
Conclusion: Diabetes induces increased oxidative stress and loss of neurons in the RVM. The decrease neuronal density detected in the RVM of STZ rats may, in part, be due to the reduced numbers of serotoninergic neurons. EGCG elicited neuroprotective effects during diabetes by preventing the oxidative stress and loss of RVM neurons, namely of serotoninergic neurons involved in descending modulation of nociceptive transmission, which may explain the analgesic effect here reported. EGCG could be a promising agent in preventing diabetes-induced neurodegeneration and pain.

Altered baseline brain activity in type 2 diabetes: a resting-state fMRI study
W. Xia, Y. Yang, Y. Zhou, P. Wang, Y. Huang, R. Cai, Q. Wei, S. Wang;
Affiliated Zhongda Hospital of Southeast University, Nanjing, China.

Background and aims: Type 2 diabetes mellitus (T2DM) has been associated with cognitive impairment, such as mild cognitive impairment (MCI) and Alzheimer's disease (AD). Our study aims to investigate whether there exists altered baseline brain activity in T2DM patients using resting-state functional magnetic resonance imaging (rs-fMRI).

Materials and methods: T2DM patients (n=28) were compared with non-diabetic age-, sex-, and education-matched control subjects (n=29) using rs-fMRI. We computed amplitude of low-frequency fluctuations (ALFF) of fMRI signal to measure the spontaneous neuronal activity, and detect the relationship between rs-fMRI information and clinical data.
Results: Compared with healthy controls, T2DM patients had significantly decreased ALFF values in bilateral middle temporal gyrus (MTG), left fusiform gyrus, left middle occipital gyrus, right inferior occipital gyrus; and increased ALFF values in both cortical and subcortical regions, including the bilateral cerebellum posterior lobe, right cerebellum culmen, and insula lobe. Moreover, we found an inverse correlation between the ALFF values in the middle temporal gyrus and both the HbA1c (r= -0.420, p= 0.026) and the score of Trail Making Test-B (TMT-B) (r= -0.451, p= 0.016) in the patient group. On the other hand, C-peptide level and HOMA2-%ß has positive correlation(r= 0.429, p= 0.023; r=0.453, p=0.016, respectively) with the ALFF value in the middle temporal gyrus.
Conclusion: The present study provides evidence that T2DM patients have altered ALFF in many brain regions, which links with poor neurocognitive performances, the severity of consistent hyperglycemic state and the impaired ß-cell function. Abnormal ALFF values in MTG may be regarded as a potential marker to identify cognitive decline associated with T2DM. Those findings may contribute to further understanding of neurological pathophysiology underlying T2DM, and present some enlightenment to clinical diagnosis in the future.

Reduced cutaneous Langerhans cell number, endothelial area, and nerve fibre density in recently diagnosed type 2 diabetic subjects
A. Strom, J. Brüggemann, I. Ziegler, B. Ringel, S. Nowak, M. Roden, D. Ziegler, for the GDS Group;
Institute for Clinical Diabetology, German Diabetes Center, Düsseldorf, Germany.

Background and aims: Microvascular abnormalities and immune-mediated processes have been implicated in the pathogenesis of diabetic polyneuropathy. Langerhans cells (LCs) are the sole dendritic cells located in the epidermis and are thus the first antigen-presenting cells exposed to pathogens at the skin surface. LCs play a pivotal role in the regulation of cutaneous immunity, exert tolerogenic properties, and are surrounded by sensory nerve endings. The aim of the present study was to determine whether cutaneous immune-mediated and neurovascular alterations are present in recently diagnosed type 2 diabetes.
Materials and methods: We assessed skin biopsies and peripheral nerve function in 97 participants of the German Diabetes Study (GDS) with recently diagnosed type 2 diabetes (age: 55.5±11.3 (SD) years; male: 70.1%; BMI: 32.0±6.0 kg/m^2; diabetes duration: 1.5±1.2 years; HbA1c: 6.5±1.0%) and 83 healthy controls (age: 54.0±18.1 years; male: 65.1%; BMI: 24.7±3.6 kg/m^2). Subepidermal endothelial area and the number of epidermal LCs were determined in subgroups of 59 patients with type 2 diabetes and 54 controls. Intraepidermal nerve fibre density (IENFD) was assessed by immunohistochemistry using PGP 9.5 antibody in 3-mm punch biopsies from the distal leg. CD31 immunohistochemistry was used to determine subepidermal endothelial area. Epidermal LC density was quantified using langerin (CD207) staining. Peripheral nerve function was assessed by motor and sensory nerve conduction velocity (MNCV, SNCV), sensory nerve action potential (SNAP) amplitudes, vibration perception thresholds (VPT), and thermal detection thresholds (TDT), neuropathy symptom score (NSS), and neuropathy disability score (NDS). Insulin sensitivity (M-value) was determined by a hyperinsulinaemic euglycaemic clamp. All comparisons were adjusted for sex, age, and BMI.
Results: When compared to the control group, type 2 diabetic patients showed reduced IENFD (10.0±3.1 vs 8.0±3.0 fibers/mm; P=0.001), peroneal MNCV (47.6±4.4 vs 43.2±5.8 m/s; P<0.0001), sural SNCV (46.9±4.4 vs 42.6±6.2 m/s; P<0.0001), and cold TDT on the foot (28.8±2.1 vs 26.2±6.5 °C; P=0.002) as well as elevated malleolar VPT (1.22±1.11 vs 2.94±4.20 µm; p=0.01). Subepidermal endothelial area was smaller in the diabetic group compared to the control subjects (3.48±2.24 vs 4.17±2.40%; P<0.0001). Moreover, a reduction of epidermal Langerhans cell number by approximately 30% was noted in the diabetic subjects compared to the control group (405±157 vs 582±194 cells/mm^2; P=0.002). In the diabetic group, multiple linear regression analysis adjusting for age, sex, BMI, and HbA1c revealed a positive association between LC number and M-value (ß=0.401; p=0.004. No relationship was noted between IENFD, epidermal LC number, and subepidermal endothelial area.
Conclusion: Apart from intraepidermal nerve fibre loss, recently diagnosed type 2 diabetic subjects show reduced subepidermal endothelial area and a marked reduction of tolerogenic Langerhans cells. The loss of Langerhans cells could promote an immunogenic imbalance toward inflammation and thereby provide a link to insulin resistance. Prospective studies are needed to determine whether these early neuro-immuno-vascular alterations contribute to the development of diabetic neuropathy.

p66Shc mediates bone marrow denervation and impairs stem cell mobilisation in diabetes
G. Fadini[1], M. Albiero[1], N. Poncina[1], S. Ciciliot[1], L. Menegazzo[1], S. Vigili de Kreutzenberg[1], M. Giorgio[2], A. Avogaro[1];
[1]Department of Medicine, University of Padova, [2]IFOM-IEO Campus, European Institute of Oncology, Milan, Italy.

Background and aims: Mobilization of bone marrow (BM) stem and proangiogenic cells is impaired in diabetes, contributing to chronic complications. Sympathetic innervation of the BM is critical for stem cell mobilization. Previous data indicate that induction of p66Shc expression mediates hypeglycemic oxidative damage, but there is no data on diabetic autonomic neuropathy (DAN). Herein, we tested whether p66Shc, a life-span regulating gene linked to oxidative stress, is involved in the diabetic stem cell mobilopathy.
Materials and methods: p66Shc gene expression was quantified by real time PCR in PBMC of 20 non diabetic patients and 20 diabetic patients (10 of whom had DAN), as well as in BM cells of control and streptozotocin (STZ)-induced diabetic mice. BM innervation was assessed by immunofluorescence staining for tyrosine hydroxilase (Tyr-OH). Stem cell mobilization was assessed by quantifying Lin-cKit+Sca1+ (LKS) cells and CD34+Flk1+ endothelial progenitor cells (EPC) before and after 4 days of G-CSF treatment in wild type and p66Shc-/- STZ mice
Results: First, we found that expression of p66Shc is increased in PBMC of diabetic patients, which is worsened by the presence of DAN. In addition, BM cells from diabetic mice showed increased p66Shc expression compared to controls. Diabetic mice showed reduced Tyr-OH immunoreactive nerve fibers and impaired stem cells and EPC mobilization. The functional role of p66Shc was tested using *p66Shc*$^{-/-}$ mice which, once made diabetic by STZ injection, showed protection from BM sympathectomy, as evidenced by the preserved Tyr-OH immunostaining of sympathetic nerve fibers. In addition, induction of diabetes in *p66Shc*$^{-/-}$ mice did not impair LKS and EPC mobiliza-

tion after G-CSF treatment, despite they were as hyperglycaemic as wild type STZ mice.
Conclusion: Deletion of p66Shc, by preserving BM SNS innervation, restores stem cell mobilization in diabetes. This can exert a protective effect against the development of complications.

Factors associated with reversibility of erectile dysfunction in men with type 1 diabetes: longitudinal findings from DCCT/EDIC
S.K. Holt[1], R.L. Dunn[2], A.V. Sarma[2], J. Goldberg[3], P. Heagerty[4], J.M. Hotaling[1], P.A. Cleary[5], H. Wessells[1];
[1]Urology, University of Washington, Seattle, [2]Urology, University of Michigan, Ann Arbor, [3]Epidemiology, University of Washington, Seattle, [4]Biostatistics, University of Washington, Seattle, [5]The Biostatistics Center, The George Washington University, Rockville, USA.

Background and aims: Diabetes imparts a 3-fold higher risk of erectile dysfunction (ED), which is associated with neuropathy, glycaemic control, microvascular complications, and duration of diabetes. The goal of this study is to describe the course of diabetic ED over time and determine factors that are related to a return of potency versus irreversible progression of ED.
Materials and methods: The Diabetes Control and Complications Trial (DCCT) randomised 761 men with T1DM to intensive or conventional glycaemic therapy from 1983-1989. The cohort (n=720) was then followed in the Epidemiology of Diabetes Interventions and Complications (EDIC) study. Within EDIC, ED was defined as a "Yes" response to a yearly single yes/no question querying the presence of "impotence". Subjects were classified as regaining potency if they answered "No" (absence of impotence) at any point during the five years following the index ED report. Pharmacologic therapy for ED was reported by a small minority of men and was not considered in this analysis. HbA_{1c} was measured at baseline, quarterly during DCCT, and annually in EDIC. Multivariable logistic regression estimated the odds of regaining potency by number of consecutive years of prior reported ED after age adjustment.
Results: Mean age of subjects at the most recent assessment was 50.4 years. The incidence of ED increased from 5.5% (n=42) at EDIC year 1 (1994) to 33.6% (n=219) by EDIC year 16 (2009). The majority of men reported ED at least once during the 16 years of follow up (53.5%) indicating that ED is not a fixed condition in all cases (see Figure). In subjects with at least 5 consecutive years of follow up within the time span of EDIC, the likelihood of regaining potency within 5 years decreased with every additional year of prior reported ED: for subjects with a single report of ED, (n=198), 67.7% regained potency within 5 years; with 2 consecutive years of ED (n=138) 50.7% regained potency; with 3 consecutive years of ED (n=96), 37.5% regained potency; with 4 consecutive years of ED (n=70), 32.9%; Those with 5 or more consecutive years of ED (n=44) had less than 20% subsequent chance of regaining potency. A1c and age were significantly associated with regaining potency only in subjects with four or less consecutive years of ED.
Conclusion: ED is a dynamic state in men with T1DM that may be modifiable when first experienced. Progressively longer periods of ED were associated with a lower likelihood of return to potency, approaching a point of no return when HbA1c no longer is associated with potency. Future work in this population needs to explore biomarkers, behaviour modification and clinical management that predict and reduce the risk of remaining impotent.

QTc prolongation is associated with three-year mortality after above ankle amputation in type 2 diabetic patients
K. Fagher[1], P. Katzman[1], A. Nilsson[2], A. Sellman[1], M. Löndahl[1];
[1]Clinical Sciences, Lund University, [2]Internal Medicine, Ängelholms Hospital, Sweden.

Background and aims: Diabetic patients have not only an increased lower extremity amputation (LEA) risk as compared to non-diabetic individuals, but also an enhanced mortality risk after above ankle amputation. There are still no clinically useful markers to identify patients with the highest mortality risk after a LEA. Heart rate corrected QT interval (QTc) interval prolongation is a potential indicator of increased cardiovascular risk in the general population, but also, as recently shown, in patients with chronic diabetic foot ulcers. The aim of this study was to evaluate whether QTc-time is a significant factor for long-term survival after above ankle amputation in patients with type 2 diabetes.
Materials and methods: All patients with type 2 diabetes during three consecutive years, who underwent an above ankle amputation at any our two Diabetic Foot Clinics were included in this study and followed for three years. Patients older than 80 years were excluded. Preoperative ECGs were analysed to calculate QTc time and patients were grouped according to QTc time ≤ and >440 ms. Mortality data was obtained from the National Death Registry. Patients who died within 14 days after amputation were excluded from the final analysis. Data are given as percentages or median and range. Appropriate non-parametric statistics were used to compare differences between groups. Cox proportional hazard regression models were applied to study the independent associations. A two-tailed p-value <0.05 was considered statistical significant.
Results: 68 patients with a median age of 72 (57-80) years were included. Two patients with pacemaker were excluded, as QTc time could not be evaluated. QTc prolongation (QTc+ group) was present in 31 patients (47%) and not present in 35 (QTc- group). There were no differences in smoking habits, diabetes medications, dyslipidemia, hypertension, dialysis, previous vascular surgical interventions or ABI between groups. A history of myocardial infarction was more commonly present in the QTc+ group; 50 vs. 30%, p=0.04. Creatinine levels in patients not on dialysis were similar between groups, 84 (43-264) vs. 81 (38-276) μmol/L. Three-year mortality was 51.5%. Three patients (1 in QTc+ vs. 2 in QTc-) died within 14 days of amputation. Mortality was significantly higher in patients with QTc-prolongation, 67% vs. 27%, p=0.002. In a cox-proportional hazard analysis including presence of myocardial infarction, renal function, age, HbA1c and QTc-prolongation only age (decades) (HR 2.1 (1.01-4.2), p=0.049) and QTc prolongation (HR 3.4 (1.4-8.4), p=0.007) were significantly associated with 3-year mortality. A history of myocardial was not a significant risk factor in this analysis, HR 1.2 (0.5-2.7), p=0.70.
Conclusion: This study indicates that QTc prolongation is associated with increased mortality in type 2 diabetes patients after above ankle amputation.

Genome-wide association studies of renal diabetes complications

E. Ahlqvist[1], H.A. Deshmukh[2], N. Sandholm[3,4], C. Ladenvall[1], M. Lajer[5], L. Marcovecchio[6], E. Rurali[7], W.N. Rayner[8], SUMMIT;
[1]Department of Clinical Sciences, Lund University, Malmö, Sweden, [2]Ninewells Hospital and Medical School, University of Dundee, UK, [3]Folkhälsan Research Center, Helsinki, [4]Division of Nephrology, Helsinki University Central Hospital, Finland, [5]Steno Diabetes Center, Gentofte, Denmark, [6]Department of Paediatrics, University of Cambridge, UK, [7]Istituto di Ricerche Farmacologiche "Mario Negri", IRCCS, Bergamo, Italy, [8]Wellcome Trust Centre for Human Genetics, University of Oxford, UK.

Background and aims: Diabetic kidney disease (DKD) is a leading cause of end-stage renal disease (ESRD) and the risk of developing DKD is partly determined by genetic factors. In the SUMMIT consortium we performed meta-analysis of genome-wide association studies in European T2D patients to identify genetic determinants of DKD. Because the genetic variants regulating early stages of disease may differ from those that determine progression to severe disease we also analyzed microalbuminuria (MiAU), reflecting early pathologic changes and endothelial dysfunction, and more severe DKD, i.e. macroalbuminuria (MaAU) and ESRD, separately.
Material and methods: DKD was defined as MiAU, MaAU or ESRD, whereas controls had normoalbuminuria and diabetes duration > 10 years. The study included four cohorts of T2D patients: GoDARTS (n=2526), the Scania Diabetes Registry (SDR, n=1313), Steno (n=322) and MNI (n=203). We analyzed ~2.3 million single nucleotide polymorphisms (SNPs), imputed based on the CEU HapMap2 reference panel, using logistic regression, adjusting for sex, age at onset and duration of diabetes, for four phenotypes: DKD, MiAU, MaAU+ESRD and ESRD alone. Meta-analyses were performed using a fixed effects model. We also performed joint analyses with four T1D studies analyzed using similar methods and phenotype definitions: FinnDiane (n=3435), Eurodiab (n=812), SDR (n=513) and Cambridge (n=400).
Results: In the T2D analyses the most strongly associated SNPs were rs2424306 (OR=0.72, $p=1.4x10^{-7}$) in the C20orf26 gene for DKD (2326 cases, 2038 controls), rs11157816 (OR=1.65, $p=2.7x10^{-7}$) close to *TMX1* for both ESRD (335 cases ,1698 controls) and MaAU+ESRD (OR=1.37, $p=7.8x10^{-7}$; 1063 cases, 1848 controls), and rs162693 (OR=1.95, $p=3.2x10^{-6}$) close to GRM7 for MiAU (1198 cases, 1681 controls). In the joint T1D+T2D meta-analysis of MiAU (2008 cases, 4246 controls), rs5749503 in SYN3/TIMP3 reached genome-wide significance (OR=0.78, $p=4.8x10^{-8}$). The association effect size was similar in T1D (OR=0.77, $p=6.5x10^{-5}$) and T2D (OR=0.80, $p=1.8x10^{-4}$). Nominally significant associations were observed also in the analysis of ESRD (OR=0.86, p=0.006) and DKD (OR=0.91, p=0.002). Interestingly, this SNP was also associated with risk of diabetic retinopathy in a combined T1D/T2D meta-analysis in the SDR sample (OR=0.64, $p=5.7x10^{-5}$, 827 cases and 283 controls).
Conclusion: We have identified a new candidate locus for DKD situated in the *SYN3* (synapsin III) gene, 50kb upstream of TIMP3 (TIMP metallopeptidase inhibitor 3). Based on available literature *TIMP3* is a likely effector gene. TIMP3 has been shown to play a role in animal models of DKD and mutations in TIMP3 cause fundus dystrophy in humans. *SYN3* is a modulator of neurotransmitter release in synapses. Our results support a role of TIMP3 in human DKD and possibly in diabetic retinopathy.

Predictors of rapid decline in renal function in type 2 diabetes

H.C. Looker[1], I. Brady[1], M. Colombo[2], T. Zeller[3], N. Dalton[4], M. Wong[5], C. Turner[4], C.N.A. Palmer[1], M.J. Brosnan[6], E. Nogoceke[7], F.V. Agakov[2], P.M. McKeigue[2], H.M. Colhoun[1], on behalf of the SUMMIT Investigators;
[1]University of Dundee, [2]University of Edinburgh, UK, [3]University Heart Center Hamburg, Germany, [4]King's College London, [5]University of Cambridge, UK, [6]Pfizer Limited, Cambridge, USA, [7]Hoffman-La Roche, Basel, Switzerland.

Background and aims: Trials of therapies for preventing end stage renal disease in type 2 diabetes (T2D) are typically conducted in those with estimated Glomerular Filtration Rate (eGFR) in the range 30-60 ml/min/m^2. Improving the power of such trials or shortening their duration by over-sampling those most at risk of progression is an important goal. Here we aimed to identify biomarkers of renal function decline in T2D beyond baseline eGFR.
Methods: From a large cohort of T2D patients from Scotland (Go-DARTS), we identified people with a baseline eGFR in the range 30-60 ml/min/m^2 at baseline. Among these we defined cases as those who had lost ≥40% of their baseline eGFR over a follow up of ≤42 months (median = 22months) and controls as those who at a follow up of ≥42 months had a decline in eGFR of <5%. In these samples (154 cases 155 controls) we measured 24 serum biomarkers - 13 by standard ELISAs or automated immunoassays and 11 by MS. We chose candidate biomarkers based on prior reports of association with renal function in diabetic or non-diabetic cohorts or based on pathways reported as involved in diabetic kidney disease. Data analysis was by logistic regression using 50-fold cross validation with forward selection and by 50-fold cross validated backward selection with LASSO penalty. Clinical factors included were age, sex, diabetes duration, eGFR, creatinine, BMI, HbA1c, BP, smoking, insulin use and antihypertensive drugs use.
Results: 6 biomarkers - N-terminal pro-B type Natriuretic Protein (NT-proBNP), Cystatin C, Asymmetric Dimethylarginine (ADMA), Symmetric Dimethylarginine (SDMA), N-Acetyl-B-D-Glucosaminidase (NAG), and Vascular Cell Adhesion Molecule 1 (VCAM1) were associated with rapid decline in renal function independently of clinical factors (table) while osteopontin may also contribute to prediction. 9 other markers made lesser contributions to improving prediction. The only clinical factors that contributed to the risk models were male sex, systolic BP and baseline eGFR. The increment in the area under the ROC curve was 0.19 (AUC for model of clinical factors and all selected biomarkers = 0.82, AUC for clinical factors only = 0.63).
Conclusion: In this cross validated study we confirm the previously reported association of Cystatin C, ADMA, SDMA and VCAM1 with subsequent decline in renal function. We report novel findings that NT-proBNP predicts renal function decline independently of eGFR with which it is associated and serum NAG, a marker of lysosomal enzyme release, may also be of use. The selected biomarkers have potential to improve prediction of decline in renal function and further validation of these biomarkers is warranted.

Logistic regression model adjusted for all clinical covariates and all selected biomarkers

Normalised Covariate	Odds Ratio per standard deviation of marker (95% Confidence Interval)	Wald p-value
Cystatin C	4.24 (2.13, 8.95)	<0.001
N-Terminal Prohormone B-type Natriuretic Peptide	2.61 (1.61, 4.52)	<0.001
Asymmetric Dimethylarginine	0.37 (0.23, 0.57)	<0.001
Vascular Cell Adhesion Molecule 1	2.20 (1.37, 3.69)	0.002
N-Acetyl-B-D-Glucosaminidase	1.88 (1.23, 2.94)	0.004
Symmetric Dimethylarginine	2.27 (1.14, 4.65)	0.022
Osteopontin	1.41 (0.92, 2.26)	0.127

Urinary proteomics predict onset of microalbminuria in normoalbuminuric type 2 diabetic patients in the DIRECT 2 study

M. Lindhardt[1], F. Persson[1], P. Zürbig[2], A. Stalmach[3], H. Mischak[2], H. Lambers Heerspink[4], A. Sjoelie[5], R. Klein[5], T. Orchard[5], M. Porta[5], J. Fuller[5], R.W. Bilous[5], N. Charturvedi[5], H.-H. Parving[5], P. Rossing[1,6];
[1]Steno Diabetes Center, Gentofte, Denmark, [2]Mosaiques Diagnostics GmbH, Hannover, Germany, [3]University of Glasgow, UK, [4]University Medical Centre, Groningen, Netherlands, [5]The DIRECT Steering Group, Odense, [6]University of Copenhagen, Denmark.

Background and aims: Early prevention of diabetic nephropathy is not successful as early interventions have shown diverging results. Urinary proteomics has shown promise as an early indicator of future development of diabetic nephropathy and could guide need for treatment. In this study we investigate that ability in a large type 2 diabetic cohort with normoalbuminuria.
Materials and methods: In a post-hoc study of the DIRECT-Protect 2 study, a randomized, controlled clinical trial of candesartan for slowing the progression of retinopathy, we studied patients with type 2 diabetes and normoalbuminuria (n=792), followed for a mean of 4.7 years. We determined a previously defined CKD risk score based on proteomic measurement of 273 urinary peptides (CE-MS), the risk-score was selected from previous cross sectional case-control studies. A Cox regression model for progression of albuminuria was built. The primary endpoint was development of persistent microalbuminuria (MA) (3 out of 4 samples).
Results: Persistent MA developed in 92 patients (11,6%). At baseline the CKD risk score was able to predict development of MA during follow-up, independent of treatment (candesartan/placebo), age, gender, baseline systolic BP, baseline UAER, baseline eGFR, baseline HbA_{1c} and diabetes duration (HR 2.0 (95% CI 1.17-3.45), p=0.012). In the placebo treated group the HR was 2.1 (1.1 to 4.2) compared to 1.6 (0.8 to 3.1) in the candesartan group.
Conclusions: In this cohort of patients with type 2 diabetes and normoalbuminuria from a large intervention study, the CKD classifier was an independent predictor of MA. This may provide a better opportunity to select normoalbuminuric patients for early prevention of diabetic nephropathy as treatment with candesartan seems to mitigate this risk.

Soluble RAGE predicts progression of late-stage diabetic nephropathy in type 1 diabetes

J.M. Söderlund[1,2], C. Forsblom[1,2], M. Lehto[1,2], M. Parkkonen[1,2], M. Saraheimo[1,2], N. Tolonen[1,2], L.M. Thorn[1,2], J. Wadén[1,2], P.-H. Groop[1,2], FinnDiane Study Group;
[1]Folkhälsan Research Center, Folkhälsan Institute of Genetics, [2]Department of Medicine, Division of Nephrology, Helsinki, Finland.

Background and aims: Soluble receptor for advanced glycation end-products (sRAGE) may ameliorate the deleterious effects that activation of its membrane bound counterpart RAGE exerts by binding to the same circulating ligands. High sRAGE concentrations in non-diabetic subjects are considered beneficial; in contrast, in diabetic nephropathy (DN) high concentrations are associated with disease. A causal relationship between sRAGE and DN has, nevertheless, not been established. To assess whether baseline sRAGE concentrations predict the development or progression of DN and also whether a temporal change in sRAGE predicts the development and progression of DN, we studied sRAGE in Finnish type 1 diabetes patients.
Patients and methods: At baseline 3107 T1D patients were studied and followed up for 6.3 years (range 1-14years). In a subset of 1143 patients, sRAGE was also measured at follow-up. Patients were grouped based on their AER in at least two out of three timed urine collections into patients with normal AER (n=2063), microalbuminuria (n=418), macroalbuminuria (n=457), and end-stage renal disease (ESRD; n=169). During follow-up 349 patients progressed (11 %) in their kidney status. sRAGE was measured from serum using a commercial kit. Repeated measures ANOVA was applied to evaluate significance of change between the time points. Nonparametric tests and Cox regression analyses were used accordingly. SPSS 15.0 was used for the analyses.
Results: Mean baseline sRAGE concentrations were higher in macroalbuminuric (1582 ± 892 pg/ml; p=5.47 x 10^{-24}) as well as in ESRD patients (1780 ± 1548 pg/ml; p= 3.08 x 10^{-5}) when compared with those with normal AER (1176 ± 435 pg/ml). Mean baseline sRAGE concentrations and quartiles did not correlate with the progression from normal AER to microalbuminuria or micro- to macroalbuminuria. On the other hand, baseline sRAGE predicted the progression from macroalbuminuria to ESRD independently of eGFR. However, although the highest baseline sRAGE quartile was associated with the progression from macroalbuminuria to ESRD (HR 4.45, 95% CI 2.15-9.20), this was no more significant after entering eGFR into the model. Baseline and follow-up sRAGE concentrations were significantly different F(1, 1142) = 12.36, (p=0.00045) and correlated with HDL, HbA_{1c}, creatinine, eGFR, AER, urate, and BMI. The sRAGE change (ΔsRAGE) between the time points was -73 ± 543 pg/ml (-5519 - 3888 pg/ml). ΔsRAGE was not significant between the groups and did not predict progression of kidney status. However, ΔsRAGE did correlate with change in eGFR, AER, HDL, BMI, and WHR.
Conclusion: Baseline sRAGE concentrations predicted progression from macroalbuminuria to ESRD independently of eGFR. A temporal change in sRAGE did not predict development or progression of DN. However, ΔsRAGE correlated with the change of several risk factors associated with DN. These data suggest that sRAGE is a predictor of progression of late-stage DN.

Long-term renal outcome in the Steno 2 study

J. Øllgaard[1], F. Persson[2], P. Rossing[2,3], H.-H. Parving[4,5], O.B. Pedersen[3,5], P.H. Gæde[6];
[1]Faculty of Health Sciences, University of Copenhagen, [2]Steno Diabetes Center, Gentofte, [3]Novo Nordisk Foundation Center for Basic Metabolic Research, Faculty of Health Sciences, Copenhagen, [4]Dept. of Medical Endocrinology, Rigshospitalet, Copenhagen, [5]Faculty of Health Sciences, Aarhus University, [6]Dept. of Internal Medicine, Slagelse University Hospital, Denmark.

Background and aims: To describe the progression in loss of renal function in patients with type 2 diabetes and microalbuminuria, originally enrolled in the Steno-2 study.
Materials and methods: 160 patients were randomized to conventional or intensified, multifactorial lifestyle and pharmacological intervention for an average period of 7.8 years. After this time point all patients received intensified intervention in an open follow-up trial. Renal function was assessed directly (51Cr-EDTA clearance) and indirectly (eGFR, MDRD-equation) after an average of 2, 3.8, 7.8, 13.3, 16 and 19 years of follow up. The primary end point for the current analysis was a composite of dialysis treatment (Danish Renal Registry) and death by any cause, secondary end point was 50% reduction in GFR or eGFR, or doubling of s-creatinine. A tertiary end point was progression to macroalbuminuria.
Results: A total of 87 patients (33 intervention, 54 control) reached the primary end point (p = 0.001). Four patients in the intervention group compared to eight in the control group required dialysis treatment and the patients in the control group underwent dialysis (median)6.6 years earlier than patients in the intervention group (p = 0.093). 63 patients (39%) (33 patients in the intervention group and 30 in the control group) reached the secondary end point (p = 0.31). Patients in the control group reaching the primary end point and/or renal function less than 60ml/min/1.73m2 had an increased risk of mortality compared to patients not progressing (p = 0.006). This was not found in the intervention group. The risk of progression to macroalbuminuria was reduced by 66% in the intervention group, p = 0.004.
Conclusion: Intensified multifactorial treatment decreased mortality and the need for dialysis. Although there was significantly decreased macroalbu-

minuria there was no difference in the renal function in survivors after 19 years of follow up. This is probably due to competing risk from cardiovascular death in the control group. Patients in the control group with deteriorating renal function had a significant increase in mortality.

96

Proteinuria reduction with probucol and telmisartan in patients with type 2 diabetic nephropathy

H. Zhu, X. Chen, G. Cai, Y. Zheng, M. Liu, W. Liu, Y. Wang, W. Li, H. Wu, J. Zhang, L. Lun, J. Li, C. Zhou;
Department of Nephrology, State Key Laboratory of Kidney Disease, General Hospital of Chinese People's Liberation Army, Beijing, China.

Background and aims: Diabetic nephropathy is the leading cause of end-stage renal disease. Telmisartan is known to not only reduce proteinuria of diabetic nephropathy, but also slow its progression. Probucol is an antioxidant and has cholesterol-lowering effects. However, combination therapy with telmisartan and probucol in the treatment of diabetic nephropathy has not been proved with sufficient clinical evidence. This study examined the clinical efficacy of telmisartan and probucol in proteinuria reduction of type 2 diabetic nephropathy.
Materials and methods: A total of 160 type 2 diabetic nephropathy patients with proteinuria (0.5 g/24h< urinary protein <3.0 g/24h) were enrolled in a randomized, double-blind, placebo-controlled, multicenter study. The patients were randomly divided into two groups. One group (telmisartan group, n=80) was administered with telmisartan (80 mg/day) and probucol placebo (1000 mg/day for 24 weeks, and then reduced to 500 mg/day for next 24 weeks). The other group (probucol group, n=80) was administered with telmisartan (80mg/day) and probucol (1000 mg/day for 24 weeks, and then reduced to 500 mg/day for next 24 weeks). All patients were further categorized into two subgroups based on urinary protein level. One subgroup has 83 patients who had urinary protein <1.0g/24h at baseline, and the other has 77 patients with urinary protein level ≥1.0g/24h at baseline. All patients were followed throughout the 48-week period, and the percentage change of urinary protein from baseline to 48 weeks was assessed.
Results: The baseline characteristics of the two groups were similar, as well as the BP and HbA1c profile over the study period. There was a significant reduction (27.02%) in urinary protein level in the probucol group from baseline to 48 weeks. However, urinary protein level was increased in the telmisartan group, with an average increase of 1.45% (P < 0.001 for the comparison with probucol group). A further analysis between the subgroups showed, that for patient subgroup with lower urinary protein (<1.0g/24h at baseline), the reduction in urinary protein level from baseline is significantly greater in probucol group than in telmisartan group (36.54% vs. 8.55%, P=0.013). For the patient subgroup with higher urinary protein (≥ 1.0g/24h at baseline), there was a significantly reduction of 15.38% in urinary protein level in probucol group from baseline. However, urinary protein was increased in telmisartan group, with an average increase of 10.96% (P=0.011 for the comparison with probucol group).
Conclusion: The combination therapy of probucol and telmisartan lowers urinary protein more effectively than telmisartan alone. This indicates administering probucol and telmisartan in combination have additive or synergistic effect to reduce proteinuria and prevent diabetic nephropathy, and maybe a new treatment for type 2 diabetic nephropathy.

OP 17 New players in the regulation of insulin secretion

97

GPR55 deletion is coupled to impaired glucose tolerance and increased islet cell apoptosis

B. Liu[1], S. Song[1], D. Baker[2], J. Bowe[1], Z. Hassan[1], R. Drynda[1], P. Jones[1], S. Persaud[1];
[1]Diabetes Research Group, Division of Diabetes & Nutritional Sciences, King's College London, [2]Barts and The London School of Medicine and Dentistry, London, UK.

Background and aims: G-protein coupled receptor 55 (GPR55) has been classified as a novel cannabinoid receptor due to its sensitivity to distinct cannabinoid ligands. In addition, the non-cannabinoid lipid L-alpha-lysophosphatidylinositol (LPI) has also been identified as an endogenous ligand of GPR55. We have previously reported GPR55 expression by mouse and human islets, and demonstrated that GPR55 activation with LPI and O-1602, an exogenous agonist, stimulates insulin secretion *in vitro*. This study investigated the phenotype of GPR55 knockout (KO) mice under normal conditions and diet-induced obesity.
Materials and methods: C57BL/6 (WT) and GPR55 KO mice were randomly assigned to two groups at 4 weeks of age and fed *ad lib* either standard chow (SC, fat: protein: carbohydrate: 14%:28%:58%) or a high fat diet (HFD, 55%:16%:29%) for 19 weeks. Daily energy consumption was calculated by multiplying daily food intake by the physiological fuel values of SC and the HFD. Glucose and insulin tolerance tests were performed following a single i.p. administration of glucose (2g/kg body weight) or insulin (0.75U/kg body weight), respectively. Tail vein blood glucose concentrations were determined using a glucose meter. Blood samples were collected before and after i.p. administration of glucose and serum insulin concentrations were determined using an ultra-sensitive ELISA. Caspase-3/7 activities of isolated islets were quantified using a luminescent assay.
Results: GPR55 KO and WT mice fed on SC did not show significant differences in weight gain over 19 weeks (KO week 1: 21.4±0.3g, week 19: 32.7±1.1g; WT week 1: 22.0±0.3g, week 19: 31.3±0.4g, n=6-7, P>0.2). However, GPR55 KO mice had a significantly higher daily energy intake on a HFD than did WT mice (17.6±0.5 kcal vs. 13.3±0.4 kcal; P<0.001), and KO mice showed a significantly greater weight gain on a HFD than WT mice over the same period (KO: 21.1±0.5g, 53.0±1.9g; WT: 20.8±0.5g, 35.9±1.3g; n=6-7, P<0.001). A small impairment in glucose handling following GPR55 deletion was observed in mice fed SC (AUC: WT vs. KO: 1,504±81 vs. 1,688±67), and this was more pronounced when mice were fed a HFD (2,477±231 vs. 2,969±218). The glucose intolerance observed in GPR55 KO mice fed a HFD was accompanied by blunted insulin secretion following i.p. injection of glucose (WT vs. KO: 136±1 vs. 98±17 pmol/ L serum insulin). Furthermore, GPR55 KO mice fed a HFD showed significantly lower insulin sensitivity than WT mice fed a HFD (HOMA-IR; WT vs. KO: 9.1±0.0 vs. 29.4±0.2; P<0.001). Finally, islets isolated from GPR55 KO mice exhibited significantly higher levels of cytokine-induced apoptosis both from mice fed SC (caspase3/ 7 activities; luminescence; WT vs. KO: 35,071±536 vs. 42,364±2,222; P<0.05) and a HFD (36,539±1,768 vs. 53,816±2,194; P<0.001).
Conclusion: GPR55 KO mice are hyperphagic and are more susceptible to diet-induced obesity. They also show impaired glucose tolerance and insulin resistance, which is most apparent under the increased metabolic demand caused by diet-induced obesity. The impaired glucose tolerance is at least partly due to reduced insulin secretion, increased β-cell apoptosis and the subsequent failure to compensate for increased insulin requirement. These data are consistent with GPR55 playing an important role in glucose homeostasis, and suggest its potential as a target for Type 2 diabetes therapies.

Modulation of beta cell function and glucose homeostasis by the bile acid farnesoid X receptor (FXR)

B. Schittenhelm[1], M. Düfer[2], V. Kähny[1], R. Wagner[1], K. Hörth[1], P. Krippeit-Drews[1], G. Drews[1];
[1]Pharmacology, Toxicology, and Clinical Pharmacy, University of Tübingen, [2]Pharmacology, University of Münster, Germany.

Background and aims: Type 2 diabetes mellitus coincides with alterations in the size and composition of the bile acid (BA) pool. We have recently shown that the BA taurochenodeoxycholic acid increases insulin release via FXR-dependent inhibition of K_{ATP} channels. We now extended our study and tested the influence of different conjugated and unconjugated BAs on stimulus-secretion coupling. In addition, we investigated the significance of FXR in a mouse model of diet-induced glucose intolerance.
Materials and methods: Islets or islet cells from wild type (WT) and FXR knockout (FXR-KO) mice were used to determine $[Ca^{2+}]_c$ by fura-2 fluorescence and insulin release by a radioimmunoassay. High fat diet (HFD) was applied to WT and FXR-KO mice for 12 weeks (45% kcal fat vs. 10% kcal fat vs. groups with 0.5% chenodeoxycholate (CDC)). Glucose and insulin tolerance were measured by intraperitoneal injection of glucose (ipGTT 2g/kg BW) and insulin (ipITT 1U/kg BW), respectively. Morphometric analysis was carried out on slices of paraffin-embedded pancreatic tissue by immunostaining of insulin and glucagon.
Results: The BAs taurochenodeoxycholate (TCDC), CDC, and glycochenodeoxycholate (GCDC) (500 nM) increased glucose-induced insulin secretion (TCDC: 1.2±0.3 ng/(islet*h), CDC: 1.0±0.2 ng/(islet*h), and GCDC: 1.1±0.2 ng/(islet*h) vs. 15 mM glucose: 0.7±0.1 ng/(islet*h) n=5, p≤0.05). The effects of the 3 BAs were absent in FXR-KO islets (n=4). In agreement with a stimulatory effect on insulin release, the BAs augmented $[Ca^{2+}]_c$ in WT but not in FXR-KO islet cells (n=3). By contrast ursodeoxycholate (UDC, 500 nM) that has no affinity to FXR showed an inhibiting effect on glucose-stimulated insulin secretion in both genotypes (n=4). FXR-KO protected against HFD-induced impairment of fasting glucose concentration and glucose tolerance. In the FXR-KO group values did not differ from WT animals on normal chow (ipGTT AUC (mM*min)): control WT 1131±48, HFD FXR-KO 1111±34 vs. HFD WT 1245±40 n=9 p≤0.05). Improved glycemic control of FXR-KO mice fed with HFD was not due to differences in body weight or insulin resistance. Adding CDC to the chow reduced weight gain of WT mice under HFD and protected against HFD-induced glucose intolerance (ipGTT AUC (mM*min)): control WT 1131±48, HFD+CDC WT 1160±34 vs. HFD WT 1245±40, n=8 p≤0.05). Insulin resistance was not altered. HFD led to an increase of the beta-cell area in WT and FXR-KO mice (HFD WT 113099±7193 (a.u.), HFD FXR-KO 116826±9715 (a.u.), vs. control WT 83220±6942 (a.u.), n=98 p≤0.001) and augmented the number of beta-cells/islet (HFD WT 114±8, HFD FXR-KO 125±11, vs. control WT 77±7, n=98 p≤0.001) The beta-cell size did not differ, indicating hyperplasia under HFD. Interestingly, CDC supplementation protected against this hyperplasia, because number and area of beta-cells were reduced.
Conclusion: BAs that activate FXR increase insulin secretion of lean mice in vitro. Surprisingly, under HFD conditions FXR-KO mice profit from receptor deficiency. Feeding WT animals with a BA that activates FXR in addition to HFD leads to improved glucose tolerance. Obviously, the nutritional status critically determines the effects of FXR on glucose tolerance. Further studies with lean and obese mice are needed to evaluate the different signalling pathways contributing to nutrition-dependent effects of FXR activation.

Intestinal gluconeogenesis controls pancreatic beta cell function

M. Soty, A. Sardella, I. Houberdon, G. Mithieux;
INSERM U855/UCBL, Lyon, France.

Background and aims: Pancreatic β-cells producing insulin play a key role in the control of glucose homeostasis. A defect in insulin secretion is a crucial factor in the development of diabetes. The pancreatic function is controlled by the sympathetic/parasympathetic nervous system. The appearance of glucose produced by the intestine in the portal vein (via intestinal gluconeogenesis, IGNG) initiates a nervous signal ("portal glucose signal") resulting in beneficial effects in the control of food intake and glucose homeostasis. We considered the role of IGNG in the regulation of the pancreatic function. We used mice knockout for the gene of the catalytic subunit of glucose-6 phosphatase (G6PC, the key enzyme of GNG) specifically in the intestine by an inducible Cre-Lox approach.
Materials and methods: We first performed in vivo insulin release test (3g/kg intraperitoneal (IP) glucose injection). Then, we studied the in vitro insulin secretion on isolated pancreatic islets from mice: 1/under basal and glucose-stimulated conditions; 2/after portal glucose infusion; 3/after treatment with a specific inhibitor of the α2 adrenergic receptors, yohimbine.
Results: In control mice, a 1.7- fold increase in insulin secretion was observed at 3 min after IP glucose injection and the insulin level re-increased at 12 min, indicating a second-phase insulin response. In I-G6pc-/- mice, the acute first-phase insulin secretory response to glucose was blunted. However, the insulin levels slightly rose after the glucose challenge, suggesting some retention of the second-phase insulin secretion in I-G6pc-/- . Then, we measured insulin secretion in response to glucose stimulation in islets isolated from I-G6pc-/- and control mice. Pancreatic islets from I-G6pc-/- mice showed an increase in insulin secretion under non-stimulated conditions (5.5mM glucose) (0.33 ± 0.02 vs 0.14 ± 0.03 % of insulin content). Besides this defect in insulin secretion in the basal state, pancreatic islets isolated from I-G6pc-/- mice exhibit an alteration in glucose stimulated insulin secretion (GSIS). While insulin secretion from control islets was increased 3-fold at 16.7mM glucose compared to 5.5mM glucose, I-G6pc-/- islets didn't show any response to glucose. Interestingly, mimicking IGNG by infusing portal glucose corrected insulin secretion defects in I-G6pc-/- mice. Indeed, the infusion of portal glucose decreased insulin secretion in the basal state and restored normal GSIS in I-G6pc-/- mice. On the other hand, the plasma concentration of epinephrine was increased in I-g6pc-/- mice (15 ± 2 vs 2 ± 1 ng / ml). A yohimbine treatment for 15 days decreased insulin secretion in the basal state and improved GSIS in I-G6pc-/- mice.
Conclusion: The absence of the intestinal IGNG is sufficient to alter the β-cells function. The activation of the sympathetic nervous system could explain this defect. These data strongly suggest the existence of an intestine-brain-pancreas nervous circuit, controlling the secretion of insulin and initiated by the intestinal IGNG.

Functional role of ERK1 on pancreatic beta cell physiology

M. Leduc[1], J. Richard[1], G. Bertrand[1], D. Muller[1], N. Linck[1], J.-F. Tanti[2], S. Dalle[1], M.A. Ravier[1];
[1]Institut de Genomique Fonctionnelle, Montpellier, [2]C3M, Nice, France.

Background and aims: Insulin secretion from pancreatic β-cells is triggered by glucose and is amplified by hormones/neurotransmitters through the activation of second messengers and protein kinases. The Extracellular signal Related Kinase 1 & 2 (ERK1/2) are known to be involved in the regulation of the β-cell mass, and it has also been proposed that they could play a role in glucose-induced insulin secretion. Since the independent role of each kinase has never been investigated in β-cells, our aim was to investigate, for the first time, the specific role of ERK1 using ERK1 knockout mice ($ERK1^{-/-}$).
Materials and methods: Free cytosolic Ca^{2+} concentration ($[Ca^{2+}]_c$) changes and insulin secretion were recorded in perifused islets isolated from $ERK1^{+/+}$ and $ERK1^{-/-}$ mice. The translocation of ERK1-YFP and the endogenous ERK1/2 activities (using EKAR) were monitored beneath the plasma membrane in living mouse β-cells using total internal fluorescence (TIRF) microscopy. The islet number and areas were determined by morphometric analysis of pancreatic sections stained with eosin/hematoxylin. The activation and regulation of ERK1/2 and of MSK1 were evaluated by western blots.
Results: $ERK1^{-/-}$ mice showed similar body weight, blood glucose and plasma insulin concentration than $ERK1^{+/+}$ mice, but displayed a mild glucose intolerance (p<0.01). In β-cells, ERK1-YFP is actively recruited beneath the plasma membrane by glucose (1.01±0.008 vs 1.25±0.038 a.u., p<0.001), a phenomenon that is abrogated by U0126 (a blocker of the upstream kinases MEK1/2), at a concentration (1μM) that neither affected cellular metabolism (NADPH fluorescence) nor $[Ca^{2+}]_c$ changes. Additionally, the natively expressed ERK1/2 were also recruited beneath the plasma membrane under glucose stimulation as shown by the phosphorylation of EKAR (a FRET-based biosensor of ERK1/2 activity) (p<0.05). Nevertheless, an increase in glucose concentration (from 3 to 15 mM) induced similar changes in $[Ca^{2+}]_c$ and insulin secretion in $ERK1^{-/-}$ and $ERK1^{+/+}$ islets. Therefore, glucose-induced a recruitment of the activated ERK1 to the plasma membrane, that is not involved in the regulation of insulin secretion. The activation of the Glucagon Like Peptide-1 (GLP-1) receptor increases insulin secretion in response to glucose, but also leads to the activation of ERK1/2. GLP-1 induced a similar two fold increase of insulin secretion in the presence of 15 mM glu-

cose in ERK1$^{-/-}$ and ERK1$^{+/+}$ islets, indicating that the kinase is not involved in the insulinotropic effects of GLP-1. To determine if ERK1 plays a role in the regulation of the β-cell mass, morphometric analysis of pancreatic sections were performed. ERK1$^{-/-}$ mice displayed a small proportion of very large islets (~1%; p<0.05), while the islet number was similar compared to ERK1$^{+/+}$ mice. Interestingly, the absence of ERK1 was not compensated by ERK2 (ie no increase in both ERK2 protein expression and/or activation by glucose), and more importantly we report for the first time that the activation of MSK1, one known key target of ERK1/2, is entirely dependent on ERK1 activity.
Conclusion: ERK1 is unlikely to play a role in the regulation of insulin secretion induced by glucose or GLP-1, even if the activated kinase is recruited beneath the plasma membrane under glucose stimulation. By contrast ERK1 seems to regulate the islet mass. Interestingly, we report that the activation of MSK1 is entirely dependent on ERK1 activity.

The orphan receptors GPRC5B and GPRC5C are highly expressed in mouse and human islets of Langerhans and regulate insulin secretion and islet cell survival
S. Amisten[1], A. Soni[2], P. Rorsman[3], A. Salehi[2], S. Persaud[1];
[1]King's College London, UK, [2]CRC, Lund University, Malmö, Sweden, [3]OCDEM, University of Oxford, UK.

Background and aims: GPRC5B and GPRC5C are orphan G protein-coupled receptors whose role in beta-cells is unknown. We have examined their expression in human and mouse islets and their impact on mouse beta-cell function.
Materials and methods: Mouse islet Gprc5b and Gprc5c were down-regulated using Lentiviral particles encoding gene-specific shRNAs. Insulin secretion and cell viability were determined by radioimmunoassay and MTS assay respectively.
Results: GPRC5B and GPRC5C mRNAs are abundantly expressed in human and mouse islets (expression rel. GLP1R: GPRC5B: 95.2+-28.4%; GPRC5C: 85.6+-11%). In islets from newborn mice, Gprc5b expression was reduced (-45.8+-18.9%, p<0.05) whereas Gprc5c expression was strongly upregulated (+150+-64.1%, p<0.05) compared to adult mouse islets. Downregulation of Gprc5b, increased basal and glucose-stimulated insulin secretion (1 mM G: +125+-25%; 20 mM G: +46.7+-16%, p<0.05), and attenuated the detrimental effects on islet cell survival following exposure to pro-apoptotic cytokines (+40±3.4% survival, p<0.01). In contrast, down-regulation of Gprc5c had no effect on basal insulin secretion and inhibited glucose stimulated insulin secretion (20 mM G: -46.6+-16%, p<0.05), whereas islet cell survival following exposure to cytokines was drastically reduced (-66.1+-3.9% survival, p<0.01). Finally, mRNA (+55± 2.5%, p<0.001) and protein (+56±3.1%; p<0.01) expression of GPRC5B was upregulated in islets from human diabetic donors, whereas GPRC5C expression was unaffected.
Conclusion: These data demonstrate that the orphan receptors GPCR5B and GPRC5C are expressed in mouse and human islets and that they mediate opposing effects on beta-cell function that make them potential targets for the development of novel therapies for the treatment and/or prevention of type 2 diabetes.

102

Membrane raft integrity constrains basal insulin secretion, but is impaired in type 2 diabetes
V. Nagaraj, J. Helgeson, C. Lewold, S. Barik, P. Buda, E. Zhang, E. Renström;
Lund University, Malmö, Sweden.

Background and aim: Patients with type 2 diabetes typically exhibit elevated basal insulin secretion under non-stimulatory conditions together with impaired stimulated insulin release, e.g. in response to glucose. Glucose-stimulated insulin release is tightly controlled by the actions of voltage- gated Ca^{2+} channels (Ca_v channels) and exocytotic SNARE proteins. The SNARE complexes are targeted to cholesterol-glycosphingolipid rich membrane raft regions in the plasma membrane. These specialised regions also anchor different types of ion channels such as the voltage-gated L-type $Ca_v1.2$ channel. The accumulation of these regulators of insulin exocytosis throws the limelight onto the role of membrane rafts in insulin secretion. By contrast, little is known about the cellular mechanisms controlling basal insulin secretion. The present study aims at addressing the importance of membrane rafts for basal and regulated insulin release.
Materials and methods: Models: Human donor islets, rat clonal INS1 832/13 cells, and rat primary islets were used as models of human insulin secretion. The human donor islets were obtained from the Nordic Network of Clincial Islet Transplantation in collaboration with the Lund University Diabetes Center Human Tissue Lab. Agents: Membrane rafts fractions were disrupted using cholesterol oxidase (COs) or Sphingomyelinase (SMase). Membrane raft localisation: Cells were stained for membrane rafts with ATTO 647N-Sphingomyelin or BODIPY FL C_5-ganglioside G_{M1}. Confocal imaging was employed to study raft localisation and for measurements of intracellular $[Ca^{2+}]$. Insulin secretion was measured by RIA. Electrophysiology: The patch clamp technique was used to measure whole-cell currents, depolarization-evoked exocytosis and single-channel activity.
Results: Membrane rafts were easily visualised in pancreatic clonal beta cells, rat islets as well as human islets. Treatment with cholesterol oxidase (COs) effectively reduced the raft fractions by 47% in human islets (p<0.01, n=3). Furthermore, high-glucose incubations for 72 hrs in 21.1 mM glucose resulted in a dramatic washout of rafts fractions in clonal beta-cells. When compared with cells cultured in normal glucose (9.7 mM glucose), fluorescence intensity fell dramatically by 91% (p<0.05, n=3). In line with this finding, membrane raft fluorescence intensity in islets from T2D donors was only 40% of that observed in islets from healthy donors (p<0.001, n=3). Interestingly, in the T2D islets, COs failed to affect membrane raft content that only decreased by 13% (n.s., n=3). COs failed to significantly impact stimulated secretion, but markedly increased basal release in all model system tested without signs of compromised cell viability. In human islets, the increase amounted to 213% (p<0.001, n=3). The latter effect coincided with enhanced intracellular Ca^{2+} signalling at both basal and stimulated conditions, which was due to increased voltage-gated Ca^{2+} influx (-19±2.2 pC vs -28±2.9 pC at 0 mV; p<0.05; n=22 and 21), in turn caused by increased single-Ca^{2+} channel open probability, as well as increased single-channel conductance.
Conclusion: a) Membrane raft integrity is a prerequisite for controlled insulin secretion. b) Membrane raft disruption leads to hyperactivation of voltage-gated Ca^{2+} channels under basal conditions. c) Impaired membrane raft organisation in islets may contribute to elevated basal insulin release in T2D.

OP 18 Central control of metabolism

103

Central apelin generates a hypothalamic ROS production that controls hepatic glucose metabolism during the establishment of type 2 diabetes

A. Drougard[1], T. Duparc[1], A. Fournel[1], P.D. Cani[2], P. Valet[1], C. Knauf[1];
[1]I2MC, Inserm, Toulouse, France, [2]Université Catholique de Louvain, Brussels, Belgium.

Background and aims: Hypothalamus is a key area involved in the control of glycaemia which receives information from various origins (hormones, neurotransmitters, metabolites) and in turn, modifies peripheral glucose utilisation and production by targeting the liver via the autonomic nervous system (ANS). Among all factors, we have demonstrated that apelin is an adipokine able to control glucose metabolism by acting directly on peripheral tissues, but also by acting as a neurotransmitter through hypothalamic neurons. We have recently published that intracerebroventricular (icv) injection of high dose of apelin, similar to that observed in the hypothalamus of obese/diabetic mice, triggers T2D characteristics in normal mice such as fasted hyperglycaemia. These data suggest the existence of a hypothalamic apelin to liver axis. Nowadays, nothing is known concerning the molecular hypothalamic actors implicated in the hypothalamic effect of apelin on hepatic function. One potential target of central apelin could be the Reactive Oxygen Species (ROS) since hypothalamic ROS are involved in central regulation of glucose homeostasis and are impaired during T2D. Moreover, data from literature show that apelin generates ROS release in cultured neurons. In this study, we demonstrate that high levels of central apelin generate ROS hypothalamic production leading to over-activation of ANS and hepatic glycogenolysis and gluconeogenesis. Thus, the brain apelin-to liver axis participates in establishment of a T2D by generating fasted hyperglycaemia.
Materials and methods: We measured fasted glycemia, biochemical assay of activity of liver enzymes, hepatic glycogen content, plasma catecholamines, real-time amperometric ROS detection (especially hydrogen peroxide H_2O_2) in the hypothalamus on 1) C57bl6 mice fed with normal, and treated with acute icv apelin, and 2) mice that lentivectors expressed-apelin in the ventromedial nuclei of the hypothalamus (VMH).
Results: Real-time amperometric measurement reveals that apelin stimulates hypothalamic ROS release (approximately 100nM in 20 minutes $p<0.001$). Moreover, we show that high levels of apelin in the hypothalamus generate fasted hyperglycaemia (raise of 20%, $p<0.05$), in accordance to an increase of hepatic glycogenolysis and neoglucogenesis activities. This results in a decrease of hepatic glycogen stocks (0.70µg/mg for the apelin group vs 2 for control group; $p<0.05$) and an increase of activity of hepatic enzymes. Plasma norepinephrine is significantly increased in icv apelin treated mice (19.6ng/ml for the apelin group versus 7.5 for control group; $p<0.005$) suggesting an over-activation of sympathetic nervous system. All these deleterious effect of apelin are reduced by icv antioxidant pre-treatment. Finally, we confirm the specific hypothalamic effect of apelin in lentivectors expressed-apelin model.
Conclusion: We demonstrate that high levels of apelin in the hypothalamus (and more particularly in the VMH) generate a hypothalamic ROS signaling pathway which targets liver via the ANS. This original signalling pathway leads to an increase of hepatic glucose production resulting in fasted hyperglycaemia, a characteristic of T2D. Thus, central apelin could be considered as a new target for the treatment of metabolic disorders.

104

Lipoprotein lipase inhibition into hypothalamus increases glucose tolerance and insulin sensitivity in mice

C. Cruciani-Guglielmacci, V.S. Moullé, A. Picard, N. Kassis, S. Luquet, C. Magnan;
[1]Physiology, University Paris-Diderot, Paris, France.

Background and aims: It has been shown that non-esterified fatty acids could activate or inhibit hypothalamic neurons, and that this lipid sensing could modulate food intake and hepatic glucose production. After a meal, plasma NEFA concentration is physiologically decreased whereas plasma triglycerides increase, thus we hypothesize that a local TG hydrolysis into hypothalamus may provide NEFA and modulate lipid sensing. Here we inhibited hypothalamic Lipoprotein Lipase (LPL) and measured glucose homeostasis.
Materials and methods: LPL lox/lox mice were bilaterally injected into ventromedian nucleus of hypothalamus (VMN) with an adenovirus coding for Cre recombinase. Food intake, weight and fat/lean body mass were monitored; energy expenditure, locomotor activity and respiratory quotient were assessed one month after injection. We performed OGTT and insulin tolerance tests.
Results: Homozygous Lpllox/lox injected with Cre adenovirus (Hyp-Lpl-/-) displayed a 30% decrease in LPL activity ($p<0.05$ vs. WT mice) whereas heterozygous mice had no phenotype. Hyp-Lpl-/- mice gained less weight during the 12 weeks of the study (28.3±0.6g for controls vs. 26.4±0.8g for Hyp-Lpl-/-, $p<0.05$), whereas their food intake and energy expenditure were unchanged. In addition, Hyp-Lpl-/- mice had better glucose tolerance (AUC of glycaemia decreased by 45% vs. controls, $p<0.05$) and better insulin sensitivity (AUC of glycaemia increased by 60% vs. controls, $p<0.05$). Using WT-mice food-restricted to match Hyp-Lpl-/- mice weight gain over time, we demonstrated that the low weight was not entirely responsible for the improvement of glucose tolerance and that specific mechanisms controlling glucose homeostasis were involved.
Conclusion: We evidenced a role for hypothalamic LPL in the control of glucose homeostasis: a decreased LPL activity inside VMN lead to a moderate underweight and improved insulin sensitivity and glucose tolerance.

Lipoprotein lipase deletion into hippocampus leads to glucose intolerance and impaired insulin secretion in mice

E. Laperrousaz, A. Picard, V. Moullé, N. Kassis, S. Luquet, C. Magnan, C. Cruciani-Guglielmacci;
University Paris 7, France.

Background and aims: Hippocampus is involved in the control of food intake, body weight and energy expenditure. In addition, it is the major site of expression and activity and of Lipoprotein Lipase (LPL) in brain, the main enzyme responsible for the hydrolysis of triglycerides into free fatty acids. We hypothesize that hippocampal LPL may play a role in the control of energy balance by modulating the brain lipid sensing.
Materials and methods: Lpl lox/lox mice were crossed with mice expressing Cre recombinase, under the control of a partial CamK2α promoter that exhibits a major expression in CA1 layer of hippocampus. The absence of recombination in other peripheral organs like pancreas was checked. Food intake, body weight and composition, energy expenditure were characterized for the descendants. Glucose homeostasis was explored by OGTT and by insulin tolerance test (ITT); glucose-stimulated insulin secretion was measured both in vivo and in vitro.
Results: Heterozygous mice for Camk2α-Lpl gene deletion presented a significant decrease in hippocampal LPL activity (-30%, $p<0.05$) and developed a transient overweight without over-eating, associated with an increase in fat mass and a decrease in energy expenditure, compared to control mice. These mice were also found to be glucose intolerant (28% increase in glycaemia AUC vs. controls, $p<0.05$), due to a defect in in vivo insulin secretion. In vitro, islets were normally responsive to glucose. In addition, Hipp-Lpl +/- mice were more sensitive to exogenous insulin (at t=15 min post-injection, glycaemia: 138 mg/dl in Hipp-Lpl+/- vs. 188 in controls, $p<0.05$). Homozygous mice did not present any phenotype or decrease in hippocampal LPL activity (due to a putative compensatory LPL expression).
Conclusion: Heterozygous LPL gene deletion behind CamK2α promoter leads to a glucose intolerance associated with a defect in in vivo insulin secretion, probably due to changes in sympatho-vagal balance. These results support a role of hippocampal LPL activity in nervous regulation of glucose homeostasis.

Revealing a functionally-relevant map from the brain to pancreatic islets

W. Rosario[1], I. Singh[2], A. Wautlet[3], C. Patterson[4], J. Flak[4], T.C. Becker[5], C.B. Newgard[5], L. Enquist[6], M.G. Myers Jr[4], C.J. Rhodes[2];
[1]Committee on Neurobiology, University of Chicago, [2]Committee on Molecular Metabolism and Nutrition, University of Chicago, [3]University of Chicago, [4]Department of Molecular and Integrative Physiology, University of Michigan, Ann Arbor, [5]Department of Medicine, Duke University, Durham, [6]Department of Molecular Biology, Princeton University, USA.

Background and aims: For more than 150 years it has been known that certain brain injuries can lead to diabetes, and that the central nervous system

(CNS) is able to exert a degree of control over insulin and glucagon secretion. However, the precise CNS area(s) that link to the endocrine pancreas are essentially unknown. Here, we reveal this direct neuronal circuit in mice with and show that it is relevant in the regulation of pancreatic endocrine secretions.
Materials and methods: A pseudorabies virus strain (PRV-BaBlu) expressing the LacZ reporter gene (PRV-BaBlu) was used as a specific neuronal retrograde transynaptic tracer to track the neuronal link from the endocrine pancreas to the CNS. Essentially, mouse pancreata were infected with PRV-BaBlu and traced over a 96h period for appearance in the CNS. Immunofluorescence (IF) analysis was used to examine β-gal expression from PRV-BaBlu, and co-localisation with glucose-sensing glucokinase (GK) in the CNS neurons. Stereotaxic brain injections of adenoviral-driven Hexokinase I (HKI) specifically to CNS regions enriched by β-gal/GK+ neurons was conducted in mice to lower glucose-sensing from the mM toward the μM range. Intraperitoneal glucose and insulin tolerance tests (IPGTT/IPITT, respectively) were carried out to examine whether altering CNS glucose-sensing affected pancreatic islet endocrine cell secretory functions.
Results: The PRV-BaBlu neuronal tracing revealed that a major neuronal circuit originating in the Arcuate (ARC), Ventromedial (VMN), Dorsomedial (DMN), and Lateral (LHA) regions of the hypothalamus, on to the Periventricular (PeVN) and paraventricular (PVN) hypothalamus around the 3rd ventricle of the brain to the periaqueductal gray (PAG) relay center, then to the dorsal motor (DMX) and solitary (NTS) nuclei in the brain stem, and ending on the endocrine pancreas. IF analysis indicated enriched GK co-localisation with PRV-BaBlu in the ARC, VMN and LHA. HK1 overexpression specifically in the ARC resulted in no effect on insulin sensitivity but significant glucose-intolerance ($p \leq 0.05$), relative to control mice. No effect was observed with HK1 overexpression specifically in the VMN. In contrast, HK1 overexpression in the LHA indicated improved glucose tolerance ($p \leq 0.05$). These contrasting effects in the ARC versus the LHA were associated with distinct changes in the balance between insulin and glucagon levels during the glucose/insulin tolerance tests.
Conclusion: Our results reveal a topographical map between the CNS and pancreatic islets that has functional relevance. Moreover, the data indicate that glucose sensing in different hypothalamic regions can have quite distinct consequences to glucose homeostasis instigated by a CNS-augmented control of insulin and glucagon secretion in vivo.

Hepatic glycogen loading increases the counter-regulatory response to hypoglycaemia by a liver-brain neural connection
J.J. Winnick, G. Kraft, J.M. Gregory, B. Farmer, M. Scott, D. Neal, E. Allen, A.D. Cherrington;
Molecular Physiology & Biophysics, Vanderbilt University, Nashville, USA.

Background and aims: The risk of iatrogenic hypoglycemia is a persistent barrier to the safe, effective treatment of people with type 1 diabetes. In response to insulin-induced hypoglycaemia, increased secretion of glucagon and epinephrine stimulates hepatic glucose production and inhibits muscle glucose utilization, thereby restoring glucose homeostasis. However, the secretion of both glucagon and epinephrine in response to insulin-induced hypoglycaemia is impaired in patients with type 1 diabetes, making augmentation of their release of therapeutic value.
Materials and methods: During the first 4h of each study, 18h fasted dogs received somatostatin and basal amounts of intraportal insulin and glucagon. Arterial plasma glucose was doubled by glucose infusion into a peripheral vein and either saline (SAL; n=6) or fructose (7.15 μmol/kg/min; n=11) was infused into the hepatic portal vein, with the latter significantly stimulating hepatic glucose uptake and glycogen deposition. This glycogen loading period was followed by a 2h hyperglycaemic/normoinsulinemic period during which the intraportal infusion of SAL or fructose was discontinued. During the final 2h period, hypoglycaemia was induced in all animals using a 16x basal intraportal infusion of insulin. Animals from FRU were divided into two groups; one group that had intact liver innervation (FRU; n=6) and one that had severed hepatic nerves (FRU-DEN; n=5).
Results: Fructose infusion led to a large increase in hepatic glycogen in both FRU groups (286±28, 446±33 and 418±44 μmol/g liver in SAL, FRU and FRU-DEN, respectively; $p<0.05$). During the final hour of the 2h hyperinsulinemic/ hypoglycaemic period, arterial plasma glucose levels were similar among the three groups (2.6±0.1, 2.6±0.1 and 2.7±0.1 mmol/l in SAL, FRU and FRU-DEN, respectively) as were the hepatic sinusoidal insulin levels (2538±114, 2340±186 and 2472±180 pmol/l, respectively). Hypoglycaemia caused greater net hepatic glucose output during this period in FRU compared to SAL (25.3±1.1 vs 8.4±1.1 μmol/kg/min, respectively; $p<0.01$) as a result of a greater increase in plasma glucagon (109±25 and 65±7 ng/l, respectively; $p=0.06$) and epinephrine (1820±365 and 902±185 ng/l, respectively; $p<0.05$). Hepatic denervation blocked each of these responses such that, despite the presence of elevated hepatic glycogen, net hepatic glucose output (12±3 μmol/kg/min), plasma glucagon (62±17 ng/l) and epinephrine (892±337 ng/l) levels were similar in FRU-DEN and SAL.
Conclusion: Our data indicate that an increase in hepatic glycogen is associated with augmented secretion of both glucagon and epinephrine in response to insulin-induced hypoglycaemia. This increase is blocked by hepatic denervation indicating that it resulted from altered afferent neural input from the liver to the brain. Thus, hepatic glycogen content can be a determinant of the counter-regulatory response to hypoglycaemia.

Hypothalamic nesfatin-1 knockdown increases gluconeogenesis by mTOR/STAT3 pathway
J. Dai[1,2], L. Li[1,2], G. Yang[1];
[1]College of Laboratory Medicine, Chongqing Medical University, [2]The Key Laboratory of Medical Diagnostics in Ministry of Education, Chongqing Medical University, China.

Background and aims: Nesfatin-1, an 82 amino acid neuropeptide, has been recently characterized as a potent metabolic regulator. However, the metabolic mechanisms directly associated with the action of nesfatin-1 have not been well delineated. To determine the role of hypothalamic nesfatin-1/NUCB2 in glucose homeostasis and metabolic signal pathway, we have determined whether attenuation of central nesfatin-1/NUCB2 signal leads to the change in peripheral glucose kinetics using a loss-of-function animal model by knocking down hypothalamic nesfatin-1/NUCB2 in rats. More importantly, we determined the molecular mechanisms by which the central nesfatin-1/NUCB2 knockdown leads to the alteration of the insulin signaling cascade.
Materials and methods: We established a loss-of-function model of hypothalamic nesfatin-1/NUCB2 signaling in rats using an adenoviru-mediated RNAi. Using this model, we assessed the effects of central nesfatin-1/NUCB2 knockdown on glucose metabolism and changes in transcription factors and signaling pathway during euglycemic-hyperinsulinemic clamping. Glucose rates of appearance (GRa) were determined with 3-[3H] glucose. Whole body GRa and glucose uptake (GRd) were calculated using the non-steady-state equation. mRNA and protein expressions were measured by qRT-PCR and Western blot, respectively.
Results: We showed that inhibition of central nesfatin-1/NUCB2 activity markedly increased feed intake in normal chow diet (NCD)-fed rats and increased hepatic glucose fluxes and decreased glucose uptake in peripheral tissue in both NCD- and high fat diet (HFD)-fed rats. The change of hepatic glucose fluxes in the hypothalamic nesfatin-1 deficiency rats was accompanied by increasing in the hepatic expression of G-6-Pase and PEPCK and decreasing in InsR, IRS-1, and AKT phosphorylation. Furthermore, knockdown of hypothalamic nesfatin-1 led to decreased phosphorylation of STAT3 and mTOR and subsequent SOCS3 expression.
Conclusion: We demonstrate here that a rapid loss of function in hypothalamic nesfatin-1/NUCB2 signaling can be induced in vivo using an adenoviru-mediated RNAi. The targeting of this vector to hypothalamus should provide a formidable tool for dissecting the contribution of this pathway to glucose metabolism and insulin signal transduction. Using this experimental tool, we unveil the critical role of hypothalamic nesfatin-1 knockdown in the regulation of liver glucose fluxes and insulin signal pathway as well as the involvement of mTOR-STAT3-SOCS3 pathway. Our data delineate that modulation of the hypothalamic nesfatin-1/NUCB2 signaling may represent a promising strategy for the treatment of obesity and the underlying metabolic syndrome by regulating mTOR-STAT3-SOCS3 signal pathway.

Dipeptidyl peptidase-4 inhibitor sitagliptin preserves islet beta cell function in patients with new-onset latent autoimmune diabetes in adults

L. Yang[1], Y. Zhao[1], Y. Xiang[1], L. Liu[1], G. Huang[1], Z. Long[1], R.D. Leslie[2], X. Wang[3], Z. Zhou[1];
[1]Diabetes Center, Institution of Metabolism and Endocrinology, The Second Xiangya Hospital and Key Laboratory of Diabetes Immunology (Central South University), Ministry of Education, Changsha, China, [2]Department of Diabetes and Metabolic Medicine, Blizard Institute of Cell and Molecular Science, London, UK, [3]Endocrinology, Division of Endocrinology and Metabolism, UMDNJ-Robert Wood Johnson Medical School, New Brunswick, USA.

Background and aims: Latent autoimmune diabetes in adults (LADA) is thought to result from chronic autoimmune destruction of pancreatic β cells. The ideal agents for LADA should aim to promote β cell proliferation and modulate immune system. The incretin drugs dipeptidyl peptidase-4 (DPP-4) inhibitor can stimulate β-cell proliferation and increase insulin content in vitro and has been shown to improve β cell function in type 2 diabetic patients. Besides, it also plays a fundamental role in immune regulation, especially in T-cell activation. Therefore, we hypothesized that LADA patients might benefit from DPP-4 inhibitor treatment and this study aimed to investigate the effect of sitagliptin on β cell function in LADA patients.
Research design and methods: Thirty newly diagnosed LADA patients with remained β cell function (fasting C-peptide more than 0.2nmol/L) were enrolled and randomized 1:1 to receive insulin plus sitagliptin (100mg/day) (insulin+SIT group, n=15) or insulin alone (insulin group, n=15) for 12 months. Plasma glucose, HbA_{1c}, fasting C-peptide (FCP) and 2h postprandial C-peptide (2hCP) during a mixed-meal tolerance test (MMTT) were determined at the baseline, 3th month, 6th month, 9th month and 12th month during the treatment. Glutamic decarboxylase antibody (GAD-Ab) and C-peptide were measured by radioimmune assays. Islet β cell function was evaluated by FCP, 2hCP and ΔCP (ΔCP=2hCP-FCP).
Results: There were no significant changes in the level of FCP, 2hCP and ΔCP in insulin+SIT group during the 12 months' observation compared with the baseline (all $P>0.05$). Whereas in the insulin alone group, not only FCP level decreased from 407.2 pmol/L at baseline to 323.3 pmol/L at the 3th month ($P<0.05$), and continued to decline to 256.8 pmol/L at the 12th month ($P<0.05$), but also 2hCP level decreased gradually from 1496.pmol/L at the baseline to 830.2 pmol/L at the 12th month (3th, 6th, 9th, 12th vs baseline, all $P<0.05$) and ΔCP level decreased significantly from the baseline of 1090.2 pmol/ L to the 12th month of 580.9 pmol/ L (3th, 9th and 12th vs baseline, all $P<0.05$). Furthermore, 2hCP and ΔCP levels were both significantly higher in insulin+SIT group than those in the insulin alone group at the 12th month (both $P<0.05$).
Conclusion: Our study demonstrates, we believe for the first time, that the sitagliptin therapy protects β-cell function in LADA patients, which provides important therapeutic implications for DPP-4 inhibitors in autoimmune diabetes.

Improved glucagon dynamics during hypoglycaemia and food-rechallenge by DPP-4 inhibition by vildagliptin in insulin-treated patients with type 2 diabetes

B. Ahrén[1], J. Farngren[1], M. Persson[2], A. Schweizer[3], J. Foley[4];
[1]Medicine, Lund University, Lund, [2]Medicine, Lund University, Malmö, Sweden, [3]Novartis, Basel, Switzerland, [4]Novartis, E Hanover, USA.

Background and aims: Glucagon counter-regulation is critical for defending hypoglycemia and lowering of glucagon is a key component for improved post-meal glycemia in type 2 diabetes (T2D). Glucagon sensitivity to glucose is increased in hyperglycemia by GLP-1 and increased in hypoglycemia by GIP. We previously showed that the DPP-4 inhibitor, vildagliptin (VILDA), reduces glucose levels without increasing hypoglycemia in patients on insulin therapy with either T2D or type 1 diabetes (T1D), reduces glucagon at hyperglycemia in T2D and T1D, and sustains glucagon counter-regulation during hypoglycemia in drug-naïve and insulin-treated T2D patients. We have now explored the effects of VILDA on glucagon dynamics during meal ingestion, during insulin-induced hypoglycemia and during subsequent food re-challenge after hypoglycemia in patients with insulin-treated T2D to examine whether VILDA improves the glucagon dynamics also when used in combination with insulin.
Materials and methods: The study was a single-center, double-blind, randomized, placebo (PBO)-controlled crossover study involving 29 patients with T2D (16M, 13F, mean age 58 yrs, diabetes duration 15 yrs, duration of insulin therapy 7 yrs, HbA1c 60 mmol/mol (7.7%), BMI 30.7 kg/m^2) treated with long acting (mean 33U/day) and, in 26 patients, additionally short-acting (mean 28U/day) insulin. Patients received VILDA (50 mg BID) or PBO as add-on to insulin for four weeks in random order with a four week washout in-between. On day 28 of the respective treatment, patients were served a standard meal (500 kcal) followed by a hyperinsulinemic hypoglycemic clamp (2.5 mmol/l for 30 min) and a subsequent food re-challenge.
Results: Glucose levels were lower during the meal with VILDA than with PBO (120 min AUC: 1.1±0.1 vs. 1.4±0.1 mol/l x min, P<0.001) whereas glucose levels were similar between the groups during the clamp (2.6±0.1 mmol/l in both groups, NS). During the meal, glucagon levels were lower with VILDA than with PBO (120 min AUC: 7.1±0.5 *vs.* 7.7±0.6 ng/ml x min, P<0.02). The glucagon counter-regulation to the insulin-induced hypoglycemia was sustained by VILDA (23.1±4.0 vs.24.2±4.2 pg/ml, NS). Also the hypoglycemia counter-regulatory responses in adrenaline, noradrenaline and pancreatic polypeptide were not different between the groups. During the food re-challenge after hypoglycemia, glucagon levels were, again, significantly lower after VILDA than after PBO (4.8±0.4 vs. 5.3±0.4 pg/ml x

min, P<0.05); glucose levels did not differ between the groups (0.12±0.01 vs. 0.14±0.01 mol/l x min, NS). After the four week treatment period, HbA1c was reduced with VILDA -4.7±0.6 mmol/mol (-0.5±0.1%) and with PBO by -1.1±0.6 mmol/mol (-0.1±0.1%(; in-between group difference -3.6±1.0 mmol/mol (-0.4±0.1%; P<0.001).
Conclusion: In insulin-treated patients with T2D, add-on with the DPP-4 inhibitor VILDA reduces glucagon during meal but preserves glucagon counter-regulation during hypoglycemia. VILDA also sustainably lowered the glucagon response after the food re-challenge following hypoglycemia. The results thus show that VILDA improves glucagon dynamics during hypoglycemia and food re-challenge in insulin-treated patients with T2D.

Gemigliptin added to ongoing metformin therapy provides sustained glycaemic control over 52 weeks and was well tolerated in patients with type 2 diabetes

E.J. Rhee[1], K.W. Min[2], H.C. Jang[3], C.H. Chung[4], I.S. Nam-Goong[5], H.Y. Bae[6], S.H. Baik[7], V.K. Shivane[8], A.R. Sosale[9], M. Dharmalingam[10], P. Gandhi[11], S.K. Gupta[12], J.Y. Ahn[13], K.S. Bang[13], M.K. Lee[14];
[1]Kangbuk Samsung Medical Center, Seoul, [2]Eulji University School of Medicine, Seoul, [3]Seoul National University Bundang Hospital, Seongnam, [4]Wonju Christian Hospital, [5]Ulsan University Hospital, [6]Chosun University Hospital, Gwangju, [7]Korea University Guro Hospital, Seoul, Republic of Korea, [8]Shivane, Mumbai, [9]Diacon Hospital, Diabetes Care and Research Centre, Bangalore, [10]Bangalore Endocrinology and Diabetes Research Centre, [11]Gandhi Research Institute, Nagpur, [12]MV Hospital and Research Centre, Lucknow, India, [13]LG Life Sciences, Seoul, [14]Samsung Medical Center, Seoul, Republic of Korea.

Background and aims: Many people with type 2 diabetes cannot maintain target blood glucose levels as monotherapy, because of the complex nature of the disease and the progressive deterioration in pancreatic β-cell function. This was a 28-week extension to a study of the efficacy and safety of gemigliptin compared with sitagliptin added to ongoing metformin therapy in type 2 diabetes patients with inadequate controlled with metformin alone. This study was designed to evaluate the long-term efficacy and safety of gemigliptin and to assess the efficacy and safety of switching from sitagliptin to gemigliptin in type 2 diabetes patients receiving background treatment with metformin. All patients received once daily gemigliptin 50 mg during extension period.
Materials and methods: We conducted a 24-week, randomized, double-blind, active-controlled study of gemigliptin with an open-label extension to 52 weeks. A total of 604 patients diagnosed with type 2 diabetes mellitus were screened and 425 eligible patients were then enrolled. About 90% of the patients who completed 24 weeks of treatment in each group consented to continue the study to receive further treatment with gemigliptin 50 mg qd for 28 weeks. Among 335 patients who consented to participate in the extension study, 315 patients (94%) completed 52 weeks of treatment. The primary endpoint for extension period was the mean change in HbA1c from baseline to week 52. Safety and tolerability based on adverse events (AEs) also assessed.
Results: All treatment groups showed clinically and statistically (*P*<.0001) significant HbA1c reduction after 52 weeks of dosing regardless of previous treatment given during initial 24 weeks. The 95% confidence interval (CI) for HbA1c reduction at week 52 was (-1.28%, -0.85%) in patients continued to receive once daily gemigliptin 50 mg. Proportion of patients achieving HbA1c <7% at week 24 in gemigliptin 25 mg bid (53.5%) and gemigliptin 50 mg qd (54.6%) was comparable to the results with once daily sitagliptin 100 mg (45.5%). It slightly increased in each group at the end of week 52 reaching 60.3% (25 mg bid) and 70.9% (50 mg qd) in gemigliptin groups and 52.3% in sitagliptin group. Gemigliptin was generally well tolerated with a low incidence of hypoglycemia and an absence of body weight gain over 52 weeks.
Conclusion: In conclusion, this study demonstrated the long term efficacy and safety of once daily administration of gemigliptin 50 mg as an add-on therapy to metformin in type 2 diabetes mellitus patients.

Cardiovascular (CV) safety of linagliptin in patients with type 2 diabetes: a pooled comprehensive analysis of prospectively adjudicated CV events in phase 3 studies

O. Johansen[1], D. Neubacher[2], T. Seck[1], S. Patel[3], H.-J. Woerle[1];
[1]Boehringer-Ingelheim, Ingelheim, [2]Boehringer-Ingelheim, Biberach, Germany, [3]Boehringer-Ingelheim, Bracknell, UK.

Background and aims: Incidence of CV events is increased in T2D, but the potential for CV risk modulation with glucose lowering therapies is debated.
Materials and methods: We compared the incidence of CV events and CV mortality in patients with T2D treated with linagliptin (lina), a once daily DPP-4 inhibitor, with non-lina comparators (placebo or active; comp) in 19 double-blind RCTs (duration ≥ 12 weeks). CV events were prospectively adjudicated by a blinded independent expert committee. The primary endpoint was a composite of CV death, non-fatal stroke, non-fatal myocardial infarction, and hospitalization for unstable angina pectoris. Other secondary and tertiary CV endpoints were also assessed.
Results: Of 9459 patients, 5847 received lina (5 mg: 5687, 10 mg: 160) and 3612 comp (placebo: 2675, glimepiride: 775, voglibose: 162). The cumulative exposure (person years) was 4421.3 for lina and 3254.7 for comp. Changes (mean±SEM) in HbA1c and weight, for linagliptin and comp, respectively were -0.68±0.01%/-0.27±0.02% and -0.1±0.1/+0.4±0.1 kg whereas there were similar changes in systolic/diastolic blood pressure and lipids. In total, 60 primary events were reported in the lina group and 62 in the comp group (36 in the placebo and 26 in the active comp group). Incidence rates of the primary endpoint (/1000 years at risk) were lower for lina (13.4) than for the comp group (18.9) in line with the hazard ratio (0.78) (TABLE).
Conclusion: This updated pooled analysis of adjudicated CV events in a large Phase 3 program continues to support that lina is not associated with an increased risk for CV events. Potential CV benefits with lina will be tested prospectively in more than 14000 patients in the active-comparator (glimepiride) **CAROLINA trial (NCT01243424) and the placebo-controlled CARMELINA trial.**

Durability of the efficacy and safety of alogliptin compared to glipizide over 2 years when used in combination with metformin

S. Del Prato[1], R. Camisasca[2], C. Wilson[3], C. Wilson[3], P. Fleck[3];
[1]UOC Malattie Metaboliche e Diabetologia, Pisa, Italy, [2]Takeda Global Research & Development Centre, London, UK, [3]Takeda Global Research & Development Center, Deerfield, USA.

Background and aims: This three-arm, multicenter, randomized, double-blind, active-controlled study was conducted to evaluate the durability of the efficacy and safety of alogliptin (ALO) compared to glipizide in combination with metformin (MET) in patients with type 2 diabetes inadequately controlled on stable-dose MET.
Materials and methods: The duration of the study was 104 weeks. The three treatment arms were: ALO 12.5 mg QD + MET (ALO 12.5) (n=880), ALO 25 mg QD + MET (ALO 25) (n=885), and glipizide 5 mg titrated up to a

maximum of 20 mg + MET (GLIP) (n=874). The primary endpoint was least square mean change from baseline in HbA1c at 104 weeks.
Results: The majority of patients were white (62.3%) and 50.3% were women. The mean age was 55.4 years; body mass index, 31 kg/m^2; diabetes duration, 5.5 years; and baseline HbA1c, 7.6%. Reductions in HbA1c at Week 104 were 0.68%, -0.72%, and -0.59% for ALO 12.5, ALO 25, and GLIP, respectively. Significantly more patients achieved an HbA1c ≤7% at Week 104 with ALO 25 (48.5%) vs GLIP (42.8%) (P=0.004); the proportion for ALO 12.5 was 45.6% (not significant vs GLIP). Changes in fasting plasma glucose at Week 104 were -0.9 mg/dL for ALO 12.5, -3.2 mg/dL for ALO 25, and 5.4 mg/dL for GLIP; both ALO reductions were significant compared with the GLIP increase (P<0.001). Mean weight changes at 104 weeks were -0.68, 0.89, and 0.95 kg for ALO 12.5, ALO 25, and GLIP, respectively; both ALO decreases were significantly different from the GLIP increase (P<0.001). More GLIP patients (23.2%) experienced one or more hypoglycemic events compared to ALO 12.5 (2.5%) and ALO 25 (1.4%) patients; severe hypoglycemia occurred in six GLIP patients, one ALO 12.5 patient, and no ALO 25 patients. Numbers of patients experiencing at least one adverse event (AE), a serious AE, or an AE leading to treatment discontinuation were similar across the three groups. The most frequently reported AEs overall and within each treatment group were upper respiratory tract infection, nasopharyngitis, diarrhea, hypertension, headache, and back pain. Pancreatitis occurred in one ALO 25 patient and three GLIP patients. Eleven deaths occurred: three in the ALO 12.5 group, three in the ALO 25 group, and five in the GLIP group.
Conclusion: The efficacy of alogliptin was sustained through 104 weeks. The safety profile was similar among the treatment arms, although considerably lower incidences of hypoglycemia were observed in the ALO dose groups.
Clinical Trial Registration Number: NCT00856284

Comparison of trough dipeptidyl peptidase-4 inhibition in patients with type 2 diabetes treated with saxagliptin, sitagliptin, and vildagliptin
H.L. Katzeff[1], D.A. Tatosian[1], Y. Guo[1], A.K. Schaeffer[1], N. Gaibu[2], S. Popa[2], R.B. Langdon[1], E. Kauh[1];
[1]Merck Sharp & Dohme, Whitehouse Station, USA, [2]Arensia Exploratory Medicine, Chisinau, Republic of Moldova.

Background and aims: Saxagliptin (Saxa), sitagliptin (Sita), and vildagliptin (Vilda) are dipeptidyl peptidase-4 (DPP-4) inhibitors currently approved as oral antihyperglycemic agents (AHAs) for use in treating type 2 diabetes. These agents have substantially different pharmacokinetic properties and DPP-4 binding characteristics that may have important implications for their pharmacodynamic profiles. Our present understanding is limited, however, because (1) in some prior studies, assay conditions were not optimized for comparison between agents, and (2) no prior study has directly compared DPP-4 inhibition in patients treated with these agents. Here, using an assay that minimized ex vivo plasma dilution (a potential source of error), we have assessed trough DPP-4 inhibition in a single cohort of patients treated with these three agents.
Materials and methods: This was a randomized, placebo-controlled, open-label, five-period crossover study. Eligible patients were 18-65 years of age and had A1C ≥6.5% and ≤10.0% when treatment-naïve or off prior AHA therapy for ≥6-12 weeks. The treatments were 5 mg Saxa q.d., 100 mg Sita q.d., 50 mg Vilda q.d., 50 mg Vilda b.i.d., and placebo q.d (PBO). Treatments lasted 5 days and were separated by ≥10 days. Plasma was prepared from blood samples collected predose on Days 1-5 and 12, 24, 36, 48, and 96 h following the morning dose on Day 5. Glycyl-propyl-amino-methylcoumarin hydrobromide solution was combined with plasma in a 1:9 ratio and DPP-4 activity was measured fluorometrically. Percent DPP-4 inhibition (%DPP-4i) was calculated for each treatment relative to the predose DPP-4 activity in each period. The primary endpoint was trough %DPP-4i measured 24 h after the morning dose on Day 5. It was analyzed using a linear mixed-effects model with fixed-effects terms for treatment and period. Pharmacokinetic data were evaluated using WinNonlin version 5.0.1.
Results: In the randomized cohort (N=22), mean (range) baseline A1C was 7.4% (6.4-9.0). Least-squares (LS) mean (95% CI) trough %DPP-4i was 73.5% (66.6%, 79.0%), 91.7% (91.4%, 92.1%), 28.9% (17.9%, 38.4%), 90.6% (88.9%. 92.1%), and 3.5% (−0.7%, 7.5%) after Saxa, Sita, Vilda-q.d., Vilda-b.i.d., and PBO treatments, respectively. In comparisons with Sita, LS-mean differences were 18.2% vs Saxa (p<0.001; positive values favor Sita), 62.9% vs Vilda-q.d. (p<0.001), 1.1% vs Vilda-b.i.d. (p=0.128), and 87.8% vs PBO (p<0.001). Given that mean %DPP-4i was ~90% at 12 h postdose for each active treatment, these between-group comparisons primarily reflect differences in duration of action. Mean apparent $t_{½}$ was 9.5 h for Saxa (14.7 h for its active metabolite 5OH-saxagliptin), 12.0 h for Sita, and 2.4-3.4 h for Vilda. Ten adverse events were reported overall, none serious. All were transient and characterized as mild or moderate in intensity. Three patients were discontinued because of hyperglycemia, one because it was determined after randomization that she did not meet eligibility criteria, and one patient withdrew consent.
Conclusion: In this study, treatment with Sita provided significantly greater DPP-4 inhibition than either Saxa or Vilda once daily and DPP-4 inhibition similar to that provided by Vilda twice daily.

Alteration of CD28 T cell costimulatory pathway protects against obesity-induced inflammation and metabolic disorders

M. Poggi[1], S. Morin[2], F. Peiretti[1], R. Govers[1], C. Favre[2], V. Giroux[2], D. Bastelica[1], M. Malissen[3], D. Olive[2], J. Nunes[2], M.-C. Alessi[1]; [1]Faculte de Medecine, INSERM 1062/INRA 1260, [2]INSERM U1068 - CNRS UMR7258, [3]CNRS, CIML, Inserm U631, Marseille, France.

Background and aims: Lymphocytes have been shown to be critical in adipose tissue (AT) inflammation and contribute to the metabolic consequences of obesity. The CD28-B7 costimulatory molecules are essential for T-cell activation and regulatory T cell homeostasis. Nevertheless their role in obesity has never been assessed. In this present study, we assess the role of T cell activation and T cell homeostasis in diet-induced obesity models by modulating CD28-mediated T cell costimulation using targeted mutations of CD28 gene or CD28/B7 pathway pharmacological blockade.
Materials and methods: CD28 wild-type (WT), knock-out (KO), knock-in (KI) with a loss of the cytoplasmic tail mice were fed a high-fat diet (HFD, 65% kcal from lipids) for 16 weeks. An additional group of WT mice was injected with CTLA4-Ig (Abatacept), an inhibitor of CD28-B7 interactions and fed HFD for 8 weeks. Metabolic and inflammatory parameters were evaluated by glucose tolerance test, FACS analysis, RNA quantification, immunohistochemistry and ELISA.
Results: CD3+, CD3+CD4+, CD3+CD8+ T cell population were reduced and regulatory T cells (CD3+CD4+CD25+FoxP3+) were almost absent in epididymal AT from CD28KO and KI compared to WT mice. In addition while T-cell activation in spleen and AT was prevented in CD28KO, it was partially retained in CD28KI mice. Despite an established obesity, CD28KO and KI mice displayed improved insulin sensitivity. Furthermore, CD28 deficiencies protect from fatty liver accumulation. In some instances the protective effect was stronger in CD28KI than in CD28KO mice with improved systemic glucose tolerance, higher levels of lipogenesis and insulin signaling mRNA in AT. In agreement, CD28KI mice exhibited higher levels of anti-inflammatory M2-macrophages while the global AT-macrophages infiltration did not differ between the groups. Short CTLA4-Ig treatment of WT mice decreased CD4+ and Tregs in AT but CD8 content and metabolic parameters were not altered.
Conclusion: These findings demonstrate that CD28 deficiencies prevent insulin resistance and liver steatosis induced by high fat diet without affecting obesity. Cell activation is not required to recruit macrophage in adipose tissue but it is for macrophage polarization, emphasizing the cooperation between activated lymphocytes and macrophages within AT.

Intra-islet inflammation in type 2 diabetes: evidence that the E3 ligase TRAF2 is a key protective factor in beta cells

E.K. Malle, S.N. Walters, N.W. Zammit, J. Cantley, R. Brink, S.T. Grey; Immunology, Garvan Institute of Medical Research, Sydney, Australia.

Background and aims: Activation of the JNK and NF-κB signaling pathways are associated with beta cell failure and apoptosis. TNFα-receptor associated factor 2 (TRAF2), an E3 ubiquitin ligase, mediates activation of both these pathways. We predicted that genetic deletion of TRAF2 in beta cells would improve beta cell function and prevent diabetes; an idea previously untested in islets.
Materials and methods: We generated beta cell specific TRAF2 knockout mice (bTRAF2), examined TNFα signaling and subjected mice to a diet-induced obesity model.
Results: bTRAF2 islets appeared normal, showed robust insulin labeling, and bTRAF2 mice displayed normal glucose tolerance at 8 weeks of age. Analyzing TNFα induced signaling ex vivo, bTRAF2 islets displayed delayed degradation of IκBα compared to wild type (WT). Phosphorylation of JNK was delayed, and also profoundly prolonged. Deleting TRAF2 in Min6 beta cells using siRNA emulated delayed and prolonged JNK activation. Further, we found increased processing of p100 to p52 in unstimulated bTRAF2 islets indicating cell intrinsic activation of the non-canonical NF-κB pathway. bTRAF2 islets were hyper-responsive to TNFα stimulation compared to WT showing 3-7 fold (**P<0.005) increased gene expression for CXCL10, ICAM1 and TNFα, genes regulated by the non-canonical pathway. Also the basal levels for these genes were increased ~2.5 fold (*P<0.05) compared to WT islets. In vivo, bTRAF2 mice subjected to an i.p. GTT showed a trend towards worsened glucose tolerance at 16 weeks of age (mean AUC±SEM: WT: 969.7±41.71, bTRAF2: 1181±80.13; n≥12; *P<0.05). When fed a high-fat diet for 8 weeks, glucose intolerance in bTRAF2 versus WT mice was greatly exacerbated (mean AUC±SEM: WT: 1420±37.8, bTRAF2: 1903±108.7; n≥12; ***P<0.001). This data was further corroborated by a trend towards lower fasting blood insulin levels and a defect in first phase insulin secretion in bTRAF2 mice determined by i.v. GTT (mean AUC±SEM: WT: 2.47±0.16, bTRAF2: 1.96±0.15; n≥10; *P<0.05). Intriguingly, TRAF2 mRNA levels were reduced in WT islets isolated from high-fat diet fed mice versus islets from chow fed mice.
Conclusion: Thus, mice lacking TRAF2 in islets exhibit severe defects in glucose control and insulin secretion under a high fat feeding regimen and bTRAF2 islets exhibit a hyper-inflammatory profile. At the molecular level TRAF2 controls the cellular tempo of JNK and NF-κB activation and reigns in the non-canonical NF-κB pathway. Loss of this control circuit exacerbates diabetes suggesting that TRAF2 functions as a key protective factor in beta cells.

Delayed intervention with pyridoxamine improves metabolic and vascular function in high-fat diet-induced obese mice

O. Brouwers[1], K. Gaens[1], T. Miyata[2], B.J. Janssen[3], J.G.R. De Mey[3], C.D.A. Stehouwer[1], C.G. Schalkwijk[1]; [1]Internal Medicine, MUMC, Maastricht, Netherlands, [2]Centre of Translational and Advanced Research, Tohoku University, Sendai, Japan, [3]Pharmacology, MUMC, Maastricht, Netherlands.

Background and aims: The development of obesity is associated with insulin resistance and is accompanied by a cluster of risk factors for cardiovascular disease, including hypertension, dyslipidaemia, and inflammation. We and others previously demonstrated increased levels of inflammation, oxidative stress and glycation in obese visceral adipose tissue (VAT). Pyridoxamine (PM), one of the three natural forms of vitamin B6, has been identified as an anti-inflammatory, anti-oxidant and anti-glycating agent. The objective of the present study was to examine the effect of a delayed PM intervention on metabolic and vascular function in high-fat diet-induced obese mice.
Materials and methods: After a run-in period on low-fat diet (Research Diets D12450H), 12 week old male C57BL/6J mice were divided into two groups. The low-fat diet group (LFD, n=15) continued on the same diet, whereas the other group switched to a high-fat diet (D12451, HFD,n=30). After 6 weeks half of the mice fed the HFD group received PM (2 g/L) in their drinking water (HFD+PM, n=15). All mice were sacrificed 18 weeks later. Glucose tolerance (GT) and insulin sensitivity (IS) were measured with glucose or insulin IP injections. Metabolic variables were measured by ELISA and colorimetric assays. Adipose inflammation was addressed with qPCR and immunohistochemistry. Vascular reactivity of aortic ring segments was measured *ex vivo* with wire myography.
Results: Bodyweight (28.2±0.4 gram), plasma glucose (10.4±0.3 mM) and plasma cholesterol (2.4±0.1 mM) were significantly (p<0.001) increased after 6 weeks of HFD compared with the LFD group (25.3±0.3, 8.0±0.4, and 1.8±0.1 respectively). Supplementation of PM, during the subsequent 18 weeks of HFD, attenuated the bodyweight gain (32.2±1 versus 37.5±2 gram), hyperglycaemia (8.1±2 versus 9.1±1 mM) and hypercholesterolemia (3.0±0.4 versus 4.2±0.3 mM) (for all, p<0.05). Furthermore also plasma insulin (1.1±0.2 ng/mL) and leptin levels (12.7±3.1 ng/mL) were significantly (p<0.05) lower in the PM supplemented group compared to the HFD untreated group (2.4±0.4 and 54.4±18 ng/mL, respectively). The decrease in GT and IS (AUC 2263±142 and 750±72 units, p<0.05) observed in the HFD group compared with the LFD group (1566±74 and 541±24) was improved by PM supplementation (1800±108 and 672±38, p<0.05). Intra-arterial diastolic (72±2 mmHg) and systolic blood pressure (100±1 mmHg) were mildly increased in the HFD group compared with the LFD group (68±2 and 93±4 respectively), and tended to be decreased in the HFD+PM group (70±1 and 97±1 respectively). Furthermore, the VAT had a pro-inflammatory profile as indicated by the significant up-regulation of MCP-1, TNFα, leptin, CD11c and MHC-II mRNA levels, and down-regulation of adiponectin compared to the LFD group (for all, p<0.05). PM supplementation significantly (p<0.05) prevented these changes in mRNA levels. Finally, myograph experiments showed an improvement in NO-independent aortic relaxation in the HFD+PM group compared with the HFD group (p<0.05).

Conclusion: Our study shows that a delayed intervention with PM is associated with improvement of several aspects of obesity including insulin resistance, adipose inflammation, and of aortic dysfunction in high-fat diet-induced obese mice.

IL-37 protects against obesity-induced inflammation and insulin resistance
D.B. Ballak[1], J.A. van Diepen[1], A.R. Moschen[2], H.J. Jansen[1], A. Hijmans[1], G.-J. Groenhof[1], P. Bufler[3], S. Kersten[4], L.A.B. Joosten[1], H. Tilg[2], C.A. Dinarello[5], M.G. Netea[1], C.J. Tack[1], R. Stienstra[1,4];
[1]General Internal Medicine, Radboud University Medical Centre, Nijmegen, Netherlands, [2]Medical University Innsbruck, Austria, [3]Children's Hospital, Ludwig-Maximilians University, Munich, Germany, [4]Department of Human Nutrition, Wageningen University, Netherlands, [5]Deparment of Medicine, University of Colorado Denver, Aurora, USA.

Background and aims: Cytokines of the IL-1 family are important modulators of obesity-induced adipose tissue inflammation with the subsequent development of systemic insulin resistance. Here, we report that IL-37, the anti-inflammatory member of the IL-1 family, plays an important role in obesity-induced inflammation and insulin resistance, in both mice and human.
Materials and methods: A high-fat-diet intervention study was performed in human IL-37-transgenic mice (hIL-37tg-mice). Furthermore, *in vitro* IL-37 silencing experiments were performed in HEPG2 cells. Lastly, adipose tissue biopsies were taken from healthy lean and obese persons.
Results: IL-37 transgenic mice (IL-37tg) did not develop an obese phenotype in response to a high-fat-diet (HFD). Unlike WT mice, IL-37tg mice exhibited reduced numbers of adipose tissue macrophages and preserved glucose tolerance and insulin sensitivity when subjected to 16 weeks of HFD. A short-term HFD intervention also revealed that the IL-37-mediated improvement in glucose tolerance is independent of bodyweight differences. Moreover, IL-37tg mice manifested a beneficial metabolic profile with higher circulating levels of the anti-inflammatory adipokine adiponectin. Additionally, *in vitro* data show that IL-37 protects insulin signalling. Importantly, in human subjects with varying levels of obesity, steady-state IL-37 adipose tissue mRNA levels were positively correlated with insulin sensitivity, with lower adipose tissue levels of leptin and with a lower inflammatory status of the adipose tissue.
Conclusion: These findings reveal IL-37 as an important anti-inflammatory modulator during obesity-induced inflammation and insulin resistance in both mice and humans and suggest IL-37 as a potential target to tackle obesity-induced insulin resistance and type 2 diabetes.

Fas (CD95) expression in myeloid cells promotes obesity-induced muscle insulin resistance
S. Wueest[1,2], R. Mueller[3], M. Blüher[4], F. Item[1,2], A.S.H. Chin[1,2], M. Wiedemann[1,2], H. Takizawa[3], L. Kovtonyuk[3], A.V. Chervonsky[5], E.J. Schoenle[1,2], M.G. Manz[3], D. Konrad[1,2];
[1]Endocrinology/Diabetology University Children's Hospital Zurich, [2]Children's Research Center, University Children's Hospital, Zurich, [3]Department of Hematology, University Hospital Zurich, Switzerland, [4]University of Leipzig, Department of Internal Medicine, Leipzig, Germany, [5]Department of Pathology, University of Chicago, USA.

Background and aims: Low grade inflammation in adipose tissue and liver has been implicated in obesity-associated insulin resistance and type 2 diabetes. Yet, the contribution of inflammatory cells to the pathogenesis of skeletal muscle insulin resistance remains elusive. The aim of this study was to investigate the contribution of Fas expression in myeloid cells to metabolic dysregulation in obesity.
Materials and methods: Glucose metabolism was determined in standard chow, high fat diet (HFD)-fed or LPS injected control and myeloid-cell specific Fas depleted mice on a C57Bl6/J or ob/ob background. In vitro, co-culture experiments with conditioned media from Fas-depleted RAW cells and L6 muscle cells, 3T3-L1 adipocytes or HepG2 liver cells were performed. In addition, monocytic Fas expression was analyzed in a large cohort of obese human individuals and correlated with insulin sensitivity and other metabolic parameters.
Results: Diet-induced obesity and LPS treatment increased Fas protein levels in myeloid cells. Consequently, myeloid specific Fas depletion (FasΔmye) prevented the development of glucose intolerance and skeletal muscle insulin resistance in high fat diet-fed (IS-GDR 34.3±3.2 mg/kg*min in control vs. 63.8±7.4 mg/kg*min in FasΔmye mice, $p<0.05$) in lipopolysaccharide (LPS)-treated C57Bl6/J mice (AUC ipGTT 1856±51 mmol*min in control vs. 1636±24 mmol*min in FasΔmye mice, $p<0.01$) as well as in ob/ob mice (IS-GDR -6.1±3.4 mg/kg*min in control vs. 3.0±1.3 mg/kg*min in FasΔmye mice, $p<0.05$). Mechanistically, Fas mediated LPS-induced TNFα production in myeloid cells promoting insulin resistance in skeletal muscle but not in adipose tissue and liver. Such muscle specific effect of myeloid-cell expressed Fas is confirmed in vitro. Conditioned medium from LPS-treated and Fas-depleted RAW cells (a mouse myeloid cell line) affected insulin sensitivity only in L6 muscle cells (insulin stimulated glucose uptake: 79.0±1.8% LPS-untreated (control) vs. 98.4±2.6% LPS-untreated (Fas-depleted), $p<0.01$) but not 3T3-L1 adipocytes or HepG2 liver cells. Importantly, in a large cohort of obese human individuals, monocytic Fas expression correlates with skeletal muscle insulin sensitivity ($r2=0.31$, $p<0.0001$) as well as serum LPS ($r2=0.2$, $p<0.0001$) and TNFα levels ($r2=0.06$, $p<0.0001$).
Conclusion: Our results reveal an important role for myeloid cell expressed Fas in mediating obesity-induced insulin resistance in skeletal muscle.

Angiopoietin like protein 2 (Angptl2) induced adipose tissue macrophage activation causes impaired glucose tolerance
Y. Sasaki, M. Ohta, D. Desai, T. Sugano, M. Yamabi, W. Yano, J. Matsumoto, K. Mizuno, K. Inoue, M. Aikawa;
Center for Interdisciplinary Cardiovascular Sciences, Brigham and Women's Hospital, Harvard Medical School, Boston, USA.

Background and aims: Obesity causes chronic low-grade inflammation which may contribute to systemic metabolic disorders including insulin resistance, type 2 diabetes, atherosclerosis and ischemic heart disease. Angiopoietin-like protein 2 (Angptl2) is a novel pro-inflammatory cytokine mainly secreted from adipose tissues as one adipokine. Serum concentration of Angptl2 increases in patients with obesity, type 2 diabetes, and cardiovascular disease. Elevated serum Angptl2 levels positively associated with the development of type 2 diabetes in a general Japanese population. Deletion of Angptl2 gene reduced inflammation of adipose tissues and ameliorated systemic insulin resistance in mice, although, the underlying mechanism is still unknown. This study aimed to explore the molecular mechanisms of Angptl2 on insulin sensitivity and identify macrophage activation as the key factor for the effects of Angptl2 in diabetic animal model.
Materials and methods: Adenovirus mediated lacZ (Ad-LacZ) or human Angptl2 (Ad-hAngptl2) was delivered via tail vain in 12 weeks old diabetic db/db mice. Oral glucose tolerance test was performed at 14 weeks old. We measured serum lipid, insulin and adipokine levels. We also examined gene expression of pro-inflammatory cytokines, lipogenesis, and glyconeogenesis related genes. Adipose tissue macrophages were isolated from epididymal fat pad and characterized by FACS analysis. We also prepared recombinant human Angptl2 (rhAngptl2) protein and treated on human endothelial cells and THP-1 monocytes /macropages, examined pro-inflammatory gene expression by quantitative PCR and TNF-α production by ELISA.
Results: Body weight, epididymal WAT and liver weight, total cholesterol, and liver cholesterol between Ad-LacZ and Ad-hAngptl2 did not differ. Fasting glucose level, liver triglyceride level, and liver glyconeogenesis related gene expression levels were greater in Ad-hAngptl2 treated mice. Also, Ad-hAngptl2 treated mice significantly impaired glucose tolerance compared to Ad-LacZ treated mice. FACS analysis on adipose tissue macrophages revealed that Ad-hAngptl2 treated mice significantly increased adipose tissue macrophage ($F4/80^+CD11b^+$) cell. Furthermore, M1 macrophage ($F4/80^+CD11b^+CD11c^+$) cells fraction significantly increased. We also investigated that rhAngptl2 protein treatment induced pro-inflammatory gene expression in human endothelial cells and THP-1 monocytes /macropages. Furthermore, rhAngptl2 protein treatment significantly increased humanTNF-α production in the conditioned media of PMA-treated THP-1 macrophages.
Conclusions: Ad-hAngptl2 treatment in db/db mice impaired glucose tolerance and increased not only adipose tissue macrophages but also pro-inflammatory M1 macrophages in adipose tissues. Angptl2 may play an important role in the development of adipose tissue inflammation and glucose intolerance by pro-inflammatory effect in peripheral tissues.

OP 21 Health economic aspects of diabetes: happy, healthy and prosperous

Impact of targeting intensive versus conventional glycaemic control on quality of life in patients with type 2 diabetes: a systematic review

B. Hemmingsen[1], C. Gluud[1], A. Vaag[2], T. Almdal[3], J. Wetterslev[1];
[1]Copenhagen Trial Unit, [2]Department of Endocrinology, Rigshospitalet, Copenhagen, [3]Department of Internal Medicine, Gentofte Hospital, Denmark.

Background and aims: Targeting intensive glycaemic control in patients with type 2 diabetes (T2D) demands extra efforts for the patients and increases the risk of hypoglycaemia. Possible benefits remain controversial. The present systematic review assesses the effects of targeting intensive versus conventional glycaemic control on physical and mental quality of life in patients with T2D.
Materials and methods: Randomised clinical trials (RCTs) were identified through searches of The Cochrane Library, MEDLINE, EMBASE, Science Citation Index Expanded, LILACS, and CINAHL. We included RCTs with a prespecified difference in glycaemic targets between intervention groups in adult patients with T2D. Two authors independently extracted data and additional information was obtained from authors of the included trials. We meta-analysed quality of life in two components: physical and mental quality of life. Meta-analyses were conducted applying the random-effects model. Due to the use of different scales in the included trials, meta-analyses were performed with standardised mean difference (SMD) and 95% confidence intervals (CI).
Results: Twenty-five RCTs including a total of 33467 patients, whereof ten trials reported health-related quality of life or well-being. The included trials were heterogeneous in design, inclusion criteria, and scales used to assess quality of life. Four of the trials reported the quality of life data in a way so they could not be applied in a meta-analysis. Six of the trials reported six different quality of life scales and evaluated quality of life in a total of 3996 patients. Three of the trials reported the 36-Item Short Form Health Survey scale or a modified version. The physical component of quality of life did not show any statistical significance between the interventions when meta-analysed with change from baseline (SMD 0.01, 95% CI -0.32 to 0.34) or with the end of follow-up values (SMD 0.00, 95% CI -0.07 to 0.07; Fig 1). The mental component of quality of life showed no statistical significance between targeting intensive versus conventional glycaemic control when meta-analysed as change from baseline (SMD 0.12, 95% CI -0.10 to 0.35) or at the end of follow-up (SMD -0.09, 95% CI -0.19 to 0.01).
Conclusion: Targeting intensive glycaemic control does not seem to influence physical or mental quality of life. Uniform reporting of quality of life in patients with T2D is recommended in future RCTs.

Long term consequences on annual earnings after childhood onset of type 1 diabetes

I. Lovén[1], K. Steen Carlsson[2], for the Swedish Childhood Diabetes Study Group;
[1]Department of Economics, Lund University, Lund, [2]Department of Clinical Sciences, Lund University, Malmö, Sweden.

Background and aims: Results from the Swedish Childhood Diabetes Register Study group have shown that onset of type 1 diabetes during childhood (ages 0-14) was associated with lower grades from compulsory and upper secondary education. Also, a detrimental effect on annual earnings has been found for people with onset of type 1 diabetes in young adulthood (age 15-34). Socioeconomic consequences of disease may vary or even accumulate over time. This study investigates long term consequences on earnings of childhood onset (ages 6-15) using two control groups 1) siblings; and 2) population controls matched for year of birth and municipality of residence.
Materials and methods: Covering the period 1990-2010, annual education and earnings data from national population registers was added to individuals from the Swedish Childhood Diabetes Register. We retrieved data on 1,381 individuals, born in 1962-1971 and diagnosed with type 1 diabetes in ages 6-15, together with data on 1,205 siblings to the individuals with diabetes, and 5,554 general population controls matched by year of birth and residence at the time of diagnosis. The development of annual earnings was analysed using Mann-Whitney tests at 5-year intervals from young adulthood into middle age (20-40 years) and using fixed-effects panel data methods. People with type 1 diabetes were compared to both siblings (with same socioeconomic status but different year of birth) and general population controls (with same year of birth but any socioeconomic status). All analyses were based on year 2007 standardised earnings calculated using the consumer price index from Statistics Sweden.
Results: The development of median earnings in ages 20-40 showed a lag in earnings for the diabetes group compared to siblings and population controls (Figure 1). Comparing median earnings at certain ages, the diabetes group had higher earnings than the population controls at age 20 ($p<0.001$) but lower from age 35 and onwards ($p<0.001$). Compared to siblings, the diabetes group had higher earnings at age 20 ($p<0.001$) but lower at age 40 ($p<0.001$). At age 40, the median annual earnings in the diabetes group was EUR 2,402 and EUR 2,860 lower than for siblings and population controls. Controlling for diabetes duration, education, demographics, and fixed effects, crude regression results confirmed an increasingly negative impact on earnings for people with diabetes compared to both siblings and population controls.
Conclusion: The significant effect of type 1 diabetes on earnings was in line with previous associations found between diabetes and earnings. The seemingly accumulative effect was seen irrespective of choice of comparator group and appeared to increase by age and duration of diabetes. Figure 1: Median annual earnings at 20, 25, 30, 35, and 40 years of age for people with type 1 diabetes onset in ages 6-15 years (D) compared to siblings (S) and population age-matched controls (C).

Health-related quality of life in adults with and without type 2 diabetes: results of a pooled analysis of German population-based cohort studies

M. Schunk[1], P. Reitmeir[1], C. Meisinger[2], A. Kluttig[3], S. Hartwig[3], S. Schipf[4], H. Völzke[4,5], A. Peters[2], R. Holle[1];
[1]Institute of Health Economics and Health Care Management, Helmholtz Zentrum München, [2]Institute of Epidemiology II, Helmholtz Zentrum München, Neuherberg, [3]Institute of Medical Epidemiology, Biostatistics and Informatics, Martin-Luther-University Halle-Wittenberg, Halle, [4]Institute for Community Medicine, University Medicine Greifswald, [5]German Center of Cardiovascular Research, Greifswald, Germany.

Background and aims: Population-based data concerning health related quality of life (HRQL) in type 2 diabetes (T2DM) are essential for health economic decision models to estimate disease burden. Results presented here analyse longitudinal individual-level data from three population-based cohort studies in Germany (KORA, SHIP, CARLA). By comparing persons with prevalent T2DM to persons with normal glucose metabolism as well as incident T2DM cases, we evaluated change in HRQL over a period of up to 14 years.
Materials and methods: This study is part of the DIAB-CORE (Economic and Health Care Research in Type 2 Diabetes) research project, drawing on a data pool of population-based studies in Germany. T2DM is defined based on self-report of physician-diagnosed diabetes or self-reported intake of oral anti-diabetic agents. HRQL was assessed by the German version of the SF12/36 (version 1). Data were pooled and SF-12 composite scores for physical and mental health (PCS, MCS) were calculated. Linear regression modeling was used to describe differences in absolute change in PCS/MCS scores per observation year between persons with prevalent T2DM, incident T2DM cases and non-diabetics, adjusted for age, sex and study region.
Results: A total of 3,739 persons aged 45-74 years had completed the SF-12 at baseline and at follow-up. Of those, 6.9% reported T2DM at baseline and 14.1 % at follow-up. Mean follow-up time was 7.3 years. The decline in HRQL was more pronounced in older age. Furthermore, the results showed a more pronounced decrease of 0.35 points per year (95% CI: 0.54; 0.16) on the PCS scale for the prevalent T2DM cases and of 0.18 points (95% CI: 0.37; 0.01) for incident cases compared to persons without T2DM. On the MCS scale, the prevalent T2DM cases showed an additional loss of 0.45 points per year (95% CI: 0.67; 0.23) against persons without T2DM and of 0.39 points (95% CI: 0.69; 0.10) against incident T2DM cases.
Conclusion: Our results provide evidence of the impact of T2DM on HRQL over 7 years on average in a large population-based sample. Using longitudinal data, we can show that the gap in HRQL between persons with and without T2DM which has been reported previously in cross-sectional analysis becomes even more apparent. Population-based surveys and longitudinal cohorts provide important data to estimate the incremental burden of diabetes.

Impact of T2DM on change in HRQL

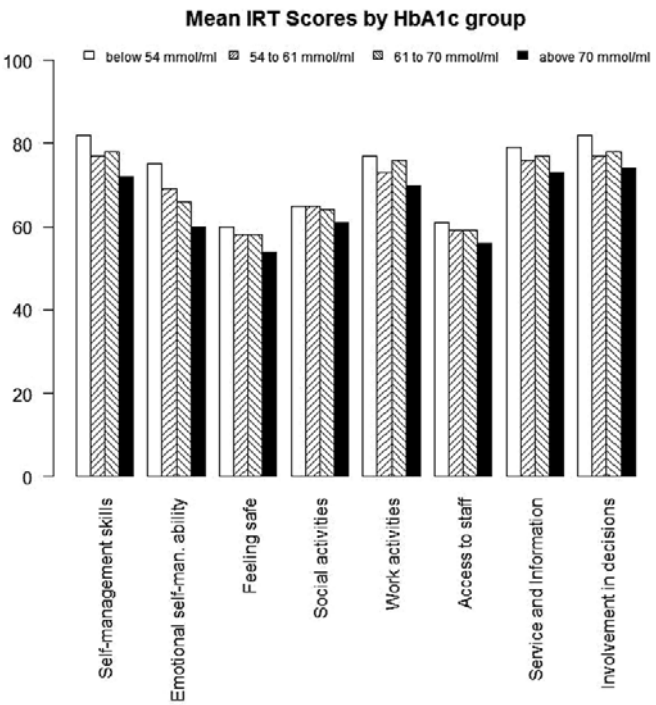
Diabetes care from the patient's perspective: combining risk factors with patient reported outcomes measures and capabilities in the national diabetes registry in Sweden

B. Palaszewski[1], S. Borg[2,3], U.-G. Gerdtham[4,3], S. Gudbjörnsdottir[1,5];
[1]The National Diabetes Registry, Gothenburg, [2]The Swedish Institute for Health Economics, Lund, [3]Faculty of Medicine, Lund University, Lund, [4]The Swedish Institute for Health Economics, Lund, Department of Economics, Lund University, Lund, [5]Sahlgrenska University Hospital, University of Gothenburg, Sweden.

Background and aims: Diabetes demands patients to be engaged in their disease and its treatment. However, the patient perspective is often missing when Diabetes care is evaluated. To better evaluate Diabetes care, we have taken on the patient perspective inspired by the Capability Approach. A person's capability is the set of things possible for the person to achieve. Functioning is what is actually achieved. HbA1c, BP and LDL are risk factors for diabetes related comorbidities, that we let represent the perspective of healthcare. We believe it is important to develop Diabetes care according to both perspectives. Our aim was to measure patient capabilities and functionings, and judgment of quality of provided care, and use these together with risk factors to evaluate the patient's health. Furthermore, to identify any differences between the perspectives of the patient, and healthcare.
Material and methods: We used patient reported outcomes measures (PROM) collected by a questionnaire developed by NDR, and Item Response Theory (IRT) to estimate values (IRT Scores) on capabilities, functionings and judgments. Risk factors were extracted and deterministically linked with the IRT Scores on the individual patient level. The analysis included 1 124 type 1, and 1 792 type 2 patients. Another 1 656 type 1 and 1 431 type 2 patients were used for validation.
Results: We obtained measures of capabilities and functionings: Self-management skills, Emotional self-management ability, Feeling safe, Ability to carry out Social and Work activities, and judgments: Access to staff, Service and information, and Involvement in decisions. For each of those, an IRT scale was successfully developed, validated, and used for estimating IRT Scores. The questionnaire was able to detect patients with poor health-related quality of life (HRQOL) according to EQ-5D. They reported significantly lower IRT scores than the examined population overall. In Type 1 and 2 Diabetes, increased HbA1c was associated with lower IRT scores in all dimensions. No such patterns were seen for BP or LDL. Neither patients with poor BP control, nor with poor LDL control, reported significantly lower IRT Scores in any dimensions. Patients with poor HbA1c control reported significantly lower Self-management skills. The risk factors could not be used to detect poor HRQOL according to EQ-5D.



Conclusion: We found that the patient perspective, i.e. capabilities, functionings, and judgments, differs from the perspective of healthcare, i.e. risk factors. Knowledge of both types of data is required in order to optimize the patient's HRQOL and to avoid diabetes related comorbidities.

Factors associated with self-rated health quality in patients with diabetes mellitus

O. Rácz[1], M. Linková[2], L. Cislakova[2], P. Takac[3], K. Jakubowski[4];
[1]Pathological Physiology, Safarik University Kosice, [2]Public Health, Safarik University Kosice, [3]Rehabilitation and Spa Medicine, Safarik University Kosice, Slovakia, [4]Jan Grodek State Vocational Academy, Sanok, Poland.

Background and aims: Self-rated health (SRH) is a powerful predictor for a number of important health outcomes, such as mortality, morbidity or utilisation of healthcare services. The tool has good psychometric properties, monitors broad spectrum of factors, reflects overall feeling of health in people, and could be easily obtained. Health-related quality-of-life and self-rated health may also provide additional information on patient risk independent of clinical and biochemical risk factors for invalidity and mortality. The aim of this study was to investigate differences in determinants of self-rated health between patients with type 1 and 2 diabetes mellitus (T1DM/T2DM).
Materials and methods: The study involved of 188 patients; 43 patients with T1DM (mean age 45,2 years, mean duration of diabetes 17,1 years) and 145 patients with T2DM (mean age 59,2 years, mean duration of diabetes 11,7 years). The analysis was based on self-rated health questionnaire Short Form 36 Health Subject Questionnaire, (SF-36), self-esteem was measured using the Rosenberg's Self-Esteem Scale (RSES) and overall life satisfaction was measured by the Cantrill's ladder of life. The study was approved by the Ethical Committee of the University.
Results: In the group of patients with T1DM we found a significant positive association between self-rated health and age ($r = 0,62$, $p < 0,05$). Negative associations were found between SRH and two clinical variables (duration of diabetes, $r = -0,45$, $p < 0.05$ and the number of microvascular complications $r = -0,54$, $p < 0,05$). Low SRH was also associated with the presence of hypertension and coronary heart disease. The self-rated health was significantly positively associated with psychological variables (satisfaction with treatment; $r = 0,57$, $p < 0,05$ and Cantrill´s ladder; $r = 0,74$, $p < 0,05$), too. We did not find any association between SRH and the frequency of hypoglycaemic episodes. In the group of T2DM patients we found weaker but significant negative associations between self-rated health and the duration of diabetes ($r = -0,22$, $p < 0,05$), BMI ($r = -0,20$, $p < 0,05$) and the number of complications ($r = -0,40$, $p < 0,05$). Low SRH was significantly associated with the presence of hypertension ($r = 0,23$, $p < 0,05$). Patients on insulin revealed lower SRH as compared with those on diet or oral drugs. The associations with Rosenberg Self-Esteem Scale and Cantrill´s ladder were similar as in T1DM ($r = 0,45$, $p < 0,05$ and $r = 0,44$, $p < 0,05$ respectively) Regular control of body weight was also associated with better SHR ($r = 0,17$, $p < 0,05$).
Conclusion: The study revealed the importance of subjective attitude of patients to their disease and a close interrelationship between clinical symptoms of illness and its psychological aspects. One should also bear in mind that T1DM and T2DM are different diseases from the point of view of their pathogenesis and early manifestation. However later in the course of disease the influence of complications on their quality of life is similar. From the aspect of everyday diabetes care the subjective dimension of this chronic disease is as important as the clinical symptoms and the results of laboratory investigations

Psychometric properties of the hypoglycaemia perspectives questionnaire (HPQ) in type 2 diabetes mellitus

A.K. Kawata[1], S.H. Ong[2], C. Therapontos[3], P. Mavrogenis[3], K. Kulich[2], W.-H. Chen[1], K. Coyne[1];
[1]United BioSource Corporation, Bethesda, USA, [2]Novartis Pharma AG, Basel, Switzerland, [3]Novartis Pharma Services Inc., Nicosia, Cyprus.

Background and aims: The Hypoglycemia Perspectives Questionnaire (HPQ) was developed with clinician and patient input to assess symptoms, behaviors, and impact of hypoglycemia on diabetic patients.
Materials and methods: The HPQ was administered to adult patients with type 2 diabetes mellitus (T2DM) on antidiabetic treatment as part of a cross-sectional, epidemiological study evaluating hypoglycemia and health-related quality of life (HRQoL) in Cyprus. Demographic and clinical data were collected. Patients also completed the Audit of Diabetes Dependent Quality of Life (ADDQoL-19), treatment satisfaction questionnaire, and EuroQol-5 Dimensions (EQ-5D). The original HPQ consisted of 45 items rating current status or behavior related to hypoglycemia on an 11-point numeric rating scale (NRS) and 7 additional descriptive hypoglycemia event frequency items. Analyses included examination of HPQ item performance, item reduction, and factor structure. Measurement properties (reliability, construct validity, known-groups validity) of the final HPQ were evaluated.
Results: 500 T2DM patients completed the HPQ with a mean age of 61±10 years; 32.6% women. Based on item evaluation, the original HPQ item pool was reduced to 22 items. Exploratory and confirmatory factor analysis identified 21 items contributing to 3 hypoglycemia domains (Symptoms [8 items], Compensatory Behaviors [7 items], Worry [6 items]) and a single-item of global symptom awareness. HPQ domains had high internal consistency reliability (Cronbach's alpha=0.78-0.92). Construct validity was demonstrated by significant correlations between HPQ scores with HRQoL, treatment satisfaction, and health status. HPQ also demonstrated ability to discriminate between known groups. Compensatory behaviors and symptom awareness were higher for patients with a recent low blood sugar event ($p<0.001$) and high symptom awareness corresponded to less concern about experiencing symptoms of low blood sugar and worry ($p<0.05$).
Conclusion: These results provide preliminary evidence that HPQ is reliable and valid for assessing the experience and impact of hypoglycemia on T2DM patients.

Intensified LDL-c target of statin therapy and risk of incident diabetes: meta-analysis of randomised statin trials

R. Cai, Y. Zhou, Y. Yang, H. Sun, W. Xia, P. Wang, Y. Huang, S. Wang;
AffiliatedZhongDa Hospital of Southeast University, Nanjing, China.

Background and aims: Intensified low-density lipoprotein cholesterol (LDL-c) goal may provide greater cardiovascular benefits. However, findings suggest that statin therapy increase the development of new-onset diabetes. We aimed to identify whether relationship exists between intensified LDL-c target goal of statin use and development of diabetes by doing a meta-analysis of large randomized controlled trials.
Materials and methods: We searched Pubmed, Embase and the Cochrane Central Register of Controlled Trials, no time limited, for randomized controlled endpoint trials of statins. We included only trials which recruited at least 1000 participants with scheduled treatment duration of at least 2 years. We excluded trials don't meet intensified target goal level of LDL-c <2.59mmol/L (100 mg/dl), or relative LDL-c reduction at least 30% of baseline in statin group. We used the I^2 statistic to measure heterogeneity between trials and calculated an overall OR with a fixed-effects model meta-analysis to identify potential effects of intensified LDL-c target of statin therapy on incident diabetes.
Results: Among 60287 participants, 2994 patients (1613 assigned to statins and 1381 assigned to placebo) developed diabetes during a mean of 4 years. Intensified LDL-c target of statin therapy was associated with an 18% increased risk for diabetes (odds ratio [OR] 1.19; 95% CI 1.10-1.28), with little heterogeneity (I^2=0.0%) between trials. There was one additional case of diabetes per 130 patients taking statin therapy for 4 years. Fail-safe number was 53(P=0.05), funnel plot was basically symmetrical and all scattered inside 95%CI (p=0.557 in egger test) in this meta-analysis.
Conclusion: Intensified compared to general LDL-c target of statin therapy increases risk of incident diabetes. Although intensified LDL-c target practice in patients with cardiovascular risk or existing cardiovascular disease should not change, blood glucose monitoring is suggested to watch out for incident diabetes.

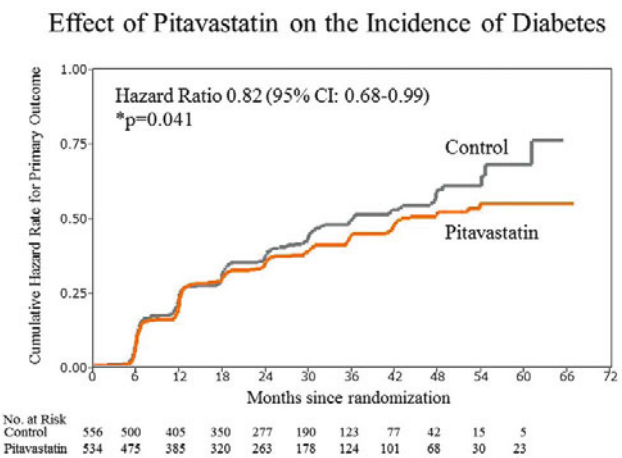
Effect of pitavastatin on the incidence of diabetes in Japanese individuals with impaired glucose tolerance

M. Odawara[1], T. Yamazaki[2], J. Kishimoto[3], C. Ito[4], M. Noda[5], Y. Terauchi[6], T. Shiba[7], H. Kitazato[8], K. Maemura[9], K. Tobe[10], Y. Iwamoto[11], Y. Akanuma[12], T. Kadowaki[13], the J-PREDICT study investigators;
[1]Tokyo Medical University, [2]The University of Tokyo Hospital, [3]Kyushu University Hospital, Fukuoka, [4]Grand Tower Medical Court, Hiroshima, [5]National Center for Global Health and Medicine, Tokyo, [6]Yokohama City University Graduate School of Medicine, Kanagawa, [7]Toho University Ohashi Medical Center, Tokyo, [8]Omori Red Cross Hospital, Tokyo, [9]Nagasaki University Graduate School of Biomedical Sciences, [10]University of Toyama, [11]Tokyo Women's Medical University, [12]The Institute for Adult Diseases, Asahi Life Foundation, Tokyo, [13]The University of Tokyo, Japan.

Background and aims: Although statin therapy is known to reduce cardiovascular risk, trial data and meta-analyses suggest that statins may also increase the risk of development of diabetes. However, in those trials, data were analyzed retrospectively, and the diagnostic criteria of diabetes differed. Accordingly, we performed the Japan Prevention Trial of Diabetes by Pitavastatin in Patients with Impaired Glucose Tolerance (J-PREDICT) study, to evaluate the effect of pitavastatin on the incidence of diabetes using a prospective study design.
Materials and methods: In a multicenter, open-label, randomized controlled trial, 1,269 individuals with impaired glucose tolerance (IGT) were randomized to either the pitavastatin group (lifestyle modification and pitavastatin [1-2 mg/day]) or the control group (lifestyle modification only). Every six months, a 75-gram oral glucose tolerance test was performed with other standard laboratory tests. The primary outcome was the incidence of diabetes mellitus, as determined by a 2-h plasma glucose ≥200 mg/dl or a fasting plasma glucose ≥126 mg/dl measured at least once.
Results: The diabetes incidence rates for the pitavastatin and control groups were 163 and 186 cases per 1,000 person-years, respectively; the hazard ratio for progression from IGT to diabetes in the pitavastatin group was 0.82 (95% CI: 0.68-0.99; P = 0.041). Analyses of patients stratified by hypertension status suggested heterogeneity in the treatment effect, with a benefit for patients without hypertension and no benefit or hazard in patients with hypertension (P = 0.01 for interaction). Even in any subgroups, pitavastatin did not accelerate the incidence, unlike the effects of statins in previous reports.
Conclusion: Pitavastatin in combination with lifestyle modification was associated with a lower incidence of diabetes than was lifestyle modification alone in Japanese patients with IGT. Statins are now used with the understanding that a slightly increased risk of diabetes is outweighed by cardiovascular benefits of the drugs. However, based on our results, it may be necessary to reconsider whether all statins really increase the risk of developing diabetes.



*P value was calculated using a log-rank test that was stratified according to the 5 assignment factors (sex, age, Body mass index, 2-h plasma glucose, and presence of hypertension).

Serum lipidomic profiling identifies biomarkers associated with progression to type 2 diabetes in the METSIM study

L. Yetukuri[1], H. Cederberg[2], M. Sysi-Aho[1], T. Hyötyläinen[1], M. Laakso[2], M. Orešič[1];
[1]VTT Technical Research Centre of Finland, Espoo, [2]University of Eastern Finland and Kuopio University Hospital, Kuopio, Finland.

Background and aims: Traditional serum lipid markers are of limited clinical utility as predictors of progression to type 2 diabetes (T2D). Better tools are needed for early detection of T2D in order to prevent the disease and its co-morbidities. Here we applied global lipidomics in a prospective study setting, with the objective of identifying novel predictive markers of progression to T2D

Materials and methods: Age-matched cases (N=110; mean age ± SE = 59.21 ± 0.55) and controls (N=220; mean age ± SE = 59.92 ± 0.36) were selected from the METSIM (Metabolic Syndrome in Men) observational study. All subjects were male and non-diabetic by both OGTT and HbA1c criteria at baseline. Case subjects were diagnosed with T2D within the 5 year follow-up period and displayed this glycemic profile at baseline: 45% IFG, 7% IGT, and 38% combined IFG/IGT. Control subjects displayed normal fasting glucose, normal glucose tolerance, and HbA1c <6.5% both at baseline and at the 5-year follow-up. Lipidomic analyses of plasma samples at baseline and follow-up were performed using ultra performance liquid chromatography coupled with time-of-flight mass spectrometry

Results: Cases and controls had very distinct lipidomic profiles at baseline as well as at follow-up. Univariate association of each lipid with T2D as assessed from logistic regression analysis after adjusting for age, BMI, blood pressure, HDL-C and LDL-C revealed that 196 out of 337 molecular lipids were significantly different between cases and controls at baseline (FDR q<0.05). Interestingly, the distinct pre-diabetic lipidomic profile remained similar, although more pronounced, after the diagnosis of progression to T2D. Progression to T2D was associated with increased triglycerides, particularly those with lower double bond and carbon content, and specific diacyl phospholipids, as well as with decreased lysophosphatidylcholine (with the most significant being LPC (18:2)). In order to develop predictive model of progression to T2D based on baseline lipidomics as well as other available clinical data, we applied stepwise multivariate logistic regression. The lipid-based model predicted T2D with AUC = 0.86, 95% CI = (0.80, 0.92), which was better than FINnish Diabetes RIsk SCore (FINDRISC) alone (AUC = 0.81, 95% CI = (0.73, 0.86)). Combining the lipid-based model with the FINDRISC significantly improved the predictive model as compared to FINDRISC alone (AUC = 0.88, 95% CI = (0.82, 0.94)).

Conclusion: We have identified molecular lipids which are associated with progression to T2D. Elevation of triglycerides with lower double bond and carbon content replicates earlier findings and highlights the potential role of fatty liver in pre-diabetes. A candidate biomarker panel has been developed which predicts T2D.

Serum lipid levels, fat storage and obesity are related to T2D risk through shared biochemical pathways and can be influenced by common genetic factors. Analysis of the genetic effects on multiple phenotypes simultaneously allows dissection of multi-trait associations. Within the ENGAGE consortium, we assessed multi-trait genetic effects on four blood lipids (high-/low-density lipoprotein and total cholesterol, triglycerides [HDL/LDL/TC/TG]) and body-mass index (BMI). The 1000 Genomes reference panel (06/2011) was used for imputation in up to 41,752 individuals from 18 European GWAS. Each study carried out multi-trait analysis by fitting a multiple logistic regression on SNP genotypes allowing for joint effects of four lipid traits and BMI and combining evidence across study-specific likelihoods. Single-trait meta-analyses, conditional on remaining traits, were used to verify the independence of trait-specific genetic effects. Joint analysis enabled identification of 26 signals with genome-wide significant (P_{LRT}<5.0x10^{-8}) multi-trait effects. At 9 loci associations were driven by the individual trait effects: a) *TRIB1* on BMI, b) *GCKR*, *FADS1*, *MLXIPL* on TG; c) *CEPT* on BMI/HDL, d) *LPL, APOA1* on BMI/TG; e) *LIPC* on HDL/TG, f) *APOE* on HDL/LDL/TG. At *TRIB1*, *CEPT*, *LPL*, *APOA1* where association with obesity was identified for the first time, higher BMI was related to higher HDL and lower TG indicating complex relationships between obesity and regulation of lipid levels. Effects on lipids at *CELSR2, ABCA1*, *HNF4A*, *MADD*, *PPP1R3B* and *RANB10* were determined by the association with HDL. At the remaining 11 loci, multiple traits contributed to the signal. We detected a substantial proportion of T2D-related metabolic trait loci with complex patterns of genetic effects, some of which may not follow epidemiological correlations.

Large-scale genome-wide association meta-analysis of the 1000 genomes project imputed data identifies novel susceptibility loci for glycaemic and obesity traits

M. Horikoshi[1], R. Mägi[2], I. Surakka[3], A.-P. Sarin[3], A. Mahajan[1], L. Marullo[4], T. Ferreira[1], T. Esko[2,5], C.M. Lindgren[5,1], A.P. Morris[1], M.I. McCarthy[1,6], S. Ripatti[3,7], I. Prokopenko[8], ENGAGE Consortium;
[1]Wellcome Trust Centre for Human Genetics, University of Oxford, UK, [2]Estonian Genome Center, University of Tartu, Estonia, [3]FIMM, University of Helsinki, Finland, [4]University of Ferrara, Italy, [5]Broad Institute, Cambridge, USA, [6]OCDEM, University of Oxford, [7]Wellocme Trust Sanger Institute, Hinxton, [8]Imperial College London, UK.

Background and aims: Genome-wide association studies (GWAS) have detected numerous associations with quantitative glycemic and obesity-related traits: only ~10-12% and 3.2-4.4% of phenotypic variance, respectively, been explained mainly by common variants (minor allele frequency, MAF >5%). To extend detection of novel association signals, especially to variants of lower frequency, we performed fixed-effects meta-analysis of GWAS data

following imputation using the 1000 Genomes Project reference panel (June 2011 release).
Materials and methods: These analyses included up to 12.7 million SNPs and were performed in up to 18 European GWAS for the following traits: fasting glucose (FG, n=46,694), fasting insulin (FI, n=24,245), body-mass-index (BMI, n=87,048) and waist-to-hip ratio adjusted for BMI (WHR, n=54,572). Both sex-combined and sex-differentiated analyses were conducted for each trait. To find independent signals at a given locus, we used approximate conditional analyses methods applied to summary-level association data.
Results: We identified novel loci reaching genome-wide significance for FG (1 locus near RMST, $p=2.0x10^{-10}$, MAF=0.10) and BMI (5 loci near GALNT10, DTX2P1, GRID1, EPYC and AKAP6; $p<4.5x10^{-8}$, MAF=0.07~0.49). We additionally detected a novel, low-frequency, female-specific FG signal near EMID2 (rs6947345, MAF=0.02, female β=0.16, $p=3.8x10^{-8}$, male β=-0.02, p=0.50, sex-differentiated $p=2.1x10^{-7}$, sex-heterogeneity $p=3.7x10^{-5}$). Through approximate conditional analysis within known GWAS loci, we identified a novel low-frequency FG-associated variant independent of the lead SNP at G6PC2 (rs150171632, MAF=0.012, β=0.18, $p=3.0x10^{-19}$, conditional $p=1.7x10^{-21}$). At the known GWAS signal for WHR near RSPO3, we detected a novel independent lead signal with stronger association and larger effect size than the previously reported signal (rs72959041, MAF=0.08, β=0.11, $p=1.7x10^{-13}$, conditional $p=9.8x10^{-11}$ vs. previous lead rs9491696, MAF=0.49, β=0.04, $p=2.1x10^{-11}$, conditional $p=1.2x10^{-8}$).
Conclusion: Our results highlight the potential advantages of imputation using the high-density reference panels for the identification of novel associated signals for both common and low frequency variants for quantitative metabolic traits.

DNA methylation changes influence type 2 diabetes
M.A. Carless, H. Kulkarni, M.C. Mahaney, H.H.H. Göring, J.E. Curran, L. Almasy, A.G. Comuzzie, J. Blangero;
Texas Biomedical Research Institute, San Antonio, USA.

Background and aims: Type 2 diabetes (T2D) is a global epidemic, becoming increasingly prevalent due to a rising incidence of obesity caused primarily by poor diet and lack of physical activity. The incidence of T2D is particularly high in Mexican American individuals and although disease development is well known to be genetically regulated, implicated loci explain only a small portion of the genetic liability. Epigenetic regulation, such as DNA methylation, is a novel mechanism that may lead to gene dysfunction and disease development. However, to date, no studies have investigated genome-wide DNA methylation changes associated with diabetes in a large population.
Materials and methods: Using Illumina HumanMethylation450 BeadChips, we performed genome-wide DNA methylation profiling of >450,000 CpG sites in peripheral blood cells from 950 Mexican American individuals from ~40 large pedigrees. For each individual, we have an array of phenotypic data relating to T2D (disease status, medication usage, fasting glucose, fasting insulin), obesity, dyslipidemia and cardiovascular disease. DNA methylation data was normalized using inbuilt controls on the arrays, BMIQ normalization to reduce technical variance and inverse normalization to correct for residual deviation from normality. Using SOLAR, we tested for heritability of each CpG site, and for association with T2D status and fasting glucose (in non-diabetic samples only). Age, age2, sex, age x sex interactions, BeadChip number and BeadChip position were incorporated as covariates. We used the Bonferroni method to correct for multiple comparisons.
Results: Of the 471,142 CpG sites that were assessed for heritability, we identified 111,600 statistically significant associations (24%; p<1.06x10-7). Of the 482,421 CpG sites that were assessed for association with T2D, we identified 12 statistically significant associations (p<1.04x10-7). The top association was for a CpG site in the *TXNIP* gene (beta=-0.51, p=5.57x10-18). Txnip is known to modulate glucose metabolism and insulin sensitivity, likely playing a role in T2D and possibly contributing to the therapeutic action of metformin. We also identified a significant association between diabetes and *ABCG1* (beta=0.39, p=5.45x10-12), which is involved in reverse cholesterol transport. Mouse knockout studies implicate ABCG1 in insulin secretion and glucose tolerance. Significant associations between DNA methylation and T2D status were also seen in other genes previously implicated in diabetes, including *CPT1A* (beta=-0.35, p=5.92x10-10) and *DHCR24* (beta=-0.33, p=7.66x10-9), as well as in potentially novel genes. Most of these genes were also at least nominally significantly associated with fasting glucose in the non-diabetic portion of our dataset (n=745). In a subset of the population (n=250) we have DNA methylation profiles and phenotypic data available at two time points, approximately 5 years apart. We are currently analyzing this data to determine whether DNA methylation changes over time influence fasting glucose levels and the evolution of diabetes.
Conclusion: Our study has identified a number of genes that show DNA methylation changes associated with T2D in a Mexican American population. We are currently conducting pyrosequencing studies to validate these findings. We show here that DNA methylation profiling is a powerful means to identify genes involved in T2D, which may ultimately aid in the development of targeted therapeutics for diabetic treatment.

MicroRNA profiling of impaired CD4+ T regulatory cells residing in the pancreatic draining lymphnodes of patients with type 1 diabetes

G. Sebastiani[1], C. Morsiani[2], A. Ferraro[2], G. Ventriglia[1], M. Battaglia[2], F. Dotta[1];
[1]University of Siena and Umberto Di Mario Foundation, [2]San Raffaele Scientific Institute, Diabetes Research Insitute, Milano, Italy.

Background and aims: Pancreatic draining lymphnodes (PLN) and peripheral blood (PB) of patients with type 1 diabetes (T1D) undergoing pancreas transplantation and of non-diabetic individuals were collected. We previously showed that PLN of patients with T1D have CD4+CD25bright T cells epigenetically imprinted to be regulatory (Treg cells) but that, for still unknown reasons, do not function as such in vitro. Importantly, this functional defect is present only in Treg cells residing in the PLN of T1D patients and not in those circulating in their PB. MicroRNAs (miRNAs) are an abundant class of small non-coding RNAs that regulate gene expression by affecting the degradation and translation of target mRNAs. When poorly regulated, miRNAs are critically involved in a range of human diseases. We hypothesize that there might be post-transcriptional regulations in Treg cells and these regulations may affect Treg cells when residing in the PLN but not when circulating in the periphery of subjects with T1D.
Materials and methods: CD4+-CD25++-CD127-Treg cells were sorted from PLN and PB of 4 patients with T1D and from PLN and PB of 3 and 8 non-diabetic donors, respectively. From each sample, 200 sorted cells were analyzed and miRNA expression profiles were performed by RT-PCR using Taqman miRNAs array card A comprising 380 unique miRNAs. Data analysis was performed using 2-ddCt method. Graphical analysis and bioinformatic miRNAs target prediction were performed using Spotfire 5.0 software and Targetscan 6.2, respectively.
Results: Specific miRNAs differentially expressed between Treg cells residing in the PLN of T1D patients and those in their PB or in PLN of non-diabetic donors were identified. Interestingly, we found 4 microRNAs with a particular expression pattern. Namely, miR-125a-5p, miR-642, and miR-155 were increased in Treg cells isolated from PLN as compared to those isolated from PB of T1D patients (p=0.017, p=0.0005, p=0.0007- paired t-test); this differential expression was not identified in Treg cells isolated from non-diabetic donors uncovering a disease-specific miRNA expression pattern. In addition, miR-146a was increased in Treg cells isolated from PLN as compared to those isolated from PB, both in T1D patients and in non-diabetic donors suggesting a tissue (i.e., PLN) specific miRNA expression pattern irrespective of the disease status. Interestingly, FOXP3 was identified as a predicted target of miR-125a-5p by Targetscan 6.2
Conclusion: Disease- and tissue-specific miRNA signatures of Treg cells isolated from PLN and PB of patients with T1D and of non-diabetic donors were for the first time delineated. These patterns may explain functional defects of Treg cells in patients with T1D in controlling autoreactive immune responses. Specifically, miR-125a-5p by targeting FOXP3, may lead to reduced FOXP3 expression and induce dysfunction in Treg cells residing in the PLN. Studies are ongoing to confirm this hypothesis also in a bigger cohort of donors collected from the nPOD network and to assess the miRNAs' role in the functional control of Treg cells.

A novel approach for immunotargeting of islet reactive CD8 T cells to prevent diabetes

F.S. Wong[1], L.K. Siew[1], S. Fishman[2], G. Gross[2];
[1]Institute of Molecular and Experimental Medicine, Cardiff University, UK, [2]Immunology Laboratory, MIGAL, Kiryat Shmona, Israel.

Background and aims: CD8 T cells play an important role in the pathogenesis of Type 1 diabetes in both humans and the Non Obese Diabetic (NOD) mouse. We have developed a new approach for selectively targeting the CD8 T cells that recognize peptides of insulin and IGRP. This utilizes beta2-microglobulin linked to a selected MHC class I binding peptide and the intracellular activation domain of CD3-zeta. When a T cell expresses this construct, combining with endogenous MHC class I, it redirects the T cell against CD8 T cells recognizing the specific MHC class I/peptide complex. We have previously shown, by a transgenic approach, that targeting insulin reactive cells inhibits CD8 T cell attack on islet beta cells and thereby prevents the onset of T1D. Our current strategy uses mRNA transfection to express an islet autoantigenic peptide construct that reprograms polyclonal CD8 T cells to target and kill islet autoantigen-specific CD8 T cells.
Materials and methods: mRNA constructs were generated, consisting of peptide-beta2microglobulin-CD3zeta. A construct encoding EGFP was used as a control. Peptides used included insulin B chain15-23 and IGRP206-214. We tested the functional expression of the constructs using a hybridoma B3Z to stimulate an insulin B15-23 reactive T cell hybridoma containing NFAT-lacZ. Specific antigenic stimulation of the insulin-reactive hybridoma was detected by a colorimetric change. We also electroporated the peptide constructs to redirect polyclonal CD8 T cells from NOD mice which were tested for their ability to kill the insulin-reactive T cell hybridoma as well as G9 insulin reactive CD8 T cells or 8.3 IGRP reactive CD8 T cells in vitro. To test for longevity of expression of mRNA constructs in vivo, CD8 T cells transfected with the EGFP mRNA construct were i.v. injected into young NOD mice and cells expressing EGFP were tested for at various times after injection in the spleen and pancreatic lymph nodes (PLN). Finally, we electroporated polyclonal CD8 T cells from NOD mice with insulin and IGRP constructs and i.v. injected these redirected CD8 T cells into young NOD mice to test for inhibition of diabetes.
Results: The hybridoma B3Z when transfected with the insulin peptide construct and K^d stimulated the insulin-reactive hybridoma cells, inducing a color change indicating that expression of the construct induced recognition by the insulin-reactive hybridoma. We then showed that redirected polyclonal CD8 T cells were able to kill the insulin-reactive hybridoma (35% specific lysis at 10:1 E:T ratio), G9 TCR transgenic CD8 T cells that recognize the insulin B15-23 peptide and 8.3 TCR transgenic CD8 T cells that recognize the IGRP peptide (both 10% specific lysis at 10:1 E:T ratio), in vitro. We next demonstrated that redirected polyclonal T cells, expressing the EGFP construct, i.v. injected into young NOD mice were detected in the spleen and PLN at least 7 days after injection (2.4% of CD8 T cells). Finally, mRNA transfected cells were i.v. injected into young NOD female mice to assess whether this strategy can be used to prevent autoimmune diabetes in NOD mice and this experiment is currently ongoing.
Conclusion: Our experiments show that, in principle, mRNA transfection can be used to induce expression of constructs that redirect CD8 T cells to kill islet autoantigen reactive CD8 T cells. This may be a novel means of selectively targeting islet reactive cytotoxic T cells to prevent diabetes which we are currently testing in vivo.

A novel immune regulatory peptide, PEPITEM, controls T cell trafficking during inflammation, a tonic inhibitory pathway that is lost in type 1 diabetes mellitus

C. Myriam[1], H.M. McGettrick[2], C.M. Yates[1], A. Kennedy[1], A. Martin[3], F. Barone[2], L.S. Walker[2], C.D. Buckley[2], G. Nash[1], G.E. Rainger[1], P. Narendran[1];
[1]School of Clinical and Experimental Medicine, University of Birmingham, [2]School of Immunity and Infection, University of Birmingham, [3]School of Cancer Sciences, University of Birmingham, UK.

Background and aims: T-cells are recruited from the blood into extra-vascular tissues during an inflammatory response. In chronic inflammatory diseases such as T1D, an inappropriate accumulation of T-cells in the pancreatic islets results in the destruction of insulin producing beta cells. We aimed to explore the role of adiponectin, an adipose derived cytokine with recognised anti-inflammatory properties, on T cell migration in T1D. Here we describe that adiponectin stimulates the expression of a unique immune-regulatory peptide that imposes a tonic inhibition of T-cell trafficking during inflammation. PEPtide Inhibitor of Trans-Endothelial Migration (PEPITEM) introduces a new paradigm into the pathways that regulate the inflammatory response. We present evidence that this new pathway is compromised in patients with T1D. We propose that loss of this regulatory pathway makes the immune system 'leaky', facilitating the inappropriate access of T-cells into the pancreatic islet, thus leading to islet inflammation.
Materials and methods: In vitro, videomicroscopy was used to assess the migration of lymphocytes isolated from healthy donors or patients with T1D across TNF-α/IFN-γ activated endothelial cells (EC). In vivo, lymphocyte recruitment was assessed in a model of zymosan driven peritoneal inflammation. PEPITEM was identified using mass spectrometry and adiponectin receptors (AR1, AR2) expression was measured by flow cytometry.

Results: Using an in vitro migration assay, we observed that the migration of human lymphocytes was dose-dependently blocked by adiponectin (EC50=37nM). The effect of adiponectin was lost when B cells were absent, but could be regained by the addition of supernatants from adiponectin stimulated B-cells. Therefore adiponectin achieved its effects on T-cell migration through the induction of a B-cell secreted mediator. We used mass spectrometry to isolate and identify the B-cell derived agent, subsequently named PEPITEM. PEPITEM corresponds in the human genome to a proteolytic excision product of the 14.3.3ζδ protein. Synthetic PEPITEM could effectively inhibit T-cell migration (EC50=18pM). Interestingly, the B-cell derived product did not act directly on T-cells; rather, it stimulated EC to release the lipid mediator sphingosine-1-phosphate, which in turn inhibited the migration of T-cells. In zymosan-induced peritonitis, T-cell recruitment was significantly increased in a mouse strain lacking B cells when compared to wild-type animals. This excess of T-cell recruitment was ameliorated by treatment with PEPITEM. Lymphocytes isolated from patients with T1D expressed lower levels of both adiponectin receptors (Frequency AR1: HC=20.2±2.3, T1D=12.6±1.1 and AR2: HC=21.1±2.5, T1D=11.2±0.8) and were released from the inhibitory effects of adiponectin. However, this regulatory pathway could be re-established by the addition of exogenous PEPITEM.
Conclusion: We propose that low adiponectin receptor expression by lymphocytes in T1D facilitates the inappropriate accumulation of islet reactive T cells in the pancreas. We also propose that targeting the PEPITEM pathway has therapeutic potential for T1D.

Identification of two distinct patterns of immune cell infiltration in the insulitic lesions in human type 1 diabetes
P. Leete[1], A. Willcox[2], S.J. Richardson[1], A.J. Bone[3], A.K. Foulis[4], N.G. Morgan[1];
[1]University of Exeter Medical School, Devon, [2]University of Bristol,
[3]University of Brighton, [4]Southern General Hospital, Glasgow, UK.

Background and aims: Type 1 diabetes is believed to result from the selective destruction of pancreatic β-cells by an immune-mediated process associated with islet insulitis. However, the mechanisms that promote and sustain islet inflammation in humans are poorly understood and the composition of the insulitic infiltrate has rarely been examined in detail. In one such study, pancreas specimens recovered from a cohort of recent-onset type 1 diabetes patients collected within the UK were investigated to establish the profile of immune cell infiltration into the islets during the active phase of β-cell destruction. This suggested that cytotoxic CD8+ T-cells form the major cellular component of the infiltrate but also revealed the ingress of significant numbers of CD20+ B-cells. In order to determine whether this pattern is seen more widely in patients with type 1 diabetes, we have now compared the immune cell composition of the insulitis in the UK cohort with that in patients from among the JDRF nPOD collection.
Materials and methods: A total of 30 T1D cases (4 nPOD; 26 UK) with proven insulitis were studied. 4um sections of formalin fixed paraffin embedded pancreas were analysed for insulin content and immune cell numbers by immunocytochemical methods. Sections were stained to reveal cells expressing CD45, CD4, CD8, CD20 or CD68 and their numbers analysed in each islet section.
Results: Initial examination of 3 nPOD cases immediately revealed a major difference from the profile seen previously within the UK samples. In particular, while CD8+ cells still formed the major component, the insulitic lesions contained markedly reduced numbers of CD20+ cells. One important variable between the 2 cohorts was the period since disease diagnosis, with the nPOD cases typically having a longer disease duration (up to 11 years). Therefore, we re-examined the larger UK cohort to determine whether this altered CD20+ cell profile could also be found in patients with shorter disease duration. This confirmed that two distinct patterns of insulitis are distinguishable in both cohorts - one in which elevated numbers of CD20+ cells are present ("CD20 hi"; 11.5±1.9 cells per islet) and another with markedly reduced CD20+ cells ("CD20 lo"; 0.8±0.1 cells per islet ($p<0.001$)). These patterns were distinct and representative of all insulitic islets within any given case. They were independent of disease duration, although "CD20 hi" cases were diagnosed at a younger age (7.8±1.5 vs 13.9±1.4 years; $p<0.01$) and contained a reduced proportion of residual insulin-positive islets (21.6±7% vs 38±6%). The total number of infiltrating immune cells was also reduced in the insulitic lesions of "CD20 lo" cases during the active phase of β-cell destruction. Nevertheless, CD8+ cells were always predominant and the major difference was in the ratio of CD8+ to CD20+ cells. This ratio was increased from a mean of only 1.5 in "CD20 hi" cases to 7.1 in "CD20 lo" cases.
Conclusion: We have identified 2 distinct patterns of insulitis in human type 1 diabetes. These differ in both the absolute numbers of immune cells present and, more particularly, in the relative proportions of CD8+ to CD20+ cells. The data imply that the presence of elevated numbers of CD20+ cells within the lesions may be indicative of a more aggressively destructive phenotype.

***Mafa* knockout NOD mice are protected from type 1 diabetes despite accelerated infiltration of lymphocytes into islets**
S. Noso, N. Babaya, Y. Hiromine, Y. Kawabata, H. Ikegami;
Department of Endcrinology, Metabolism and Diabetes, Kinki University School of Medicine, Osaka-Sayama, Japan.

Background and aims: Type 1 diabetes is an organ-specific autoimmune disease against pancreatic islets, characterized by lymphocyte infiltration into islets, leading to destruction of insulin-producing beta cells. *Mafa* is an insulin transactivator that is specifically expressed in pancreatic beta cells. Recently, we reported that "intra-thymic" expression of *Mafa,* as well as *Ins2*, was reduced in NOD (non-obese diabetic) mice in comparison with that in control mice, and identified unique variants in the promoter region of $Mafa^{nod}$, which cause reduced promoter activity of *Mafa*. Systemic disruption of *Mafa* resulted in reduction of *Ins2* and *Mafa* expression in the thymus, indicating that *Mafa* is a key regulator of insulin expression in the thymus. To clarify the role of *Mafa* in the development of insulitis and type 1 diabetes *in vivo*, we generated *Mafa* knockout NOD mice and studied the phenotypic changes and islet pathological features in comparison with those in *Mafa* knockout control mice.
Materials and methods: All mice were housed under specific pathogen-free conditions. $Mafa^{-/-}$ ICR mice were backcrossed for five generations onto the NOD/Shi background. Microsatellite markers in the vicinity of *Idd* loci were genotyped by PCR method in each generation for selective breeding. Pancreata were removed from the three groups of pre-diabetic NOD females ($Mafa^{-/-}$: KO, $Mafa^{-/+}$: HT and $Mafa^{+/+}$: WT) at 8 weeks of age. Four non-consecutive tissue sections were prepared for hematoxylin-eosin staining. More than twenty islets in each pancreas were examined by light microscopy, and the degree of insulitis was scored (grade 0: insulitis-free, grade 1: peri-insulitis, grade 2: 0~25%, grade 3: 25~50%, grade 4: 50~75%, grade 5: 75~100%). The cumulative incidence of diabetes was compared using the Kaplan-Meier method with 95% confidence intervals; p values less than 0.05 by the log-rank test were considered statistically significant. Populations of lymphocytes infiltrated around islets were analyzed by immunohistochemical staining.
Results: All microsatellite markers were confirmed to be replaced with the NOD genotype at N5 generation. Thecumulative incidence of spontaneous development of diabetes in N5 females was significantly lower in KO mice (5.6%) than in HT mice (60.0%, $p=0.0004$) and WT mice (95.6%, $p<0.0001$), and was significantly lower in HT mice than in WT mice (60.0% vs. 95.6%, $p=0.0004$, Figure, left panel). However, insulitis scores of KO mice (proportion of grade 1 to 5: 20.3%) and HT mice (21.9%) were higher than that of WT mice (9.2%) at 8 weeks of age (Figure, right panel).
Conclusion: Disruption of *Mafa* caused accelerated infiltration of lymphocytes into pancreatic islets, but suppressed spontaneous development of diabetes in the NOD mouse, suggesting the involvement of a regulatory mechanism in benign insulitis.

Relationships between major epitopes on the IA-2 autoantigen in type 1 diabetes

C.C. Richardson, M.R. Christie, K.A. McLaughlin;
Diabetes and Nutritional Sciences, King's College London, UK.

Background and aims: Studies on the natural history of Type 1 diabetes indicate that spreading of autoimmunity within and between autoantigens represents a critical element of disease progression. Intra- and inter-molecular spreading is clearly demonstrated in IA-2 autoimmunity, where antibodies appearing early in disease frequently bind linear epitopes in the juxtamembrane (JM) region, subsequently spreading to epitopes in the tyrosine phosphatase (PTP) domain and to IA-2beta. By the time of disease onset, antibodies to the PTP domain predominate. In animal models of diabetes, B-cells play a critical role in epitope spreading. We hypothesise that B-cells reactive to the JM domain may facilitate spreading of autoimmunity by promoting uptake and presentation of peptides in the PTP domain, potentially as a consequence of close structural alignment of these determinants. The aim of this study was to investigate structural and immunological relationships of JM and PTP domain epitopes by competitive binding studies with IA-2 antibodies and investigating associations of T- and B-cell responses to these regions.
Materials and methods: Sera were obtained from Type 1 diabetic patients within 6 months of diagnosis. Human monoclonal IA-2 antibodies were generated by transformation of B-cells from diabetic patients and mouse monoclonal antibodies by immunization with IA-2 cytotoplasmic domain. Reactivity of antibodies to radiolabelled constructs representing the cytoplasmic (605-979) or JM (605-693) domains of IA-2 were determined by radioligand binding assay after capture of immune complexes with protein A or protein G Sepharose. Linear epitopes in the JM domain were localised by blocking antibody reactivity with synthetic 20-mer peptides. Overlap of antibody epitopes was analysed by competition studies with Fab fragments of monoclonal antibodies. T-cell reactivity to synthetic IA-2 peptides was determined in peripheral blood lymphocytes from diabetic patients by cytokine ELISPOT.
Results: Three distinct patterns of binding of antibodies to the JM domain in sera of diabetes patients could be categorized according to ability of synthetic peptides to block reactivity to the JM construct: JM1: blocked by 601-620 and 611-631 peptides, JM2: blocked by 611-631 and 621-640 peptide and JM3: blocked only by 611-630 peptide. Mouse monoclonal antibodies to JM epitopes were identified that could also be categorized as JM1, JM2 or JM3 epitope-reactive according to peptide blocking. Fab fragments of these mouse antibodies inhibited binding of JM-reactive autoantibodies in patients' sera. The mouse JM antibodies also inhibited binding of human monoclonal autoantibodies to a defined epitope in the 831-860 region of the IA-2 PTP domain. Furthermore, T-cell reactivity in Type 1 diabetic patients to peptide 841-860 of IA-2 was strongly associated with presence of antibodies to JM domain epitopes ($p<0.001$).
Conclusion: The epitope specificities of JM antibodies generated after immunization of mice with IA-2 protein mimic those of the human IA-2 autoantibodies developing early in the Type 1 diabetes. Blocking studies with Fab fragments of the mouse antibodies indicate close structural relationships of JM and PTP domain epitopes. The association of antibodies to the IA-2 JM domain with T-cell responses to PTP domain determinants supports a role for B-cells in promoting intramolecular spreading of the IA-2 autoimmune response.

The mechanism of action of the splice variant VEGF165b in decreasing proteinuria in mouse models of type 1 diabetic nephropathy

M. Stevens, Y. Qiu, J. Ferguson, A. Salmon, D. Bates, S. Harper, S. Oltean;
Physiology and Pharmacology, University of Bristol, UK.

Background and aims: Several studies have shown diabetes to be associated with increased levels of vascular endothelial growth factor (VEGF, main isoform VEGF165), both in the plasma and urine. Studies in rodents have also shown that inhibition of VEGF in diabetic nephropathy models reduces the levels of proteinuria. VEGF165 increases permeability to water in the glomerulus, however its splice isoform, VEGF165b, displays the opposite actions. We investigated the effect of VEGF165b on proteinuria in mice with type I diabetes as well as its mechanism of action, both in vitro and in vivo.
Materials and methods: Transgenic C57Bl/6 mice (TG) over-expressing VEGF165b under a nephrin promoter were generated. Both TG and wild-type (WT) littermate controls were rendered diabetic using STZ injections (100mg/kg for 3 consecutive days) and the subsequent urinary albumin:creatinine ratio (uACR) was measured in each group. Triple transgenic mice with podocyte-specific over-expression of both human VEGF165b (constitutively) and mouse VEGF164 (inducible) were rendered diabetic using the low-dose AMDCC STZ protocol (50 mg/kg for 5 consecutve days). 4 weeks after the onset of hyperglycaemia, VEGF164 overexpression was induced for 7 days by adding doxycycline in drinking water. Diabetes was also induced in DBA2J mice using the AMDCC low-dose STZ protocol. After 2 consecutive weeks of hyperglycaemia (>20mmol/L), baseline albumin-creatinine ratios (uACR) were measured, and mice received saline, 1µg VEGF165b or 5µg VEGF165b injections i.p. twice weekly for 6 weeks. VEGFR-2 expression and phosphorylation was assessed by immunofluorescence staining on the diabetic DBA/2J kidney sections with/without VEGF165b treatment. In vitro studies involved treating glomerular endothelial cells (GEnCs) with 30mM glucose for 7 days and assessing phosphorylation of VEGFR-2 in the presence or absence of VEGF165b (2.5nM).
Results: Control STZ-injected mice had a significantly increased uACR compared to sham-treated controls and this was partially rescued in heterozygous neph-VEGF165b STZ mice ($n=5$-9, $p<0.05$). Over-expression of VEGF164 for 7 days led to an increased uACR in STZ-induced diabetic mice and this was partially rescued if the mice also constitutively over-expressed VEGF165b ($p<0.05$). In diabetic DBA/2J mice uACR increased progressively in the sham group while in the treated groups remained constant at pre-treatment levels (1µg VEGF165b) or decreased (5µg VEGF165b) (two-way ANOVA for treatment $p< 0.01$). Glomeruli from diabetic DBA/2J mice showed both an increase in expression and phosphorylation of VEGFR-2 when treated with VEGF165b compared with diabetic controls ($n=3$, $p<0.05$). GEnCs treated with 30mM D-glucose have increased phosphorylation of VEGFR-2, compared with 30mM Mannitol controls, which is further increased by the addition of VEGF165b.
Conclusion: The over-expression of VEGF165b in the podocytes of diabetic mice partially rescues high levels of albuminuria. This is also the case when podocytes are over-expressing VEGF164, suggesting that the balance between the two isoforms determines the phenotype. VEGF165b is shown to be signalling, at least in part, through VEGFR-2 leading to an increase in phosphorylation of the receptor GEnC in vivo and this can be also reproduced in vitro in GEnCs in culture exposed to high glucose concentrations. Surprisingly, VEGF165b administration in vivo also increases expression of VEGFR2 in GEnC.

Clusterin/apolipoprotein J attenuates angiotensin II-induced renal fibrosis

G.-S. Jung[1], Y.-A. Jung[2], M.-K. Kim[2], K.-H. Bae[1], I.-K. Lee[1], K.-G. Park[1];
[1]Department of Internal Medicine, Kyungpook National University School of Medicine, Daegu, [2]Department of Internal Medicine, Keimyung University School of Medicine, Daegu, Republic of Korea.

Background and aims: The blockade of angiotensin II (Ang II) is a main therapeutic target of diabetic nephropathy. Ang II acts through two receptors, angiotensin type 1 receptor (AT1) and angiotensin type 2 receptor (AT2). Most of the known actions of Ang II, including vasoconstriction and fibrosis, are due to AT1 activation, which is upregulated via sequential activation of the transcription factors NF-kB, ELK-1 and AP-1. In addition, AT2 decreases AT1 expression and function via nitro oxide (NO)/cyclic guanosine monophosphate (cGMP). Clusterin/apolipoprotein J is a conserved secreted glycoprotein expressed in a wide array of tissues and being implicated in several physiological processes. Increased expression of clusterin has been established in several renal diseases and nephrotoxicity models suggesting that clusterin may have a protective role against nephropathogenesis. Here, we examined clusterin prevents Ang II-induced renal fibrosis via downregulation of AT1 but upregulation of AT2.
Materials and methods: Clu-/- and wild type mice were infused with Ang II using osmotic mini pump. The effects of clusterin on renal fibrosis and AT receptor expression in vivo were assessed by Ang II-induced renal fibrosis model. NRK-52E cells, a stable cell line derived from rat proximal tubules were cultured. The effects of adenovirus mediated overexpression of clusterin on Ang II-induced fibrorsis and AT receptor expression in NRK-52Es were measured by Western blot and qRT-PCR analysis. The effect of clusterin on NF-kB-DNA binding activity was examined by co-immunoprecipitation assay. The inhibitory effect of the AT2 receptor on AT1 receptor expression was measured by the nitric oxide synthase inhibitor L-NAME or cGMP inhibitor 1H-[1,2,4] oxadiazolo-[4,3-a] quinoxalin-1-one.
Results: In kidneys of Clu-/- mice, renal fibrosis and expression of AT1 were increased compared with those in kidneys of wild-type mice. In addition, loss of clusterin accelerated Ang II-stimulated renal fibrosis and AT1 expression. But, AT2 expression was markedly decreased in kidneys of Clu -/- mice. Adenovirus mediated overexpression of clusterin in NRK-52E cells inhibited Ang II-stimulated PAI-1, collagen 1 type, fibronectin and AT1 expressions, but increased AT2 expression in a dose dependent manner. Moreover, infusion of Ang II using osmotic minipump markedly increased PAI-1, type I collagen, fibronectin and AT1 expressions but decreased AT2 expression. These changes were prevented by clusterin over-expression by adenovirus. Clusterin inhibited Ang II-induced NF-kB translocalization to nucleus. Furthermore, inhibition of NO production or blockade of cGMP abolished the inhibitory effect of clusterin on AT1 expression.
Conclusion: This study shows that clusterin attenuates renal fibrosis by inhibiting the AT1 but activating AT2 expression. Therefore, the present study raises the possibility that clusterin can be a target for the prevention of Ang II-induced renal fibrosis.

141

Pivotal involvement of CX3CL1-CX3CR1 system in the pathogenesis of diabetic nephropathy in streptozotocin-treated mice

M. Furuta[1], Y. Shimizu[1], A. Yamana[1], M. Ueyama[1], S. Morita[1], A. Doi[2], Y. Ishida[3], M. Nosaka[3], T. Kondo[3], T. Sanke[4];
[1]Clinical Laboratory Medicine, Wakayama Medical University, [2]The First Department of Medicine, Wakayama Medical University, [3]Department of Forensic Medicine, Wakayama Medical University, [4]Insititute for Diabetes, Fuchu Hospital, Izumi, Japan.

Background and aims: Several lines of accumulating evidence implied that CX3CL1 and CX3CR1 seem to be involved in the progression of diabetic nephropathy. Actually, we found that urinary CX3CL1 levels were significantly higher in diabetic patients with albuminuria, compared with those with non-albuminuria and non-diabetic ones. Thus, in the present study, we established a model of diabetic nephropathy in streptozotocin (STZ)-induced diabetic mice, and examined pathogenic roles of CX3CL1-CX3CR1 system in diabetic nephropathy using CX3CR1-deficient mice.
Materials and methods: Male CX3CR1$^{+/+}$ (WT) and CX3CR1$^{-/-}$ (KO) mice aged 8-12 weeks were employed. For the induction of diabetic nephropathy, mice were intraperitoneally injected STZ (200 mg/kg ip). At the indicated time intervals after STZ injection, urine and blood samples were collected to measure the urinary albumin excretion and to evaluate blood glucose and blood urea nitrogen levels, respectively. Systolic blood pressure was also measured using tail-cuff method. After the sacrifice of mice at 3 and 6 month after STZ challenge, kidney samples were harvested, histopathological and immunohistochemical analyses were performed to evaluate fibrotic changes and macrophage recruitment. Moreover, intrarenal gene expression of cytokines, collagen and adhesion molecules was examined by real time RT-PCR.
Results: In WT, the intrarenal gene expression of CX3CL1 and CX3CR1 were apparently enhanced at 3 and 6 months after STZ challenge. Immunhistochemically, CX3CR1 protein was mainly expressed on intrarenal macrophages, and CX3CL1 protein could be detected on macrophages and renal tubular cells. These observations implied that CX3CL1-CX3CR1 axis might be involved in the pathogenesis of STZ-induced diabetic nephropathy. Blood glucose levels were Increased, to a similar extent, in KODM mice, compared with WTDM mice. Moreover, there was no significant difference in systolic blood pressure and blood urea nitrogen levels between WTDM and KODM mice. Urine albumin excretion, a hallmark of diabetic nephropathy, was elevated in both WTDM and KODM mice at 3 and 6 months after STZ challenge, whereas it was significantly lower in KODM mice than in WTDM ones. Histopathologically, the PAS-positive area in the glomeruli and interstitial fibrotic changes were less evident in KODM mice than in WTDM ones at 6 months after STZ administration. Actually, the gene expression of type IV collagen and TGF-β was significantly attenuated in KODM mice. Additionally, macrophage accumulation in the glomeruli was attenuated in KODM mice, compared with WTDM mice. These observations indicated that the absence of CX3CR1 could alleviate STZ-induced diabetic nephropathy, with a concomitant of attenuated macrophage recruitment. Moreover, intrarenal gene expression of ICAM-1, VCAM-1, iNOS and MMP-2 was less enhanced in KODM mice, compared with WTDM mice, implying that CX3CL1-CX3CR1 axis could regulate these molecules.
Conclusion: CX3CL1-CX3CR1 system plays detrimental roles in STZ-induced diabetic nephropathy, and might be a good therapeutic target for diabetic nephropathy.

PDK1 protects podocytes from apoptosis

P.H. Saurus[1], M. Ristola[1], C. Fogharty[2], M. Lehto[2], M. Saleem[3], P.-H. Groop[2], H. Holthöfer[4], S. Lehtonen[1];
[1]Department of Pathology, Haartman Institute, University of Helsinki, [2]Folkhälsan Research Center, Folkhälsan Institute of Genetics, Helsinki, Finland, [3]Southmead Hospital, University of Bristol, UK, [4]Department of Bacteriology and Immunology, Haartman Institute, University of Helsinki, Finland.

Background and aims: Apoptosis is one of the mechanisms of podocyte loss in diabetic nephropathy. We hypothesized that 3-phosphoinositide-dependent kinase-1 (PDK1), an activator of protein kinase B (PKB)/Akt, would be a prosurvival factor for podocytes by increasing the phosphorylation level of Akt.
Matherials and methods: To study the role of PDK1 in podocyte apoptosis, PDK1 was knocked down in cultured human podocytes using lentiviral small hairpin RNAs (shRNAs). The apoptotic rate of podocytes was measured by Annexin V staining and flow cytometry. The involvement of phosphatidylinositol 3-kinase/Akt (P13-K/Akt) and p38 mitogen-activated protein kinase (p38MAPK) signaling cascades and the expression levels of proapoptotic BAX and antiapoptotic BCL-2 after knockdown of PDK1 were analyzed by quantative Western blotting. Expression level of PDK1 was also studied in podocytes treated with serum obtained from patients with type 1 diabetes and macroalbuminuria and compared to cells treated with serum obtained from microalbuminuric patients. Further, the expression level of PDK1 in glomeruli of lean and obese Zucker rats and in human patients with diabetes was studied.
Results: PDK1 is expressed in rat glomeruli and tubules and in cultured human podocytes. Knockdown of PDK1 increased apoptosis in cultured human podocytes, and inhibited the PI3-K/Akt and activated the p38MAPK pathways. BCL-2 level was decreased and BAX increased after PDK1 knockdown. Expression of PDK1 was lower after treatment with serum from macroalbuminuric patients compared to serum from normoalbuminuric patients. Furthermore, PDK1 was found to be downregulated in glomeruli of obese Zucker rats compared to lean littermates and in podocytes of human patients with diabetes.

Conclusion: Our data show that PDK1 may protect podocytes against apoptosis. Downregulation of PDK1 in Zucker rat glomeruli prior to proteinuria suggests that PDK1 could have a protective role in the development of podocyte injury.

Linagliptin and the angiotensin II receptor blocker telmisartan show comparable efficacy but different renoprotective pathways in rats with 5/6 nephrectomy

B. Hocher[1], O. Tsuprykov[1], M. Alter[2,3], K. von Websky[1,2], L. Chaykovska[4], V. Antonenko[1], J. Rahnenführer[1,2], T. Klein[5], C. Reichetzeder[1,2];
[1]University of Potsdam, [2]Charité Campus Mitte, Berlin, [3]Charité Campus Benjamin Franklin, Berlin, Germany, [4]University Hospital of Zürich, Switzerland, [5]Boehringer Ingelheim, Biberach, Germany.

Background and aims: DPP-4 inhibitors were shown to delay disease progression in experimental diabetic nephropathy and may also have renoprotective properties and diabetes-independent effects. In this study, we compared the effect of linagliptin with an angiotensin II receptor antagonist in preventing renal disease progression in non-diabetic rats with 5/6 nephrectomy. Furthermore, we analysed kidney tissue- and plasma-biomarkers at study end in order to determine the potential differences in the underlying mechanisms of action.
Materials and methods: Male Wistar rats were allocated to 4 groups: sham operated; 5/6 nephrectomy (5/6 Nx) plus placebo treatment (placebo); 5/6 Nx plus linagliptin (0.083 mg/kg/d in chow); 5/6 Nx plus telmisartan (5 mg/kg/d in drinking water). Study duration was 130 days. Histological analysis for interstitial fibrosis, glomerulosclerosis, and nephrin was performed. Plasma was investigated for TIMP-1, calbindin, osteopontin, and β2 microglobulin (B2M), as well as circulating macrophage-derived chemokine (MDC) and plasma macrophage colony-stimulating factor-1 (M-CSF-1).
Results: Interstitial fibrosis increased by 69% in placebo vs sham rats ($p<0.05$), and decreased by 48% with linagliptin ($p<0.05$) and 24% with telmisartan (p=ns) vs placebo rats. Glomerular size increased by 28% in placebo vs sham rats ($p<0.01$), and decreased by 18% ($p<0.001$) with linagliptin but not significantly with telmisartan vs placebo rats. The glomerulosclerosis index was significantly increased in placebo vs sham rats ($p<0.05$). There was a trend towards decreased glomerulosclerosis with linagliptin and telmisartan. The urinary albumin/creatinine ratio increased 14-fold in placebo vs sham rats ($p<0.001$), and decreased by 66% with linagliptin ($p<0.05$) and 92% with telmisartan ($p<0.01$) vs placebo rats. Blood pressure was lowered by telmisartan (31 mmHg; $p<0.05$) and unaffected by linagliptin. Expression of the tissue split membrane forming protein nephrin increased 3.2-fold ($p<0.01$) in placebo vs sham rats. Linagliptin and telmisartan treatment abolished this effect. Plasma TIMP-1, calbindin, osteopontin, and B2M were all significantly increased (all $p<0.05$) in the placebo vs sham rats. Linagliptin decreased plasma levels of TIMP-1, calbindin, osteopontin, and B2M vs placebo rats (all $p<0.05$), whereas telmisartan significantly decreased osteopontin ($p<0.05$). M-CSF-1 concentration increased by 45% ($p<0.05$) in placebo vs sham rats. Linagliptin had no effect on the M-CSF-1 concentrations, whereas telmisartan abolished this effect. MDC concentrations were significantly reduced by 51% in linagliptin-treated rats only ($p<0.05$). Telmisartan had no effect on MDC plasma concentrations. Plasma concentrations of the T-cell-specific protein RANTES increased by 2.5-fold ($p<0.05$) with telmisartan. Linagliptin abolished this effect.
Conclusion: Linagliptin is as effective as telmisartan in preventing renal disease progression in rats with 5/6 Nx. Furthermore, analysis of biomarkers revealed that the underlying molecular mechanisms of renoprotection appear to be substantially different.

Luseogliflozin (TS-071), a novel SGLT2 inhibitor, protects against diabetic nephropathy in diabetic db/db mice

Y. Takiyama, K. Agatsuma, M. Yasuda-Kobayashi, J. Honjo, Y. Fujita, T. Yanagimachi, H. Kitsunai, Y. Makino, M. Haneda;
Department of Medicine, Asahikawa Medical University, Asahikawa, Japan.

Background and aims: SGLT2 is responsible for reabsorption of ~90% of filtered glucose in the S1 segments of proximal tubule. Now, SGLT2 represents a novel target for normalizing glycemia. To address in vivo the issue of the efficacy and tolerance of a novel SGLT2 inhibitor Luseogliflozin (LUSEO), we investigated whether LUSEO can prevent renal insufficiency and glomerulosclerosis in diabetic mice, and determined potential mechanisms of renoprotecitve effects.
Materials and methods: Initially, eight weeks old male diabetic *db/db* mice or nondiabetic *db/m* mice were treated with 15 mg/kg LUSEO for eight weeks. Body weight, fasting blood glucose, HbA1c, blood pressure, and urinary albumin were measured. Renal histology, expressions of SGLT2, hypoxia-probe pimonidazole were evaluated at the end of the study. Second, we examined the expression of SGLT2 or inflammatory molecules in human renal proximal tubular epithelial cells (HRPTEC) by RT-qPCR.
Results: Diabetic *db/db* mice showed higher body weight and fasting blood glucose levels, HbA1c, compared with control *db/m* mice. LUSEO had an impact on urinary glucose excretion (UGE) even in *db/m* mice (0.97±0.67 *vs.* 367.31±45.92 mg/day, *db/m*, *db/m*+LUSEO), without hypoglycemia and weight loss. LUSEO had significant effects on plasma glucose levels in *db/db* mice (HbA1c; 7.32±0.85 *vs.* 13.50±0.44 %, *db/db*+LUSEO, *db/db*, respectively, $p<0.001$), which apparently lead to rescue pancreatic islet loss. Then, consistent with lowerd filtrated glucose load, UGE in *db/db* treated with LUSEO was decreased (1,127.06±537.82 *vs.* 2,041.7±713.03 mg/day, *db/db*+LUSEO, *db/db*, respectively, $p<0.05$). Moreover, LUSEO showed renoprotective effects, which significantly attenuated urinary albumin excretion rates, glomerular mesangial matrix expansion, glomerular and interstitial fibronectin accumulation, and Armanni-Ebstein lesions in *db/db* mice to almost the level observed in *db/m* mice. Consequently, LUSEO preserved the expression of SGLT2 in brush border membrane of the proximal tubules of *db/db* mice against tubular injury. Of interest, LUSEO augmented pimonidazole staining of the S3 segment of the proximal tubules cells which expressed SGLT1, in outer stripe of the kidney of *db/db* mice, suggesting hypoxia caused by the overload of glucose and sodium via blocking SGLT2 in the S1 segment. Subsequently, we evaluated the expression of its target molecule SGLT2 using HRPTEC. HRPTEC constitutively expresses SGLT2 mRNA. High glucose (25.5 mM) did not affect the expression of SGLT2 mRNA, and insulin (100 nM) slightly increased SGLT2 mRNA expression by ~120% of control. Whereas, profibrotic TGF-ß1 markedly decreased SGLT2 mRNA expression (48.3±10.4 %, $p<0.01$). Intriguingly, Hepatocyte Nuclear Factor (HNF)-1alpha, a modulator of SGLT2 expression, was drastically decreased by TGF-ß1 treatment, thereby providing a mechanism by which TGF-ß1 represses SGLT2 mRNA expression through decreased HNF-1alpha. In addition, LUSEO alone failed to affect the expressions of SGLT2 and the inflammatory molecules, however, significantly inhibited TGF-ß1-induced fibronectin expression.
Conclusion: These results suggest that chronic treatment with the SGLT2 inhibitor LUSEO can protect against the progression of diabetic nephropathy, which is probably sufficient to overcome the adverse effects of TGF-ß1.

Dissociation between metformin plasma exposure and its glucose-lowering effect: a novel gut-mediated mechanism of action

A. Baron[1], R. DeFronzo[2], J. Buse[3], T. Kim[1], S. Skare[1], M. Fineman[1];
[1]Elcelyx Therapeutics, San Diego, [2]UT Health Science Center, San Antonio, [3]UNC School of Medicine, Chapel Hill, USA.

Background and aims: We tested the hypothesis that metformin (Met) reduces plasma glucose primarily by stimulating release of glucoregulatory hormones such as glucagon-like peptide-1 (GLP-1) and peptide YY (PYY) from enteroendocrine L-cells via a mechanism that is independent of Met plasma concentration. We designed a delayed release (DR) Met tablet that targets the lower bowel and exhibits reduced bioavailability relative to currently available metformin formulations.
Materials and methods: The pharmacokinetics of 1000 or 500 mg Met DR twice daily (BID) was compared to commercially available immediate release (IR) Met (1000 mg BID) and extended release (XR) Met (2000 mg QD) in healthy subjects. Subsequently, a randomised, double-blind, crossover study compared 500 and 1000 mg Met DR BID and 1000 mg Met IR BID for 5 days in patients with type 2 diabetes withdrawn from diabetes therapy 2 weeks prior to randomisation.
Results: In healthy subjects, a single day of treatment with 1000 or 500 mg Met DR BID was associated with plasma Met concentrations that were 52% and 68% lower than 1000 mg Met IR BID and 48% and 65% lower than 2000 mg Met XR QD (N=19; all $p<0.0001$). In patients with type 2 diabetes, Met exposure also was reduced by 45% and 57% with 1000 and 500 mg Met DR compared to 1000 mg Met IR (N=19, both $p<0.0001$). The reduction in fasting plasma glucose from baseline (197 to 200 mg/dl) was similar for all treatments (LSmean±SE: -22±7 mg/dl, 1000 mg Met IR; -20±5 mg/dl, 1000 mg Met DR; 16±4 mg/dl, 500 mg Met DR; all $p<0.01$ vs. baseline). The 10h glucose AUC was similarly reduced in all treatments by 8 to 14% (all $p<0.0001$ vs. baseline). Insulin AUC was unchanged from baseline. All treatments increased fasting and postprandial PYY and GLP-1 (all $p<0.05$ vs. baseline). The GLP-1 AUC increased by 87, 62 and 69% and the PYY AUC increased by 55, 38, and 46% for 1000 mg Met IR, 1000 mg Met DR and 500 mg Met DR (all $p<0.0001$ vs. baseline). Nausea (9%) and vomiting (9%) occurred with Met IR but not Met DR. Diarrhea (10 to 15%) occurred in all treatments.
Conclusion: Despite marked reductions in exposure, a Met DR formulation that targets the lower bowel was as effective as Met IR with better tolerability. These results support the hypothesis that metformin's glucose-lowering effects are predominantly due to actions on enteroendocrine L-cells in the lower bowel and that plasma Met exposure is not required for efficacy.
Clinical Trial Registration Number: NCT01677299

Efficacy of bile acid sequestrant treatment for glycaemic control in type 2 diabetes - systematic review with meta-analysis of randomised controlled trials

M. Hansen, D.P. Sonne, K.H. Mikkelsen, L.L. Gluud, T. Vilsbøll, F.K. Knop;
Department of Internal Medicine, Gentofte Hospital, Diabetes Research Division, Hellerup, Denmark.

Background and aims: Studies suggest that bile acid sequestrants (BASs) can lower blood glucose in addition to their lipid-lowering effects. Three oral BASs are approved for hypercholesterolaemia: colestipol, colestyramin and colesevelam. In 2008, the American Food and Drug Administration approved colesevelam for treatment of hyperglycaemia in type 2 diabetes. We evaluated the glucose-lowering effect of BASs in a systematic review with meta-analyses of randomised clinical trials (RCTs).
Materials and methods: The protocol was registered in the Prospero database and the results are reported in accordance with the preferred reporting items for systematic reviews and meta-analyses (PRISMA). Literature searches included manual searches and electronic searches in The Cochrane Library, MEDLINE and EMBASE. Included RCTs assessed patients with type 2 diabetes randomised to BAS, placebo or an active comparator. The primary endpoint was change in HbA1c. Secondary endpoints included changes in fasting plasma glucose, and adverse events.
Results: Ten RCTs (10 on colesevelam and 7 on colestimide) with a duration of 2 to 52 weeks, including 2,118 patients were included in the analysis. Six RCTs in which 399 patients were randomised to BAS treatment versus 391 in the control group reported end of treatment HbA1c. Random effects meta-analysis showed that BASs reduced HbA1c compared with controls (weighted mean difference (WMD) (95% confidence interval (CI)): -0.59% (-0.70 to -0.48%). Six RCTs on colesevelam reported end of treatment fasting plasma glucose and random effects meta-analysis revealed a greater reduction in patients randomised to BAS treatment (n=769 vs. n=759 patients; WMD (95% CI): -0.52% (-0.68 to -0.37)). No evidence of small study effects was identified, but we found evidence of bias related to the trial design. Treatment with BASs increased the risk of drug-related adverse events (relative risk (95% CI): 1.89 (1.32 to 2.67)), constipation being the most common. No increased risk of serious adverse events was reported.
Conclusion: This review found that BAS treatment improves glycaemic control in patients with type 2 diabetes.

A new anti-inflammatory and immune-modulatory peptide therapeutic improves glycaemic control and beta cell function in the db/db and STZ diabetes models

S. Mogelsvang, D. Austin, A. Turner, C. Gelber;
Serpin Pharma, LLC, Manassas, USA.

Background and aims: Loss of glycaemic control and beta cell function contribute to the pathologies of type I and II diabetes. Using the alpha-1-antitrypsin protein as template, we identified a small anti-inflammatory and immune-modulatory peptide, SP16. To test if SP16 treatment would reduce inflammation and thereby improve glycemic control and beta cell function, we administered the peptide to db/db mice and mice with STZ-induced diabetes.
Materials and methods: Peptides: The SP16 peptide (17 aa) was synthesised by CPC Scientific and the INGAP peptide (15 aa) was provided by Exsulin. Animal studies: Five week old, pre-diabetic db/db animals were assigned to groups of 10 and IP injected with 12 μg SP16, 25 mg/kg Rosiglitazone or saline twice a week for 36 days. C57BL/6j animals were injected daily with 50mg/kg STZ for 5 days to induce beta cell loss and development of diabetes. Groups of 5 animals received 12 μg SP16, 0.5 mg INGAP, 12 μg SP16 plus 0.5 mg INGAP, or saline by daily injection for 41 days. For both studies, non-fasted blood glucose levels were determined twice a week, and HbA_{1c} and c-peptide levels measured at the end of the study. Mechanism of action: An engineered TLR-2 indicator cell line (HEK-Blue mTLR2, Invivogen) was incubated with SP16 or Pam3SK for 24 hours, in the presence or absence of a blocking antibody. A scrambled peptide was included as negative control. Assays were done in triplicate. In vitro safety testing: For initial safety assessment of the SP16 peptide, non-GLP hERG testing and receptor panning studies were executed.
Results: Animal studies: In db/db animals, SP16 and Rosiglitazone treated animals showed improved glycaemic control (lowered non-fasted blood glucose and HbA_{1c} levels, $p<0.05$), improved beta cell function (increased c-peptide levels and decreased islet hyperplasia, $p<0.05$), improved glucose tolerance in an oral glucose tolerance test, reduced inflammation (decreased levels of c-reactive protein, $P<0.05$) and increased serum TGFβ levels ($p<0.05$). In the STZ study, the combination of SP16 and INGAP resulted in significantly lowered non-fasted blood glucose levels ($p<0.05$) and all animals of this group were diabetes free at the end of the study. Mechanism of action: Cell-based assays showed that SP16 induces TLR2 signaling, in a concentration dependent manner, and the signaling could be blocked by addition of a TLR2 blocking antibody. We hypothesise SP16 induces expansion of Fox3P+ Tregs via TLR2, to favorably shift the Teff/Treg balance. In vitro safety testing: The *in vitro* safety studies showed that SP16 had no impact on hERG activity at up to 25 uM and did not impact the activity of the 111 different human receptors and enzymes of the GenSep explorer panel. The SP16 peptide did not elicit any immune response in the animal studies. In summary, SP16 is expected to have a favorable safety profile, without immuno- and cardiotoxicity.
Conclusion: SP16 is a novel, alpha-1-antitrypsin derived, anti-inflammatory and immune-modulatory peptide. SP16 treatment improves glycaemic control and beta cell function in db/db mice and in the STZ model of diabetes. Our cell-based assay data support the hypothesis that SP16 works by TLR2 mediated expansion of protective Tregs. Together, our data, combined with the fact that SP16 is derived from a drug that has been used for treatment of

AAT-deficient patients for over two decades, predict that SP16 is a safe drug with significant therapeutic potential.

Effect of a dual agonist of glucagon-like peptide-1/glucose-dependent insulinotropic peptide (MAR701) on insulin secretion rate and gastric emptying in healthy volunteers

M. Hompesch[1], L. Morrow[1], K. Win[1], L. Vignati[2], J. Hauptmann[3];
[1]Profil Institute for Clinical Research, Inc, Chula Vista, [2]Marcadia Biotech, Indianapolis, [3]Hoffmann-La Roche, Nutley, USA.

Background and aims: MAR701 is a novel long-acting peptide analogue with activity on both glucagon-like peptide-1 and glucose-dependent insulinotropic peptide receptors. The effects of MAR701 on insulin secretion rate (ISR) and gastric emptying (GE) were assessed in this phase I, two part, placebo- and active-control, sequential, single blind study in healthy volunteers.
Materials and methods: Part 1. After a >10 h overnight fast subjects (Cohort 1; n=6, all male, mean age 35.0 years, mean BMI 26.9 kg/m^2) received 2 s.c. injections of placebo (-120 and 0 min) in the abdomen on Day 1 followed by 2 s.c. injections of exenatide 5 μg (10 μg total at -120 and 0 min) in the abdomen on Day 2. Part 2: Subjects (n=18, 15 male, mean age 35.9 years, mean BMI 26.9 kg/m^2) received placebo on Day 1 followed by MAR701 8 mg on Day 2 (Cohort 2, n=6), placebo on Day 1 followed by MAR701 4 mg on Day 2 (Cohort 3, n=6), and placebo on Day 1 followed by MAR701 16 mg on Day 2 (Cohort 4, n=6). ISR was assessed using a 2.5 hr graded glucose infusion (GGI) at 2, 4, 6, 8, and 12 mg/kg/min (30 min per step of 20% dextrose, IV) with sampling for glucose, insulin and C-peptide. GE was assessed by measuring absorption of 1000 mg oral acetaminophen elixir over 240 min.
Results: A dose-dependent increase in ISR was observed in response to exenatide at each GGI rate compared with placebo (p<0.001). MAR701 at all doses significantly increased ISR in a dose-dependent manner during each GGI step (p<0.0001). In contrast to exenatide, treatment with MAR701 did not significantly delay GE at any dose. Treatment with MAR701 was generally safe and well tolerated. The most common adverse events associated with treatment with MAR701 were hypoglycaemia (occurring after discontinuation of the GGI) and mild nausea that was not dose-dependent.
Conclusion: MAR701 significantly increased ISR at doses that had either no or minimal effects on GE.

149

Pharmacogenetic study of selected gene variants related to the pharmacodynamics of metformin with response to metformin treatment in type 2 diabetes

M. Javorsky[1], L. Klimcakova[2], Z. Schroner[1], E. Babjakova[1], M. Stolfova[1], H. Hermanova[2], M. Kozarova[1], I. Tkac[1];
[1]4th Department of Medicine, PJ Safarik University, [2]Department of Medical Biology, PJ Safarik University, Kosice, Slovakia.

Background and aims: The glucose lowering effect of metformin is mediated by activating AMP-activated protein kinase (AMPK) and possibly also by another mechanism. Previous pharmacogenetic studies observed associations of several gene variants related to pharmacodynamic effect of metformin with the response to metformin treatment. Among those genes, PRKAA1 encodes the A-subunit of AMPK. Proteins encoded by STK11 and probably also by ATM genes activate AMPK. The inhibition of gluconeogenesis downstream of AMPK is also mediated by inhibition of phosphoenolpyruvate carboxykinase encoded by PCK1 gene. The aim of the present study was to examine possible associations of the variants of the mentioned genes with the therapeutic response to metformin.
Materials and methods: 148 drug-naive patients with newly diagnosed type 2 diabetes (72 men/76 women) were included in the present study. Mean age (± SEM) was 57.5±0.9 years, mean baseline HbA1c was 7.64±0.09% (60.0±0.9 mmol/mol), and the mean daily metformin dose was 1400±40 mg. PRKAA1 rs249429 A>G, ATM rs11212617 A>C, STK11 rs8111699 C>G, and PCK1 rs4810083 C>T were genotyped using real-time PCR with subsequent melting curve analysis. HbA1c reduction after 6-month metformin treatment (ΔHbA1c) was the primary endpoint of the study. Genetic models were statistically adjusted for age, sex, BMI, metformin dose, baseline HbA1c and creatinine level (p_adj).
Results: In the entire study group, 6-month treatment with metformin led to a reduction in HbA1c by 0.66±0.08%. All examined genotypes followed the Hardyho-Weinberg equilibrium. PCK1 rs4810083 C>T variant was significantly associated with ΔHbA1c [CC (n=38): 0.98±0.16%; CT (n=76): 0.62±0.12%; TT (n=34): 0.39±0.13%; p=0,038]. In the dominant genetic model, the CC homozygotes had significantly greater reduction in HbA1c in comparison with T-allele carriers (CC: 0.98±0.16% vs. CT+TT: 0.55±0.09%; p=0.021; p_adj=0.029). Beside the PCK1 genotype, significant predictors of the HbA1c reduction were also the baseline HbA1c (p<0.001) and the daily metformin dose (p=0.010). Further examined ATM, STK11, and PRKAA1 variants were not significantly associated with the response to the metformin treatment.
Conclusion: To the best of our knowledge, we observed for the first time an association between rs4810083 variant in PCK1 and the therapeutic response to metformin in patients with type 2 diabetes. 25% of patients who were CC homozygotes had greater decrease in HbA1c by 0.4% (4.7 mmol/mol) in comparison with the rest of the study group. This study needs further replication in a different population.

The novel glucagon-neutralising Spiegelmer NOX-G15 ameliorates hyperglycaemia in murine models of type 1 and type 2 diabetes

A. Vater[1], S. Sell[1], P. Kaczmarek[2], C. Maasch[1], K. Buchner[1], E. Pruszynska-Oszmalek[2], P. Kolodziejski[2], W.G. Purschke[1], K.W. Nowak[2], M.Z. Strowski[3], S. Klussmann[1];
[1]NOXXON Pharma, Berlin, Germany, [2]Department of Animal Physiology and Biochemistry, Poznan University of Life Sciences, Poland, [3]Department of Hepatology and Gastroenterology and Interdisciplinary Centre of Metabolism, Charité, Berlin, Germany.

Background and aims: Excessive secretion of glucagon significantly contributes to hyperglycemia in type 1 and type 2 diabetes mellitus (T1DM and T2DM). Accordingly, immunoneutralization of glucagon or genetic deletion of the glucagon receptor improved glucose homeostasis in animal models of diabetes. Despite this strong evidence, agents that selectively interfere with endogenous glucagon have not been implemented in clinical practice yet. We aimed to discover a mirror-image mixed aptamer (Spiegelmer) that binds and inhibits glucagon, and hypothesized that glucagon neutralization with this agent would reduce hyperglycemia in murine models of T1DM and T2DM.
Materials and methods: Using an in vitro selection process we have generated NOX-G15, a plasma-stable mirror-image (L)oligonucleotide (a so-called Spiegelmer), that directly binds and inhibits glucagon. The Spiegelmer was optimized in terms of pharmacokinetics by site-directed PEGylation. Affinity to glucagon and related peptides was determined using surface plasmon resonance (Biacore). Inhibition of glucagon action was demonstrated in cell-based cAMP formation assays using glucagon receptor-expressing CHO cells. A pilot pharmacokinetics study was performed in healthy mice with a single intraperitoneal injection of 10 mg/kg. Intraperitoneal glucose tolerance tests were performed in streptozotocin (STZ)-treated mice (T1DM) and high-fat diet plus STZ-treated mice (T2DM) after a single intraperitoneal injection of 10 mg/kg or 1 mg/kg. The glucagon receptor antagonist Des-His1-Glu9-glucagon and vehicle were used as controls (n=8-9).
Results: The Spiegelmer candidate NOX-G15 binds glucagon with an affinity of 6.3 nM. NOXG15 shows no cross-reactivity with related peptides, such as glucagon-like peptide1 (GLP-1), GLP-2, gastric-inhibitory peptide, and prepro-vasoactive intestinal peptide (prepro-VIP). *In vitro*, NOX-G15 inhibits glucagon-stimulated cAMP-production in CHO-cells overexpressing the human glucagon receptor with an IC_{50} of 3.4 nM. NOX-G15 has a terminal plasma half-life of 7 h. A single intraperitoneal injection of NOX-G15 (10 mg/kg or 1 mg/kg) ameliorated glucose excursions in intraperitoneal glucose tolerance tests (ipGTT) in mice with streptozotocin-induced (T1DM) diabetes and in a non-genetic mouse model of T2DM as shown by significantly reduced AUC (p<0.01 by One-way ANOVA and Tukey post-test).
Conclusion: The data suggest the novel glucagon-neutralizing Spiegelmer NOX-G15 as a therapeutic candidate with the potential to acutely attenuate hyperglycemia in T1DM and T2DM.

OP 26 Incretins: mechanisms of cardiovascular protection

Inhibition of DPP-4 activity: potential role of non-GLP-1-mediated cardioprotection in the post MI diabetes setting

K.A. Connelly, J. Desjardins, G. Kabir, M. Mitchell, Y. Zhang, K. Thai, S. Advani, A. Advani, R.E. Gilbert;
Medicine/Cardiology, Keenan Research Centre in the Li Ka Shing Knowledge Institute, St. Michael's Hospital and University, Toronto, Canada.

Background and aims: In addition to degrading glucagon-like peptide-1 (GLP-1), di-peptidyl peptidase 4 (DPP-4) also inactivates several chemokines. Among these is stromal derived factor-1 (SDF-1), a pro-angiogenic and cardiomyocyte protective protein that is currently in human trials for ischaemic heart disease. Accordingly, we hypothesized that DPP-4 inhibition may confer benefit following myocardial infarction (MI) in the diabetic setting as a consequence of enhanced SDF-1 availability rather than potentiating GLP-1. To test this hypothesis, we compared DPP-4 inhibition with GLP-1 agonism. In order to demonstrate SDF-1 specificity, we then antagonised SDF-1's cognate receptor, CXCR4, with AMD3100.
Materials and methods: To avoid the confounding effects of glucose-lowering of GLP-1, studies were conducted in Fischer F344 rats with streptozotocin (STZ)-diabetes. Rats were randomized to receive the DPP-4 inhibitor, saxaglitpin (10 mg/kg/d), liraglutide (1mg/kg/sc/d), saxagliptin and AMD3100 (1mg/kg/sc), or vehicle. Two weeks later, animals underwent experimental MI, induced by ligation of the left anterior descending coronary artery. Cardiac function, assessed by conductance catheterisation and echocardiography, were examined 4 weeks post-MI.
Results: Glycemic control was similar in all groups, as was MI size, systolic BP, and heart size (P=NS). DPP-4 activity was increased in diabetic animals when compared with control, and reduced by saxagliptin treatment ($p<0.05$). Four weeks post MI, mortality was reduced in saxagliptin-treated animals when compared with those receiving vehicle ($p<0.05$). When compared with untreated post-MI rats, those receiving saxagliptin had improved fractional shortening ($p<0.05$) and better function in both early and late phases of diastole, as measured by Tau and the slope of the end diastolic pressure-volume relationship, respectively ($p<0.05$ for both). By contrast, cardiac function in liraglutide-treated animals closely resembled that of vehicle-treated animals. Antagonism of CXCR4 in saxagliptin-treated animals prevented the improvement in systolic and diastolic function and was associated with increased mortality (all $p<0.05$) when compared with saxagliptin-treated animals.
Conclusion: Saxagliptin-mediated DPP-4 inhibition but not liraglutide-mediated GLP-1 agonism improved ventricular systolic and diastolic function post myocardial infarction in a model of type 1 diabetes. These findings suggest that non-GLP-1 effects such as SDF-1 potentiation may underlie the cardioprotective effects of DPP-4 inhibition.

Insights into the mechanism of action of linagliptin in reducing ischaemic brain damage following stroke in diabetic and non-diabetic mice

V. Darsalia[1], A. Olverling[1], T. Nyström[1], H. Ortsäter[1], H. Rosenbrock[2], Å. Sjöholm[1], T. Klein[2], C. Patrone[1];
[1]Karolinska Institutet, Stockholm, Sweden, [2]Boehringer Ingelheim, Biberach, Germany.

Background and aims: Type 2 diabetes (T2D) is a strong risk factor for stroke. Linagliptin is a dipeptidyl peptidase (DPP)-4 inhibitor in clinical use for the treatment of T2D. We recently demonstrated that linagliptin had superior neuroprotective efficacy to glimepiride in a stroke animal model in both normal and diabetic mice. The aim of this investigation was to determine the effect of linagliptin and glimepiride treatment on adult neurogenesis and neuroinflammation. Additional experiments were conducted to determine if linagliptin's neuroprotective effect was mediated via increased glucagon-like peptide (GLP)-1 levels in the brain.
Materials and methods: C57BL/6J male mice were fed a high-fat diet for 32 weeks to induce T2D. Mice were treated for 7 weeks with either linagliptin (10 mg/kg) or glimepiride (2 mg/kg). Stroke was induced at Week 4 of treatment by transient middle cerebral artery occlusion (MCAO). Blood DPP-4 activity, GLP-1 and glucose levels were assessed throughout the experiments. Ischaemic brain damage was measured by determining stroke volume and by stereological quantification of surviving neurons in striatum/cortex. Stroke-induced adult neural stem cell proliferation and neuroblast formation were assessed by quantifying Ki67 and doublecortin-positive cells, respectively. Striatal neurogenesis and gliogenesis were assessed by quantifying BrdU/NeuN- and BrdU/S100-positive cells, respectively. Neuroinflammation was assessed by quantifying Iba-1-positive microglial cells in striatum and cortex using stereological methods. GLP-1 levels in the brain were quantified after perfusion by ELISA in naïve mice treated with vehicle or linagliptin.
Results: Anti-stroke efficacy of linagliptin was shown in both diabetic and normal mice, whereas glimepiride was efficacious against stroke in normal mice only. These results suggest a linagliptin-mediated neuroprotective effect that is glucose-independent and may involve increased GLP-1 levels both in the blood and brain. Additional studies demonstrated that linagliptin treatment increased levels of active GLP-1 in the brain. Furthermore, adult neural stem cell proliferation increased in linagliptin-treated diabetic mice compared with glimepiride and vehicle controls. Interestingly, no differences between the treatment groups were observed in normal mice. Neuroblast formation, neurogenesis, and gliogenesis were unaffected between the groups. Thus, because anti-stroke efficacy by linagliptin was achieved in both normal and diabetic mice, no correlation was found between neural stem cell activation and linagliptin-mediated anti-stroke efficacy. Finally, no regulation of brain inflammation was observed with either linagliptin or glimepiride.
Conclusion: The mechanism of action at the basis of linagliptin's anti-stroke efficacy requires further study. However, if translated to humans, our findings may provide a basis for the use of DPP-4 inhibitors for the prevention and treatment of stroke in both diabetic and non-diabetic patients. Moreover, we hypothesise that diabetic patients at high risk for stroke may derive further benefit because of the increased proliferation of stem cells.

The suppressive effect of dipeptidyl peptidase-4 inhibitor on atherosclerosis is mainly attributable to the action of incretin in both non-diabetic and diabetic mice

M. Terasaki[1], M. Nagashima[1], K. Nohtomi[1], K. Kohashi[1], M. Tomoyasu[1], K. Shinmura[1], Y. Nogi[1], K. Sato[2], F. Itoh[2], T. Watanabe[2], T. Hirano[1];
[1]Department of Medicine, Division of Diabetes, Metabolism, and Endocrinology, Showa University School of Medicine, Tokyo, [2]Laboratory of Cardiovascular Medicine, Tokyo University of Pharmacy and Life Sciences, Tokyo, Japan.

Background and aims: Several recent reports have revealed that dipeptidyl peptidase (DPP)-4 inhibitors have a suppressive effect on atherosclerosis in hypercholesterolemic mice. It remains to be seen, however, whether this suppressive effect stems from increased levels of the active incretins, namely, glucagon-like peptide-1(GLP-1) and glucose-dependent insulinotropic polypeptide (GIP).
Methods: Male apolipoprotein E-null ($Apoe^{-/-}$) mice and db/db mice were fed an atherogenic diet for 4 weeks. Diabetes was induced in a subset of the $Apoe^{-/-}$ mice by multiple injections of streptozotocin. Mice were administered the DPP-4 inhibitor vildagliptin in drinking water over the same period. While receiving vildagliptin, the mice were subcutaneously infused with either saline, the GLP-1 receptor blocker exendin-9 (Ex-9), the GIP receptor blocker (Pro3)GIP, or both Ex-9 and (Pro3)GIP, via osmotic minipumps. Aortic atherosclerosis and oxidized low-density lipoprotein-induced foam cell formation in exudate peritoneal macrophages were determined. The gene expressions of GLP-1 and GIP receptors were measured by RT-PCR using 10-11 primers covering all exons. The direct effect of DPP-4 on foam cell formation was also determined.
Results: Vildagliptin treatment increased GLP-1 and GIP levels without affecting the food intake, body weight, blood pressure, or plasma lipid profile, though it reduced HbA1c only in diabetic mice. Diabetic $Apoe^{-/-}$ mice exhibited further-progressed atherosclerotic lesions and foam cell formation compared with nondiabetic counterparts. Nondiabetic and diabetic $Apoe^{-/-}$ mice showed a comparable response to vildagliptin, namely, remarkable suppression of atherosclerotic lesions with macrophage accumulation and foam cell formation in peritoneal macrophages. Ex-9 or Pro3 partially attenuated the vildagliptin-induced suppression of atherosclerosis. The two receptor blockers in combination abolished the anti-atherosclerotic effect of vildagliptin in nondiabetic mice but incompletely attenuated it in diabetic mice. Vildagliptin

treatment also suppressed foam cell formation in peritoneal macrophages in nondiabetic Apoe$^{-/-}$ and diabetic (Apoe$^{-/-}$ and db/db) mice, and this suppressive effect was abolished by infusions with Ex-9 plus Pro3. Gene expressions of GLP-1 and GIP receptors were detectable in peritoneal macrophages and J774 cells. Although these receptor genes were far less abundant than those in the vasculature or the pancreas, incretins elicited cyclic AMP generation in J774 cells, Incubation of DPP-4 or vildagliptin had no effect on macrophage foam cell formation.
Conclusion: Vildagliptin exhibits a substantial anti-atherosclerotic effect in both nondiabetic and diabetic mice, mainly via the action of the two incretins. However, the partial attenuation of atherosclerotic lesions by the dual incretin receptor antagonists in diabetic mice implies that vildagliptin partly confers an anti-atherogenic effect beyond that from the incretins.

The DPP-IV inhibitor saxagliptin inhibits palmitate-induced apoptosis of human endothelial cells and cardiac progenitor cells
L. Laviola, M. Incalza, M.R. Orlando, C. Caccioppoli, A. Leonardini, R. D'Oria, V. Andrulli Buccheri, A. Natalicchio, S. Perrini, F. Giorgino;
Endocrinology & Metabolic Diseases, University of Bari, Italy.

Background and aims: Exposure of endothelial cells and cardiomyocytes to the fatty acid palmitate results in cell dysfunction and apoptosis. DPP-IV inhibitors may exert protective actions on the cardiovascular system. The aim of this study was to investigate the protective effects of the DPP-IV inhibitor saxagliptin on palmitate-induced apoptosis of human umbilical vein endothelial cells (HUVEC) and human cardiac progenitor cells (hCPC).
Materials and methods: Human cardiac progenitor cells isolated from right auricle biopsies and HUVEC were exposed to 0.25 mM palmitate up to 24 h, with or without pretreatment with the DPP-IV inhibitor saxagliptin (0.05 mM). Gene expression was evaluated by quantitative RT-PCR. Expression and phosphorylation levels of the proteins under investigation were evaluated by immunoblotting techniques. Cell apoptosis was detected by measurements of caspase-3 cleavage and cytosolic release of oligosomes.
Results: Expression of DPP-IV in HUVEC and hCPC was confirmed at the mRNA level by quantitative RT-PCR, and at the protein level by immunoblotting and immunofluorescence. Exposure of HUVEC to 0.25 mM palmitate for up to 24 h resulted in reduced Akt phosphorylation, increased expression of the adhesion molecule ICAM-1 ($p<0.05$) and of the pro-apoptotic mediator Bax ($p<0.05$), and was associated with a 5- to 7-fold increase in cellular apoptosis ($p<0.05$). Continuous long-term exposure to palmitate also increased apoptosis of hCPC by 5-fold ($p<0.05$). Pretreatment with the DPP-IV inhibitor saxagliptin (0.05 mM) for short times (5 to 15 min) resulted in a dose-dependent increase in the phosphorylation of Akt, Erk-1/2 and eNOS in HUVEC, and of Akt in hCPC ($p<0.05$). Importantly, both in HUVEC and hCPC exposed to palmitate, saxagliptin restored Akt phosphorylation and almost completely abrogated palmitate-induced apoptosis ($p<0.05$); however, this response required preincubation of the cells for at least 2 h, whereas shorter times were ineffective. Pretreatment with the GLP-1 receptor agonist exendin-4 (20 nM for 2 h) resulted in inhibition of palmitate-induced apoptosis in HUVEC, and this effect was abrogated in the presence of the GLP-1 receptor antagonist exendin 9-39. However, pretreatment of the cells with exendin 9-39 did not alter the ability of saxagliptin to counteract palmitate-induced apoptosis.
Conclusion: Saxagliptin prevents palmitate-mediated apoptosis of HUVEC and hCPC, thereby augmenting the potential for vessels and heart regeneration under conditions of lipotoxicity. Even though saxagliptin can activate Akt signaling within minutes, inhibition of cellular DPP-IV for at least 2 h is required to observe the anti-apoptotic effect of the drug, which appears to occur independently of the GLP-1 receptor. Altogether, these findings suggest that saxagliptin may promote cell survival via increased bioavailability of non-GLP-1 peptides.

Exendin-4 counteracts palmitate-induced apoptosis by inhibiting de novo production of ceramides in human cardiac progenitor cells
A. Leonardini, L. Laviola, R. D'Oria, M. Incalza, V. Andrulli Buccheri, M.R. Orlando, A. Natalicchio, S. Perrini, F. Giorgino;
Endocrinology & Metabolic Diseases, University of Bari, Italy.

Background and aims: Ceramides have been suggested to promote lipotoxicity-induced apoptosis in various cell types. Increased apoptosis of cardiomyocytes and cardiac progenitor cells in response to metabolic and oxidative stressors has been proposed as a mechanism of myocardial damage and dysfunction. Glucagon-like peptide-1 (GLP-1) and GLP-1 receptor (GLP-1R) agonists have been shown to exert prosurvival effects on cardiac cells. The aim of this study was to investigate the mechanisms of fatty acid-mediated apoptosis and the protective effects of the GLP-1R agonist exendin-4 in human cardiac progenitor cells (hCPCs).
Materials and methods: Human cardiac progenitor cells were isolated from right auricle biopsies and exposed to 0.1 to 0.5 mM palmitate up to 24 h, with or without pretreatment with 20 nM exendin-4 for 16 h. Expression and activation levels of the proteins under investigation were evaluated by immunoblotting techniques. Cell apoptosis was detected by TUNEL assay and by the evaluation of caspase-3 activation, caspase-3 cleavage and cytosolic release of oligosomes. Intracellular ceramide content was evaluated by fluorescent microscopy. Fumonisin-B1 was used to inhibit ceramide synthase (CerS5), a key enzyme in ceramide generation. Silencing of CerS5 was obtained by specific siRNA sequences. Exendin 9-39, a GLP-1R antagonist, was used as a competitive inhibitor of exendin-4.
Results: Palmitate led to apoptosis of hCPCs in a dose- and time-dependent manner ($p<0.05$). In hCPCs, palmitate induced significant increases in both intracellular ceramide content and mRNA and protein levels of CerS5. Conversely, palmitate did not modify gene and protein expression of serine palmitoyltransferase and dihydroceramide desaturase 1, other enzymes involved in de novo ceramide synthesis. Co-incubation of hCPCs with fumonisin-B1 prevented ceramide accumulation and partially inhibited palmitate-induced apoptosis. Moreover, knockdown of CerS5 with specific siRNAs partially protected hCPCs from the apoptotic effects induced by palmitate. When cells were pretreated with the GLP-1R agonist exendin-4, the palmitate-induced increase in ceramide levels was prevented ($p<0.05$), and cell apoptosis was coordinately reduced ($p<0.05$). Furthermore, exendin-4 prevented the increase in CerS5 expression, both at the gene and protein levels, which occurred in response to palmitate. The protective effects of exendin-4 were abolished when cells were co-incubated with the GLP-1R antagonist exendin 9-39.
Conclusion: Palmitate induces CerS5, a key enzyme of de novo ceramide synthesis, and this results in increased cellular content of ceramide and apoptosis of hCPCs. The GLP-1R agonist exendin-4 prevents palmitate-mediated increase in CerS5 expression, thus counteracting palmitate-induced ceramide accumulation and cell apoptosis. Amelioration of lipotoxicity via ceramide modulation may contribute to the cardioprotective effects of GLP-1R agonists in individuals with type 2 diabetes.

Incretin-based treatments suppress human macrophage foam cell formation and VSMCs migration and proliferation contributing to atherosclerosis prevention
M. Tomoyasu[1], T. Watanabe[2], J.r.K. Kaneyama[3], M. Terasaki[1], K. Nohtomi[1], K. Sato[2], F. Itoh[2], A. Miyazaki[3], T. Hirano[1];
[1]Department of Medicine, Division of Diabetes, Metabolism and Endocrinology, Showa University School of Medicine, Tokyo, [2]Laboratory of Cardiovascular Medicine, Tokyo University of Pharmacy and Life Sciences, Tokyo, [3]Department of Biochemistry, Showa University School of Medicine, Tokyo, Japan.

Background and aims: We previously reported the suppressive effects of glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP) on macrophage-driven atherosclerosis in apolipoprotein E-deficient (Apoe$^{-/-}$) mice. Our present study investigated the suppressive effects of these incretins as well as GLP-1 analogs on human macrophage foam cell formation and human vascular smooth muscle cells (VSMCs) migration and proliferation in relation to atherosclerotic lesion prevention in Apoe$^{-/-}$ mice.
Materials and methods: Receptors for GLP-1 and GIP in human VSMSc, monocytes and macrophages were measured with real time PCR. GLP-1 (10

nmol/L), GIP (1 mol/L) or exendin-4 (100 nmol/L) was added to the cultured medium of human monocytes and adherent monocytes were incubated for 7days.Cellular lipids were extracted and the radioactivity of the cholesterol [3H]oleate and cholesterol esterification assay was measured by thin-layer chromatography.CD36 in macrophages was measured by Western blot. VSMCs were seeded and cultured in smooth muscle cell basal medium(SmBM) and the cells were exposed to 5'-bromo-2'-deoxyuridine(BrdU). VSMCs were incubated for 48~72 hours with platelet-derived growth factor-BB(PDGF-BB)and the indicated concentrations of GLP-1 or GIP. BrdU-positive cells were visualized by immunostainning and determined under the microscope. Cell migration was measured using modified Boyden chambers. VSMCs were plated and incubated for 20 hours with PDGF-BB and the indicated concentrations of GLP-1 or GIP. Migration was quantified by counting the number of stained cells. Apoe-/- mice at 17-week-old were infused of GLP-1(2.2 nmol/ kg/ day), GIP(25nmol/kg/day) or liraglutide(107nmol/kg/day) for 4 weeks and were measured their aortic atherosclerotic lesions.

Results: Receptors for GLP-1 and GIP were expressed in human VSMCs, monocytes and macrophages.GLP-1 (10 nmol/L), GIP (1 nmol/L) or exendin-4 (100 nmol/L) significantly suppressed oxidized low-densitylipoprotein(oxLDL)-induced foam cell formation mainly via CD36 down-regulation in human monocyte-derived macrophages. GLP-1(1nmol/L),GIP(1nmol/L),exendin-4 (100 nmol/L) and liraglutide (100 nmol/L) significantly suppressed the proliferation of VSMCs, via the individual receptors. GLP-1(1nmol/L), GIP(1nmol/L) suppressed the migration of VSMCs. Above experiments were performed with the treatment of dipeptidyl peptidase-4 inhibitors to prevent the degradation of GLP-1 and GIP. Infusion of GLP-1 or GIP into Apoe$^{-/-}$mice significantly suppressed the occupied areas of migrated monocytes/macrophages and proliferative phenotype of VSMCs within aortic atherosclerotic lesions. Further, infusion of liraglutide into Apoe$^{-/-}$mice significantly suppressed aortic atherosclerotic lesions associated with the suppression of oxLDL-induced foam cell formation and CD36 expression in macrophages.

Conclusion: Incretin treatments suppress human macrophages foam cell formation and VSMCs migration and proliferation, leading to the prevention of atherosclerotic lesion development.

OP 27 Pregnancy: GDM diagnosis and foetal outcomes

157

Gestational diabetes mellitus (GDM) using the new IADSPG criteria: relative importance of different abnormal glucose values and evaluation of risk factors

V. Vasileiou, L. Spanou, A. Papadimitriou, A. Saltiki, M. Alevizaki, E. Anastasiou;
1st Endocrine Section, Diabetes Center, Alexandra Hospital, Athens, Greece.

Background and aims: The adoption of the new IADPSG diagnostic GDM criteria based on the HAPO study has significantly increased its prevalence. An interesting finding of this study was the observed differences in the relative diagnostic importance of the fasting (FPG) or one of the two post glucose values, which may give the opportunity for a simplification of the testing procedure.The aim of this study was to apply retrospectively the IADPSG GDM criteria on a large sample of pregnant women and to evaluate (a) the contribution of different abnormal glucose OGTT values on GDM diagnosis; (b) the significance of risk factors on GDM development

Materials and methods: Over a period of 15 years, at a tertiary hospital, 9829 pregnant women without known DM underwent a 100g or 75g OGTT in the third trimester of pregnancy. For GDM diagnosis the IADPSG criteria were applied. Age, pre-pregnancy BMI, family history (FH) of DM, parity, education status and smoking were recorded. For statistical analysis stepwise logistic regression was applied and odds ratios (OR-95%CI) calculated.

Results: 5300/9829 (53.9%) women presented with GDM, using IADPSG criteria vs 33% with the previous ADA-2000 criteria. The percentage of GDM diagnosed by each glucose measure in the OGTT were as follows: FPG≥threshold without regard to 1-h and 2-h value=56%, 1-h PG≥threshold without regard to 2-h value and FPG<threshold=34% and only 2-h PG≥threshold=10%. Further, independent risk factors for GDM prevalence, using a stepwise logistic regression model, were: BMI>25 kg/m2 OR=1.99 (1.82-2.17), Age>30y OR=1.98 (1.81-2.16), Maternal FH OR=1.73 (1.48-2.02), Paternal FH OR=1.34 (1.16- 1.56). When all the four risk factors were present in a woman the possibility to develop GDM was calculated to 83.3%. Parity, education status and smoking were not found to be risk factors for GDM.

Conclusion: The adoption of the new IADPSG criteria for GDM diagnosis, as expected, increased significantly the prevalence of GDM. As 90% of GDM women in our center were diagnosed based on the abnormal values of fasting and 1-h samples, it seems reasonable to consider omitting the 2-h sample for patient convenience and cost effectiveness. Further, this large study evaluated the importance of risk factors for GDM prevalence independently and showed that BMI>25 kg/m2 and age>30y are of equal value, while the family history of DM on the maternal side is more important risk factor than on the paternal side

158

Maternal insulin resistance affects foetal brain activity

K. Linder[1], F. Schleger[2], C. Ketterer[1], L. Fritsche[1], I. Kiefer-Schmidt[3,2], A. Hennige[1,4], H.-U. Häring[1,4], H. Preißl[2,4], A. Fritsche[1,4];
[1]Internal Medicine IV, Endocrinology and Diabetology, Angiology, Nephrology and Clinical Chemistry, University Hospital Tübingen, [2]FMEG Center, Eberhard Karls University Tübingen, [3]Department of Obstetrics and Gynecology, University Hospital Tübingen, [4]Institute for Diabetes Research and Metabolic Diseases of the Helmholtz Center Munich at the University of Tübingen (Paul Langerhans Institute Tübingen), Member of the German Center for Diabetes Research (DZD), Tübingen, Germany.

Background and aims: Fetal programming plays an increasingly important role in the attempt to explain the pathogenesis of metabolic syndrome and type 2 diabetes mellitus. Recent studies underline the importance of the insulin resistance of the central nervous system in this process. The aim of the present study was to investigate whether maternal metabolic changes during OGTT (oral glucose tolerance test) have an impact on fetal brain activity in humans.

Materials and methods: 14 healthy pregnant women (mean gestational age 31 ± 3 weeks) underwent an oral glucose tolerance test (75g). Glucose and insulin levels were measured after 0, 60 and 120 minutes, and insulin resist-

ance (HOMA IR) was calculated. Each blood extraction was preceded by fetal brain activity recordings on a fetal magnetoencephalographic device (fMEG). Response latencies of auditory evoked fetal brain responses were extracted.
Results: During OGTT, insulin increased roughly 15 fold and glucose 2 fold 60 minutes after glucose ingestion as expected. A MANOVA was performed to test the effect of time during OGTT on response latencies There was a marginally significant main effect of time on response latency ($F(2)=2.89$, $p=0.073$) resulting in a delay of response to the auditory stimulus during OGTT from baseline to 60 minutes after glucose administration (0.043 post hoc test). Furthermore, there was a positive correlation between insulin resistance of the mother and auditory evoked response at 60 minutes after glucose ingestion ($p=0.018$, $r2=0.34$). The auditory evoked response showed also a positive correlation of the mothers insulin level 60 minutes after glucose ingestion and the corresponding auditory evoked response of the fetus ($p=0.022$, $r2=0.31$).
Conclusion: Higher maternal insulin resistance leads to slower fetal brain responses in postprandial conditions suggesting that the genesis of central insulin resistance may occur already during fetal development.

159

Maternal glucose variability and neonatal metabolic outcome in women with pregnancy complicated with type 1 diabetes
E. Wender-Ozegowska, A. Zawiejska, J. Brazert;
Dept. of Obstetrics and Women's Diseases, Poznan Univ. of Medical Sciences, Poland.

Background and aims: Diabetic pregnancy is associated with impaired perinatal outcome also in women who improved their metabolic control throughout gestation. Therefore, novel markers of metabolic control are tested for their usefulness in diabetic pregnancy. In our study, we investigated whether there is any association between maternal parameters of glucose variability (GV) and metabolic outcome in newborns born to women with type 1 diabetes mellitus (T1DM).
Materials and methods: A prospective observational study including N=85 women with T1DM, in early singleton pregnancy. In all participants, 18-point daily glycaemic profile was taken once in each trimester and GV was calculated for each trimester. Upon delivery, following parameters were taken in newborn: birth weight, neonatal glycaemia (measured within six hours after delivery), umbilical cord insulin, glucose and IGFBP levels (collected immediately after delivery). Then, we sought for associations between GV (mean, SD, mean amplitude of glycaemic excursion-MAGE, JINDEX, low blood glucose index-LBGI and high blood glucose index-HBGI) and data collected from newborns.
Results: Characteristics of the study group: gestational age at booking: 13.5±7.5 weeks, HbA_{1c} at booking: 7.7±1.1%, prepregnancy body weight: 63.8±12.7 kg, prepregnancy BMI: 23.7±4.3 kg/m2, microvascular complications: N= 42 (49.4%). We did not find any association between neonatal characteristics and GV from Ist and IInd trimester. We found significant correlations (for all, $p<0.05$) between cord insulin and IIIrd trimester mean, SD, JINDEX and HBGI (Spearman's coefficient: 0.30, 0.26, 0.32, 0.32, respectively), between cord insulin/ glycaemia ratio and IIIrd trimester mean, SD, JINDEX and HBGI (Spearman's coefficient: 0.33, 0.27, 0.33, 0.29, respectively), between neonatal glycaemia and IIIrd trimester mean and JINDEX (Spearman's coefficient: 0.26, 0.25, respectively) and neonatal glucose/ insulin ratio and IIIrd trimester mean, SD, JINDEX and HBGI (Spearman's coefficient: 0.39, 0.32, 0.39, 0.36, respectively). Neonatal hypoglycaemia was associated with significantly higher mean and JINDEX (for all, $p<0.05$). Birth weight above 4000g was associated with significantly lower LBGI ($p<0.05$).
Conclusion: Maternal GV is associated with increased markers of poor metabolic neonatal outcome in women with T1DM, confirming the role of proper and stable glucose levels during diabetic pregnancy.

Parameters of maternal glucose variability as predictors of birth weight and neonatal metabolic status in pregnancy complicated with gestational diabetes mellitus
A. Zawiejska, E. Wender-Ozegowska, J. Brazert;
Dept. of Obstetrics and Women's Diseases, Poznan University of Medical Sciences, Poland.

Background and aims: Gestational diabetes mellitus (GDM) is a perinatal complication of increasing prevalence. As neonatal risk is elevated also in women who managed to improve their metabolic control throughout gestation, different maternal characteristics are studied to find out whether they can add to prediction and prevention of neonatal complications in this population.
Materials and methods: A prospective observational study including N=115 women with GDM, in singleton, viable pregnancy, referred to our Department for further treatment. In all participants,18-point daily glycemic profiles were taken in the IIIrd trimester and parameters of glucose variability (GV) were calculated using EasyGV version 8.7 software. Upon delivery, following parameters were taken in newborn: birth weight, neonatal glycemia (measured within six hours after delivery), umbilical cord c-peptide, insulin, glucose and IGFBP levels (collected immediately after delivery). Then, we investigated whether GV (mean, SD, mean amplitude of glycemic excursion-MAGE, M-value, JINDEX, low blood glucose index-LBGI and high blood glucose index-HBGI) can serve as predictors for neonatal metabolic status.
Results: Characteristics of the study group: gestational age at booking: 28.5±7.5 weeks, HbA1c at booking: 6.5±1.1%, prepregnancy body weight: 69.5±16.0 kg, prepregnancy BMI: 26.5±6.0 kg/m2, insulin therapy: N=38 (33.0%), prepregnancy obesity: N=36 (31.3%). IIIrd trimester LBGI and M-value were significant predictors for birth weight above 4000g (for LBGI: AUC 0.74, $p<0.001$, sensitivity 80.0%, specificity 64.9% for a cut-off value 3.18, for M-value: AUC 0.74, $p<0.001$, sensitivity 70.0%, specificity 76.3 for a cut-off value 3.44). None of studied GV parameters were predictive of neonatal hypoglycemia (glucose level below 40 mg/dL/ 2.2 mmol/L), low cord glycemia (measured as below 25th percentile for a study group), high c-peptide cord level (measured as above 75th percentile for a study group) or high/ low IGFBP cord level (measured as above 75th/ below 25th percentile for a study group).
Conclusion: 1/ short term maternal glucose variability measured in the last trimester has an impact on fetal growth in women with GDM.

161

Decreased cord blood serum dipeptidyl-peptidase 4 (DPP4) enzymatic activity in gestational diabetes mellitus
O. Hadarits[1], Z. Al-Aissa[1], K. Rosta[1,2], J. Harreiter[2], A. Zóka[1], D. Bancher-Todesca[2], A. Patócs[1], J. Rigó[1], A. Somogyi[1], A. Kautzky-Willer[2], G. Firneisz[1];
[1]Semmelweis University, Budapest, Hungary, [2]Medical University of Vienna, Austria.

Background and aims: Tissue-specific DPP4 dysregulation in adults with diabetes mellitus including that diabetes reduced DPP4 activity in the bone marrow stem cell niche was described. Alterations of the DPP4-incretin axis have not been studied in fetal life in gestational diabetes mellitus (GDM). We have assessed the DPP4 activity and the GLP-1 hormone levels in cord blood samples taken at delivery of healthy and GDM pregnancies.
Materials and methods: One hundred-twenty five pregnant women were enrolled to the study after signing the informed consent: 54 women with GDM and 71 age-matched pregnant females with normal glucose tolerance (age: Mean±SD: GDM: 32.6±5, Controls: 31.6±5.1 years). Obviously there were significant ($p<0.05$, independent T-test) differences between the GDM and control groups in the OGTT values assessed on the 24th-28th gestational week (plasma glucose 0': 4.47±0.54 vs 4.75±0.62 mmol/L; 60': 6.72±1.6 vs 9.52±0.6 mmol/L; 120': 5.54±1.14 vs 8.04±1.46 mmol/L in the control and GDM group, respectively). Women with GDM gained more weight during pregnancy than controls (13.8±4.8 vs 10.3±6.3 kg, $p=0.0005$, independent T-test), but neither in the pregestational BMI nor in the neonatal birthweight were differences detected between the two groups. There were 2 twin pregnancies in the GDM group. DPP4 enzymatic activity was measured in human cord blood serum at 37°C in continuous monitoring microplate based kinetic assay on Varioskan Flash (Thermo Scientific) reader at 405nm for 30 min using Gly-Pro-PNA (Bachem) as substrate. Results were expressed in unit per liter (U/L). Cord plasma samples were taken in tubes containing EDTA, pro-

tease inhibitor cocktail (Sigma-Aldrich) and sitagliptin to measure biologically active forms of plasma GLP-1 [GLP-1 (7-36 amide) and GLP-1 (7-37)]. Fluorescence ELISA assay (GLP-1 active kit, Millipore) was used under conditions as suggested by the manufacturer on a Varioskan Flash ELISA reader. For statistical analysis Shapiro-Wilks, Mann-Whitney-U (MW-U) and independent T-tests were used.
Results: DPP4 activity in human cord serum samples from GDM pregnancies (n=56) was significantly lower than that of controls (n=71) (Mean±SD: 29.31±10.37 U/L vs 35.84±12.8 U/L, MW-U p=0.0017). There was no difference in the serum cord blood DPP4 activity within the GDM group when the insulin treated (12 pts) and non-insulin treated (32 pts) groups were compared (27.71±7.08 U/L vs 30.39±11.5 U/L, p=0.64). The level of biologically active GLP-1 hormone was significantly higher in the cord plasma of neonates born from GDM pregnancies (Mean±SD: 4.99±2.95 pM) than that of controls (3.07±1.39 pM, p=0.022, MW-U). Due to the smaller set of samples in GLP-1 measurements (GDM n=11, control n=21) applied additional cord plasma samples should be assessed and be analyzed for potential correlations with other data.
Conclusion: To our knowledge this is the first study that assessed the DPP4 activity and GLP-1 hormone levels in cord samples of neonates born from GDM and healthy pregnancies. The decreased serum DPP4 activity in neonates from GDM pregnancies might be the result of an adaptive fetal response or part of an early dysregulation in entero-insular axis in fetal life. The consequences of decreased DPP4 activity might be beyond the alterations of incretin hormone levels.

Earlier management with continuous monitoring blood glucose decrease gestational weight gain in gestational diabetes mellitus: a randomised clinical trial
Q. Wei, S. Wang, Y. Yang, Z. Sun;
Zhongda Hospital, Southeast University, Nanjing, China.

Background and aims: To examine the effectiveness of continuous glucose monitoring on maternal glycemic control, gestational weight gain, infant birth weight in women with gestational diabetes mellitus.
Materials and methods: A total of 106 pregnant women at 22-28 gestational weeks diagnosed with gestational diabetes mellitus (GDM) were randomly allocated to have continuous glucose monitoring system (CGMS, n =51) or self-monitoring blood glucose (SMBG, n = 55), based on similar dietary, aerobic exercise and antenatal care. In 24 out of 51 used CGMS during second trimester, the rest (n =27) used during third trimester. The primary outcome was maternal glycemic control, total weight gain and drug-treated proportion. Birth weight, Apgar score and customized birth weight centiles were defined as secondary outcome. Statistical analyses were done on an intention to treat basis.
Results: Women randomized to continuous glucose monitoring had lower gestational weight gain compared with women randomized to self-monitoring blood glucose (difference between groups, p =0.040). The data also found that wearing CGMS during second trimester lead to lower proportion maternal weight gain than those during third trimester, p =0.018).In patients monitored with insulin-treated was introduced (16/51) whereas only 7/55 in the self-monitoring group were drug-treated (difference between groups, p = 0.032). There were no statistically significant differences between the groups regarding maternal age, family history of diabetes, hypertension in pregnancy, pre-pregnancy BMI, HbA1c, fasting plasma insulin, fasting C-peptide, postprandial 2h C-peptide , total cholesterol, HDL cholesterol, triglycerides and gestational weeks at delivery, Apgar score, infant birth weight or neonatal hypoglycemia.
Conclusion: Continuous glucose monitoring system, especially used during second trimester is associated with lower gestational weight gain, a higher proportion of insulin-treated patients were found using CGMS.

OP 28 Replacement of beta cell mass and function

163

Conditional expression of a constitutively active EGF-R in beta cells protects against diabetes
E. Hakonen[1], J. Ustinov[1], D.L. Eizirik[2], P.J. Miettinen[1,3], T. Otonkoski[1,3];
[1]Biomedicum Stem Cell Center, Research Program Unit, University of Helsinki, Finland, [2]Laboratory of Experimental Medicine, Universite Libre de Bruxelles, Belgium, [3]Children's Hospital, Helsinki University Central Hospital, Finland.

Background and aims: EGF-R signalling is required for normal pancreatic beta-cell development and proliferation. The beta-cell specific dominant negative EGF-R mice (E1-DN) become diabetic two weeks after birth with a 70-85 % reduced beta-cell mass. In the present study we investigated the effects of a constitutively active EGF-R on beta cell replication, mass and survival.
Materials and methods: We generated transgenic mice with tetracycline-inducible expression of a constitutively active EGF-R in beta cells (INS-CA-EGFR). This was done by crossbreeding INS-rtTA mice with TetOP-hEGFR-L858R mice. The double transgenic mice were given doxycycline-containing (DOX) diet to activate the transgene. Mice of different ages (E12.5-3 months) were given DOX for different time periods (1-9 months) and beta-cell proliferation and mass were analysed. Furthermore, the mice were challenged either with a single or multiple low doses of streptozotocin (MLDS) followed by blood glucose and insulin monitoring. Isolated islets from INS-CA-EGFR and INS-rtTA DOX-treated mice were exposed to cytokines (IL-1β, IFNγ, Tnf-α), and cell death was evaluated by live-dead assays. The expression profiles of selected genes were studied by quantitative RT-PCR.
Results: DOX administration and thus CA-EGFR expression from E12.5 to P30 increased beta cell volume as analysed by optical projection tomography (insulin positive volume 1,6% vs 1,1%; $p < 0.05$; $n = 6$). When DOX was given to adult mice during one or three months, there was no significant increase in beta cell proliferation or beta cell mass. Expression of the transgene improved survival and glycemia of the INS-CA-EGFR mice after a single injection of STZ: at two weeks post-injection 90% of the CA-EGFR mice were alive (mean blood glucose 21,4 mM), whereas only 60% of the STZ-injected control mice survived (mean blood glucose 33,2 mM, $p < 0.01$). Furthermore CA-EGFR improved glycemia and reduced lymphocyte infiltration after MLDS treatment (cumulative percentage of diabetes 100% in the control group vs 43% in INS-CA-EGFR mice, $p < 0.01$). In addition CA-EGFR protected isolated mouse islets from cytokine induced beta cell death (after 48h cytokine stimulation 9% dead cells vs 19% in control islets, $p < 0.05$; $n = 6$), which was likely mediated through repression of the proapoptotic protein Bim (1.7 vs. 1.0 fold induction in control vs. INS-CA-EGFR islets, $p<0.05$).
Conclusion: Expression of constitutively active EGFR in the developing pancreas, but not in adult pancreas, increases beta cell mass. Interestingly, EGF-receptor mediated signalling protects beta cells against streptozotocin- and cytokine-induced cell death.

PTP1B a key player in the improvement of survival of transplanted islet grafts
H. Figueiredo[1,2], A. Garcia[1,2], R. Fernandez[1,2], H.S.M. Farghaly[1,3], R. Gomis[1,2], R. Malpique[1,2];
[1]Diabetes and Obesity, IDIBAPS-Hospital Clinic, Barcelona, [2]CIBERDEM, Barcelona, Spain, [3]Faculty of Medicine, Assiut, Egypt.

Background and aims: Pancreatic islet transplantation is recognized as a hopeful and potentially curative treatment for type 1 diabetes, however clinically it remains limited by a post-transplantation massive islet loss and/or graft failure. Protein tyrosine phosphatases contribute for the regulation of critical phospho-tyrosine levels in the signal transduction pathways essential for intracellular signalling, cell growth, apoptosis or gene transcription. Protein tyrosine phosphatase 1B (PTP1B) is a negative regulator of insulin, leptin and growth-factor signalling. Recent studies have shown that PTP1B also negatively regulates angiogenic signalling. In view of these data, we hypothesised that PTP1B inhibition might be involved in graft survival and revascularisation and therefore constitute a potential therapeutic target for islet transplantation protocols.

Materials and methods: Islets isolated from wild-type and PTP1B-knockout mice were transplanted (150-200 islets/animal) into the anterior chamber of the eye of BALB/c diabetic mice (single injection of streptozotocin - 160mg/Kg, 8 days before transplantation). The animals were divided into 3 groups (n=9 animals per group): T - transplanted with wild-type isolated islets; T - KO - transplanted with PTP1B-KO isolated islets; CTRL - non-transplanted. In vivo studies were performed during 25 days of treatment to evaluate weight, glycaemic levels, and after treatment accessing cell viability and islet graft revascularisation. Post-mortem morphometric analysis and functional studies were conducted on graft-containing eyes.
Results: The T group exhibited a slight decrease in glycemia as compared to the CTRL group (T:418±48mg/dL, CTRL:528±20mg/dL, p<0.05). Remarkably, the T-KO group showed a more robust decrease in glycaemia (211±26 mg/dL) both when compared to the T group (49% decrease, p<0.01) or to the CTRL group (60% decrease, p<0.01). In vivo propidium iodide injection revealed a 73% decrease in cell death in the T-KO relative to the T group (0.25% and 0.95%, respectively; p<0.001). Concerning islet revascularization (functional vasculature), accessed by in vivo dextran injection, a 58% increase in vascular density (0.0297±0.0035% versus 0.0187±0.0053%; p<0.05) as well as a 2-fold increase in vascularisation area (23.180±1.9% versus 10.027±2.6%; p<0.001) was found for the T-KO when compared to the T group. In accordance with these findings, morphometric analyses of the graft-containing eyes revealed a 3-fold increase in the percentage of endothelial cells on islets from the T - KO group when compared with the T group (0.121±0.0096% and 0.0351±0.005%; p<0.001). No differences were found regarding proliferation rates measured by Ki-67 immunostaining.
Conclusion: Our results support the hypothesis that PTP1B plays a negative role on the survival and revascularisation of islet grafts, and may be a potential target for therapeutic treatment after islet transplantation. Future work will focus on further unravelling the molecular mechanism involved in these findings.

Acetyl-CoA carboxylase 1 is a critical regulator of beta cell mass
J. Cantley[1], P.T. Whitworth[1], A. Davenport[1], K.L. Hoehn[2], D.E. James[1], T.J. Biden[1];
[1]Diabetes and Obesity Program, Garvan Institute of Medical Research, Sydney, Australia, [2]Department of Pharmacology, University of Virginia Health System, Charlottesville, USA.

Background and aims: An adequate, functional beta cell mass is essential to maintain glucose homeostasis. Beta cells sense glucose and trigger insulin secretion using oxidative mitochondrial pathways. A distinctive feature of beta cells is the relatively high proportion of glucose-derived pyruvate entering mitochondrial anaplerotic pathways (non-oxidative), driving citrate export and cytosolic acetyl-CoA production, supporting the concept of an alternative glucose-sensing pathway. Acetyl-CoA Carboxylase-1 (ACC1) is the cytosolic, citrate-activated enzyme, coupling glucose metabolism to lipid biosynthesis by catalysing malonyl-CoA production from acetyl-CoA. We sought to test the role of this ACC1-coupled pathway in vivo.
Materials and methods: Beta cell ACC1 activity was ablated in mice using Cre/loxP mediated gene deletion.
Results: Constitutive ACC1-ablation in beta cells using Ins2-cre (bACC1KO) caused impaired in vivo glucose-stimulated insulin secretion (GSIS) and glucose intolerance (mean±SEM blood glucose excursion after 2g kg-1 i.p. bolus: cre-control 2023±76, bAcc1KO 2470±64, mmol l-1 120min-1; P<0.001 by unpaired 2-tailed t-test; n=17/29), with no effect on insulin action nor adiposity. Surprisingly, in vitro GSIS from sized-matched isolated islets was normal. Histological analysis revealed a marked reduction in beta cell mass in bACC1KO pancreata (cre-control 2.203±0.169, bACC1KO 1.042±0.107, mg; P<0.01; n=3), due to a reduction in both beta cell size and proliferation. Finally, we utilised a tamoxifen-inducible system to delete ACC1 in the beta cells of adult mice: this caused glucose intolerance four weeks post-ACC1 ablation, indicating that ACC1 plays an active role in maintaining a functional beta cell mass.
Conclusion: Our data reveal a critical role for ACC1, and potentially glucose-driven lipid synthesis, in regulating beta cell mass.

The LRH-1 agonist BL001 improves human islet survival and blunts development of hyperglycaemia in the RIP-B7.1 mouse model of experimental autoimmune diabetes
N. Cobo-Vuilleumier[1], M. Baquié[2], M. Bugliani[3], D. Bosco[4], G. Parnaud[4], M. Cejudo-Guillén[5], A. Spyrantis[6], P. Marchetti[3], B. Boehm[6], D. Pozo[5], L. St-Onge[7], B.R. Gauthier[1];
[1]Stem Cells, CABIMER-CSIC/US/UPO/JA, Sevilla, Spain, [2]Neurix SA, Geneva, Switzerland, [3]Dept. Clinical and Experimental Medicine, Universtiy of Pisa, Italy, [4]Cell Isolation and Transplantation Center, University of Geneva, Switzerland, [5]Cell Signalling, CABIMER-CSIC/US/UPO/JA, Sevilla, Spain, [6]Ulm University, [7]Munich, Germany.

Background and aims: We have previously shown that the orphan nuclear receptor LRH-1 is expressed in human and mouse islets and that its over expression protects β-cells against stress-induced apoptosis. Herein we evaluated whether a small LRH-1 agonist codenamed BL001 could improve human islet survival and function as well as to prevent development of hyperglycaemia in the RIP-B7.1 mouse model of experimental autoimmune diabetes (EAD).
Materials and methods: Mouse and human islets were pre-treated with 10 μM BL001 for 24 hours and subsequently exposed to cytokines for an additional 24 hours prior to assessing apoptosis. Insulin secretion in response to 16.5 mM glucose was measured on islets derived from healthy and Type 2 diabetic (T2D) human donors that were treated or not with BL001. For in vivo studies, RIP-B7.1 mice were pretreated with BL001 (10 mg/Kg body weight) once daily for 5 days prior to preproinsulin cDNA vaccination to induce the autoimmune response. Animals were then injected daily for up to 8 weeks with BL001 and blood glucose levels were measured weekly. Pancreas and spleen were extracted at various time points to performed histological studies and splenocyte proliferation assays.
Results: Cytokine-treated human and mouse islets exhibited a 60% increase in apoptosis as compared to control islets. In contrast, islets pretreated with BL001 were refractory to cytokine-induced apoptosis. Of note, control islets treated exclusively with BL001 exhibited a 40% reduction in cell death suggesting an improved viability subsequent to isolation. We next evaluated whether BL001 could ameliorate impaired insulin secretion of T2D islets as compared to healthy islets. The stimulatory index (SI, glucose-stimulated/basal insulin secretion) of T2D islets was 1.5 as compared to 2 for healthy islets confirming impaired insulin secretion. However, in the presence of BL001 the SI of T2D islets increased to 2 whereas the index of healthy islets remained constant. The impact of BL001 was then assessed in the RIP-B7.1 animal model of EAD. Within 8 weeks post vaccination, 60% of vehicle-treated animals developed hyperglycaemia whereas only 20% of BL001-treated animals exhibited high blood glucose. Autoreactive T-cells were detected in normoglycaemic BL001/vaccinated mice confirming that these animals mounted a proper immune response. Histological analyses performed on pancreas sections from normoglycaemic BL001/vaccinated animals revealed marginal insulitis as compared to hyperglycaemic vaccinated mice. These results suggest that BL001 treatment blunted the diabetes-prone detrimental immune response by regulating local inflammation.
Conclusion: Activation of LRH-1 using the small synthetic agonist BL001 rescues function of cultured human T2D and prevents development of hyperglycaemia in RIP-B7.1 mice, a process that appears to partly involve modulation of the local immune response. We thus provide proof-of-concept that LRH-1 is an attractive druggable target for the treatment of diabetes.

Insulin receptor internalisation and Erk signalling require caveolin-1 in pancreatic beta cells
J.D. Johnson[1], T. Albrecht[1], G.E. Lim[1], M. Piske[1], S. Li[1], I.R. Nabi[1], P. Gilon[2];
[1]Department of Cellular and Physiological Sciences, University of British Columbia, Vancouver, Canada, [2]Université Catholique de Louvain, Brussels, Belgium.

Background and aims: Type 2 diabetes is associated with defects in insulin receptor (InsR) signalling and a loss of functional beta-cells. The overall goal of this study was to understand the mechanisms by which insulin transmits its signals in beta-cells. It has been shown that internalization of the activated InsR complex is necessary to initiate full insulin signalling, but this process in beta-cells remains poorly understood. Our aim was to determine the proteins

involved in InsR internalization and elucidate their roles in InsR signalling, with a particular focus on Caveolin-1 (Cav1) which has been implicated in InsR traffic in other cell types.
Materials and methods: The InsR was labelled with monomeric fluorescent proteins in a non-critical linker region between the furin-like region and the transmembrane domain. InsR trafficking in MIN6 beta-cells was monitored using confocal microscopy and fast live cell total internal reflection microscopy (TIRFM). Super-resolution stimulated emission depletion (STED) microscopy was applied to resolve the organization of membrane nanodomains harbouring the InsR. InsR signalling was addressed by western blotting. In vivo effects of Cav1 deficiency were examined using systemic Cav1 knockout mice.
Results: TIRFM in living cells revealed that Cav1 is recruited to InsR membrane domains immediately before receptor internalization. To investigate the role of Cav1, we compared the plasma membrane content of the InsR in cells expressing Cav1 mutants of the Y14 tyrosine phosphorylation site. MIN6 cells over-expressing dominant negative Cav1-Y14F showed defective InsR internalization, with significant accumulation of InsR at the plasma membrane. Conversely, cells expressing the phosphomimetic Cav1-Y14D mutant had excess InsR internalization into large vesicles, also strongly suggesting a requirement for Cav1 in InsR internalization. Insulin stimulated Erk phosphorylation was decreased in MIN6 cells expressing the dominant negative mutant Cav1-Y14F. Conversely, Erk phosphorylation was enhanced in cells expressing Cav1-wt and Cav1-Y14D. Interestingly, insulin stimulated Akt phosphorylation was not affected by the overexpression of wild-type or mutant Cav1. siRNA mediated knock-down of Cav1 confirmed the requirement of Cav1 in Erk but not Akt signalling. These results were further validated by the analysis of Erk translocation in beta-cells of pancreatic sections obtained from Cav1 deficient mice. Interestingly, these mice display a significantly reduced beta-cell mass compared to littermate controls. These findings support a role for Cav1 in the mitogenic effects of insulin-induced Erk activation on beta-cells.
Conclusion: We identified Cav1 as a key protein in InsR trafficking and signalling. We discovered that Cav1 phosphorylation is specifically required for InsR internalization and the subsequent activation of Erk signalling. Our data support a model wherein Akt mediated InsR signalling occurs from receptors located at the plasma membrane and is therefore independent of Cav1 mediated InsR internalization. We demonstrated that Cav1-mediated InsR signalling plays a critical role in the maintenance of adult beta-cell mass. Together, our data provide new molecular insights into the mechanisms of insulin receptor trafficking in pancreatic beta-cells.

Protection from diabetes in mice with genetically engineered K-cells expressing modified proinsulin
M. Mojibian[1], S. Sassani[1], A. Asadi[1], R. Baker[1], T. Kieffer[1,2];
[1]Laboratory of Molecular and Cellular Medicine, Department of Cellular & Physiological Sciences, [2]Department of Surgery, University of British Columbia, Vancouver, Canada.

Background and aims: Several cell sources have been investigated for the development of surrogate insulin producing pancreatic beta-cells. The majority of candidate cell types do not have the machinery for proinsulin processing and meal regulated insulin secretion. Enteroendocrine K-cells line the intestinal epithelium and produce glucose-dependent insulinotropic polypeptide (GIP) and may be a good candidate for engineering to restore endogenous insulin production. In beta-cells, proinsulin is fully processed into mature insulin via prohormone convertases (PC) 1/3, PC2 and carboxy-peptidase E. However, unlike beta-cells, it has been shown that the majority of K-cells do not express PC2. The aim of this study was to optimize the processing of proinsulin in K-cells using a genetically modified insulin gene.
Material and methods: We generated transgenic mice with a transgene consisting of a rat GIP promoter linked to a modified proinsulin gene. Using a PCR based mutagenesis strategy, we changed the P4 residue in the proinsulin PC1/3 site from methionine to lysine to enhance PC1/3 cleavage at this site, and changed two residues in the PC2 site to resemble a PC1/3 cleavage site. Mice harbouring this transgene and their non-transgenic littermate controls were monitored for glucose homeostasis and body weight over one year, along with circulating GIP and insulin. An insulin tolerance test, oral glucose tolerance test and intraperitoneal glucose tolerance test were performed. Food intake, respiratory exchange rate, physical activity, and energy expenditure were assessed using metabolic cages. Lipid levels were profiled by measuring cholesterol, triglyceride and free fatty acid in collected plasma. The proportion of fat/lean tissues was evaluated with dual-energy X-ray absorptiometry. Protection from diabetes was assessed following injection with the pancreatic beta-cell toxin streptozotocin (STZ).
Results: Transfection experiments in gut cells (STC-1) with this GIP/Ins construct and Western blots of transgenic gut tissue validated proinsulin processing to mature insulin. Transgenic mice had equivalent body weight and insulin sensitivity to non-transgenic littermates but maintained significantly lower fasting blood glucose levels and dramatic improvements in glucose tolerance following either intraperitoneal or oral glucose. GIP levels were significantly lower in transgenic versus non-transgenic mice whereas insulin levels were ~50-fold higher, unchanged by STZ, and protected transgenic mice from STZ-induced diabetes. Isolated islets of transgenic animals were equally responsive to glucose stimulation but released less insulin at basal glucose concentrations compared to littermate islets. The transgene had no impact on body weight, fat/lean ratio, metabolic cages parameters and circulating levels of cholesterol, triglyceride and free fatty acids.
Conclusion: Our studies demonstrate simple genetic alterations to improve proinsulin processing and further support K-cells as candidate surrogate beta-cells for insulin replacement.

Genome-wide association studies for renal complications of type 1 diabetes

N. Sandholm[1,2], H. Deshmukh[3], E. Ahlqvist[4], N.W. Rayner[5], C. Ladenvall[4], C. Forsblom[1,2], V. Harjutsalo[1,6], L. Marcovecchio[7], FinnDiane Study Group, SUMMIT;
[1]Folkhälsan Institute of Genetics, Folkhälsan Research Center, Helsinki, [2]Division of Nephrology, Helsinki University Central Hospital, Finland, [3]Ninewells Hospital and Medical School, University of Dundee, UK, [4]Department of Clinical Sciences, Diabetes and Endocrinology, Lund University, Malmö, Sweden, [5]Wellcome Trust Centre for Human Genetics, University of Oxford, UK, [6]Diabetes Prevention Unit, National Institute of Health and Welfare, Helsinki, Finland, [7]Department of Paediatrics, Institute of Metabolic Science, University of Cambridge, UK.

Background and aims: Diabetic nephropathy (DN) is a major complication of diabetes and the leading cause of end-stage renal disease (ESRD) and there is evidence of a considerable heritable component. Hence we performed a meta-analysis of four genome-wide association studies (GWAS) of DN in type 1 diabetes (T1D) to identify genetic determinants of DN.
Materials and methods: DN was defined as microalbuminuria, macroalbuminuria or ESRD, whereas controls were defined as T1D patients with normoalbuminuria and T1D duration at least 15 years. GWAS data were available from four cohorts: FinnDiane (N=3,435), Eurodiab (N=812), Scania Diabetes Registry (SDR; N=513) and Cambridge (N=400), with ~2.4 million single nucleotide polymorphisms (SNPs) imputed with HapMapII CEU reference panel. Using logistic regression adjusted for age at onset of T1D, sex and duration of T1D, we studied the association of these SNPs with DN (2,563 cases and 2,597 controls in total) and with three additional case definitions: microalbuminuria (879 cases), the combination of macroalbuminuria and ESRD (1,743 cases), and ESRD alone (822 cases; Cambridge excluded due to low number of ESRD cases). Meta-analysis was performed using the fixed effects model.
Results: We identified several suggestive associations ($P<10^{-5}$). rs11123857, intronic in *NPAS2,* was associated with DN (OR=1.26, $P=7.3\times10^{-7}$) and microalbuminuria (OR 1.35, $P=4.8\times10^{-6}$). *NPAS2* is involved in the circadian rhythm pathway. Variants in *AFF3* were associated with ESRD (rs13405175, OR=2.04, $P=9.0\times10^{-7}$), as reported also in a recent meta-analysis including both the FinnDiane and the SDR studies. rs476865 between the *EN1* and *INSIG2* (insulin induced gene 2) was associated with the combined macroalbuminuria and ESRD phenotype (OR=0.69, $P=8.5\times10^{-7}$); SNPs in the same intergenic region have been suggestively associated with multiple traits including creatinine and LDL cholesterol. rs12640850 between the *RAPGEF2* and *FSTL5* was associated with microalbuminuria (OR=1.45, $P=1.2\times10^{-6}$), only 13kb away from a SNP earlier associated with VLDL cholesterol. We also examined SNPs previously reported for DN from GWAS or candidate gene studies, but only the association in *AFF3* remained significant after adjustment for multiple testing (four phenotypes and 35 SNPs, $P<0.0003$). However, this cannot be considered independent replication since the previous report of association at this locus included a subset of the same data.
Conclusion: We identified several putative loci for DN in T1D, but replication in independent studies is still required to confirm these findings. Imputation with 1000G reference panel may reveal more loci and help fine-map the implicated regions. Furthermore, functional analysis will be undertaken in SUMMIT to explain the affected biological pathways.

Background and aims: Although numerous prospective investigations have confirmed a lower risk of coronary artery disease (CAD) among individuals with diabetes carrying the Haptoglobin (Hp) 1-1 genotype, we recently reported a direct association between Hp 1-1 and stroke incidence in a cohort of type 1 diabetes (T1D). Given previous evidence in patients with hypertension of a correlation between Hp and extent of cerebral deep white matter lesions, we conducted neuroimaging studies to evaluate the presence of differences in brain white and gray matter volume by Hp genotype in our T1D population.
Materials and methods: Participants from the Epidemiology of Diabetes Complications (EDC) study, a prospective investigation of childhood onset T1D, attending the 24 year EDC study follow-up were recruited for a neuroimaging study during 2010-2012. A brain Magnetic Resonance Imaging (MRI) was completed using a Siemens 12-channel head coil in a 3T Siemens Tim Trio MR scanner in 112 eligible and willing participants (mean age, 48.7 and diabetes duration, 41 years).
Results: Among the 112 eligible and willing to participate, data on Hp were available for 96, of which 15.6% and 39.6% were homozygous for the Hp 1 and Hp 2 allele, respectively. Despite the small sample size, a trend toward increased total white matter hyperintensities volume (WMH) was observed with an increasing number of Hp 1 alleles (p-trend=0.03, Table 1). This association appeared localized in the corpus callosum (p-trend=0.004), especially the posterior part (p-trend=0.006). This association, though attenuated, remained significant for the total corpus callosum (p-trend=0.04) after adjustment for diabetes duration, but again differences in the posterior (p-trend=0.02) appeared stronger than in the frontal portion (p-trend=0.11). In separate models in a restricted sample with complete covariate data, further allowing for waist to hip ratio, HbA1c, systolic blood pressure and HDL cholesterol did not change these findings. No significant differences by Hp were noted in gray matter areas.
Conclusion: Despite being inversely related to CAD risk in T1D, the Hp 1-1 genotype correlates with WMH localized in the inter-hemispheric connecting fibers of the corpus callosum in this population. WMH are common in adults >65 years but rare in younger groups. The presence of WMH in the brain of middle aged adults with T1D may thus indicate an accelerated aging process, which appears linked to the presence of the Hp 1 allele. Further, including mechanistic, studies on the role of the Hp genotype in cerebrovascular disease are needed to shed light on the pathophysiology of these associations and possible therapeutic interventions.

Table 1. Total white matter volume (voxels) and corpus callosum by Hp

White matter areas	Hp 1-1 (n=15)	Hp 2-1 (n=37)	Hp 2-2 (n=35)	p-value	p-trend*
White matter hyperintensities x10^4	12.527 (7.372, 24.582)	8.990 (6.144, 15.164)	8.946 (5.279,13.312)	0.19	0.03
Posterior corpus callosum x10^4	1.16 (0.21, 4.29)	0.92 (0.12, 2.29)	0.29 (0.02, 0.77)	0.04	0.006
Frontal corpus callosum x10^4	2.63 (1.34, 5.06)	1.86 (1.09, 3.12)	1.41 (0.78, 1.98)	0.05	0.01
Corpus callosum x10^4	3.92 (2.28, 8.45)	2.74 (1.33, 6.12)	2.01 (0.97, 2.98)	0.03	0.004

Data are presented as median (interquartile range) * Logarithmically transformed variables were used

Known SNPs in ADAMTS7, the 9p21 region and UBE2E interact with type 2 diabetes status to modify the risk of coronary artery disease in large populations

N.R. van Zuydam[1,2], B. Voight[3], C. Ladenvall[4], R. Strawbridge[5], S. Willems[6], J. Hartiala[7], E. Vlacholpoulou[8], E. Mihailov[9], L. Kwee[10], L. Qu[3], A. Goel[1], J. Kumar[11], S. Kanoni[12], CARDIoGRAMplusC4D, SUMMIT;
[1]University of Oxford, [2]University of Dundee, UK, [3]University of Pennsylvania, Philadelphia, USA, [4]University of Lund, [5]Karolinska Institutet, Stockholm, Sweden, [6]Erasmus University, Rotterdam, Netherlands, [7]University of Southern California, Los Angeles, USA, [8]University of Helsinki, Finland, [9]University of Tartu, Estonia, [10]Duke University, Durrham, USA, [11]University of Uppsala, Sweden, [12]Sanger Institute, Cambridge, UK.

Background and aims: Patients with type 2 diabetes (T2D) are 3-4 times more likely to suffer from coronary artery disease (CAD) than individuals without T2D. Despite diabetic status contributing to the risk of CAD, no

overlapping loci between CAD and T2D have been identified by the largest genetic association studies to date. In this study, we aimed to: identify loci that modify the risk of CAD in patients with T2D; assess whether known CAD loci have a different effect on CAD risk in patients with T2D; and evaluate the influence of known T2D loci on CAD risk in non-diabetic individuals compared to patients with T2D.
Materials and methods: Summary statistics for 2,295,146 (directly typed and imputed) SNPs from 16,942 patients with T2D (6,022 CAD cases and 10,920 CAD free controls) and 28,727 non-diabetic individuals (10,892 CAD cases and 17,835 CAD free cases) were combined in a fixed effects meta-analysis and stratified by T2D status. The effects of 45 known CAD SNPs on CAD risk were tested for an interaction with T2D status and the effects of 61 known T2D SNPs on CAD were also tested for different effects in non-diabetic individuals compared to patients with T2D.
Results: The meta-analysis of SNP effects on CAD in patients with T2D identified associations in ADAMTS7 at genome wide significance that were represented by two independent SNPs previously reported for CAD. Rs11072811 (OR=1.17, effect allele frequency=0.53, proxy for rs7173743, p=3.9E-11) and rs11634042 (OR=1.15, effect allele frequency=0.58, proxy for rs4380028, p=5.7E-08) were associated with CAD in patients with T2D: rs11072811 had a smaller effect on CAD risk in non-diabetic individuals (OR=1.08, p=1.2E-02) when compared to its effect in patients with T2D, and this interaction with T2D status was nominally significant (p=3.5E-02). Atherosclerosis is a major underlying cause of CAD and is accelerated in patients with T2D. The meta-analysis of SNP effects in non-diabetic individuals also identified associations in the 9p21 region with CAD at genome wide significance. The signal was represented by rs1556516 (OR=1.17, effect allele frequency=0.48, p=2.9E-10) which is a proxy for the well-known CAD SNP rs1333049. Allelic effect sizes at this locus were smaller in patients with T2D (OR=1.10, p=3.9E-03), and the interaction with T2D status was nominally significant (p=4.2E-02). Investigation of the known T2D-risk loci revealed that the major allele (frequency=0.89) of rs7612463, in UBE2E2, decreased the risk of CAD in patients with T2D (OR=0.86, p=7.4E-03) but increased the risk of CAD in non-diabetic individuals (OR=1.11, p=3.7E-02). This interaction was significant after Bonferroni correction (p=7.2E-04).
Conclusion: This study suggests that known CAD SNPs in ADAMTS7 and 9p21, and known T2D SNPs in UBE2E may differentially modify CAD risk based on T2D status.

ADAMTS17 interacts with smoking status to increase the risk of lower extremity arterial disease in non-smokers and also increases the risk of LEAD in patients with diabetes
H. Colhoun[1], G. Þorleifsson[2], S. Grétarsdóttir[2], A. Paterson[3], C. Palmer[1], N. van Zuydam[1,4], SUMMIT;
[1]University of Dundee, UK, [2]deCODE Genetics, Reykjavik, Iceland, [3]The Hospital for Sick Children, Toronto, Canada, [4]University of Oxford, UK.

Background and aims: Lower extremity arterial disease is a major complication of type 1 and type 2 diabetes mellitus (DM) with smoking being an exacerbating risk factor. To date few large genetic association studies have been conducted for LEAD therefore the aim of this study was to identify genetic loci associated with LEAD in those with and without DM and to consider the impact of smoking on any genetic associations.
Materials and methods: LEAD cases were defined based on a history of lower limb amputations not due to trauma, vascular laboratory confirmed diagnoses, LEAD associated corrective procedures and medication to treat claudication; the control group excluded any individuals that conformed to the case definition. We performed fixed-effects meta-analysis of allelic effects, from 2381275 directly typed and imputed SNPs, estimated in an analysis of 2774 LEAD cases and 17941 controls. Analyses were also stratified by DM status (n= 1582 LEAD cases and 7715 controls with DM) and smoking status regardless of DM status (n=1904 LEAD cases and 17754 controls who ever smoked).
Results: A combined meta-analysis of patients with DM and non-diabetic individuals identified rs10757269, in CDKN2A/B, previously associated with LEAD as the most strongly associated SNP (OR=1.16, effect allele frequency=0.45 and p=1.62E-06), and replicated a previously reported association of rs1051730 (OR=1.16, effect allele frequency=0.66 and p=2.62E-05) in CHRNA3, an established locus for nicotine dependence, with LEAD. Other suggestive signals (p < 1E-07) were detected in CADM2, HIBADH, LPHN2, KAT2B, GAS7 and BMPR1A. A sub-group analysis of patients with DM found that rs10757269 CDKN2A/B was also associated with LEAD and had a similar allelic effect (OR=1.16 and p=3.46E-04) as overall, but rs1051730 was not associated with LEAD (OR=0.97, effect allele frequency=0.66 and p=5.24E-01. Suggestive associations were observed, in the meta-analysis of patients with DM, in or near gene regions plausibly associated with LEAD because of their roles in lipid metabolism and blood coagulation - LIPG, CTNNA3, LPHN2, LRP2 and LAPTM4B (p < 1E-07). The smoking interaction analysis revealed a significant interaction (p=8.79E-07) for rs12593235 in ADAMTS17, that increased the risk of LEAD in never smokers (OR=1.58, effect allele frequency=0.40, effect allele frequency=0.40, 95% CI (1.43 - 1.74), p=2.31E-07) when compared to its effect in ever smokers (OR=0.98, effect allele frequency=0.40, 95%CI (0.90 - 1.05), p=6.45E-01). The same risk allele was nominally significant for an increased risk of LEAD in patients with DM (OR=1.11, effect allele frequency=0.40, 95%CI (1.02 - 1.20), p= 3.41E-02) regardless of smoking status. Rs12593235 is part of a large quantitative trait locus that has been shown in other studies to interact with smoking status to increase blood pressure in non-smokers.
Conclusion: In this study we have detected signals in loci possibly associated with LEAD with some differences between the diabetes only and overall analyses. This would indicate that distinct genetic mechanisms underlie the development of LEAD in individuals who smoke and those that have diabetes. Additional analyses that include more individuals will be used to investigate this hypothesis.

Genome-wide association study for circulating levels of soluble receptor for advanced glycation end-products (sRAGE)
H. Deshmukh[1], P.M. McKeigue[2], H.C. Looker[1], N. Van Zuydam[3], E. Ahlqvist[4], G.A. Hitman[5], C.N.A. Palmer[1], H.M. Colhoun[1], on behalf of the CARDS Executive Committee, and the SUMMIT Investigators;
[1]University of Dundee, [2]University of Edinburgh, [3]Wellcome Trust Centre for Human Genetics, University of Oxford, UK, [4]Lund University, Malmö, Sweden, [5]Blizard Institute, Barts and The London, UK.

Background and aims: sRAGE levels have been found to be decreased in chronic inflammatory diseases including atherosclerosis, diabetes, renal failure and the aging process and is considered as a valuable vascular biomarker. However, the genetic determinants of the circulating sRAGE levels are not fully characterized.
Materials and methods: To identify loci associated with circulating sRAGE we combined genome-wide association study data from CARDS participants (n=594), genotyped using the Perlegen 6 SNP set and data from the GoDARTS type 2 diabetes cohort genotyped on Affymetrix Mapping 6 (n=348) and Illumina OmniExpress (n=440) platforms. Imputation of genotype at loci not directly typed was done to the HapMap II dataset using IMPUTE2. sRAGE was measured using the Quantikine Immunoassay (R&D Systems). We tested for an association of both directly typed and imputed SNPs with sRAGE using multiple linear regression implemented in SNPTEST adjusted for age, sex and BMI. Conditional logistic regression analysis in SAS 9.2 was used to test for the independence of associations found.
Results: 22 SNPs reached the genome-wide significance level of $p<10^{-8}$, all of which lie within 500kb of the *RAGE* locus. These markers were tagged by two SNPs, rs2070600 (MAF=5%, P=8.25E-18, beta= -0.14(±0.02)) the *Gly82Ser* variant in *RAGE* on chromosome 6 and rs9272346 an autoimmunity associated variant in the *HLA-DQA1* region (MAF=42%, P= 7.30E-09, beta= -0.05 (±0.01)). These markers were associated with sRAGE levels independently of each other. After adjustments for rs2070600, age, sex, and BMI, rs9272346 was significantly associated with sRAGE levels (P=0.0003). Together variation at these two loci explained 12% of the variance in circulating sRAGE. We note that both these SNPs (rs2070600 $MAF_{European}$=5% vs. $MAF_{African}$=10%; rs9272346 $MAF_{European}$=42% vs. $MAF_{African}$=48%) show ethnic variation in a direction that is consistent with the previously reported much lower total sRAGE in those of African Caribbean origin versus European populations.
Conclusion: We report a novel tagging variant rs9272346 in the *RAGE-HLA-DQA1* region independently associated with sRAGE levels and confirm the known association of sRAGE levels with the *Gly82Ser* variant (rs2070600) in the *RAGE* gene. Variation in the frequencies of these tagging markers, as seen in the HapMap samples may explain the ethnic differences in circulating sRAGE levels.

Circulating microRNAs and micro/macrovascular complications of type 1 diabetes

F. Barutta, S. Grimaldi, N. Chaturvedi, P. Cavallo Perin, G. Bruno, J.H. Fuller, G. Gruden;
Department of Medical Science, University of Turin, Italy.

Background and aims: MicroRNAs (miRNAs) are small non-protein-encoding RNAs that post-transcriptionally regulate gene expression via suppression of target mRNAs. Specifically, miRNAs bind through canonical base pairing to a complementary site in the 3' untranslated region of their target mRNAs and can direct the degradation or translational repression of these transcripts. MiRNAs are critically involved in many biological processes in health and diseases and there is preliminary evidence of a role of miRNAs in cardiovascular diseases and diabetic complications. MiRNAs are also present in the circulation in a remarkably stable form. Circulating miRNAs have been investigated in myocardial injury, coronary artery disease, and heart failure. In addition, a recent study has shown that loss of miRNA-126 is a charactheristic feature of patients who will develop type 2 diabetes. Vascular complications are major causes of morbidity and mortality in patients with type 1 diabetes (DM1); however, a systematic analysis of circulating miRNAs in DM1 patients with vascular complications has not yet been performed.
Materials and methods: We performed a cross-sectional nested case-control study from the EURODIAB Prospective Complications Study. A total of 531 DM1 patients, diagnosed at <36 years of age, were studied. Cases (n=363) were defined as those with one or more complications of diabetes and control subjects (n=168) were those with no evidence of any complication. Total RNA was extracted from pooled serum samples (10 µl/subject) from either cases or controls (profiling step) as well as from individual serum samples (n=531) (validation step) using the Triazol reagent. Synthetic C. elegans miR-39 was added to all samples prior to RNA extraction. Total RNA was reverse transcribed and pre-amplified. The Human TaqMan miRNA Arrays Card A (Applied Biosystem) was used to perform expression profiling of 376 miRNAs. Values were normalised using the external control c.ele-miR-39 and the endogenous controls U6 snRNA. Differentially expressed miRNAs with Ct values ≤35 were identified.
Results: MiRNA expression profiling identified 41 miRNAs expressed in pooled serum samples from DM1 patients. Among them 25 miRNAs were differentially expressed in DM1 patients with micro/macrovascular complications. The difference in miRNA expression between cases and controls was 2 to 10 fold for miR-106a and miR-16; 10 to 20 fold for miR-29a, miR-126, miR-146a, miR-17, miR-222, miR-223, miR-320, and miR-484; and over 20 fold for the other miRNAs (miR-155, miR-134, miR-145, miR-150, miR-191, miR-197, miR-885-5p, miR-92a, miR-342, let-7e, miR-24, miR-574-3p, miR-483-5p, miR-486-3p, miR-486-5p). Validation of profiling results using individual case/control sample is currently ongoing.
Conclusion: These results show that miRNA are detectable in serum samples from DM1 patients and that the expression of circulating miRNAs differs in DM1 with and without vascular complications.

Deletion of both Rab-GTPase activating proteins TBC1D1 and TBC1D4 in mice eliminates insulin- and AICAR-stimulated glucose transport

A. Chadt[1], A. Immisch[2], C. de Wendt[1], Z. Zhou[1], T. Peter[1], J. Loffing[3], D. Loffing-Cueni[3], H.-G. Joost[2], H. Al-Hasani[1];
[1]Biochemistry, German Diabetes Center (DDZ), Duesseldorf, [2]Pharmacology, German Institute of Human Nutrition (DIfE), Potsdam-Rehbruecke, Germany, [3]Institute of Anatomy, University of Zurich, Switzerland.

Background and aims: Previously, the Rab-GTPase activating proteins TBC1D1 and TBC1D4 (AS160) were shown to regulate GLUT4 translocation in response to activation of AKT and AMP-dependent kinase. However, knockout mice lacking either Tbc1d1 or Tbc1d4 displayed only partially impaired insulin-stimulated glucose uptake in fat and muscle tissue. The aim of this study was to determine the impact of the combined inactivation of Tbc1d1 and Tbc1d4 on glucose metabolism. Therefore, we characterized energy- and substrate metabolism of Tbc1d1/Tbc1d4- double-deficient (dbKO) mice.
Materials and methods: Tbc1d1-deficient mice (RCS.B6.SJL-Nob1.10) were crossbred with conventional Tbc1d4 knockout mice to yield double-deficient mice on a C57BL/6J background. We analyzed males fed a standard chow. Substrate utilization was determined by indirect calorimetry with 10-week-old mice (TSE systems). Glucose, insulin and AICAR tolerance were investigated after i.p. injection into 12-16 wk old mice. Ex vivo glucose uptake and fatty acid oxidation (FAO) were performed with intact isolated Extensor digitorum longus (EDL) and soleus muscle by measuring 3H-palmitate oxidation and 3H-2-DOG (deoxyglucose) uptake. 14C-2-DOG uptake was determined in isolated adipose cells. GLUT4 protein abundance was determined by Western blot.
Results: Tbc1d1/Tbc1d4- double-deficient (dbKO) mice showed a tendency towards lower body weight and reduced fat mass. Postprandial glucose levels were decreased (Con: 7.31 ± 0.18 mmol/l vs. dbKO: 6.34 ± 0.24 mmol/l; $p<0.05$) but fasting glucose levels were unchanged. Glucose and AICAR tolerance were reduced (AUC Con: 124.94 ± 7.10 vs. dbKO: 162.98 ± 9.28; $p<0.05$ and Con: 266.75 ± 27.01 vs. dbKO: 365.52 ± 40.89; $p<0.05$). DbkKO mice displayed reduced respiratory quotient (RQ) during the dark phase (Con: 1.00 ± 0.01 vs. dbKO: 0.97 ± 0.01; $p<0.05$). Glycolytic EDL muscle of dbKO mice showed substantially increased FAO in the basal state (Con: 1.14 ± 0.12 pmol/(mg*min) vs. dbKO: 2.54 ± 0.60 pmol/(mg*min); $p<0.05$) and no further increase was observed after stimulation with AICAR. In contrast, FAO in soleus muscle was not different between the genotypes. GLUT4 protein expression in dbKO mice was substantially reduced in skeletal muscle and WAT (~50% of Con). Basal glucose uptake was normal in muscle of dbKO mice (EDL 1.74 ± 0.20 and soleus 2.07 ± 0.17 nmol/mg/20 min). However, insulin- and AICAR-stimulated glucose uptake was completely abolished (Ins Con; dbKO: EDL 5.37 ± 0.44; 2.75 ± 0.38; soleus 4.46 ± 0.54; 2.28 ± 0.34; AICAR Con; dbKO: EDL 3.98 ± 0.50; 2.59 ± 0.32; soleus 4.32 ± 0.56; 2.36 ± 0.32 nmol/mg/20 min).
Conclusion: Our results show that both TBC1D1 and TBC1D4 are required for insulin- and AICAR-stimulated glucose uptake in skeletal muscle. As indicated by the elevated RQ and increased FAO in skeletal muscle, dbKO mice compensate for the severe impairment in peripheral glucose utilization by increased use of lipids as fuel.

Role for SREBP-1c in inducing skeletal muscle insulin resistance via repressing IRS-1 transcription and promoting inflammatory response

Y. Bi[1], Y. Chen[2], W. Wu[2], M. Cai[2], H. Liang[2], D. Zhu[1];
[1]Endocrinology Department, Drum Tower Affiliated to Nanjing University Medical School, Nanjing, [2]Endocrinology Department, 3rd Affiliated Hospital of Sun Yat-sen University, Guangzhou, China.

Background and aims: Sterol regulatory element binding protein 1c (SREBP-1c) is a master regulator of lipogenesis. Insulin receptor substrate-1 (IRS-1) is a key insulin signaling molecular in skeletal muscle. Little information is available on the specific role of SREBP-1c activation on IRS-1 associated insulin signaling pathway in skeletal muscle. This study was aimed to determine

the regulatory effect and molecular mechanisms of SREBP-1c on IRS-1-associated insulin signaling in myotubes.
Materials and methods: Adenovirus vectors expressing SREBP-1c were tranfected into rat primary and L6 myotubes to study the regulatory effects of SREBP-1c activation on transduction of IRS-1-associated insulin signaling and expressions of inflammatory cytokines. Luciferase reporter analysis, electrophoretic mobility shift assay, and chromatin immunoprecipitation assay were used to detect the direct binding site of SREBP to the IRS-1 promoter.
Results: We found that accumulation of SREBP-1c decreased gene and protein levels of IRS-1 and suppressed insulin-stimulated p-IRS-1(Tyr608) and p-Akt (Ser473) activation in a dose dependent manner. Concomitantly, SREBP-1c induced gene expressions of fatty acid synthase (FAS) and promoted expressions of tumor necrosis factor α (TNF-α) and interleukin 1β (IL-1β) with increasing titers of transfection. *In vitro* and *in vivo* interaction assays showed that SREBP-1c directly inhibited IRS-1 transcription activity through non-SRE domain at a location of -200 to +50bp of the promoter.
Conclusion: In this study, we report a new mechanism for insulin resistance in lipotoxicity that a high level of SREBP-1c, a pivotal transcription factor regulating de novo lipogenesis, can result in muscular insulin resistance through a direct effect of suppressing IRS-1 transcription, as well as an indirect effect of promoting the release of inflammatory cytokines. Our study highlights reciprocal relationships between metabolic pathways and suggests that SREBP-1c could be one pathogenesis involved in skeletal muscle insulin resistance.

Potent anti-inflammatory properties of adiponectin on the skeletal muscle
M. Abou-Samra[1], O. Schakman[2], E. Culot[1], L. Noel[1], P. Gailly[2], S. Brichard[1]; [1]EDIN, Université Catholique de Louvain, Brussels, [2]IoNS, Université Catholique de Louvain, Brussels, Belgium.

Background and aims: Adiponectin (ApN) is an adipokine, which is decreased in the metabolic syndrome, thereby playing a key role in the pathogenesis of these disorders. We have previously shown that ApN exerts important anti-inflammatory effects on skeletal muscle in mice exposed to acute inflammation (LPS injection) or metabolic stress (obesogenic diet). The aim of this work is to test the potency of the anti-inflammatory properties of ApN by using a model with severe and sustained inflammation.
Materials and methods: Mdx mice (a mouse model of Duchenne muscular dystrophy, where persistent inflammation worsens the consequences of the genetic deficiency) were crossed with transgenic mice that over-express adiponectin (Tg-ApN mice) in order to generate mdx-Tg-ApN mice. Different markers of inflammation/oxidative stress (TNF-α, IL-1β, NF-κB, CD68, CD3, peroxiredoxin 3/5 (PRDX3/5), 4-hydroxynonenal (HNE)) were studied and quantified by immunohistochemistry, ELISA and western blot. In vivo functional tests were also carried out to determine the global force of mice. Finally, the extent of muscle damage was quantified by Evans Blue Dye (EBD) injection following an eccentric exercise.
Results: Compared to WT mice, muscles of mdx mice presented significant increases (+ 10 to 15 fold; p<0.001) in the expression of pro-inflammatory factors (TNF-α, IL-1β, NF-κB) and oxidative stress markers (PRDX3/5, HNE) as well as a massive infiltration of macrophages and T lymphocytes, as shown by CD68 and CD3 immunolabeling respectively. All of these abnormalities were drastically reduced in mdx-Tg-ApN mice (- 60 to 75 % vs mdx; p<0.001). In addition, mdx-Tg-ApN mice exhibited higher global muscular force (+ 50 % vs mdx; p<0.01) along with a significant decrease in EBD content in their muscle fibers (- 50 to 60 % vs mdx; p<0.001).
Conclusion: Adiponectin proves to be an extremely potent anti-inflammatory agent that protects muscle against injury. These anti-inflammatory properties of ApN are of interest in the metabolic syndrome as well as in other diseases where inflammation plays a triggering or worsening pathogenic role.

Fractalkine is a novel myokine which protects myotubes from TNF-alpha induced insulin resistance
P. Plomgaard[1,2], J. Hansen[1,2], V. Bianda[3], B.K. Pedersen[2], K. Bouzakri[3]; [1]Department of Clinical Biochemistry, Rigshospitalet, Copenhagen, [2]Centre of Inflammation and Metabolism, Rigshospitalet, Copenhagen, Denmark, [3]Department of Genetic Medicine and Development, Geneva University, Switzerland.

Background and aims: Fractalkine has been shown to be secreted by adipose tissue and associated with type 2 diabetes. We have previously demonstrated that its mRNA expression was increased in skeletal muscle cells treated with TNF-alpha. Nevertheless, fractalkine secretion, regulation and action on skeletal muscle remain to be studied. The aims of our study were to identify the physiological source of fractalkine and to evaluate the impact of fractalkine on human skeletal muscle cells with or without induction of insulin resistance by TNF-alpha.
Materials and methods: Fractalkine levels were measured in plasma from 5 healthy males performing 3h of bicycling exercise at 50% VO2 max. and in skeletal muscle biopsies for mRNA and protein. In 9 healthy subjects performing 2 h of one legged knee extensor exercise, muscle biopsies were obtained at 0, 2, 5 and 24h from both resting and exercising leg. Plasma fractalkine was also measured in 10 healthy males who had received 4h TNF-alpha infusion or placebo on 2 different days. Human skeletal muscle biopsies were collected from abdominal muscle and cells were cultured in order to measure the impact of fractalkine on 3H-2-deoxyglucose uptake (60 min) and insulin signalling with or without induction of insulin resistance by TNF-alpha (20 ng/ml for 1 or 24h).
Results: Plasma fractalkine increased rapidly after the beginning of exercise, reaching a maximum after 3h of bicycling (1.4+/-0.4 μg/l; p<0.01) and returning to basal levels by 24h. Using a model of one legged knee extensor exercise, fractalkine mRNA in the exercising leg muscle was increased 6.6+/-1.8-fold (p<0.01) and protein expression 4.2+/-0.8-fold (p<0.01) when compared to the resting leg. Moreover, human volunteers who received TNF-alpha infusion showed an increase of plasma fractalkine after 2h, with a maximum after 4h (8.2+/-0.8 μg/l; p<0.001). In order to explore autocrine action, human primary myotubes were treated with recombinant fractalkine for 24h and then with TNF-alpha to induce insulin resistance. Myotubes pretreated with fractalkine showed an increase of basal glucose uptake (120+/-18 vs. 190+/-8 cpm/mg protein/min; p<0.05). Nevertheless, fractalkine protected myotubes from the impact of TNF-alpha on glucose uptake after insulin stimulation (140+/-31 for 1h TNF-alpha vs. 220+/-12 fractalkine + TNF-alpha and 146 +/-25 for 24h TNF-alpha vs 245 +/-9 for Fractakine + TNF-alpha; p<0.05). Fractalkine pretreatment (25 ng/ml for 24h) also protected against the negative impact of TNF-alpha on AS160, Akt, and IRS-1 phosphorylation after insulin stimulation (10 min, 100 nmol/l). Moreover, TNF-alpha (24h) induced phosphorylation of ERK, mTOR and NFkB was prevented in human skeletal muscle cells pretreated with 25 ng/ml of fractalkine for 48h.
Conclusion: Our study using human subjects shows that fractalkine is expressed by skeletal muscle and regulated by exercise and TNF-alpha infusion. We further show that fractalkine protects human skeletal muscle cells from TNF-alpha induction of insulin resistance, indicating a possible autocrine role in the exercising state in addition to the previously suggested endocrine role following release from adipose tissue.

G-CSF, a novel fatty acid-dependent myokine
A.-M. Ordelheide, N. Gommer, H.-U. Häring, H. Staiger; Internal Medicine IV, UKT Tübingen, Germany.

Background and aims: We recently identified *CSF3* as a palmitate-responsive myocyte gene encoding G-CSF. Yamada et al. and others showed elevated

G-CSF plasma levels upon exercise, however they did not specify its origin. Since elevated saturated fatty acid concentrations contribute to proinflammatory processes and insulin resistance in muscle cells, we intended to further analyze the stimuli and pathways inducing *CSF3* in human myotubes and C_2C_{12} cells.
Materials and methods: Protein levels were measured by ELISA and mRNA concentrations by RT-PCR.
Results: The strongest induction of *CSF3* was seen in human myotubes treated with the saturated fatty acids palmitate and stearate ($p<0.05$), while the unsaturated fatty acids palmitoleate, oleate and linoleate showed weak or no effects. Compared to other fatty acid-induced myokines like *TNF* (10-fold) and *IL6* (2.2-fold), *CSF3* showed the strongest response to palmitate (133-fold). Co-incubation of myotubes with palmitate and the unsaturated fatty acids oleate or linoleate blunted *CSF3* induction. This was also evident at protein level. This might reflect a protective effect of unsaturated fatty acids. Since palmitate induces the expression of several myokines, we analyzed their effect on *CSF3* expression. Only TNF-α induced a significant increase in *CSF3* expression (12-fold, $p<0.05$) while IL-6, IL-8, IL-15 and MCP-1 did not have any effect. TLR4 inhibition with TAK-242 in human myotubes and down regulation in C_2C_{12} cells blunted the palmitate effect on *CSF3*, while down regulation of TLR2 did not show any effects. Inhibition of the stress kinases JNK, MEK1/2 and p38 did blunt the palmitate effect on *CSF3* expression as well. Treatment of human myotubes with 0.1ng/ml G-CSF for five days revealed mitogenic properties of this protein (WST, 1.4-fold, $p<0.05$).
Conclusion: In conclusion, we describe G-CSF as a novel saturated fatty acid-dependent myokine of potential auto/paracrine relevance.

Evidence against a beneficial effect of irisin in humans
H. Gassenhuber[1], S. Raschke[2], M. Elsen[2], M. Sommerfeld[1], U. Schwahn[1], B. Brockmann[1], T. Romacho[2], K. Eckardt[2], J. Eckel[2];
[1]Sanofi, Frankfurt, [2]Paul-Langerhans-Gruppe für Integrative Physiologie, Deutsches Diabetes-Zentrum, Düsseldorf, Germany.

Background: Irisin has been described as a new hormone that participates in the regulation of energy consumption. Irisin was published to be released in mouse muscle upon exercise in a PGC1-α-dependent fashion and to increase energy expenditure in adipose tissue. The main body of evidence was generated in mouse, but the high interest in irisin is clearly fuelled by hope that the principle can be transferred to humans.
Materials and methods: Genomic DNA, mRNA, and expressed sequence tags of FNDC5 were analysed using bioinformatic methods. HEK293 cells were transiently transfected with human and mouse expression vectors, FNDC5 protein expression was analysed via Western blot. Human pre-adipocytes were differentiated into adipocytes in the presence of recombinant irisin, FNDC5, and BMP7. Expression of genes was analysed using quantitative RT-PCR.
Results: The analysis of genomic DNA and mRNA data show that FNDC5, the gene coding for the precursor of irisin, is present in rodents and most primates, but shows a deleterious mutation of the conserved start codon ATG to ATA in human. According to the current UniProt entry Q8NAU1 this is potentially a non-canonical start site and could still lead to full length FNDC5, that could be proteolytically cleaved to release irisin. Hence we tested the ability of the human transcript to be translated into protein. We cloned mouse and human FNDC5 with the naturally occurring ATA and additionally mutated it to ATG. In HEK293 cells the human expression vector with ATG as start codon produced similar amounts of full length protein compared to mouse FNDC5. In contrast, the human transcript with ATA as potential start codon was translated from the downstream in-frame ATG (represented by NP_715637) with strongly reduced efficiency. To test the proposed activity of irisin on human cells we isolated preadipocytes from primary human subcutaneous AT and differentiated these cells to mature adipocytes in the presence of recombinant FNDC5, irisin, or BMP7 as positive control. Further analysis confirmed that BMP7 potently induced a brown-fat-like gene program in cultured adipocytes. BMP7 treatment during differentiation induced an increased expression of the general differentiation marker for adipogenesis, PPARγ (3.6-fold). Notably, UCP1, known as a brown/brite marker, was even more strongly enhanced (6.4-fold). Additionally, the mRNA expression of TCF21, which is a marker for white AT, was significantly reduced after BMP7 treatment. Neither recombinant FNDC5 nor recombinant irisin had an effect on PPARγ, UCP1 or TCF21 mRNA expression.
Conclusion: FNDC5 in humans should be annotated as a transcribed pseudo-gene. A shorter protein version is translated only with low efficiency, but this protein has lost the signal protein and almost 50% of the irisin sequence. Could irisin nevertheless be a potential drug-target in humans, as the loss of irisin is in an evolutionary context a recent event and the downstream regulatory pathways might still exist? To verify this hypothesis we treated human pre-adipocytes with irisin or recombinant FNDC5 but this had no effect on browning. Thus in humans irisin does not exist and we conclude that the function of irisin proposed for mice is not observable in humans.

Dapagliflozin-induced weight loss impacts 24 week HbA_{1c} and blood pressure levels

C.D. Sjöström[1], M. Hashemi[1], J. Sugg[2], A. Ptaszynska[3], E. Johnsson[1]; [1]AstraZeneca, Mölndal, Sweden, [2]AstraZeneca, Wilmington, USA, [3]Bristol-Myers Squibb, Princeton, USA.

Background and aims: The majority of patients with type 2 diabetes (T2DM) are overweight or obese. Weight loss in patients with T2DM has been shown to improve glycaemic control, lipid profile and blood pressure (BP) and is recommended by EASD, ADA and IDF. It is not clear if comparatively small weight losses would contribute significantly to improvements in cardiovascular risk factor profile. In this study we investigated, by linear regression analyses, the extent to which changes in HbA1c and BP after 24 weeks of treatment with the sodium glucose co-transporter 2 inhibitor dapagliflozin (DAPA) were dependent on the simultaneously attained weight loss.

Materials and methods: Data were pooled from 7 studies evaluating DAPA 10 mg either as monotherapy or in combination with an antihyperglycaemic medication (metformin, sulphonylurea, thiazolidinedione, insulin). The investigated covariates were: baseline (BL) age, BL HbA1c, BL estimated glomerular filtration rate, BL total body weight (BW), BL seated systolic and diastolic blood pressure (SBP, DBP), gender, change in weight, smoking status, antihypertensive medication use at BL, treatment assignment, and possible treatment covariate interactions.

Results: Pooled demographic and BL characteristics were balanced between the DAPA group (N=1066: men, 47.9%; mean age, 55 years; mean HbA1c, 8.3%, mean BW, 88.7 kg) and the placebo (PBO) group (N=988: men, 49.6%; mean age, 56 years; mean HbA1c, 8.3%; mean BW, 88.1 kg). Over 24 weeks, greater reductions from BL in adjusted mean [95% CI] BW were observed with DAPA (-2.29 [-2.53 to -2.05] kg) compared with PBO (-0.27 [-0.51 to -0.03] kg). In addition, over 24 weeks there were also greater adjusted mean reductions with DAPA compared with PBO in HbA1c levels (DAPA -1.10 [-1.15 to -1.04] %; PBO -0.60 [-0.66 to -0.54] %), SBP (DAPA -4.72 [-5.67 to -3.76] mm Hg; PBO -1.04 [-1.93 to -0.16] mm Hg) and DBP (DAPA -2.36 [-2.95 to -1.77] mm Hg; PBO -0.57 [-1.11 to -0.02] mm Hg). Linear regression was used to estimate the contribution of the change in weight to the change in HbA1c, SBP and DBP. For the reduction in HbA1c, the β-value (HbA1c (%) per kg) of the weight change variable was estimated to be 0.028 (P<0.0001) and it is estimated that an overall weight loss of 3 kg and 5 kg would contribute to 8.0% and 13%, respectively of the total reduction in HbA1c for DAPA. For the reductions in SBP and DBP, the β-value (mm Hg per kg) estimates for the weight change variable were 0.61 (P<0.0001) and 0.25 (P<0.0001), respectively. With an overall weight loss of 3 kg and 5 kg there is estimated to be an approximately 37% and 49% contribution of weight loss to the total reduction in SBP for DAPA (Figure) and 32% and 44% contribution of weight loss to the total reduction in DBP for DAPA.

Conclusion: The results from this pooled analysis indicate that there is an added benefit of weight loss during DAPA treatment that contributes to overall changes in HbA1c and particularly to changes in blood pressure after 24 weeks of treatment.

Canagliflozin demonstrates durable glycaemic improvements over 104 weeks compared with glimepiride in subjects with type 2 diabetes mellitus on metformin

G. Langslet[1], W.T. Cefalu[2], L.A. Leiter[3], K.-H. Yoon[4], P. Arias[5], J. Xie[6], D. Balis[6], D. Millington[6], F. Vercruysse[7], W. Canovatchel[6], G. Meininger[6]; [1]Lipid Clinic, Oslo University Hospital, Norway, [2]Pennington Biomedical Research Center and LSUHSC School of Medicine, Baton Rouge and New Orleans, USA, [3]Keenan Research Centre in the Li Ka Shing Knowledge Institute of St. Michael's Hospital, University of Toronto, Canada, [4]The Catholic University of Korea, Seoul St. Mary's Hospital, Seoul, Republic of Korea, [5]University of Rosario Medical School and Litoral University Medical School, Rosario and Santa Fe, Argentina, [6]Janssen Research & Development, LLC, Raritan, USA, [7]Janssen Research & Development, Beerse, Belgium.

Background and aims: Canagliflozin (CANA) is a sodium glucose co-transporter 2 (SGLT2) inhibitor developed for the treatment of patients with type 2 diabetes mellitus (T2DM). The 104-week efficacy and safety of CANA compared with glimepiride (GLIM) were assessed in this randomised, double-blind, Phase 3 study, which represents the longest follow-up of CANA treatment to date.

Materials and methods: Subjects with T2DM on metformin (MET; N = 1,450; mean age, 56.2 years; HbA_{1c}, 7.8%; fasting plasma glucose [FPG], 9.2 mmol/L; body mass index [BMI], 31.0 kg/m^2; estimated glomerular filtration rate [eGFR], 90.2 mL/min/1.73 m^2) received CANA 100 or 300 mg or GLIM (up to 6 or 8 mg/day) during a 52-week core period, followed by a 52-week extension (n = 1,050).

Results: At Week 104, both CANA doses reduced HbA_{1c}, FPG, body weight, and systolic blood pressure (BP) compared with GLIM. Both CANA doses were also associated with increases in high-density lipoprotein cholesterol (HDL-C) and low-density lipoprotein cholesterol (LDL-C) that were stable from Week 26 to Week 104, with smaller increases in triglycerides relative to GLIM. Fewer subjects had hypoglycaemia events with CANA 100 and 300 mg than with GLIM (7%, 8%, 41%, respectively). The coefficient of durability (rate of HbA_{1c} rise from Week 26 to Week 104) was lower with CANA (0.16% both doses) than with GLIM (0.37%). (Table) Overall incidences of adverse events (AEs) were 73%, 78%, and 78% with CANA 100 and 300 mg and GLIM, and incidences of serious AEs were 10%, 10%, and 14%; discontinuation rates due to AEs were low across groups. Genital mycotic infection rates were higher in the pooled CANA group than the GLIM group (women, 15% vs 3%; men, 9% vs 2%). Higher rates of osmotic diuresis-related AEs (6%, 7%, 2%) and urinary tract infections (11%, 9%, 7%) were seen with CANA 100 and 300 mg compared with GLIM. Rates of these AEs were generally lower in the 52-week extension period versus the 52-week core period. A larger decrease in eGFR was seen with GLIM (6%) than with CANA (~1-3%) at Week 104.

Conclusion: In summary, CANA showed durable glycaemic improvements compared with GLIM and was generally well tolerated in subjects with T2DM on MET over 104 weeks.

Table. Summary of Efficacy Endpoints at Week 104 (mITT, LOCF)

Parameter*	CANA 100 mg (n = 483)	CANA 300 mg (n = 485)	GLIM (n = 482)
HbA_{1c} change, %	−0.65 (0.04)	−0.74 (0.04)	−0.55 (0.04)

The sodium glucose co-transporter-2 (SGLT2) inhibitor empagliflozin improves glycaemic control in patients with type 1 diabetes: a single-arm clinical trial

B.A. Perkins[1], D.Z. Cherney[2], H. Partridge[3], N. Soleymanlou[4], H. Tschirhart[3], B. Zinman[1], N. Fagan[5], S. Kaspers[6], H.-J. Woerle[6], U.C. Broedl[6], O. Johansen[6]; [1]Endocrinology and Metabolism, Mount Sinai Hospital, Toronto, [2]Nephrology, University Health Network, Toronto, [3]Endocrinology and Metabolism, University Health Network, Toronto, [4]Boehringer Ingelheim, Burlington, Canada, [5]Boehringer Ingelheim, Ridgefield, USA, [6]Boehringer Ingelheim, Ingelheim, Germany.

Background and aims: Adjunctive therapy to basal-bolus insulin regimens may provide an added strategy to improve glycemic control in patients with type 1 diabetes.
Materials and methods: In an 8-week single-arm open-label proof of concept pilot study of the SGLT2 inhibitor empagliflozin 25 mg po QD in subjects receiving optimized standard of type 1 diabetes care, we evaluated the efficacy on glycemia and rates of hypoglycemia compared to a 2-week placebo run-in period. Other outcome measures were urinary glucose excretion (UGE), insulin requirement, and anthropometrics.
Results: We recruited 42 normoalbuminuric patients (28 insulin pump, 14 multiple daily injection) with mean±SD age 24±5 years, A1c 8.0±0.9%, and fasting plasma glucose (FPG) 10.0±4.8 mmol/L. 40 patients completed 8 weeks of treatment with empagliflozin and the mean A1c decreased by 0.4% to 7.6±0.9% (p<0.0001). FPG decreased non-significantly to 8.6±3.1 mmol/L (p=0.06). Symptomatic hypoglycemia (<3.0 mmol/L) declined from 0.12 to 0.04 events per day (p=0.005) and mean daily insulin dose declined from 55±20 to 46±19 U/day from the placebo run in period (p<0.0001). The mean UGE increased from 19±19 at baseline to 134±61 g/day at 8 weeks (p<0.0001). Weight decreased by 2.7 kg from 72.6±12.7 (p<0.0001) and waist circumference decreased by 3.8 cm from 82.9±8.7 (p<0.0001). Apart from hypoglycemia, polyuria (79%) and thirst (74%) were the most frequent adverse events. Two subjects were withdrawn after the early occurrence of diabetic ketoacidosis (one in the setting of gastroenteritis, the other in the setting of insulin pump failure).
Conclusion: In patients with type 1 diabetes, empagliflozin as adjunctive to insulin therapy was generally well-tolerated and associated with improvement in glycemic control, a reduction in rates of hypoglycemia and reduced insulin requirement and body weight. A randomized clinical trial of the efficacy of adjunctive empagliflozin in type 1 diabetes is warranted.

Luseogliflozin, a selective SGLT2 inhibitor, added on to glimepiride for 52 weeks improves glycaemic control with no major hypoglycaemia in Japanese type 2 diabetes patients

N. Inagaki[1], Y. Seino[2], T. Sasaki[3], A. Fukatsu[4], M. Ubukata[5], H. Umeuchi[5], S. Sakai[5], Y. Samukawa[5];
[1]Kyoto University Graduate School of Medicine, Kyoto, [2]Kansai Electric Power Hospital, Osaka, [3]Jikei University School of Medicine, Tokyo, [4]Yachiyo Hospital, Aichi, [5]Taisho Pharmaceutical Co., Ltd., Tokyo, Japan.

Background and aims: Luseogliflozin, a highly selective sodium glucose cotransporter 2 inhibitor, reduces plasma glucose by increasing urinary glucose excretion. The insulin-independent mechanism of luseogliflozin would be expected to be beneficial in combination with other oral antidiabetic drugs. The aim of current study was to assess the efficacy and safety, including the risk of hypoglycemia, of luseogliflozin administered with glimepiride for 52 weeks.
Materials and methods: Japanese patients with type 2 diabetes mellitus (T2DM), who has not been sufficiently controlled (HbA1c : 6.9-10.4%) by glimepiride monotherapy over 12 weeks, received luseogliflozin once daily for 52 weeks. This study consisted of double-blind period (week 0-24) to assess mainly the safety comparing with placebo and open-label period (week 24-52). In double-blind period, a total of 221 patients were randomized to receive placebo (N = 71) or luseogliflozin 2.5 mg (N = 150). Then, in open-label period, all patients received luseogliflozin 2.5 mg (patients who had insufficient glycemic control received 5 mg) and 141 patients received luseogliflozin for 52 weeks. Change from baseline (BL) in glycemic and other efficacy endpoints were assessed. Adverse events (AEs) were monitored throughout the study.
Results: HbA1c was significantly decreased by luseogliflozin compared with placebo (-0.88%) at week 24, and was significantly decreased from BL (-0.63%) at week 52. Fasting plasma glucose (FPG) and body weight (BW) were also significantly decreased by luseogliflozin compared with placebo at week 24, and was significantly decreased from BL at week 52 (Table). In addition, systolic/diastolic blood pressure, plasma lipid (triglyceride, HDL-cholesterol), fasting insulin, plasma C-peptide, insulin sensitivity (HOMA-R) and intact proinsulin significantly improved compared with BL at week 52. In patients who received luseogliflozin for 52 weeks, incidences of AEs, AEs leading to discontinuation and serious AEs were 81.3%, 2.7%, 6.0%, respectively. Most AEs were mild in severity. Incidences of hypoglycemia observed in double-blind period were 4.2% with placebo and 8.7% with luseogliflozin. Incidence of hypoglycemia with patients who received luseogliflozin for 52 weeks was 10.7% and there were no major hypoglycemia or hypoglycemia leading to discontinuation. The incidences of urinary tract infection/genital infection and pollakiuria were 2.7% and 2.8%, and every event was mild in severity.
Conclusion: Add-on therapy with luseogliflozin for 52 weeks significantly ameliorated glycemic control and reduced BW, and was well tolerated with no major hypoglycemia in Japanese patients with T2DM poorly controlled by glimepiride monotherapy.

Table Summary Efficacy Endpoints at Week 24 (LOCF) and Week 52

	Double-blind period		Throughout the study
	Placebo	Luseogliflozin	Luseogliflozin
	Week 24 (N = 71)	Week 24 (N = 150)	Week 52 (N = 141)

Efficacy and safety of tofogliflozin administered for 52 weeks as monotherapy or combined with other oral hypoglycaemic agents in Japanese patients with type 2 diabetes

Y. Tanizawa[1], E. Araki[2], K. Tobe[3], Y. Terauchi[4], K. Utsunomiya[5], Y. Iwamoto[6], H. Watada[7], K. Kaku[8], for the Tofogliflozin 004 and 005 Study group;
[1]Yamaguchi University, Ube, [2]Kumamoto University, [3]University of Toyama, [4]Yokohama City University, [5]Jikei University, Tokyo, [6]Tokyo Women's Medical University, [7]Juntendo University, Tokyo, [8]Kawasaki Medical School, Kurashiki, Japan.

Background and aims: Tofogliflozin, a highly selective sodium-glucose cotransporter 2 (SGLT2) inhibitor, reduces blood glucose and body weight by inhibiting renal glucose reabsorption and promoting urinary excretion of excess blood glucose in patients with type 2 diabetes mellitus (T2DM). The characteristics of tofogliflozin, which include high selectivity toward SGLT2, a short half-life and an insulin-independent mode of action, mean that it exerts sustained efficacy with low hypoglycemic risk and can be used in combination with any existing T2DM therapy. This study was undertaken to verify the efficacy and safety of tofogliflozin administered for a long period of time to Japanese patients with T2DM with inadequate glycemic control on diet/exercise therapy alone or on diet/exercise therapy plus one oral hypoglycemic agent (OHA).
Materials and methods: The study was designed as a randomized, open-label, parallel-group comparison. Tofogliflozin 20 or 40 mg was orally administered once daily for 52 weeks to 191 patients as monotherapy (MONO) and to 593 patients as combination therapy (COMBO) (sulfonylurea + glinide, n=190; dipeptidyl peptidase-4 inhibitor, n=103; biguanide, n=101; thiazolidine, n=101; and α-glucosidase inhibitor, n=98). The primary endpoint was the change in HbA1c from baseline to the end of treatment.
Results: With tofogliflozin monotherapy, the change in HbA1c from baseline to week 52 of treatment was −0.7% (both 20 mg and 40 mg), and the changes in body weight were −3.1 kg (20 mg) and −3.4 kg (40 mg). With tofogliflozin combination therapy, changes in HbA1c from baseline to week 52 of treat-

ment were −0.8% and −0.9%, and the changes in body weight were −2.5 kg and −3.0 kg, in the 20 mg and 40 mg groups, respectively. Weight loss reached maximum values at 24 weeks, and these were maintained until the end of study. Moreover, reduced systolic and diastolic blood pressure, improved HOMA-R and Matsuda index, reduced abdominal circumference, increased levels of adiponectin, HDL-C, and decreased levels of uric acid, alanine aminotransferase and γ-glutamyl transferase were secondarily observed. Regarding safety, the incidences of adverse events in the 20 mg and 40 mg groups were 76.6% and 86.6%, respectively (MONO), and 86.3% and 84.7%, respectively (COMBO). Adverse drug reactions occurring at an incidence ≥5% in either the monotherapy or combination therapy group included increased blood ketone bodies, pollakiuria and thirst. The incidence of hypoglycemia was higher in patients receiving tofogliflozin in combination with sulfonylurea/glinide 11.9%(20mg) and 8.1%(40mg) than in all other groups. There were no clinically significant adverse events in any treatment groups.

Conclusion: In Japanese patients with T2DM, tofogliflozin administered once daily was sustainably effective for glycemic and body weight control used in monotherapy or combination therapy with other OHAs throughout the 52-week study period, and additional beneficial effects were also observed. Tofogliflozin at doses of 20 mg and 40 mg was also well tolerated.

Favourable gastrointestinal and genitourinary safety profile of LX4211 added-on to metformin in a Phase 2b study

G.-L. Ye, I. Ogbaa, P. Lapuerta, B. Zambrowicz, P. Banks, K. Frazier, A. Sands; Lexicon Pharmaceuticals, Inc., The Woodlands, USA.

Background and aims: LX4211 is a dual inhibitor of SGLT1 and SGLT2, the major glucose transporters in the gastrointestinal (GI) tract and kidney. It has shown a favorable GI and genitourinary (GU) safety profile in healthy subjects and Phase 2 studies of patients with type 2 diabetes.

Materials and methods: In a 12-week dose ranging study, 299 patients with inadequately controlled T2DM on metformin were randomly assigned to LX4211 (75 mg qd, 200 mg qd, 200 mg bid, or 400 mg qd) or placebo (PBO). The GI and GU tolerability and overall safety of LX4211 were evaluated.

Results: In the safety population, the incidences of diarrhea and nausea were comparable between all LX4211-treated patients and PBO. Diarrhea was 7.2 vs 6.7% and nausea was 6.8 vs 5.0% in all LX4211-treated patients vs PBO, respectively. Diarrhea was not dose-dependent or related to initiation of dosing. Nausea and diarrhea were generally mild and resolved without treatment. Constipation and vomiting were less common with LX4211 vs PBO; constipation 3.4 vs 6.7%, and vomiting 0.4 vs 5.0%. Urinary tract infections occurred evenly among treatment groups. Vaginal yeast or bacterial infections were seen only with LX4211; they were mostly mild, their incidence was low, and none led to therapy discontinuation. There were no deaths, treatment related serious AEs, or episodes of hypoglycemia reported.

Conclusion: LX4211 combined with metformin was safe and well-tolerated in this study. Studies of greater exposure duration are needed to characterize long term safety of LX4211.

OP 32 Hypoglycaemia: balancing glucose control

187

Lower rates of overall, nocturnal and severe hypoglycaemia during maintenance treatment with IDegAsp vs biphasic insulin aspart 30 in patients with type 2 diabetes mellitus: a meta-analysis

A. Vaag[1], J.S. Christiansen[2], L. Niskanen[3], S. Rasmussen[4], T. Johansen[4], G. Fulcher[5];
[1]Rigshospitalet, Copenhagen, [2]Aarhus University Hospital, Denmark, [3]Central Hospital Finland, Jyväskylä, Finland, [4]Novo Nordisk A/S, Søborg, Denmark, [5]Royal North Shore Hospital, Sydney, Australia.

Background and aims: IDegAsp is a soluble co-formulation of 70% insulin degludec (IDeg) and 30% insulin aspart (IAsp) that provides ultra-long-acting basal insulin and rapid-acting bolus insulin in one injection. The aim of this *post-hoc* meta-analysis was to compare hypoglycaemia rates for IDegAsp vs biphasic insulin aspart 30 (BIAsp 30).

Materials and methods: This patient-level meta-analysis included the two phase 3a, randomised, treat-to-target trials in which twice-daily IDegAsp and BIAsp 30 were compared in patients with type 2 diabetes (T2D; IDegAsp: n=504; BIAsp 30: n=364). Both trials were 26 weeks and open-label; insulin was given with breakfast and the main evening meal. HbA_{1c}, fasting plasma glucose (FPG), bodyweight and insulin dose was analysed using a linear model; hypoglycaemia was analysed using a negative binomial model. Confirmed hypoglycaemia was defined as PG <3.1 mmol/l or severe (requiring assistance); nocturnal confirmed hypoglycaemia had an onset 00:01-05:59.

Results: Treatments were similar in terms of end-of-trial HbA_{1c} (7.06 vs 7.07%, estimated treatment difference [ETD] IDegAsp-BIAsp 30: 0.00 [-0.11; 0.10], p=0.96). IDegAsp was associated with a greater reduction from baseline in FPG (ETD: -1.12 mmol/l [-1.38; -0.85], p<0.0001) and less weight gain (ETD: -0.50 kg [-0.88; -0.11]; p=0.012). Daily insulin doses at end-of-trial were lower for IDegAsp than BIAsp 30 (0.9 vs 1.1 U/kg; estimated dose ratio: 0.84 [0.80; 0.89]; p<0.0001). For the full trial period, rates of overall confirmed hypoglycaemia were lower (by 19%; p=0.03) with IDegAsp than BIAsp 30 (table) as were rates of nocturnal hypoglycaemia (by 57%; p<0.0001). Few severe hypoglycaemic episodes were reported; IDegAsp was associated with a numerically lower rate of severe hypoglycaemia vs BIAsp 30 (p=0.27). For the maintenance period (defined as after 16 weeks of treatment when glucose targets and insulin doses were near final levels), the rate of severe hypoglycaemia was lower (by 84%; p=0.0061) for IDegAsp (table). Similarly, differences in rates of overall and nocturnal confirmed hypoglycaemia (IDegAsp vs BIAsp 30) were more pronounced during the maintenance period (table). No apparent differences in standard safety variables were observed for IDegAsp vs BIAsp 30, including major adverse cardiovascular events (4 vs 7 events).

Conclusion: Patients with T2D treated with twice-daily IDegAsp had a significantly greater reduction in FPG, less weight gain, lower insulin use, and significantly lower rates of hypoglycaemia than BIAsp 30. The finding of a significantly lower rate of severe hypoglycaemia during maintenance, when patients have become familiar with IDegAsp, supports the need for additional studies to further explore its efficacy and safety profile.

Meta-analysis of hypoglycaemia		
	Estimated rate ratio (IDegAsp/BIAsp 30)	
	Full trial period	Maintenance period [a]
Overall confirmed hypoglycaemia	0.81 [0.67; 0.98], p=0.0341	0.69 [0.55; 0.87], p=0.0015
Nocturnal confirmed hypoglycaemia	0.43 [0.31; 0.59], p<0.0001	0.38 [0.25; 0.58], p<0.0001
Severe hypoglycaemia	0.61 [0.26; 1.45], p=0.2661	0.16 [0.04; 0.59], p=0.0061

Retrospective analysis of the burden of drug-induced hypoglycaemia in diabetes (SIMEU study)

G. Marchesini[1], G. Veronese[1], G. Forlani[1], G. Forlani[1], A. Fabbri[2], the Italian Association of Emergency Medicine (SIMEU) Study Group;
[1]Unit of Metabolic Diseases & Clinical Dietetics, Alma Mater Studiorum University of Bologna, [2]Emergency Department, G. Morgagni Hospital, Forlì, Italy.

Background and aims: The direct burden of hypoglycemia for people with diabetes and for the National Health System is difficult to determine. Very few data exist on the extent of service use by subjects with diabetes, including frail people with Type 2 disease, after episodes of hypoglycemia.
Materials and methods: We report the interim results of a retrospective analysis of patients' attendance to 38 Italian Emergency Departments (EDs) following 2,889 episodes of referred hypoglycemia in a 18-month period (January 2011-June 2012). Cases were identified in the individual databases of the different centers using a predefined Case Report Form. The centers were part of a network, repeatedly involved in collaborative studies.
Results: After excluding cases of cancer-related cachexia or terminal conditions, 2,675 episodes were identified in subjects with DM (mean age, 71; 51% Males; referred mean blood glucose - when available and measurable - 44 mg/dL). Current drug use was recorded in 2,599 cases. Insulin was present in 64%, alone or coupled with any other treatment (32% and 32% of total cases, respectively). Among non-insulin treated cases (n=882), a variable combination of antidiabetic drugs was recorded. Metformin was present in 55%, sulfonylureas in 62%, repaglinide in 15%, pioglitazone in 2%, GLP-1 agonists in 1%, DPP-4 inhibitors in 2%, acarbose in 4%. In over 80% of non-insulin-related hypo cases, either sulfonylureas or repaglinide were present. Among sulfonylureas, the drug most commonly involved in hypoglycemic events was glibenclamide (61%), followed by glimepiride (22%), gliclazide (14%), gliquidone and glipizide (1%). In 234 cases the hypogycemic event was associated with trauma (insulin, 157), in 39 with motor vehicle accidents (insulin, 25). Out of hospital, hypoglycemia had been self-treated in 18% of cases, was treated by the Emergency personnel in 51%. When in ED, blood glucose was on average 78 ± 53 mg/dL; in ED, hypoglycemia was treated by oral glucose (19%), i.v. glucose (28%), i.m. glucagon (2%). Following visit and/or treatment, 44% of cases were immediately referred to their GPs, 18% were kept under observation for less than 24 hours, 31% were admitted to different medical units, 7% refused admission; 6 patients died in ED. When admitted, median length of stay was 8 days (interquartile range, 6) and death occurred in 77 cases (9% of total admitted cases).
Conclusion: Hypoglycemic events generate a significant burden to persons with diabetes and are an important cost for the National Health system, not limited to subjects treated with insulin. Outcome is poor in many cases, reflecting the frailty of most patients, exacerbated by hypoglycemia.

The effect on insulin analogues on the risk of severe hypoglycaemia in patients with type 1 diabetes and recurrent severe hypoglycaemia: the HypoAna trial

U. Pedersen-Bjergaard[1], P.L. Kristensen[1], H. Beck-Nielsen[2], K. Nørgaard[3], H. Perrild[4], J.S. Christiansen[5], T. Jensen[6], P. Hougaard[7], H.-H. Parving[6], B. Thorsteinsson[1], L. Tarnow[8];
[1]Endocrinology Section, Hillerød Hospital, [2]Odense University Hospital, [3]Endocrinology Section, Hvidovre Hospital, [4]Endocrinology Section, Bispebjerg Hospital, Copenhagen, [5]Aarhus University Hospital, [6]Rigshospitalet, Copenhagen, [7]University of Southern Denmark, Odense, [8]Steno Diabetes Center, Gentofte, Denmark.

Background and aims: Insulin therapy in type 1 diabetes is limited by the risk of severe hypoglycaemia. Insulin analogues are developed to improve insulin treatment of diabetes in respect to glycaemic control and avoidance of hypoglycaemic episodes. The effect of insulin analogues on glycaemic control is documented in large trials, while their effect on the frequency of severe hypoglycaemia is less clear, especially in patients with recurrent severe hypoglycaemia. The trials comparing the effect of insulin analogues and human insulin's in type 1 diabetes have invariably excluded patients at high risk of severe hypoglycaemia from participation, i.e. those with recurrent severe episodes or hypoglycaemic unawareness. In clinical practice, however, many patients at high risk of severe hypoglycaemia have changed treatment regimen from human insulin to insulin analogues based on a non-evidence-based belief in a potential of analogues to reduce occurrence of severe hypoglycaemia. In the HypoAna Trial we therefore tested whether a treatment regimen based on insulin analogues is superior to human insulin in reducing the rate of severe hypoglycaemic episodes in patients at high risk of severe hypoglycaemia.
Materials and methods: The study was a two-year investigator-initiated, prospective, randomised, open, blinded endpoint (PROBE) trial including 159 patients with type 1 diabetes and two or more episodes of severe hypoglycaemia in the preceding year. Subjects were randomized to treatment with basal-bolus therapy based on analogue (aspart/detemir) and human (regular/NPH) insulin in a balanced cross-over design. Primary endpoint was the number of episodes of severe hypoglycaemia defined by need for treatment assistance from others. A blinded adjudication of endpoints according to Whipple's triad and severity was applied.
Results: Treatment with the analogue-based insulin regimen resulted in a 31% (12-49%) rate reduction (p=0.007) in the intention-to-treat analysis and a 30% (95% CI: 10%-49%) rate reduction (p=0.012) in the per-protocol analysis corresponding to an absolute reduction of 0.5 episodes per patient-year. The reduction was primarily due to reduction in the rate of nocturnal severe hypoglycaemia. There was no difference between the treatments in markers of severity of the reported episodes. The result was obtained despite maintenance of baseline glycaemic control (HbA1c: 8.0±1.0% (64±11 mmol/mol) (mean±SD)) throughout both treatment arms. The number of patients needed to treat to avoid one episode of severe hypoglycaemia was approximately two patients in one year.
Conclusion: In patients with type 1 diabetes and recurrent severe hypoglycaemia treatment with insulin aspart/detemir resulted in a clinically significant reduced rate of severe hypoglycaemia at the same level of glycaemic control as compared to treatment with human insulin.

Exercise-related hypoglycaemia occurs at similar frequency with insulin degludec and insulin glargine

D.S. Oyer[1], S. Heller[2], S.C.L. Gough[3], K.H. Jensen[4], O. Kinduryte[4], A. Philis-Tsimikas[5];
[1]Northwestern University Feinberg School of Medicine, Chicago, USA, [2]University of Sheffield, [3]Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, UK, [4]Novo Nordisk A/S, Søborg, Denmark, [5]Scripps Whittier Diabetes Institute, La Jolla, USA.

Background and aims: During exercise, increased glucose requirements as well as increased insulin sensitivity can lead to hypoglycaemia in patients with diabetes. Exercise intensity, dose timing and the individual pharmacodynamic properties of insulin can affect the risk of hypoglycaemia. Insulin degludec (IDeg) is a new basal insulin with an ultra-long and stable glucose-lowering effect and this property might be expected to alter the susceptibility to exercise-related hypoglycaemia.
Materials and methods: We investigated exercise-related hypoglycaemia in seven randomised, open-label, treat-to-target, clinical trials with IDeg vs insulin glargine (IGlar) once daily. Trials were of 26 or 52 weeks in type 1 (T1D; n=1116) and type 2 diabetes (T2D; n=3598). Patients reported hypoglycaemic episodes in their subject diaries and were instructed to note any relation to exercise (based on their own judgment). Confirmed hypoglycaemia was defined as plasma glucose <3.1 mmol/L or severe episodes requiring assistance. Nocturnal hypoglycaemia was defined as any episode between midnight and 6:00AM.
Results: The proportion of patients experiencing ≥1 confirmed hypoglycaemic episode related to exercise was similar with IDeg and IGlar for T1D and T2D (table). In both arms, more exercise-related hypoglycaemia occurred in patients with T1D than with T2D.
Conclusion: In conclusion, the data suggest no increased risk of self-reported exercise-related hypoglycaemia with IDeg compared with IGlar.

	T1D		T2D basal-bolus therapy		T2D basal-oral therapy	
	IDeg	IGlar	IDeg	IGlar	IDeg	IGlar
Total n subjects	801	315	753	251	1734	860
Total n subjects with confirmed hypoglycaemic episodes	769	303	609	206	779	380
Total n subjects with ≥1 exercise-related confirmed hypoglycaemic episode (% of n with confirmed hypoglycaemic episodes)	614 (80%)	242 (80%)	311 (51%)	106 (51%)	163 (21%)	83 (22%)

Trials: T1D: NN1250-3770, NN1250-3583 (basal–bolus therapy), T2D: NN1250-3586, NN1250-3668, NN1250-3672, NN1250-3579 (all basal ± oral), NN1250-3582 (basal–bolus therapy). Safety analysis set: subjects exposed to ≥1 dose of trial product.

A prospective, randomised study in patients with type 1 diabetes on the need for additional carbohydrates with standardised physical activity to prevent hypoglycaemia

H. Frenzke, A. Varnhorn, H. Schulze, M.A. Nauck;
Diabeteszentrum Bad Lauterberg, Germany.

Background and aims: Patients with type 1 diabetes treated with intensified insulin regimens tend to develop hypoglycaemia with physical activity, and need to compensate for the glucose-lowering effect with additional carbohydrates or with reductions in insulin doses. It is not known, which category, timing or quantity of carbohydrate is necessary to prevent hypoglycaemia. We wanted to study this question with a prospective cross-over design in patients with type 1 diabetes on intensified insulin regimens.
Materials and methods: 24 subjects with type 1 diabetes (age 41 ± 12 years; 11 women, 13 men; body-mass-index 26.5 ± 4.7 kg/m2; diabetes duration 16 ± 11 years; HbA1c 9.1 ± 1.5 %; insulin dose 0.64 ± 0.22 IE/kg per day; 1.7 ± 1.5 symptomatic hypoglycaemic episodes per week; estimated hypoglycaemia awareness threshold 60 ± 15 mg/dl) participated. In randomized order, the volunteers participated in one afternoon session without and three afternoon sessions with a standardised physical activity (4 km walk lasting approximately 60 min) beginning at 2 p.m. (a) without additional carbohydrates, (b) with 10 g carbohydrates, or (c) 20 g carbohydrates, each at the start of and 30 min after commencing physical activity (muesli bar). Blood glucose was determined at 2:00 p.m., 2:30 p.m., 3:00 p.m., 6:00 p.m., and 8:00 p.m. (laboratory-based method). Hypoglycaemic episodes and hypoglycaemia-induced additional carbohydrate intake were monitored between 2:00 and 6:00 p.m., i.e. during and after physical activity. Statistical analysis: Repeated-measures ANOVA.
Results: During and after physical activity, independent from the regimen of preventive carbohydrate replacement, blood glucose uniformly fell from approximately 175 mg/dl at 2 p.m., i.e. 1-2 h after lunch, to approximately 100-110 mg/dl at 2:30 p.m. Later, it increased again with larger quantities of additional carbohydrates ($p = 0.0036$ for 40 vs. 0 g). With preventive administration of carbohydrate, less additional carbohydrate needed to be administered due to intercurrent hypoglycaemic episodes (20 g: $p = 0.017$; 40 g: $p = 0.015$). During and after physical activity hypoglycaemic episodes were often asymptomatic and were only detected by frequent blood glucose measurements.
Conclusion: The amounts of carbohydrates employed for the prevention of hypoglycaemia induced by physical activity in our prospective study protocol turned out to be too small, and their influence to elevate blood glucose was observed too late. For the prevention of hypoglycaemic episodes induced by physical activity of intermediate intensity and one hour's duration more than 40 g carbohydrates need to be recommended, and the initial step should be the administration of more rapidly absorbed carbohydrates. Further studies are warranted to define the optimum recommendations for type 1 diabetic patients.

Which algorithms best reduce the risk of hypoglycaemia during exercise for patients with type 1 diabetes on pump therapy?

S. Franc[1,2], M.H. Petit[2], O. Juy[2], E. Pussard[3], A. Daoudi[2], L. Boursiquot[1], C. Petit[2], A. Pochat[2], P. Dupont[1], L. Canipel[2], F. Koukoui[1], G. Charpentier[2,1];
[1]Centre Hospitalier Sud Francilien, Corbeil-Essonnes, [2]CERITD, Evry, France, [3]Hormonologie, CHU Bicêtre, Le Kremlin-Bicêtre, France.

Background and aims: In T1 diabetic (T1D) subjects on pump therapy, there is no consensus regarding the adjustment of insulin doses in the event of physical activity (PA). Taking into account the time of exercise relative to meals, we tested several adjustments of insulin doses according to the intensity of PA.
Materials and methods: Twenty T1D patients with HbA1c < 9% and practicing leisure PA were included. $VO2_{max}$ was recorded for all subjects on entering the study. The subjects performed 4 physical tests at least 48 hours apart (30-min cycling sessions on an bicycle ergometer) 3h after lunch (basal tests), in random order, at 2 levels of PA (moderate and intensive, i.e. 50% and 75% $VO2_{max}$), with 2 options each time regarding reduction in basal rate (BR): BR reduction of 50% or 80% in the case of 50% $VO2_{max}$ and of 80% or 100% in the case of 75% $VO2_{max}$. Each time, BR was reduced during the exercise period and the following 2 hrs, except for the last one, as the pump was switched ON at the end of the exercise period. A resting test served as a reference. Blood glucose and insulin levels were measured during the exercise (or rest) period and over the following 2 hrs. On each test day, patients wore an iPro2 device from lunchtime until breakfast the next day. We focused on the occurrence of hypoglycemic events recorded on the CGM system.
Results: Patients (11 men, BMI 24±5 kg/m2, age 45±12 yrs, HbA1c at baseline 7.9±0.7%, diabetes duration 17.6±10 yrs, on pump therapy for 5 years, practicing 4.3 hrs/week of PA) performed 137 physical tests between 02/2011 and 02/2013, 100 basal tests and 37 prandial tests. For moderate PA, the comparison revealed that an 80% BR reduction led to fewer hypoglycemic events than a 50% reduction, with no concomitant increased occurrence of hyperglycemic events. For intensive PA, the adjustment that led to the fewest hypoglycemic events was switching the pump OFF during PA and ON at the end of PA. In all cases, the nadir of BG values occurred at the end of the exercise session (30 min). The reduction in glycemia was 72 mg/dl for both 50% $VO2_{max}$ sessions and of 67 and 72 mg/dl respectively for BR-100% and BR-80% during the 75% $VO2_{max}$ sessions.
Conclusion: To prevent the occurrence of hypoglycemic events with moderate PA, BR-80% + 2hrs could be suggested to begin with then adjusted if necessary. For intensive PA, the solution of turning the pump OFF during exercise and turning it ON at the end of exercise could be proposed first. In all cases, the action of insulin on board must be kept in mind, even with the pump OFF. These results should incite healthcare providers to advise patients to reduce their BR at least 30 min before the start of exercise in order to prevent hypoglycemia.

OP 33 Mitochondrial metabolism

193

Participation of CDK4 in the regulation of mitochondrial metabolism and energy homeostasis

I.C. Lopez-Mejia[1], C. Chavey[2], S. Lagarrigue[1], E. Gari[3], L. Fajas[1];
[1]Département de physiologie, Université de Lausanne, Switzerland, [2]Institut de Génétique moléculaire de Montpellier, France, [3]Departament de Ciències Mèdiques Bàsiques, Institut de Recerca Biomèdica de Lleida, Spain.

Background and aims: Much has been studied about the participation of CDKs, in cell growth, proliferation and development, whereas little attention has been paid to their implication in metabolic pathways. Interestingly, Cdk4 inactivation *in vivo* led to marked metabolic phenotypes. We are currently testing several hypotheses that point to the participation of Cdk4 in key steps of energy metabolism, including: 1) mitochondrial biogenesis and function; 2) lipid oxidation; and 3) glycolysis.
Material and methods: Yeast-two hybrid experiments were conducted using CDK4 as bait, and screening a library of human protein fragments. Differentiated brown adipose tissue (BAT) cells were used to study the effects of CDK4 inhibition on oxygen consumption. Undifferentiated primary MEFs were used to perform fatty acid oxidation assays. Oxygen consumption and fatty acid oxidation experiments were carried out using an XF24 seahorse analyzer. C57/Bl6 wild-type mice (n = 3 to 5 per experiment) were used to evaluate the effects of the treatment with the CDK4/6 inhibitor PD-0332991 on mitochondrial gene expression. PD-0332991 or the vehicle were administered daily by oral gavage. Mice were fasted over-night prior to organ harvest. All statistical tests were two-tailed t-tests.
Results: Our experiments point towards an implication of CDK4 in mitochondrial metabolism and mitochondrial function, in glucose and fatty acid degradation and in the TCA cycle. First of all, yeast two-hybrid experiments using CDK4 as bait identified the mitochondrially encoded Cytochrome C oxidase subunit II (MT-CO2) as a CDK4 partner. Second, electron microscopy imaging in liver and BAT sections from $Cdk4^{-/-}$ mice showed that the absence of Cdk4 leads to an increase in mitochondrial size and number, as well as to a decrease in the size and the number of lipid droplets. Moreover, our preliminary experiments using PD-0332991, a chemical inhibitor of CDK4 kinase activity, also suggest that CDK4 is an anabolic regulator, since BAT cells treated with this compound exhibit a modest (1.2 fold) but significant (p=0.0001) increase in oxygen consumption. *In vivo,* 3 days of treatment with PD-0332991 caused a 1.5-2 fold increase in the expression of numerous mitochondrial genes, like PGC1a (p=0.05), its target genes TFAM (p=0.016) and NRF1 (p=0.011), the mitochondrial complex II subunit SDHA (p=0.019), and the mitochondrial complex I subunits Ndufs8 (p=0.033) and Ndufc1 (p=0.015), in BAT. When fatty acid oxidation (FAO) was measured with the seahorse flux analyzer in MEFs from $Cdk4^{+/+}$, $Cdk4^{-/-}$ and $Cdk4^{R24C/R24C}$ (from mice carrying a gene encoding for a CDK4 protein that is resistant to the inhibition by Ink4 family members), we observed that the deletion of Cdk4 led to an increase in FAO whereas a constitutively active Cdk4 drove a significantly decreased FAO. At the level of oxygen consumption, we observed a two-fold increase when comparing $Cdk4^{+/+}$ and $Cdk4^{-/-}$ MEFs. This increased mitochondrial was correlated to an increase in PGC1a protein expression.
Conclusion: Overall, our results implicate that CDK4 has an anabolic role in energy metabolism that can very well be independent of E2f1 transcriptional activity.

Background and aims: White adipose tissue (WAT) plays a crucial role in the regulation of glucose homeostasis owing to its endocrine and lipid storage functions. In addition, compelling evidence suggest that adipocyte mitochondrial function is a crucial determinant of whole body insulin sensitivity. In support of this view, mitochondrial dysfunction has been observed in WAT of insulin-resistant individuals and a variety of rodent models for type 2 diabetes. Consistent with a reduced mitochondrial function, clinical studies have shown that patients with insulin resistance or type 2 diabetes have decreased mitochondrial mass in WAT. Furthermore, WAT is the main target of thiazolidinediones (TZDs), which exert their insulin sensitizing effects by promoting de novo adipogenesis and, presumably, also by stimulating mitochondrial biogenesis and function. Although the action of TZDs on mitochondrial gene expression has been attributed to their capacity to increase the expression of the PGC-1α coactivator, we have recently shown that PGC-1α is not required to sustain basal or rosiglitazone-induced mitochondrial biogenesis in WAT, suggesting that other factors may play a more relevant role in the control of mitochondrial gene expression in white adipocytes. Here, we address the role of PGC-1β in the function of WAT and its contribution to energy and glucose homeostasis.
Materials and methods: To study the function of PGC-1β in WAT, we have generated a new mouse model in which the gene encoding for PGC-1β has been ablated specifically in adipocytes by homologous recombination (PGC1β-FAT-KO mice). Mice were fed a high fat diet to induce insulin resistance and then treated with either vehicle or 10 mg/Kg of rosiglitazone for 15 days.
Results: Genome-wide expression profiling analysis of WAT from PGC1β-FAT-KO mice reveals that PGC-1β function is mostly restricted to the regulation of a specific subset of mitochondrial genes involved in ATP production (i.e. OxPhos system, TCA cycle). Accordingly, WAT of PGC1β-FAT-KO mice exhibits decreased mitochondrial protein content and oxidative capacity. In addition, we have found that rosiglitazone-induced expression of mitochondrial genes and activity is severely blunted in WAT of PGC1β-FAT-KO mice. This is in contrast with our results in mice lacking PGC-1α in WAT, in which mitochondrial biogenesis and function were normally induced by TZDs. Similarly to our in vivo observations, knockdown of PGC-1β but not PGC-1α impairs basal and rosiglitazone-induced mitochondrial gene expression and oxygen consumption. Despite a decrease in mitochondrial function comparable to that observed in WAT of insulin resistant or type 2 diabetic patients, we have found that lack of PGC-1β in mouse adipocytes does not induce tissue-specific or whole body insulin resistance. Moreover, PGC1β-FAT-KO mice normally respond to the insulin-sensitizing effects of TZDs.
Conclusion: Our findings provide evidence that PGC-1 coactivators play differential roles in WAT, being PGC-1β the major regulator of basal and TZD-induced mitochondrial oxidative function. Our results show that mitochondrial dysfunction in WAT is not associated to the development of insulin resistance and also suggest that full mitochondrial oxidative function is not required for the effects of TZDs on insulin sensitivity.

Lack of PGC-1α is associated with dysregulation of AICAR mediated AMPK regulation of ACC and PDH

A. Gudiksen, R.S. Biensø, H. Pilegaard;
Section for Molecular and Integrative Physiology, University of Copenhagen, Denmark.

Background and aims: A sedentary lifestyle has been shown to be associated with metabolic inflexibility, defined by an impaired ability to adjust fuel oxidation with changes in fuel availability. Pyruvate dehydrogenase (PDH) is a key enzyme in mammalian oxidative glucose metabolism. In addition, the intracellular energy sensor, AMP activated protein kinase (AMPK), is known to be an important regulatory protein in substrate utilization, and previous studies have indicated that AMPK may regulate PDH. AMPK is activated by muscle contractions, but can also be pharmacologically activated by 5-aminoimidazole-4-carboxamide ribonucleoside (AICAR). Lack of peroxisome proliferator-activated receptor γ co-activator (PGC)-1α is known to cause a change in phenotype to a more glycolytic muscle and appear to be associated with metabolic inflexibility. Therefore, skeletal muscle without PGC-1α may be seen as a model for a sedentary lifestyle, and it is possible that AMPK-mediated regulation of substrate utilization potentially via PDH is changed in such muscles. The purpose of this study was therefore to test the hypothesis that in vivo injections with AICAR regulates AMPK signaling and PDH in skeletal muscle, and that this regulation is impaired in muscles lacking PGC-1α.
Materials and methods: Plasma and quadriceps muscles were obtained from littermate wild type (WT) and muscle-specific PGC-1α knockout mice (MKO) 1 hour after injections with either saline or AICAR.
Results: PDH-E1α and cytochrome *c* protein content was lower ($p<0.05$) and hexokinase II protein tended to be lower ($0.05<p<0.1$) in PGC-1α MKO than

in WT mice, whereas GLUT4 protein content was similar in PGC-1α MKO and WT mice. AICAR treatment increased glucose-6-phosphate ($p<0.05$) in WT with no change in PGC-1α MKO mice. Plasma glucose concentration decreased ($p<0.05$) with AICAR in WT mice, but remained unchanged in PGC-1α MKO mice. AICAR treatment increased AMPK phosphorylation similar in skeletal muscle from PGC-1α MKO and WT mice, but while AICAR increased ($p<0.05$) ACC phosphorylation in WT mice, no change was evident in skeletal muscle from PGC-1α MKO mice. AICAR induced in WT mice an increase ($p<0.05$) in PDH-E1α site 2 phosphorylation without an associated change in PDHa activity, and in PGC-1α MKO mice a dephosphorylation ($p<0.05$) of PDH-E1α together with decreased ($p<0.05$) PDHa activity indicating regulatory dysfunction in acute metabolic regulation when PGC-1α is lacking.
Conclusion: *In vivo* AICAR-mediated PDH regulation seems to involve dissociation between PDH-E1α phosphorylation and PDHa activity. The blunted ACC phosphorylation and the changed PDH regulation in skeletal muscle from PGC-1a MKO mice in response to AICAR may indicate an impaired ability to increase fatty acid oxidation and an impaired acute regulation of substrate utilization when PGC-1α is lacking. Together these findings may suggest that a sedentary lifestyle, with decreased expression of PGC-1α, leads to metabolic inflexibility in part through dysregulation of ACC and PDH.

196

Effects of the mtAtp-8 OXPHOS mutation on susceptibility to diet-induced lipoinflammation in conplastic B6-mt^{FVB} mice
F. Koch, H. Weiss, J. Niemann, S. Baltrusch, M. Tiedge;
Institute of Medical Biochemistry and Molecular Biology, Rostock, Germany.

Background and aims: The conplastic mouse strain B6-mt^{FVB} with a mutation in the ATP synthase complex of the OXPHOS system shows an increased mitochondrial ROS production in various tissues and a pathological mitochondrial phenotype. Feeding a high fat diet induced an impaired glucose tolerance, insulin resistance and ultimately premature death after high fat diet in comparison to the B6-mt^{AKR} control strain. As lipoinflammation plays a pathogenetic role for nonalcoholic fatty liver disease (NAFLD) it was the aim of this study to investigate the effect of HFD on (a) hepatic triglycerides, (b) gene expression of proinflammatory cytokines in adipose tissue and, (c) protein level of fetuin A after 3 and 12 months in conplastic B6-mt^{FVB} mice.
Materials and methods: B6-mt^{AKR}(AKR) control and B6-mt^{FVB} (FVB) mice were fed high fat diet (HFD, 60 % fat) or control diet (CD, 10 % fat) after weaning. After 3 or 12 months animals were killed and tissues were collected for different assays. Expression of proinflammatory cytokines (IL-6, IL-1β, TNFα, INFγ) and adipokines (adiponectin, resistin, leptin) in adipose tissue was quantified by RT-qPCR. Hepatic triglyceride content was determined by photometric assay. Fetuin A serum levels were quantified by ELISA.
Results: AKR mice showed increased proinflammatory cytokines (IL-6 3-fold; $p<0.001$, IL-1β 4-fold; $p<0.01$, TNFα 4.6-fold; $p<0.001$) in adipose tissue after 3 months HFD. Only IL-6 expression was 4-fold increased in FVB mice after HFD ($p<0.001$). Gene expression of proinflammatory cytokines (TNFα, IL-1β) increased at the age of 12 months irrespective of strain and diet. After 3 months of HFD adiponectin gene expression were not different between the FVB and AKR. However, after 12 months of HFD adiponectin expression was 30 % lower in FVB mice than in AKR mice. HFD resulted in a 6.4-fold higher resistin expression in FVB mice compared to AKR HFD ($p<0.05$). Hepatic triglyceride content was 15 % higher in both strains after 3 months of HFD ($p<0.01$) whereas after 12 months of HFD a 47 % increase ($p<0.05$) could be observed in AKR compared to FVB mice. Leptin gene expression was 2.3-fold increased after 3 months of HFD in the FVB strain (2.3-fold; $p<0.05$) but did not show a difference to the AKR strain after a prolonged HFD for 12 months. In the AKR strain serum fetuin A serum levels showed an age-dependent increase in response to a HFD while in FVB mice fetuin A levels were not affected by the diet.
Conclusion: The *Atp8* mutation in the ATP synthase resulted in an increased susceptibility to HFD at the age of 3 months. The reduced life span of the FVB strain in response to HFD does not result from significant lipoinflammation but may be modulated by adiponectin and resistin levels. Our data indicate that mtDNA variations in the OXPHOS system negatively affect life span after metabolic stress irrespective of proinflammatory cytokines from adipose tissue. Importantly, hepatic triglyceride content appears not to be the predisposing factor for increased mortality of B6-mt^{FVB} mice in response to HFD.

Effects of the mt-*Cytb* mutation in the B6-mt$^{129S1/SvlmJ}$ strain on metabolism, ROS defence and OXPHOS proteins after high fat diet
H. Weiss, L. Oesterwinter, F. Koch, M. Borchert, J. Niemann, S. Baltrusch, M. Tiedge;
Institute of Medical Biochemistry, University of Rostock, Germany.

Background and aims: Polymorphisms in the mitochondrial cytochrome b (*Cytb*) gene of the oxidative phosphorylation system (OXPHOS) have been associated with obesity in young adults. To elucidate this mitochondrial phenotype, we generated the conplastic mouse strain B6-mt$^{129S1/SvlmJ}$ which carries a mitochondrial DNA mutation in the *Cytb* gene coding for a subunit of Complex III of the respiratory chain. It was the aim of this study to investigate the effects of a long term HFD on metabolic parameters, gene expression of antioxidative enzymes and protein expression of the respiratory chain.
Materials and methods: B6-mt$^{129S1/SvlmJ}$ (mt129) were fed high fat (HFD, 60% fat) or control diet (CD, 10% fat) directly after weaning. Metabolic characterization comprised serum insulin, leptin, glucose tolerance and insulin sensitivity after 3 and 6 months of diet. Gene expression of Catalase, Superoxide dismutase 1 (SOD) and 2, uncoupling protein 2 (UCP) and mammalian target of Rapamycin (mTOR) were quantified by real-time PCR analyses. The protein expression of OXPHOS complexes were measured by western blot analysis in liver tissue.
Results: Mean blood glucose levels after 3 and 6 months of HFD or CD were not significantly different. Serum insulin levels in the mt129 were 4 times higher after 3 months (3.5 ±0.8 vs. 0.9 ± 0.1 µg/l; $p<0.05$) and 3-fold higher after 6 months of HFD (7.6 ± 1 vs. 2.5 ± 0.5 µg/l; $p<0.001$). mt129 showed a pronounced increase of serum leptin levels after 3 months of HFD (130 ±16 ng/ml vs. 34 ± 20 ng/ml). HFD for 3 and 6 months resulted in an impaired glucose tolerance and insulin sensitivity ($p<0.05$) in the mt129 strain. In liver tissue gene expression for the mitochondrial antioxidative enzyme SOD2 showed a significant twofold increased. Cytosolic SOD 1 and catalase gene expression were not affected by HFD in mt129 mice. Also UCP2 (2-fold, $p<0.05$) and mTOR (1.5-fold, $p<0.01$) were upregulated in HFD fed animals indicating compensatory mechanisms to the mitochondrial phenotype. The protein expression levels of complex III showed no differences while protein expression of complex I was significantly downregulated ($p<0.05$) at all investigated time points.
Conclusion: In line with the observation in obese adults we could demonstrate that long term high fat diet in *Cytb* mutant B6-mt$^{129S1/SvlmJ}$ mice leads to impaired glucose tolerance and insulin resistance in response to metabolic stress. The reduced complex I expression in the B6-mt^{129} strain could protect these mice against potential mitochondrial ROS production after metabolic challenge by nutrients. This view is supported by the observation that HFD induced antioxidative defense mechanisms (SOD 2) and OXPHOS uncoupling (UCP2) counteracting ROS production. The B6-mt^{129} could be an interesting model to study mitochondrial mechanisms that confer a high risk of obesity in early adulthood.

Hepatic mitochondrial function in human obesity: association with insulin sensitivity and oxidative stress
C. Koliaki[1], J. Szendroedi[1], K. Kaul[1], T. Jelenik[1], P. Nowotny[1], M. Dubiak[1], M. Krausch[2], W. Knoefel[2], F. Jankowiak[3], M. Schlensak[4], M. Roden[1,5];
[1]Institute of Clinical Diabetology, German Diabetes Center, Heinrich Heine University, [2]Department of General, Visceral and Pediatric Surgery, Heinrich Heine University, [3]Institute of Pathology, Heinrich Heine University, [4]General Surgery Department, St. Martinus Hospital, [5]Department of Endocrinology and Diabetology, Heinrich Heine University, Düsseldorf, Germany.

Background and aims: Hepatic energy metabolism can be lower in patients with overt type 2 diabetes, but it remains controversial whether alterations of hepatic mitochondrial oxidative capacity precede insulin resistance and occur in states such as human obesity. The present study assessed hepatic mitochondrial function in obese humans compared to healthy lean controls, and its association with insulin sensitivity and markers of systemic and hepatic oxidative stress.
Materials and methods: Sixteen non-diabetic obese patients scheduled for bariatric surgery (age 43±10 years, body mass index 51±9 kg/m^2) and seven non-diabetic controls (46±10 years, 26±2 kg/m^2) underwent euglycemic-hy-

perinsulinemic clamps with infusion of deuterated glucose to assess whole-body and hepatic insulin sensitivity. During surgery, liver samples were obtained and maximal mitochondrial respiratory capacity was measured in both intact tissue and isolated mitochondria using ex vivo high-resolution respirometry. Reactive oxygen species (ROS) production was measured in isolated mitochondria with the Amplex Red method, while lipid peroxidation in serum and liver was assessed by measuring thiobarbituric acid reactive substances (TBARS).
Results: Obese participants presented markedly lower insulin sensitivity (M-value 3.3±1.5 vs. 6.5±2.5 $mg.kg^{-1}.min^{-1}$, p=0.03) and 34% greater hepatic mitochondrial respiratory capacity for pyruvate and glutamate oxidation than controls (59±14 vs. 39±10 $pmol.s^{-1}.mg^{-1}$, p=0.006). They also tended to have higher maximal capacity for glutamate oxidation in isolated mitochondria (638±87 vs. 335±200 $pmol.s^{-1}.mg^{-1}$, p=0.06). In addition, obese subjects featured higher hepatic levels of hydrogen peroxide (973±181 vs. 618±201 pmol/min/mg protein), higher TBARS in liver tissue (114±21 vs. 82±30 μmol/mg protein) and in serum (36±13 vs. 27±10 μmol/mg protein) than controls (all p<0.05). Across all subjects, hepatic ROS production correlated positively with mitochondrial beta oxidation (r=0.68, p=0.04) as well as with pyruvate and glutamate respiration (r=0.83, p=0.006), while serum TBARS correlated positively with hepatic maximal glutamate oxidation (r=0.47, p=0.05). Furthermore, hepatic maximal glutamate oxidation correlated positively with hepatic insulin sensitivity (r=0.82, p=0.001).
Conclusion: Our study provides direct evidence that hepatic mitochondrial oxidative capacity is upregulated in non-diabetic obese humans and associates with augmented hepatic and systemic oxidative stress. This upregulation could be due to a transitional hepatic adaptation to lipid overload, which might precede impaired hepatic energy metabolism in overt type 2 diabetes.

Cardiovascular mortality in type 2 diabetes patients with incident exposure to long-acting insulin analogues
S. Ioacara[1,2], C. Guja[1], C. Ionescu-Tirgoviste[1], S. Fica[2], A. Reghina[2], O. Georgescu[2], M. Roden[3];
[1]"I. Pavel" Outpatient Clinic, Bucharest, [2]"Elias" Hospital, Bucharest, Romania, [3]Institute for Clinical Diabetology, German Diabetes Center, Düsseldorf, Germany.

Background and aims: To investigate the impact of insulin glargine exposure on cardiovascular mortality in type 2 diabetes (T2DM) patients with incident insulin initiation.
Materials and methods: All consecutive diabetes patients aged over 40 years, residing in a major urban area were screened at their first diabetes outpatient visit between 01/01/2001-12/31/2008 (n=79869). Exclusion criteria were insulin treatment at screening (n=14752), no insulin treatment until 12/31/2008 (n=55795), <6 months of glucose-lowering treatment alone before insulin initiation (n=1154), insulin prescription before glargine became available (04/17/2003, n=1761), age <40 or ≥80 years at first insulin prescription (n=406), and <6 months of insulin treatment following insulin initiation (n=1011). A total of 4990 subjects (58.4% females) were followed-up for death until 12/31/2011, based on death certificate and using data from the National Institute of Statistics. Baseline was defined at 6 months after insulin initiation. Data on mean dose of oral antidiabetics at insulin initiation, time between screening and insulin exposure, gender, age, time-dependent oral and insulin treatment (by each available active substance) during follow-up were available. Adjusted time-dependent competing risk regression analysis, with daily updates of treatment modalities was performed. Simultaneously use of cumulative exposure and ever exposed term of the available treatment options, a "fixed" cohort, cumulative exposure limited to that attained one year prior to death (minimizing the reverse causation), and a propensity score analysis completed the evaluation.
Results: Mean baseline age was 62±9 years, with a mean follow-up of 4.7±1.9 years (23179 person-years). During 23179 person-years exposure time, there were 521 cardiovascular deaths and 366 deaths from other causes (competing events). Glargine cumulative dose exposure (10,000 IU increments) significantly lowered overall cardiovascular mortality risk, subhazard ratio (SHR) 0.977 (95% CI 0.960-0.993, p=0.006), but not specifically for myocardial infarction, SHR 0.961 (95% CI 0.922-1.002, p=0.064) and stroke, SHR 0.974 (95% CI 0.929-1.021, p=0.266). Glargine cumulative time exposure (one year increments) significantly lowered overall cardiovascular, SHR 0.963 (95% CI 0.944-0.981, p<0.001), and myocardial infarction mortality risk, SHR 0.945 (95% CI 0.899-0.994, p=0.028), but not that for stroke SHR 0.973 (95% CI 0.927-1.020, p=0.257). Cumulative exposure limited to that attained one year prior to death showed a glargine cumulative exposure time SHR 0.940 (95% CI 0.919-0.960, p<0.001) and cumulative dose SHR 0.954 (95% CI 0.934-0.974, p<0.001) as regards cardiovascular mortality. "Fixed" cohort analysis showed no significant cardiovascular mortality hazard associated with baseline glargine exposure. Propensity score analysis did not significantly changed original results.
Conclusion: Both cumulative dose and cumulative time exposure to insulin glargine were associated with a lower risk of cardiovascular mortality. The effect was mostly driven by myocardial infarction end-point, with no significant contribution for stroke. These data support the concept of macrovascular benefit for basal analog insulin use in type 2 diabetes.

Combination therapy with metformin plus sulfonylureas versus metformin plus DPP-4 inhibitors and risk of all-cause mortality
C.J. Currie[1], S. Jenkins-Jones[2], J. Mukherjee[3], C.L. Morgan[1];
[1]Department of Primary Care and Public Health, Cardiff University, [2]Global Epidemiology, Pharmatelligence, Cardiff, UK, [3]Global Health Economics and Outcomes Research, Bristol-Myers Squibb, Wallingford, USA.

Background and aims: The aim of this study was to evaluate the comparative risk of all-cause mortality for patients exposed to dual therapy with metfor-

min and sulfonylureas (SUs) compared with metformin and DPP-4 inhibitors (DPP-4i).
Materials and methods: Retrospective data were extracted from the Clinical Practice Research Datalink (CPRD): a data resource comprising approximately 10% of all patients treated in primary care in the United Kingdom. Patients with type 2 diabetes initiated with dual regimens comprising metformin with either a SU or a DPP-4i between 2007 and 2012 were selected, regardless of where these regimens were used in the natural history of the disease. The primary endpoint was all-cause mortality. Time to all-cause mortality was compared using Cox proportional hazards models. In addition to the main comparative analysis adjusting for key covariates within the model, two additional sensitivity analyses were performed. Firstly, a matched-cohort study comparing those treated with SUs (exposed) versus DPP-4i (non-exposed) using the following matching criteria at baseline: age (±2 years), gender, diabetes duration (±1 year), BMI (±3 kg/m2), serum creatinine (±10 μmol/L) and HbA1c (±1%). Secondly, patients were also matched by propensity score predicted by the same candidate variables.
Results: In the main analysis, 27,251 patients were prescribed metformin in combination with SUs, and 5,215 were prescribed metformin in combination with a DPP-4i. 3,454 patients were included in each arm of the direct matched cohorts and 4,703 in each arm when propensity matched. With respect to all-cause mortality; the hazard ratio was significantly increased for metformin+SUs compared with metformin+DPP-4i for those matched directly (adjusted hazard ratio [aHR]=2.314; 95%CI 1.348—3.973), for all subjects (aHR=1.265; 0.900—1.779), and for those matched on propensity score (aHR=1.691; 1.135—2.519; see table).
Conclusion: There was a consistent reduction in mortality for patients prescribed metformin in combination with DPP-4i versus metformin in combination with SUs. These data should be considered when initiating combination therapy with metformin.

Table | Events, crude rates and adjusted hazard ratios for all-cause mortality: metformin plus sulfonylurea versus metformin plus DPP4 inhibitors

	Cohort	Patients	Events	Crude rates (pkpy)	aHR	95% CI		p-value
All subjects	SU	27,251	818	16.9	1.265	0.900	1.779	0.176
	DPP-4i	5,215	50	7.6

Association between first-line monotherapy with sulfonylurea versus metformin and risk of all-cause mortality
S. Jenkins-Jones[1], C.J. Currie[2], J. Mukherjee[3], C.L. Morgan[2];
[1]Global Epidemiology, Pharmatelligence, [2]Public Health and Primary Care, Cardiff University, UK, [3]Global Health Economics and Outcomes Research, Bristol-Myers Squibb, Wallingford, USA.

Background and aims: The aim of this study was to evaluate the comparative risk of all-cause mortality for patients exposed to first-line diabetes monotherapy with either sulfonylureas or metformin.
Materials and methods: Retrospective data were extracted from the Clinical Practice Research Datalink (CPRD): a data resource comprising approximately 10% of all patients treated in primary care in the United Kingdom. Patients with type 2 diabetes initiated with first-line, glucose-lowering regimens between 2000 and 2012 were selected. The primary endpoint was all-cause mortality. Time to clinical endpoints was compared using Cox proportional hazards models. In addition to the main comparative analysis adjusting for key covariates within the model, two additional sensitivity analyses were performed. Firstly, a matched-cohort study comparing those treated with sulfonylureas (exposed) versus metformin (non-exposed) using the following matching criteria at baseline: age (±2 years), gender, year of index exposure, diabetes duration (±1 year), BMI (±3 kg/m2), serum creatinine (±10 μmol/l) and Hba1c (±1%). Secondly, patients were matched by propensity score predicted by the same candidate variables.
Results: In the main analysis, 76,811 patients were prescribed metformin monotherapy (mean follow-up 2.9 years), and 15,687 sulfonylureas (mean follow-up 2.9 years). 2,048 patients were included in each arm of the direct matched cohorts and 8,836 in the propensity matched. With respect to all-cause mortality, using all three analytical approaches the hazard ratio was significantly increased for sulfonylureas compared with metformin: adjusted HR=1.580 (95% CI 1.483—1.684) for the main analysis, 1.902 (1.733—2.088) for those matched on propensity score and 1.338 (1.051—1.704) for the directly matched analysis (see table).
Conclusion: Mortality was significantly increased in patients prescribed sulfonylureas as first-line, glucose lowering mon—therapy, compared with metformin monotherapy. Whilst residual confounding and confounding by indication may remain, this study indicates that treatment with first-line monotherapy with sulfonylureas should be reconsidered.

Table 1 | Events, crude rates and adjusted hazard ratios for all-cause mortality: sulfonylurea versus metformin first-line monotherapy

Myocardial infarction in subjects using anti-diabetic and/or anti-depressant agents compared to non-users: a nationwide register study in Sweden
K. Rådholm[1], A.-B. Wiréhn[2], M. Falk[1], J. Marcusson[3], C. Östgren[1];
[1]Division of Community Medicine, Primary Care, Department of Medical and Health Sciences, [2]Local Health Care R & D Unit, the County Council in Östergötland, [3]Department of Geriatrics, Faculty of Health Sciences, Linköping University, Sweden.

Background and aims: We prospectively explored the gender- and age-specific risk of developing myocardial infarction (MI) in patients treated with anti-diabetic and/or anti-depressant drugs compared to subjects with no pharmaceutical treatment for diabetes or depression in a nationwide register study.
Materials and methods: A cohort of all Swedish residents born between 1925 and 1963, n= 3 738 524, were followed in an individual-level register study by cross-linkage of three nationwide registers. The prescription and dispensing of anti-diabetics, anti-depressants and anti-hypertensive drugs were used as markers of disease. Subjects with prior MI before the start of the study period were excluded from analyses. We categorised all subjects as having "diabetes" or "depression" according to the different drug classes prescribed and dispensed in Swedish pharmacies. Thus, all subjects were categorised as; 1) diabetes and depression combined, 2) depression only, 3) diabetes only or, 4) neither depression nor diabetes. The cohort was followed over a period of three years, 2008-2010. All participants were redefined and categories were updated every year. Data were analysed using binary logistic regression. The outcome was first fatal or non-fatal MI event. Present hypertension was used for adjustment.
Results: During follow-up, 44 298 subjects suffered a first MI of which 15 782 (36%) were females and 28 516 (64%) were males. Of the total number of MIs, 16 569 were fatal which comprised 37% of all MIs in both females and males respectively. Compared to women without diabetes or depression, the Odds ratio (OR) for MI was 7.1 (95% CI: 6.1-8.2) for women with both diabetes and depression in the age category 45-64 years. The corresponding OR for men with diabetes and depression was 2.8 (2.5-3.2) compared to men without diabetes or depression. The OR for females, 45-64 years, with diabetes alone was 5.0 (4.4-5.6) compared with females without diabetes or depression. In the same age category, the corresponding OR for males with diabetes alone was 2.5 (2.3-2.6) compared with men without diabetes or depression. The results were virtually unchanged when adjusted for hypertension.
Conclusion: Use of both anti-diabetics and anti-depressants as markers of diabetes and depression was associated with a higher risk for MI compared to diabetes alone. This increased risk was in relative terms most substantial in middle-aged women compared to middle-aged men.

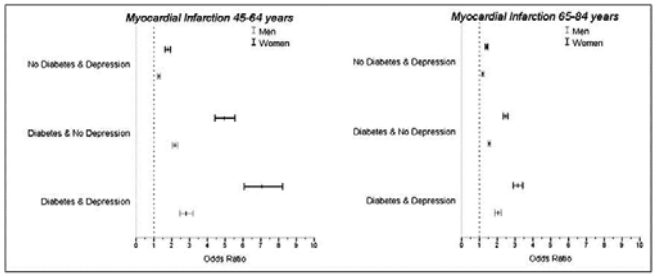

Figure 1. Odds Ratios with 95% CI for myocardial infarction in different groups of treatment categories in relation to subjects with neither treatment for diabetes nor depression stratified for age.

KCNJ11 E23K polymorphism increases susceptibility for cardiovascular mortality in patients with type 2 diabetes

S. Alkayyali[1], G. Hindy[2], M. Åkerlund[1], M. Lajer[3], D. Pasko[4], A. Hattersley[4], T. Frayling[4], P. Rossing[3], L. Groop[1,5], M. Orho-Melander[2], V. Lyssenko[1,3];
[1]Diabetes and Endocrinology, Lund University, Malmö, [2]Diabetes and Cardiovascular Disease Genetic Epidemiology, Lund University, Malmö, Sweden, [3]Steno Diabetes Center A/S, Gentofte, Denmark, [4]Molecular Genetics (Diabetes) Research Group, Exeter Medical School, UK, [5]Molecular Medicine Finland FIMM, University of Helsinki, Finland.

Background and aims: Type 2 diabetes is caused by interactions between genetic and environmental factors. Diabetes and its complications are considered as a major cause of morbidity and mortality. Genome-wide association studies have identified more than 60 genetic variants associated with type 2 diabetes and/or glucose and insulin traits, but their effect on total mortality or cardiovascular (CVD) mortality has not yet been studied. The aim of this study was to explore whether these variants were also associated with total or CVD-mortality in patients with type 2 diabetes.
M**aterials and methods:** Discovery analyses included 30-36 common genetic variants in total of 3,610 patients from the local Malmö Scania Diabetes Registry (SDR), the Malmö Diet and Cancer Study (MDCS) and the Diabetes Alliance for Research in England (DARE) cohorts. Replication of KCNJ11 rs5219 (E23K) for association with total and CVD mortality was performed in the Botnia, the Diabetes Genetics Initiative (DGI) and the Steno studies. The Cox proportional hazards model was used to estimate relative genotype and phenotype effect on the risk of total and CVD-mortality.
Results: In the combined analyses of the SDR, MDCS and DARE cohorts, carriers of the T-allele (K-allele) of KCNJ11 rs5219 had increased total mortality rates (42.0% vs 39.5%; $HR_{additive}$ 1.10, 95% CI 1.15-1.20, p = 0.020), particularly CVD-related mortality (44.5%vs 39.5%, HR 1.26, 95% CI 1.10-1.44, p = 0.0006). In the meta-analyses of discovery and replication studies in up to 4,608 patients with type 2 diabetes, 820 of whom were cases of CVD-related deaths, carriers of the T-allele had a 1.21-fold increased risk for CVD-mortality (95% CI, 1.10, 1.34, p=0.00011).
Conclusion: We demonstrated that the KCNJ11 E23K variant is associated with increased risk of CVD-mortality in patients with type 2 diabetes, and, thus, seems to be a common denominator in the pathogenesis of type 2 diabetes and cardiovascular complications.

Diabetes, incretin therapy, pancreatitis and pancreas cancer: meta-analyses

P. Boyle[1], M. Bota[1], J. Rosenstock[2];
[1]International Prevention Research Institute, Lyon, France, [2]Dallas Diabetes and Endocrine Center, Dallas, USA.

Background and aims: Concerns have been raised on the potential association between incretin-related therapies for type 2 diabetes and the risk of developing pancreatitis. Most recently, the debate has extended to the potential for the potential incretin-induced pancreatitis resulting in an increased risk of pancreas cancer.
Materials and methods: Meta-analyses were undertaken, following PRISMA guidelines, of the potential associations between (i) diabetes and pancreas cancer; (ii) diabetes and risk of pancreatitis; (iii) use of incretin therapies and risk of pancreatitis; (iv) use of GLP-1 RAs and risk of pancreatitis; (v) use of DDP-4 inhibitors and risk of pancreatitis. The aim was to shed light on the presence, strength and magnitude of this complex series of associations
Results: Patients with diabetes have an increased risk of pancreas cancer [SRR=1.62, 95% CI (1.42, 1.86)] (based on 48 prospective studies) and of being diagnosed with pancreatitis [SRR=1.86, 95% CI (1.59, 2.19)] (9 studies). Pancreatitis, in all its forms and irrespective of having diabetes, bears an increased risk of going on to develop pancreas cancer [SRR=10.52, 95% CI (6.49, 17.06)] (27 studies) although patients specifically with chronic pancreatitis have an even greater risk of pancreas cancer [SRR=13.2, 95% CI (6.43, 27)](9 studies). Patients with diabetes prescribed incretin therapies have a SRR=1.27 (95% CI (0.97, 1.66)) for pancreatitis compared to patients using other anti-diabetic medications. The use of GLP-1 RAs does not appear to have an increased risk of pancreatitis [SRR=1.31, 95% CI (0.85, 2.03)] (13 studies) although the unexplained variability in the individual findings is substantial. Similarly, DPP-4 inhibitors do not appear to have an increased risk of pancreatitis when all studies are considered together [SRR=1.23, 95% CI (0.84, 1.79)](6 studies). SRRs are lower when short-term randomized trials are excluded: GLP-1 RAs [SRR=1.13, 95% CI (0.77, 1.65)](6 studies) and DPP4i [SRR=1.40, 95% CI (0.92, 2.150](4 studies). There are important limitations of these meta-analysis including incomplete data sources, selective populations, short follow-up, inconsistent criteria for diagnosing pancreatitis and, consequently, a large degree of unexplained variability between individual study findings which limit drawing definitive conclusions.
Conclusion: Patients with diabetes have an increased risk of pancreatitis. When all available data are analyzed together, there does not appear to be an increased risk of pancreatitis in incretin-treated patients when compared to patients on other anti-diabetic therapies. However, the poor quality of the data available precludes any definitive conclusions apart from observing that any potential increased risk of pancreatitis associated with incretin therapies will be small. Patients with diabetes have an increased risk of pancreas cancer although whether this is mediated through pancreatitis is an open question. The inability to come to firm conclusions highlights once again the limitations of short-term observational studies. Carefully designed large prospective, population-based registry studies with good follow-up and key clinical information are urgently needed to answer these critical safety questions and provide reassurance to diabetic patients and their clinicians.

OP 35 Diabetes prediction: is stratification the solution?

205

Genetic variation near SEPSECS/LGI2 associated with metformin treatment failure

N. van Leeuwen[1], G. Nijpels[2], J.M. Dekker[2], E. van 't Riet[2], K. Zhou[3], E. Pearson[3], L.M. 't Hart[1,4];
[1]Molecular Cell Biology, Leiden University Medical Center, [2]EMGO Institute for Health and Care Research, VU University Medical Center, Amsterdam, Netherlands, [3]Medical Research Institute, University of Dundee, UK, [4]Dept. of Molecular Epidemiology, Leiden University Medical Center, Netherlands.

Background and aims: Metformin is the first line treatment for type 2 diabetes. Unfortunately the glycaemic response to metformin is highly variable between individuals and genetic factors appeared to be involved in this variability. A genome-wide association study (GWAS) by Zhou et al identified a locus near the *ATM* gene associated with metformin treatment response in T2D patients and we were able to replicate this association in our cohort. In addition to the *ATM* locus other loci reached borderline significance in the study by Zhou et al. ($p<10^{-5}$) and await confirmation in other studies. In the current study we aimed to replicate the reported effect of these genetic loci on metformin treatment response in T2D patients.
Materials and methods: Eleven SNPs with a minor allele frequency >5% in the by GWAS identified loci were measured in 600 patients on metformin monotherapy from the Diabetes Care System (n=7500), a large longitudinal cohort of Dutch type 2 diabetic subjects, using a Sequenom assay. Twenty-eight percent of the patients on metformin monotherapy did not reach the treatment target of an HbA1c <53 mmol/l (7%) within one year after initiation of therapy. We assessed if this treatment failure was associated with genetic variation using logistic regression with baseline HbA1c, eGFR and metformin dose as covariates.
Results: We found that rs10007566 a SNP with a minor allele frequency of 42% and located between the *SEPSECS* and *LGI2* genes on chromosome 4 is associated with treatment failure (OR=0.69 95% CI 0.53-0.89, p=0.005). This is in line with the original finding in the GWAS study and a meta-analysis combining our results with the published GWAS results in an OR=0.71 (95% CI 0.61-0.82, $p=5.2*10^{-7}$). Interestingly, *SEPSECS* is required for selenoprotein biosynthesis, a protein that is associated with T2D. There was no significant effect on treatment response observed with the other measured SNPs in our study, however five SNPs showed a trend in the same direction as in the original finding.
Conclusion: Using a large cohort of Dutch patients with type 2 diabetes, we have replicated that genetic variation near the *SEPSECS/LGI2* genes is associated with metformin treatment failure.

Biomarkers of cardiac stress and risk of microvascular events in patients with type 2 diabetes: results from the ADVANCE trial

P. Welsh[1], M. Woodward[2], G. Hillis[2], J. Chalmers[2], N. Sattar[1];
[1]BHF Glasgow Cardiovascular Research Centre, University of Glasgow, UK, [2]The George Institute for Global Health, Sydney, Australia.

Background and aims: Emerging data indicates that N-terminal pro B-type natriuretic peptide (NT-proBNP) and high sensitivity troponin T (hsTnT) may be clinically useful in the prediction of macrovascular risk. However, whether they link to microvascular disease is not known. We therefore aimed to clarify the association of these cardiac biomarkers with microvascular risk in a cohort with type 2 diabetes.
Materials and methods: The ADVANCE trial (Action in Diabetes and Vascular disease: PreterAx and DiamicroN MR Controlled Evaluation) recruited 11,140 middle-aged type 2 diabetes patients. After 5 years follow-up we conducted a case cohort study in stored samples, measuring plasma NT-proBNP and hsTnT in 439 incident cases of new or worsening microvascular disease (including 283 incident cases of nephropathy and 183 incident cases of retinopathy), and a subcohort of 3423 non-cases.
Results: Median (IQR) concentrations of NT-proBNP in cases (all microvascular) and non-cases were 119pg/ml (46-324pg/ml) and 87pg/ml (34-211pg/ml), respectively, where for hsTnT result were 8ng/L (4-15ng/L) and 5ng/L (1.5-11ng/L). After adjustment for age, sex and treatment the HR (95% CI) for CVD per 1 standard deviation increase in the log-transformed NT-proBNP was 1.63 (1.44-1.84) and for hsTnT 1.67 (1.51-1.85). After adjusting for classical and diabetes-related CVD risk factors, renal function, CRP, and each other, the associations were 1.22 (1.08-1.38) and 1.31 (1.16-1.47) respectively. Estimates for associations with nephropathy and retinopathy were similar in fully adjusted models. In a prediction model including only events from the random subcohort, the baseline c-statistic of 0.731 (0.669-0.763) did not improve on addition of NT-proBNP and hsTNT (p=0.43 and p=0.14 respectively). However, the IDI increased 0.004 (0.001, 0.0082) and 0.00109 (0.0053, 0.0164) for NT-proBNP and hsTnT respectively. The corresponding figures for net reclassification (NRI) in a 3-category model were 0.7% (-3.3%, 4.8%) and 1.2% (-4.5%, 6.3%).
Conclusion: Cardiac biomarkers NT-proBNP and hsTnT were strongly positively associated with risk of microvascular events in ADVANCE, but the associations were largely attenuated by classical risk factors, such that addition of these biomarkers to risk scores does not improve risk prediction beyond these classical risk factors. Cardiac biomarkers have more utility for macrovascular risk prediction.

Durability of oral hypoglycaemic agents in drug naïve patients with type 2 diabetes: observational study from the Swedish National Diabetes Register (NDR)

N. Ekström[1], M. Miftaraj[2], A.-M. Svensson[2], K. Andersson Sundell[3], K. Eeg-Olofsson[1], J. Cederholm[4], B. Zethelius[5,6], S. Gudbjörnsdottir[2,1], B. Eliasson[1];
[1]Dept of Medicine, University of Gothenburg, [2]Center of Registers in Region Västra Götaland, [3]Dept of Community Medicine and Public Health, University of Gothenburg, Göteborg, Sweden, [4]Department of Public Health and Caring Sciences/Family Medicine and Clinical Epidemiology, Uppsala University, [5]Department of Public Health and Caring Sciences/Geriatrics, Uppsala University, [6]Medical Products Agency, Uppsala, Sweden.

Background and aims: At diabetes onset, early initiation of oral hypoglycemic agents is advocated in order to control glucose levels and prevent long-term complications. Due to the progressive nature of type 2 diabetes, treatment intensification is often required. The aim of this study was to evaluate the durability of initiated mono therapy with metformin, sulphonylureas (SUs)/meglitinides, and non-pharmacological treatment in drug naïve patients, in clinical practice.
Materials and methods: Men and women with type 2 diabetes, non-pharmacologically treated for at least twelve months prior to the study start, initiating continuous mono therapy with metformin, SUs/meglitinides, or continuing non-pharmacological treatment, and registered in the Swedish National Diabetes Register (NDR) July 2005 - December 2011, were included in the study (n=143,642). At least 12 months continuous treatment with the initiated drug was required to be included. Patients were grouped based on glucose-lowering treatment, and the proportion of patients experiencing therapy failure (drug change, addition of other glucose-lowering drugs or cessation of the initial treatment) and mean time to therapy failure were analysed in each group.
Results: Of the total population, 66,076 patients (46%) remained non-pharmacologically treated, 72,146 (50%) were allocated metformin, and 5420 (4%) were allocated SUs/meglitinides. Patients were relatively newly diagnosed in all groups, with mean diabetes duration at baseline ranging between 2.5 years (non-pharmacological treatment) and 4.3 years (SUs). In the non-pharmacologically treated group 7% (n=4349) of the patients experienced therapy failure, while the corresponding proportions for metformin and SUs/meglitinides were 92% (n=66,360) and 86% (n=4674). Time to therapy failure was shortest for patients allocated metformin, 29.2 months (confidence interval (CI): 29.1 - 29.4). For patients on SUs/meglitinides and non-pharmacological treatment mean time to therapy failure were 32.9 months (CI: 32.4 - 33.5) and 33.4 months (CI: 33.2 - 33.6) respectively. Mean HbA1c-levels decreased during the study period in patients using metformin, SUs, and meglitinides, while HbA1c-levels increased in patients on non-pharmacological treatment.
Conclusion: The majority of patients were initiated on metformin at the start of the study, but a rather large proportion remained non-pharmacologically treated despite mean diabetes duration of 2.5 years. Pharmacologically treated patients, in general, were more likely to experience therapy failure, and metformin was associated with the shortest time to therapy failure. These findings, reflecting results from clinical practice, are most likely affected by

factors such as different treatment intensity in the treatment groups and need to be further analysed, including comparisons adjusted for important covariates.

208

Estimating the interval between onset and diagnosis of type 2 diabetes from the time-course of retinopathy prevalence

M. Porta[1], G. Curletto[1], E. Coppo[1], A. Raviolo[1], E. Sitia[1], S. Albani[1], F. Schellino[1], M. Trevisan[1], M. Trento[1], P. Dalmasso[2], F. Cavallo[2];
[1]Dept. of Medical Sciences, [2]Dept. of Public Health and Peadiatric Sciences, University of Turin, Italy.

Background and aims: Type 2 diabetes (T2DM) may remain undiagnosed for years. The time preceding diagnosis has been estimated, on a population basis, at longer than 10 years, by extrapolating the correlation between known diabetes duration after diagnosis and prevalence of diabetic retinopathy (DR). However, those calculations were based upon questionable assumptions: 1) that such correlation is linear, 2) any degree of DR was considered, including very mild lesions observed in 10% of non diabetic individuals, 3) uncertain definition of T2DM, 4) time from onset of diabetes to first appearance of any DR arbitrarily set at 5 years. The aim of this study was to estimate the interval preceding diagnosis of T2DM after correcting the above assumptions.
Materials and methods: 12,074 patients subjected to screening for DR in 1991-2010 (35,545 screening episodes) were stratified into Younger-Onset (YO) if age at diagnosis was <30 or Older-Onset (OO, ≥30) and currently on insulin treatment (IT) or not (NIT). DR was assessed by 2-field retinal photography and considered either as including all lesions from very mild (ETDRS grade 20) to more severe (AnyDR) or moderate (ETDRS grade 35) and more severe (ModDR). The best-fits between known duration of diabetes and prevalence of AnyDR and ModDR were calculated by the coefficient of determination (R2) and Akaike's information criterion. The time preceding diagnosis of T2DM was estimated by adding the extrapolated negative intercept on the horizontal axis of the best-fitting correlation line between known duration of OO-NIT (equivalent to T2DM) and prevalence of ModDR (estimating time from appearance of ModDR to diagnosis) to the positive intercept of the best-fitting correlation between duration of YO-IT (equivalent to T1DM) and appearance of ModDR (estimating time from known onset of diabetes to appearance of ModDR).
Results: There were 7,298 OO-NIT, 1,719 with AnyDR and 685 with ModDR, and 1,725 YO-IT, 756 with AnyDR and 385 with ModDR. In the OO-NIT, a linear model suggested that AnyDR had appeared 8.26 years before diagnosis of T2DM. However, the best-fits were a quadratic model, suggesting appearance of AnyDR 3.89 years before diagnosis of T2DM, and a linear model with ModDR appearing 2.66 years before diagnosis. Appearance of AnyDR following onset of YO-IT could not be timed, whereas a quadratic model suggested appearance of ModDR 3.29 years after onset of YO-IT. The resulting estimate was (2.66+3.29) 5.95 years between onset and diagnosis of T2DM. Applying a standard approach, ie a linear model with AnyDR plus 5 years for appearance of DR, would have resulted in (8.26+5) 13.26 years.
Conclusion: Use of appropriate fitting models and stratification by insulin treatment and DR severity lowered the estimate of unknown duration of T2DM before diagnosis to about 6 years, which appears more realistic than previous estimates.

209

A population-based study of diabetes incidence by ethnicity and age: support for the development of ethnic-specific prevention strategies

M.I. Creatore[1], G.L. Booth[1], R. Moineddin[2], D. Manuel[3], R.H. Glazier[4];
[1]St. Michael's Hospital, Toronto, [2]Department of Family Medicine, University of Toronto, [3]Ottawa Hospital Research Insititute, [4]Institute for Clinical Evaluative Sciences, Toronto, Canada.

Background and aims: As compared with individuals of European ethnic ancestry, a number of ethnic groups experience a higher risk for developing diabetes. This elevated risk may also begin at a younger age, particularly among people of South Asian descent. Current clinical guidelines are not clear about the optimal age at which to initiate screening in high risk populations.
Materials and methods: We conducted a longitudinal, population-based, retrospective cohort study using linked administrative health and immigration records for 592,376 immigrants to Ontario, Canada. We used Cox-Proportional Hazard models to: 1) generate adjusted incidence rates by ethnicity, sex and age; and 2) to determine the age cut-offs at which different ethnic groups experienced equivalent risk of developing diabetes.
Results: Individuals from South Asia had the highest overall incidence rate (age-sex adjusted rate of 15.7 per 1,000 person-years), which was 3.3 times higher than in the Western European group ($p < 0.05$). The risk for developing diabetes among 40 year-old Western European men (3.7 per 1,000 person-years) was roughly equivalent to the risk experienced by South Asian men and women at age 25. For all other non-European ethnic groups, the equivalent risk was experienced between age 30 and 35. For women of Western European origin, the diabetes risk at age 40 (1.7 per 1,000 person years) was lower than observed at any age in South Asian women. These risk differentials persisted despite controlling for income, education, immigration category and time in Canada.
Conclusion: By age 40, there was a marked disparity in diabetes incidence between South Asian and Western European populations - in the order of 5-fold for men and 9-fold for women. High risk ethnic groups display a similar level of diabetes risk between 10 and 15 years younger than individuals of Western European origin. This has practical implications for primary and secondary prevention efforts.

Long term age-related trajectories of cardiovascular risk factors are affected by cohort effects: the Whitehall II study

D.R. Witte[1], A. Hulmán[2], T.A. Nyári[2], M. Kivimäki[3], A.G. Tabák[3,4], E.J. Brunner[3];
[1]Centre d'Etudes en Santé, Centre de Recherche Public de la Santé, Strassen, Luxembourg, [2]Department of Medical Physics and Medical Informatics, University of Szeged, Hungary, [3]Department of Epidemiology and Public Health, University College London, UK, [4]Department of Medicine, Semmelweis University, Budapest, Hungary.

Background and aims: Analysis of long-term changes in cardiovascular risk factors based on sequential measurements can give insight into the process of ageing, but longitudinal analyses may be influenced by cohort effects and secular trends. Our aim was to investigate how age-related trajectories of obesity, blood pressure and lipid levels were affected by year of birth.
Materials and methods: We fitted quadratic age-related trajectories for BMI, waist circumference, systolic and diastolic blood pressure as well as total and HDL cholesterol between the ages of 35 and 80 based on the Whitehall II study, a longitudinal dataset of 10,308 individuals with 36,692 observations obtained during over 25 years of follow up. Year of birth and its interaction term with age and age^2 were added to the models in order to evaluate cohort effects. Smooth kernel distributions were fitted for subgroups of participants aged 57 to 61 at each of four study phases (5 years apart) to visualise the cohort effect.
Results: BMI and waist circumference distributions for the age group 57-61 showed a higher degree of right-skewing with each subsequent phase in both sexes, whereas a right-shift in the distribution was observed for men but not for women. In both sexes distributions of diastolic blood pressure and total cholesterol showed a left-shift with each subsequent phase, whereas HDL-cholesterol showed a slight right-shift. There were marked differences in BMI, diastolic blood pressure and total cholesterol trajectories depending on the year of birth (Figure 1). For any given age, younger birth cohorts had higher BMI and a steeper increase in BMI with age. At any given age over 50 both total cholesterol and diastolic blood pressure were lower in younger birth cohorts. A model that does not take birth year into account (Figure 1, dashed line) underestimated the age-related decrease in total cholesterol in men and in diastolic blood pressure in both sexes.
Conclusion: Lifetime exposure to cardiovascular risk factors differs markedly for people born as little as 5 years apart, with cohort effects of opposite directions and different magnitudes. These effects are likely due to the different age and stage of life at which each subsequent generation experienced the changes in society, diet, exercise, and developments in cardiovascular risk detection and management seen during the past decades. Cohort effects should be taken into account when investigating the effects of ageing in longitudinal datasets.

ARX knockout hESCs show biased pancreatic endocrine specification to unihormonal somatostatin cells

B.K. Gage[1], A. Asadi[1], R.K. Baker[1], T.D. Webber[1], T.J. Kieffer[1,2];
[1]Cellular and Physiological Sciences, [2]Surgery, University of British Columbia, Vancouver, Canada.

Background and aims: Humans with a genetic syndrome known as X-linked lissencephaly with abnormal genitalia (XLAG) have null mutations in the gene Aristaless-related homeobox (*ARX*). *ARX* is expressed in the developing and adult brain, heart, skeletal muscle, testis, and pancreas. The pancreatic islets of XLAG patients lack glucagon-positive alpha cells but retain insulin-positive beta cells and somatostatin-positive delta cells. Mice lacking functional *Arx* expression have no alpha cells while beta and delta cells increase in numbers. To model human developmental *ARX* deficient pancreatic phenotypes, we have developed *ARX* knockout human embryonic stem cells (hESCs) and subjected them to pancreatic endocrine differentiation conditions.
Material and methods: *ARX* knockout hESCs (ARXko) were generated by zinc-finger nuclease mediated targeted genomic editing. Two independent clones were differentiated to pancreatic endocrine cells with C-peptide, glucagon and somatostatin release measured by RIA or EIA. Flow cytometry was used to assess the progressive differentiation of hESCs to CXCR4-positive definitive endoderm, PDX1-positive foregut endoderm, and NKX6.1-positive pancreatic progenitors. Final hormone-positive populations and transcription factor expression profiles were assessed by immunofluorescence.
Results: Two independent ARXko clones were isolated with either a 23 or 41 base pair deletion in exon 1 of *ARX*, both of which created a frameshift mutation resulting in a premature stop codon. Both clones retained embryonic morphology and expression of OCT4 and SSEA3. Following a stage-specific differentiation protocol aimed at forming pancreatic endocrine cells, ARXko hESCs were compared to unmodified hESCs (WT). ARXko cells efficiently formed CXCR4-positive definitive endoderm cells (WT: 94±1%, ARXko1: 95±1%, ARXko2: 95±2%). These cells continued developing into PDX1-positive foregut endoderm (WT: 91±3%, ARXko1: 94±3%, ARXko2: 96±1%), which subsequently developed into NKX6.1-positive pancreatic progenitors (WT: 49±3%, ARXko1: 70±2%, ARXko2: 66±4%, $p<0.05$) that co-expressed PDX1 by immunohistochemistry. Continued culture yielded similar fractions of pancreatic endocrine cells in both WT and ARXko (24-28%). Interestingly, examination of the endocrine subpopulations revealed an increase in unihormonal somatostatin-positive cells (WT: 18±2%, ARXko1: 73±4%, ARXko2: 75±2%, $p<0.05$) at the expense of both insulin (WT: 76±1%, ARXko1: 27±4%, ARXko2: 24±2%, $p<0.05$) and glucagon-positive (WT: 40±9%, ARXko1: 4±1%, ARXko2: 5±1%, $p<0.05$) cell lineages in ARXko cells.
Conclusion: While XLAG and ARXko hESCs endocrine populations both contain a near complete absence of glucagon-positive cells, we found a dramatic increase in unihormonal somatostatin-positive cells at the expense of insulin-positive cells, which were more common in XLAG pancreas samples compared to differentiated ARXko hESCs. The approximately 3-fold decrease in insulin-positive cells in the ARXko hESCs suggests a specific deficit of the current *in vitro* culture system that favours unihormonal somatostatin-positive cells. Thus ARXko hESCs warrant further study into the human pancreatic endocrine cell fate specification process with the goal of understanding the mechanisms that distinguish the beta and delta-cell lineages.

Efficient generation of definitive endoderm from human embryonic stem cells by GSK3 beta inhibition and nodal signalling

O. Naujok, U. Diekmann, S. Lenzen;
Institute of Clinical Biochemistry, Hannover Medical School, Germany.

Background and aims: The generation of insulin-producing cells from embryonic stem cells (ES cells) requires the stepwise transfer of developmental principles to in vitro differentiation protocols. It is accepted that treatment of human ES cells with high concentrations of activin A by activation of the Nodal/Tgf-beta pathway is the biochemical reason for differentiation of ES

cells into cells reminiscent of definitive endoderm (DE). However, the thesis that Nodal/Tgf-beta is solely responsible for in vitro differentiation of ES cells into DE appears as a simplification of developmental mechanisms in particular when compared to early in vivo events during gastrulation. Consequently, the differentiation protocols used so far have not yet yielded DE-like cells with 100% purity. The inhibition of the GSK3 beta was recently discovered as a promising method to generate DE-like cells in vitro. We analyzed the role of the GSK3beta inhibitor CHIR-99021 in a comparative study against a classic endoderm differentiation protocol.
Materials and methods: Human ES cells (Hues8) were differentiated with a control protocol comprising the treatment with wnt3a (25 ng/ml) and activin A (100 ng/ml) for 3 days and a protocol designed to initiate a primitive-like stage by a 24 h GSK3 beta inhibition with 5 μM CHIR-99021 (Chir) followed by a 48 h treatment with activin A (100 ng/ml). The differentiation into DE was monitored by flow cytometry of the DE-surface markers CXCR4 and CD49e, qPCR, and immunofluorescence staining.
Results: The control protocol yielded 22±4% CXCR4/CD49e-positive cells and was inferior to cells in which Chir was added initially for 24 h followed by a further 48 h treatment with activin A (57±8%). Analysis of typical DE-related genes revealed an expression pattern similar to developmental kinetics with T and MIXL1 expressed after induction with wnt3a and activin A for 24 h from where it decreased. SOX17 and FOXA2 were induced and reliably detectable after 3 days of differentiation. In Chir/activin A treated cells T expression was 17.3 fold higher expressed and MIXL1 7.4 fold higher after 24 h. Upon change of the medium to activin A, both genes were downregulated and SOX17 and FOXA2 mRNA transcripts were detectable 3.6 and 6 fold higher (for FOXA2 and SOX17, respectively) compared to control cells. In immunofluorescence stainings, Chir/activin A treatment resulted in predominantly brachyury-positive cells after the 24 h GSK3 beta inhibition with distinct outgrowth of SOX17/FOXA2 double-positive cells later in the differentiation. SOX17/FOXA2 double-positive were not detected before day 2 from where they increased until near homogeneity at day 3. Generally the wnt3a/activin A protocol was less efficient, thereby confirming the flow cytometry results. A dilution of activin A after the induction with Chir showed that activin A concentrations can be significantly lowered to 25-50 ng/ml to yield the same results.
Conclusion: Our analyses revealed the inductive effect of CHIR-99021 which directs human ES cells into cells reminiscent of the primitive streak independent of the Nodal/Tgf-beta pathway. By addition of low doses of activin A, these cells can be effectively differentiated into definitive endoderm. This demonstrates that human ES cell differentiation into DE is initially Wnt-pathway dependent and subsequently Nodal/Tgf-beta dependent.

NADPH oxidase promotes pancreatic endocrine cell differentiation via mediation of SOX9
J. Liang, P.S. Leung;
The Chinese University of Hong Kong, China.

Background and aim: NADPH oxidase is a pivotal reactive oxygen species-generating enzyme, involved in organogenesis, regeneration and differentiation. Nonetheless, the potential role of NADPH oxidase in regulating endocrine cell specification remains unclear. This study was aimed to investigate the expression and function of NADPH oxidase in endocrine cell differentiation.
Material and methods: Mouse embryonic pancreata were dissected at indicated embryonic-days to assess relevant gene and protein expression by real-time PCR and immunohistochemistry. In the *ex vivo* experiments, pancreata were dissected at e12.5 from mouse embryos and cultured for three days with or without diphenyleneiodonium (DPI), a NADPH oxidase inhibitor, to evaluate gene expression.The potential mechanism involved was further studied using an *in vitro* human cell model of pancreatic progenitor cells (PPCs) by Western blot analysis.
Results: Our real-time PCR results showed that *Nox4* and *p22^{phox}*, the subunits of NADPH oxidase, were expressed during embryonic pancreas development and peaked at e15.5, then subsequently declined and disappeared in neonatal pancreas. Meanwhile, NOX4 was detected along with beta-cells, acinar-cells and ductal-cells at e15.5 shortly after secondary transition. However, its expression was decreased in acinar-cells and ductal-cells at e17.5, and persisted along with high level of insulin in endocrine cells, as evidenced by immunocytochemistry; NOX4 also had a high expression at e15.5 within NGN3-expression cells, the progenitors specific for the fate of endocrine cell lineage. On the other hand, *ex vivo* DPI treatment reduced the expression of *Ngn3* (87.8%, ***p<0.001), *Pax4* (91.07%, ***p<0.001), *Nkx6.1* (89.2%, ***p<0.001), insulin (99.64%, ****p<0.001), and glucagon (99.67%, ***p<0.001) at the dosage of 1μM in the cultured embryonic pancreas. Further study showed that *Id2* and *Hes-1*, the suppressor of *Ngn3*, were not affected by DPI while Sox9 (it binds to the promoter region of *Ngn3*) were reduced both in mRNA and protein levels. Furthermore, DPI decreased NGN3 expression in human PPCs while its overexpression of SOX9 abolished the effect exerted by DPI.
Conclusion: Our data suggest that NADPH oxidase enhances pancreatic endocrine cell differentiation, which is probably mediated via the expression of SOX9.

Contribution of Ins$^+$GLUT2$^-$ progenitor cells to endocrine pancreas regeneration after streptozotocin ablation in the neonatal mouse
C.A. Beamish, B.J. Strutt, D.J. Hill;
Lawson Health Research Institute, London, Canada.

Background and aims: A renewable source of insulin-producing β-cells in the pancreas is required for patients with diabetes, yet evidence suggests that "all" new β-cells originate from pre-existing β-cells. However, the contribution of progenitor cell source to β-cell mass is less well defined, especially within the context of induced regeneration, such as after administration of the β-cell toxin, streptozotocin (STZ). Neonatal rodents exhibit the ability to regenerate some of their endocrine pancreas after STZ ablation, but this response is mitigated when STZ is administered in adulthood. As a glucose mimetic, STZ accesses the β-cell via the Glucose Transporter-2 (GLUT2). A rare sub-population of β-cells, Ins$^+$GLUT2$^-$ cells, have been identified as pancreatic multi-potential progenitor cells, found in adult mouse and human islets. We have recently shown a significantly higher population of these Ins$^+$GLUT2$^-$ cells in neonatal (postnatal day7, P7) extra-islet β-cell aggregates (<5 β-cells, BCA) than in intact islets, which are proliferative and can differentiate into multiple lineages. We hypothesized that because of the numerous Ins$^+$GLUT2$^-$ progenitor cells, neonatal rodents are able to regenerate their β-cell mass after STZ administration because these cells are spared exposure to the toxin.
Materials and methods: Neonatal RIPCreER;Z/AP transgenic mice were used to tag a proportion of β-cells with a human placental alkaline phosphatase (HPAP) reporter, by administration of Tamoxifen at P5. 100mg/kg STZ was given at P7, and EdU at P8 to track cell proliferation. Cells were followed during β-cell regeneration, and pancreata collected between D7-D30 for immunofluorescence.
Results: Glycaemia was affected during acute injury, and recovered, although not to pre-STZ levels. HPAP tagged ~35% of insulin-expressing (β-) cells in islets, which was slightly lower in BCA. After STZ, the proportion of HPAP$^+$ β-cells in islets displayed a significant increase at P14 vs control mice (p<0.05), indicating that some β-cell regeneration in the islet occurred by self-duplication. However, response in the BCA was blunted as compared to the islet. There was a significant decrease in HPAP$^+$ β-cells in BCA at P21, possibly indicating that these cells had developed from BCA into small islets. β-cell mass decreased after STZ administration in islets by P14 (p<0.01, P7 vs P14), concomitant with overt diabetes; in contrast, there was a non-significant decrease in β-cell mass in the BCA, indicating that many of these cells were spared STZ-mediated death. Ins$^+$GLUT2$^-$ cells decreased in number from P7 to P30 in control mice, although interestingly there was an increase in Ins$^+$GLUT2$^-$ cell numbers between P7 and weaning at P21, which decreased thereafter. After STZ treatment, there were a higher number of Ins$^+$GLUT2$^-$ cells at P14 than in control mice; by P30, the cell population decreased in both groups.
Conclusion: These data indicate that Ins$^+$GLUT2$^-$ cells contribute to endocrine pancreas regeneration in the neonatal mouse after STZ administration, and represent a possible cell target for intervention in the human during diabetes progression.

Foxo1 ablation increases endocrine progenitor cells in the adult pancreas
C. Talchai[1,2], D. Accili[1];
[1]Medicine, Columbia University, New York, USA, [2]Anatomy, Chulalongkorn University, Bangkok, Thailand.

Background and aims: Deterioration of β–cell function and decrease of β–cell mass are the sine qua non of diabetes. Previously, we showed that Foxo1 gain-of-function in pancreatic β–cells suppresses proliferation of mature β–cells under physiological condition, in response to insulin resistance and to Glp-1 analogs, but the role of Foxo1 in β–cell differentiation and function remains unclear.
Materials and methods: To address this question, we generated conditional knockouts of Foxo1 driven by Pdx1-cre, Neurogenin3-(Neurog3)cre and Insulin-(Rip)cre, resulting in somatic deletion of Foxo1 in all pancreatic cells (Pdx1-cre), in endocrine progenitors (Neurogenin3-cre), or in terminally differentiated β–cells (Rip-cre).
Results: We report that conditional inactivation of Foxo1 in pancreatic precursors, but not in endocrine progenitors, results in 2-fold increase in pancreas size of 6-month-old mice. Immunohistochemical studies and FACS analyses show that islets and ductal epithelium from adult Pdx1-Foxo1, but not Neurog3-Foxo1 knockout mice are enriched with the pancreatic precursor cell marker Sox9, but are not hyper-proliferative. These results indicate that the increase in pancreas size is likely due to an expanded number of pancreatic precursors. In addition, we illustrate the role of Foxo1 in β–cell development. We found a 5- to 10-fold expansion of β–cell mass in 12-month-old Pdx1-Foxo1 knockouts, and in 12- to 15-month-old Neurog3-Foxo1 knockouts, but not in Rip-Foxo1 knockouts. Quantitative mRNA analysis, FACs analysis and immunohistochemistry demonstrate the presence of Neurog3-positive cells in adult mice, a highly unusual finding, since these progenitor cells are normally restricted to prenatal life. This result was also confirmed when crossing the Pdx1-Foxo1 knockout mice with Neurog3-Gfp reporter. Proliferation rates of β–cells in Pdx1- and Neurog3- Foxo1 knockouts are insufficient to account for the increase in β–cell mass. In addition, lack of Foxo1 in mature β–cells does not affect β–cell replication nor β–cell mass.
Conclusion: Thus these data indicate that the enlarged β–cell mass is due to an increase in Neurog3 progenitors rather than β–cell self-duplication. Together these data provide evidence for a critical role of insulin/growth factor signaling through Foxo1 in β–cell differentiation and β–cell function.

LKB1 and AMPK differentially regulate pancreatic beta cell fate
G.A. Rutter[1], G. Sun[1], T.J. Pullen[1], M. Kone[1], J. Ferrer[2], M. Ibberson[3], B. Thorens[4], A. Swisa[5], Y. Dor[5], T. Hildebrandt[6], I. Uphues[6];
[1]Dept. Cell Biology, Div. Diabetes, Endocrinology & Metabolism, Imperial College, London, [2]Div. Diabetes, Endocrinology & Metabolism, Imperial College, London, UK, [3]Swiss Institute of Bioinformatics, University of Lausanne, [4]Centre for Integrative Genomics, University of Lausanne, Switzerland, [5]School of Medicine-IMRC, Hebrew University of Jerusalem, Israel, [6]Pharma, Boehringer Ingelheim International GmbH, Ingelheim, Germany.

Background and aims: Inactivation in beta cells of the tumour suppressor Liver kinase B1 (LKB1/STK11) or the downstream enzyme AMP-activated protein kinase (AMPK) exerts dramatic, but opposing, effects in vivo. Thus, loss of LKB1 causes hyperplasia and loss of normal cell polarity whereas AMPK deletion inhibits insulin secretion. To examine the molecular mechanisms involved we have explored the transcriptional landscape of islets inactivated selectively in the beta cell for either kinase.
Materials and methods: Mice null for LKB1 or both AMPK catalytic (α1, α2) subunits were generated by Ins2- (beta cell and brain), Ins1Cre- (beta cell), or Pdx1CreER- (adult beta cell) mediated deletion of flox'd alleles. Islets were isolated from four 12 week old mice per genotype. After 24 h culture at 11 mM glucose RNA was extracted (RNAEasy) before deep sequencing (RNASeq) on a Hiseq 2000 platform (Illumina, San Diego, CA, USA) or microarray analysis (Affymetrix mouse Gene 2.0 array). Enrichment against functional gene categories was performed using the Functional Annotation Clustering algorithm of DAVID (version 6.7) or Gene Set Enrichment Analysis using mouse MSigDB gene sets.
Results: Consistent with the differing effects of deleting either kinase in beta cells, overlap between LKB1 and AMPK-regulated genes was limited (80/1034 mRNAs up-regulated and 32/980 down-regulated by deletion with Ins2Cre). mRNAs up-regulated by LKB1 deletion, but unaffected by AMPK inactivation, included those encoding neuron- (Dlgap2, Pdyn, Nptx2, Astn1, Cartpt, Mt3) and liver- (Fbp2, Iyd and Alb) enriched genes. mRNAs affected by deletion of either kinase included mcoln3, Th, Lgi (down-regulated), Kcna2, Kcnq2 (up-regulated). Examination of gene classes revealed that endoplasmic reticulum function (mboat1, clstn2) was enhanced by LKB1, but not AMPK, deletion. Conversely, AMPK, but not LKB1 deletion, decreased expression of lysosomal and peroxisomal genes (Hpse, Il4i1) but increased that of G-protein coupled receptors (Ptgit, Galr1) and GTP-binding proteins (Arhgap20, Rap1Gap).
Conclusion: An important function of LKB1 is to repress non-beta cell programs in beta cells, since its absence leads to the de-repression of alternate programs leading to neuronal and hepatic characteristics. This action of LKB1 is largely independent of AMPK which, conversely, maintains degradative pathways whilst restricting specialised functions such as receptor signalling.

The effect of early intensive diabetes treatment on long-term glycaemic control in newly diagnosed type 2 diabetes: multicentre randomised parallel trial

S. Chon[1], S. Chin[1], S. Rhee[1], S. Oh[1], J.-T. Woo[1], Y. Kim[1], K. Ahn[2], S. Baik[3], Y. Park[4], M. Nam[5], K. Lee[6], S. Yoo[7], G. Koh[8];
[1]Kyung Hee University Hospital, Seoul, [2]Kyung Hee University Hospital at Gangdong, Seoul, [3]Korea University Guro Hospital, Seoul, [4]Hanyang University Medical Center, Guri, [5]Inha University Hospital, Inchon, [6]Ajou University Medical Center, Suwon, [7]KyuThe Catholic University of Korea Bucheon St.Mary's Hospital, Bucheon, [8]Jeju National University Hospital, Jeju, Republic of Korea.

Background and aims: Early intensive insulin therapy in newly diagnosed type 2 diabetes has been reported to improve pancreatic beta-cell function and facilitate long term glycaemic control. However, it is unclear whether those results are by virtue of the effect of elimination of glucotoxicity or of insulin therapy itself. We performed a multicenter randomized trial to compare the long term effects of early short-term intensive diabetes treatment modalities: intensive insulin therapy (IIT) versus combined oral antidiabetic therapy (COAD).
Materials and methods: Eligible newly diagnosed 97 patients (aged 25-70 years, HbA1c 8-12%, drug naïve) were randomised to IIT group (50, multiple daily insulin therapy with glargine and glulisine) or COAD group (47, glimepiride and metformin) for early intensive diabetes treatment in eight diabetes centers of Korea between 2007 and 2009. Early intensive treatment was performed in outpatient clinic setting according to the protocols and was stopped after achieving HbA_{1c} < 7% or total inulin requirement < 10U/day or 12 weeks of treatment duration. Patients were then followed-up every 1-3 months for 2 years on diet/exercise alone or rescue drug therapy as a protocol in case of HbA1c more than 8%. Primary endpoint was long term glycaemic control and remission (HbA_{1c}<7% without drug) rate at 2 year after early intensive therapy. Analysis was per protocol.
Results: After early intensive treatment, the mean HbA_{1c} significantly decreased from 10.1±1.0 to 6.8±0.7 % in IIT and 10.0±1.2 to 6.6±0.6 % in COAD group with no significant difference between two groups. In IIT group, mean HbA_{1c} was reduced below 7% at 8 weeks but at 12 weeks in COAD group. During the 104 weeks of follow-up period, both groups maintained good glycemic control with mean HbA_{1c} around 7% ($P = 0.093$, linear mixed model analysis IIT vs. COAD), but the proportion of patients with HbA_{1c} < 7% was significantly higher in IIT groups through the follow-up period (68.1%-88.6% in IIT vs. 47.1-65.0% in COAD). In IIT group, 58.1% at 1 year and 51.4% at 2 year maintained glycaemic control with diet/exercise alone, but 33.3% and 21.4%, respectively in COAD group. Remission rate at 104 weeks was significantly higher in IIT groups than in COAD group ($P = 0.022$).
Conclusion: Early intensive diabetes treatments with IIT or COAD in newly diagnosed type 2 diabetes were effective on long glycaemic control, but IIT was more favorable on the remission rate and maintenance of optimal glycaemic control than COAD.

Exogenous insulin and risk of all-cause mortality in type 2 diabetes: a dose-response association

S.E. Holden[1], G. Schernthaner[2], S. Jenkins-Jones[3], C.J. Currie[1];
[1]School of Medicine, Cardiff University, UK, [2]Department of Medicine, Rudolfstiftung Hospital Vienna, Austria, [3]Pharmatelligence, Cardiff, UK.

Background and aims: Along with a clinical and biological rationale, epidemiological data have emerged that raise questions about the widespread use of exogenous insulin in people with type 2 diabetes. In the absence of specifically designed randomised trials, here we explore the hypothesis that if insulin increases the risk of death in these people, there should be a dose-response association.
Materials and methods: Data were from a 10% sample of the UK population available from the Clinical Practice Research Datalink. Using strict data quality criteria, subjects with type 2 diabetes were selected if they had progressed to treatment with insulin. The first prescription of insulin was used as the index date. Annual, average, weight-based, prescribed insulin dose was estimated by attributing a quantity to recorded prescriptions. Our outcome was all-cause mortality, and the risk of death was evaluated in Cox models that accounted for common risk factors. Dose was evaluated as a time-dependent covariate. Prescribed dose categories were set at ≤0.5, >0.5 and ≤1.0, >1.0 and ≤1.5, and >1.5 iu/kg/day using the lowest dose as the referent.
Results: We identified 8,414 people exposed to an insulin-only regimen and receiving at least two consecutive prescriptions for insulin. Of these, 7,538 patients had complete insulin dose (with an average dose ≤4iu/kg/day), weight and time-to-event information; 2,193, 3,818, 1,013 and 514 patients were allocated to the ≤0.5, >0.5 and ≤1.0, >1.0 and ≤1.5, and >1.5 iu/kg/day insulin-dose groups, respectively, in year 1. The overall mean age at baseline was 64.6, 64.7, 64.4 and 64.9 years; 63%, 55%, 51% and 47% were males; and average HbA1c at baseline was 9.2%, 9.7%, 9.9% and 9.6% for each increasing dose category, respectively. The risk of death increased in the lowest HbA1c quintile and above 1.0 iu/kg/day (figure) in a generally increasing pattern. The pattern of association with dose was consistent in a number of phenotypic subgroups such as those with good glucose control at baseline. In comparison with the low-dose insulin group (≤0.5iu/kg/day), adjusted hazard ratios for the high-dose group (>1.5iu/kg/day) were 1.36 (0.56-3.34), 1.43 (0.87-2.35), 2.04 (1.52-2.75) and 2.89 (2.22-3.77) for patients aged ≤55, >55 and ≤65, >65 and ≤75, and >75 at baseline.
Conclusion: There was a dose-response association between insulin and the risk of death in subjects with type 2 diabetes. Those progressing to insulin therapy in older age and with good glucose control were at particularly high risk.

IDegLira, a novel fixed-ratio combination of insulin degludec and liraglutide, is efficacious and safe in subjects with type 2 diabetes: a large, randomised phase 3 trial

S.C.L. Gough[1], J.B. Buse[2], V.C. Woo[3], H.W. Rodbard[4], S. Linjawi[5], P. Poulsen[6], L.H. Damgaard[6], B.W. Bode[7];
[1]Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, UK, [2]UNC, Chapel Hill, USA, [3]University of Manitoba, Winnipeg, Canada, [4]Endocrine and Metabolic Consultants, Rockville, USA, [5]Coffs Endocrine & Diabetes Services, Coffs Harbour, Australia, [6]Novo Nordisk A/S, Søborg, Denmark, [7]Atlanta Diabetes Associates, Atlanta, USA.

Background and aims: IDegLira is a novel fixed-ratio combination of insulin degludec (IDeg) and liraglutide (Lira). The aim of this trial was to evaluate the safety and efficacy of IDegLira compared to its individual components, Lira or IDeg alone, in subjects with type 2 diabetes (T2D).
Materials and methods: In this 26-week randomised, parallel three-arm, open-label trial in subjects with T2D inadequately controlled on metformin ± pioglitazone, IDegLira was added OD and compared to IDeg or Lira (Victoza®1.8 mg) added alone. IDegLira and IDeg were titrated to the same fasting glucose [FPG] (4-5 mmol/L [72-90 mg/dL]). Of 1,663 adults (mean age: 55 yrs, diabetes duration: 6.6 yrs, BMI: 31.2 kg/m^2), 834 were randomised to IDegLira, 414 to IDeg, and 415 to Lira.

Results: The primary endpoint, HbA_{1c}, decreased by 1.9% from 8.3% to 6.4% with IDegLira. This decrease was significantly greater than with IDeg (-1.4% to 6.9%) or Lira (-1.3% to 7.0%) (Table). More subjects on IDegLira achieved an HbA_{1c} of <7% (81%) or ≤6.5% (70%) compared to IDeg (65%; 48%) and Lira (60%; 41%). At 26 weeks, mean FPG was similar for IDegLira (5.6 mmol/L [100 mg/dL]) and IDeg (5.8 mmol/L [104 mg/dL]) and significantly higher for Lira (7.3 mmol/L [131 mg/dL]). Nine-point glucose profiles showed significantly lower mean prandial increments with IDegLira and Lira compared to IDeg. IDegLira resulted in a mean weight reduction of -0.5 kg and a 32% lower rate of hypoglycaemia than IDeg. Few subjects reported hypoglycaemia with Lira. Gastrointestinal (GI) side effects with IDegLira were less than with Lira (nausea: 8.8% vs. 19.7%; vomiting: 3.9% vs. 8.5%).

Conclusion: IDegLira substantially improves glycaemic control in subjects with T2D with a low risk of hypoglycaemia, weight gain or GI complaints.

Table. Key results with IDegLira vs. IDeg or Lira alone

	IDegLira vs. IDeg Estimate [95% CI]	p-value	IDegLira vs. Lira Estimate [95% CI]	p-value

New insulin glargine formulation: glucose control and hypoglycaemia in people with type 2 diabetes using basal and mealtime insulin (EDITION I)

M.C. Riddle[1], G.B. Bolli[2], M. Ziemen[3], I. Muehlen-Bartmer[3], F. Bizet[4], P.D. Home[5];
[1]Oregon Health & Science University, Portland, USA, [2]University of Perugia, Italy, [3]Sanofi-Aventis Deutschland GmbH, Frankfurt am Main, Germany, [4]Sanofi, Paris, France, [5]Newcastle University, Newcastle upon Tyne, UK.

Background and aims: Insulin glargine 100 U/mL (Gla-100) is widely used in people with type 2 diabetes (T2DM). A new insulin glargine formulation, 300 U/mL (Gla-300), has a more prolonged and flatter pharmacokinetic profile than Gla-100. The phase 3 EDITION I study compared the efficacy and safety of Gla-300 *vs* Gla-100 in people with T2DM using basal plus mealtime insulin.

Materials and methods: In a multicentre, open-label study, 807 people [mean age 60.0 yr (SD: 8.6 yr), duration of T2DM 15.8 yr (SD: 7.5 yr), body mass index 36.6 kg/m^2 (SD: 6.4 kg/m^2), HbA_{1c} 8.15% (SD: 0.78%), total insulin dose 1.2 U/kg (SD: 0.47 U/kg), basal insulin dose 0.67 U/kg (SD: 0.25 U/kg)] were randomized (1:1) to Gla-300 (n=404) or Gla-100 (n=403), administered once daily in the evening, while continuing mealtime insulin. The dose was titrated seeking fasting plasma glucose 4.4-5.6 mmol/L. Primary endpoint was change in HbA_{1c} from baseline to month 6, and first secondary endpoint was percent of people with ≥1 severe or confirmed (≤3.9 mmol/L) nocturnal hypoglycaemia from month 3 to month 6.

Results: Gla-300 was non-inferior to Gla-100 for change in HbA_{1c} [least squares mean change -0.83% (SE: 0.06) in both groups; difference -0.00% (95% CI: -0.11 to +0.11)]. No relevant differences were seen for the other measures of glucose control such as fasting plasma glucose, 8-point self-monitored plasma glucose profiles and pre-injection plasma glucose. Fewer people using Gla-300 experienced severe or confirmed nocturnal hypoglycaemia during months 3-6 (first secondary endpoint: 36.1% *vs* 45.5%; relative risk 0.79 (95% CI: 0.67 to 0.94; p=0.0070). Occurrence of any hypoglycaemic event (% of people with at least one event) during study period was numerically lower in the Gla-300 group than in the Gla-100 group. No between-treatment differences in adverse events were seen.

Conclusion: In people with T2DM, Gla-300 was as effective as Gla-100 in control of blood glucose and was associated with a 21% reduction in severe or confirmed nocturnal hypoglycaemia from month 3 to month 6. Gla-300 was well tolerated.

Frailty and the relationship between blood pressure and mortality in elderly patients with type 2 diabetes (ZODIAC-34)

K.J.J. van Hateren, G.W.D. Landman, N. Kleefstra, S.T. Houweling, H.J.G. Bilo;
Diabetes Centre, Zwolle, Netherlands.

Background and aims: Several studies have found an inverse association of blood pressure with cardiovascular and all-cause mortality in elderly patients with type 2 diabetes mellitus (T2DM). Frailty has been suggested as an explanation for this consistent finding. Unfortunately, measures of frailty were lacking in previous studies. We aimed to investigate whether adjustment for frailty influences the inverse relationship of blood pressure with mortality.
Materials and methods: Patients aged older than 60 years were selected from two cohorts (1998 and 2001) of the prospective observational ZODIAC study (n=1232). Frailty was defined as a score lower than 80 on the subscale 'physical functioning' of the RAND-36 questionnaire. Data on frailty were available for 791 patients (64%). After a follow-up time of 10 years, Cox regression analyses were performed to evaluate the association of the different measures of blood pressure with cardiovascular and all-cause mortality. Analyses were performed in strata according to the level of frailty ('physical functioning' score <80 and ≥80) and were repeated for the oldest elderly (>75 years). Age, gender, smoking (yes or no), BMI, duration of diabetes, serum creatinine level, macrovascular complications (yes or no), albuminuria (yes or no) and total cholesterol-HDL ratio were selected as possible confounders.
Results: Frailty was highly prevalent in our study group; 573 out of 791 patients (72%) fulfilled the criterion of frailty compared to 229 out of 260 elderly patients (88%). During follow-up, 370 (47%) patients died, of which 161 patients (44%) from cardiovascular causes. The results of the Cox regression analyses are presented in table 1. Higher blood pressure was independently associated with increased cardiovascular mortality in non-frail subjects in the total study group. An inverse relationship was observed between diastolic blood pressure and all-cause mortality for frail subjects. For the oldest elderly, systolic and diastolic blood pressure were inversely related to all-cause mortality in frail subjects. Even in this age category, a positive association was observed between systolic blood pressure and all-cause mortality for non-frail subjects.
Conclusion: Frailty modifies the relationship between blood pressure and mortality in elderly patients with T2DM. These results underline the importance of considering the level of frailty when determining individual target values. Also, trials in old age should always contain frailty indicators in order to facilitate translating the results of studies into daily practice.

Table 1. Hazard ratios and their 95% confidence intervals of blood pressure for mortality.

	Total group		**>75 years**	
	All-cause mortality	*CVD mortality*	*All-cause mortality*	*CVD mortality*
Non-frail subjects				
SBP	1.11 (0.98-1.24)	1.22 (1.02-1.43)	1.45 (1.06-1.86)	1.30 (0.82-1.80)
DBP	1.35 (1.08-1.63)	1.73 (1.30-2.17)	1.72 (0.98-2.15)	1.51 (0.65-2.45)
Frail subjects				
SBP	0.96 (0.91-1.01)	0.96 (0.88-1.04)	0.89 (0.82-0.96)	0.93 (0.83-1.04)
DBP	0.88 (0.77-0.99)	0.88 (0.71-1.05)	0.72 (0.58-0.87)	0.83 (0.60-1.06)

Background and aims: The phenotype of resistant hypertension (RH) has not been characterized in subjects with type 2 diabetes. This analysis was aimed at assessing the independent correlates of RH and the association of this condition with complications in subjects with type 2 diabetes.
Materials and methods: We used the baseline data from the Renal Insufficiency And Cardiovascular Events (RIACE) Italian Multicenter Study, including 15,773 patients consecutively visiting 19 Diabetes Clinics in years 2007-2008. RH was defined as systolic and/or diastolic blood pressure values not on-target (i.e.>130 and 80 mmHg, respectively) in subjects on ≥3 antihypertensive agents or on-target but using >4 drugs (n=2,363; 15% of the whole RIACE cohort). Patients on-target with 2 drugs (Ctr1; n=1,369) and 3 drugs (Ctr2, n=803) served as control groups. GFR was estimated using the simplified MDRD equation, albuminuria was measured by immunonephelometry or immunoturbidimetry, retinopathy was evaluated by fundus examination, and cardiovascular disease (CVD) was adjudicated based on hospital discharge records.
Results: No clinically significant differences among groups were observed for age, diabetes duration, HbA_{1c}, BMI, waist and lipid profile. Subjects with RH had higher albuminuria, lower eGFR and, hence, higher prevalence of chronic kidney disease (CKD) than control groups (56.3% vs 41.9% in Ctr1 and 46.1% in Ctr2; p<0.0001). Likewise, rate of advanced retinopathy, but not of CVD, was higher in individuals with RH. Logistic regression analysis showed that RH was independently associated with age (1.020 [1.012-1.027]), waist (1.026 [1.020-1.032]), micro (1.379 [1.201-1.583]) and macroalbuminuria (2.131 [1.644-2.762]), eGFR 30-59 ml/min/1.73m^2 (1.269 [1.053-1.529]) and <30 ml/min/1.73m^2 (1.527 [1.007-2.318]), and advanced retinopathy (1.271 [1.048-1.542]). Moreover, RH was associated with a higher risk of Stages 1-2 (1.510 [1.282-1.778]), nonalbuminuric Stages 3-5 (1.366 [1.135-1.645]), and particularly albuminuric Stages 3-5 (1.954 [1.594-2.395]) CKD. No independent correlation was found between RH and CVD, either total or by vascular bed.
Conclusion: In subjects with type 2 diabetes, RH is associated with age, waist, and microangiopathy, especially albuminuric CKD, but not with macroangiopathy. These data suggest a strict bi-directional relationship between RH and renal damage.

Antihypertensive treatment in patients with type 1 diabetes according to the stages of diabetic nephropathy

R. Lithovius[1,2], V. Harjutsalo[1,2], C. Forsblom[1,2], M. Saraheimo[1,2], P.-H. Groop[1,2];
[1]Folkhälsan Institute of Genetics, Folkhälsan Research Center, [2]Division of Nephrology, Department of Medicine, Helsinki University Central Hospital, Helsinki, Finland.

Background and aims: Intensive treatment of elevated blood pressure (BP) has been shown to prevent or delay the progression of kidney disease in type 1 diabetes. While previous studies have established the prevalence of resistant hypertension (RH) in the general hypertensive population, the rate is unknown in patients with type 1 diabetes with respect to different stages of diabetic nephropathy. Therefore, we estimated the prevalence of resistant hypertension, as well as the effectiveness of antihypertensive treatment in patients with type 1 diabetes stratified by stage of nephropathy.

Materials and methods: The Finnish Diabetic Nephropathy Study (FinnDiane) data (N=2,857; mean age 38.1 ± 11.8 years, 51.7 % men, mean duration of diabetes 22.3 ±11.9 years) were linked to the Drug Prescription Register to obtain all purchases of antihypertensive drugs 6 months before the baseline visit. Based on their urinary albumin excretion rate (AER) patients were divided into four nephropathy groups: normoalbuminuria, microalbuminuria, macroalbuminuria and end-stage renal disease (EASD). We used treatment targets published by The American Diabetes Association (ADA 2000). RH was defined as failure to reach blood pressure goals (BP <130/85) despite the use of ≥3 antihypertensive drugs of different classes (one of which is diuretic).
Results: In patients with normal AER 13.6% were on antihypertensive treatment and of them 25% had BP on target. The corresponding figures were 60.1% and 30.9% for the microalbuminuria group, 90.4% and 20.5% for the macroalbuminuric patients, as well as 90.1% and 9.7% for patients with ESRD. In the normalbuminuric group 56.5% and in the microalbuminuric group 62.2% were taking only one antihypertensive drug, although the patients had not reached the BP targets. In general, the prevalence of RH was 8.6% for all patients and 21.7% for the drug treated patients. When the patients were stratified by nephropathy status the prevalence of RH was 1.2% in patients with normal AER, 4.2% in microalbuminuric, 28.1% macroalbuminuric patients and 30.6% in the ESRD group. The prevalence of RH of the drug treated patients was 8.0%, 7.0%, 31.1% and 33.9%, respectively.
Conclusion: The number of patients who had not reached the BP treatment targets and the prevalence of RH increased with the severity of diabetic nephropathy. Our data suggests that there is urgent need for improvement of antihypertensive treatment, and especially in those with diabetic nephropathy.

Prognostic impact of treatment resistant hypertension on clinical events during 2-year follow-up in outpatients with diabetes and hypertension: results of the 3A Registry

S. Schmidt[1], R.E. Schmieder[1], R. Dechend[2], T. Riemer[3], I. Hagedorn[4], U. Zeymer[5];
[1]Nephrology and Hypertension, University of Erlangen-Nürnberg, [2]Experimental and Clinical Research Center, Charité-Campus Buch and HELIOS Klinikum Berlin Buch, Berlin, [3]IHF GmbH - Institut für Herzinfarktforschung, Ludwigshafen, [4]Novartis Pharma Nürnberg, [5]Medizinische Klinik B, Klinikum der Stadt Ludwigshafen, Ludwigshafen, Germany.

Background and aims: Aim of this study was to determine the incidence of treatment resistant hypertension (TRH) and prognostic value of TRH on cardiovascular events during 2-year follow-up in a large number of hypertensive diabetic outpatients in Germany.
Materials and methods: The non-interventional 3A Registry included hypertensive outpatients in whom the physician had decided to initiate or modify antihypertensive therapy in patients not achieving blood pressure (BP) control or where a modification was required for other reasons. 2512 subjects (28.9%) of the total cohort had type 2 diabetes. We defined TRH at baseline as BP > 140/90 mm Hg (for diabetic *and* non-diabetic patients) despite treatment with at least 3 antihypertensive drugs including a diuretic.
Results: Out of a total of 8697 patients with a 2-year follow up, 2772 (32%) had TRH, of whom 1170 had diabetes (46.6% of all diabetic patients) and 1602 had not diabetes (26% of all non-diabetic patients), respectively. Thus, TRH was more frequent in diabetics (p<0.001). The incidence of clinical events during the 2 year follow-up period is depicted in table 1.

Table 1

	Treatment resistant hypertension (N=2772)	Diabetic Ss. (N=1170) BP > 140/90 mmHg	Non-diabetic Ss. (N=1602) BP > 140/90 mmHg	P-Value
Age (years)	68.3	69.6	67.2	<0.001
No. of drugs	4.3	4.5	4.1	<0.001
Events during 2-year follow-up				
Death (%)	3.6	4.4	2.9	<0.05
Myocardial infarction (%)	0.9	1.3	0.6	0.07
Stroke (%)	1.1	1.4	0.8	0.15
MACCE (%)	4.8	6.2	3.8	0.01

Conclusion: In this real life analysis patients with TRH had a higher prevalence of diabetes. Treatment resistant hypertension, if coexisting with diabetes, was associated with an increased incidence of cardiovascular events during follow-up. Therefore, in particular diabetic patients with TRH need better BP control to improve their outcome.

Association of hypertriglyceridaemia with complications in subjects with type 2 diabetes

G. Penno[1], A. Solini[2], G. Zoppini[3], C. Fondelli[4], E. Orsi[5], G. Zerbini[6], R. Trevisan[7], M. Vedovato[8], G. Gruden[9], O. Lamacchia[10], M.G. Baroni[11], G. Pugliese[12];
[1]Department of Endocrinology and Metabolism, [2]Department of Internal Medicine, University of Pisa, [3]Division of Endocrinology and Metabolic Diseases, University of Verona, [4]Diabetes Unit, University of Siena, [5]Endocrinology and Diabetes Unit, Fondazione IRCCS Cà Granda – Ospedale Maggiore Policlinico, Milan, [6]Complications of Diabetes Unit, San Raffaele Scientific Institute, Milan, [7]Endocrinology and Diabetes Unit, Ospedali Riuniti, Bergamo, [8]Department of Clinical and Experimental Medicine, University of Padua, [9]Department of Internal Medicine, University of Turin, [10]Department of Medical Sciences, University of Foggia, [11]Department of Medical Sciences, University of Cagliari, [12]Department of Clinical and Molecular Medicine, La Sapienza University, Rome, Italy.

Background and aims: Atherogenic dyslipidemia, i.e. high triglyceride (TG) and low HDL cholesterol levels, contributes to the increased morbidity and mortality for cardiovascular disease (CVD) in subjects with type 2 diabetes. We assessed whether raised TG levels are associated with an increased burden from renal, retinal and CVD complications in patients with type 2 diabetes from the Renal Insufficiency And Cardiovascular Events (RIACE) Italian Multicenter Study.
Materials and methods: Subjects from the RIACE (n=15,773) were divided in 4 groups depending on whether they had plasma TG levels below (NTG) or above (HTG) 150 mg/dl and were or not on statin therapy, which reduces TGs by up to 40%. TGs were assessed by standard colorimetric methods, estimated GFR (eGFR) was calculated using the simplified MDRD equation, albuminuria was measured by immunonephelometry or immunoturbidimetry, retinopathy was evaluated by fundus examination, and CVD was adjudicated based on hospital discharge records or specialist visits.
Results: HGT subjects, either with or without statin, had higher HbA_{1c}, BMI, waist, non-HDL cholesterol and albuminuria, and lower HDL cholesterol and, only for subjects on statin, eGFR, as compared with NTG individuals (P<0.001). HTG patients, particularly if on statin, had higher prevalence of chronic kidney disease (CKD), especially albuminuric, than NTG subjects. In contrast, CVD and (advanced) retinopathy were more prevalent in subjects on statin than in those not, independently of TG levels. Logistic regression analysis with backward variable selection confirmed that HTG without or with statin was independently associated with a higher risk of CKD, Stages 1-2 (1.227 [1.081-1.393] and 1.246 [1.090-1.426]), and Stages 3-5 albuminuric (2.003 [1.654-2.427] and 2.667 [2.213-3.214]) and nonalbuminuric (1.535 [1.294-1.820] and 1.838 [1.553-2.175]). NTG with statin therapy was associated only with the latter. Conversely, in NTG and HTG subjects, statin treatment was independently associated with a higher risk of CVD, total (2.893 [2.621-3.195] and 2.705 [2.399-3.049]) and by vascular bed (coronary, cerebrovascular and peripheral), but not of any or advanced retinopathy.
Conclusion: HTG is associated with all CKD phenotypes independently of statin treatment, whereas the latter correlates with CVD independently of TG levels. These data point to a possible role of HTG in the development of CKD and to the importance of treating atherogenic dyslipidemia.

Relationship between serum cholesterol efflux capacity and glucose tolerance status in Japanese-Americans

M. Kubota, M. Hirano, S. Maeda, M. Yoneda, T. Awaya, S. Nakanishi; Department of Molecular and Internal Medicine, Hiroshima University, Japan.

Background and aims: Serum cholesterol efflux has been suggested to be a key mechanism of the anti-atherogenic function of high-density lipoprotein (HDL). Although dysfunctional HDL is reported to be present in patients with diabetes, it remains unclear whether serum cholesterol efflux capacity is impaired in cases of newly diagnosed glucose intolerance. We therefore hypothesized that serum cholesterol efflux capacity as an HDL function may be impaired in subjects with glucose intolerance, causing a residual risk of atherosclerosis. To demonstrate this, we compared serum cholesterol efflux capacity according to the glucose tolerance status and assessed the relationship between serum cholesterol efflux capacity and glucose intolerance.
Materials and methods: We measured the capacity of whole-serum to mediate cholesterol efflux from human THP-1 macrophages in a cohort of 439 Japanese-Americans living in Los Angeles (186 men, 253 women, mean age 59.2±14.7 years old). Glucose tolerance status was ascertained in individual subjects (normal glucose tolerance: NGT, impaired glucose tolerance: IGT and diabetes mellitus: DM) by 75g oral glucose tolerance test. We then compared serum cholesterol efflux capacity depending on category of glucose tolerance status by using age and sex adjusted analysis of covariance for comparison. Next, we defined study subjects by combining the IGT and DM group to form a glucose intolerance group and assessed the relationship between serum cholesterol efflux capacity and glucose intolerance by using multiple regression analysis after adjusting for age and sex.
Results: Serum cholesterol efflux capacity was 33.2±6.1% in the NGT group, 31.4±6.0% in the IGT group and 31.5±6.2% in the DM group, respectively. We found no significant difference among the three groups (P=0.061). In all subjects, we found significant positive associations between serum cholesterol efflux capacity and each of serum total cholesterol (T-Cho) (β=0.127, P=0.012), HDL-C (β=0.107, P=0.034) and apolipoprotein-AI (apo-AI) (β=0.102, P=0.047), and negative associations between serum cholesterol efflux capacity and each of C-reactive protein (CRP) (β=-0.129, P=0.010) and glucose intolerance (β=-0.125, P=0.012) after adjustment was made for age and sex. Moreover, the association between serum cholesterol efflux capacity and glucose intolerance remained significant even after further adjustment was made for each of T-Cho (model 1: β=-0.128, P=0.010), HDL-C (model 2: β=-0.113, P=0.024), apo-AI (model 3: β=-0.116, P=0.021), T-Cho, and CRP (model 4: β=-0.103, P=0.041).
Conclusion: Serum cholesterol efflux capacity tended to be reduced in subjects with IGT or DM than in subjects with NGT, although the difference was not significant. However, glucose intolerance was found to be independently and negatively associated with cholesterol efflux capacity. This finding may suggest that an impaired anti-atherogenic function in HDL may lead to increased risk of atherosclerotic disease in subjects with glucose intolerance.

227

Influence of HDL cholesterol levels on endothelial progenitor cells function in patients with type 2 diabetes mellitus

D. Lucchesi[1], S.G. Popa[2], V. Sancho Bornez[1], L. Pucci[3], E. Russo[1], M. Garofolo[1], R. Russo[3], A. Dardano[1], L. Giusti[1], R. Miccoli[1], G. Penno[1], S. Del Prato[1], M. Mota[2];
[1]Endocrinology and Metabolism, University of Pisa, Italy, [2]Diabetes, Nutrition, Metabolic Diseases Discipline - University of Medicine and Pharmacy, Craiova, Romania, [3]Institute of Agricultural Biology and Biotechnology, CNR, Pisa, Italy.

Background and aims: High-density lipoprotein (HDL) levels are inversely associated with coronary heart disease. The mechanisms responsible for this beneficial effects are still controversial. Additional atheroprotective actions of HDL have been claimed on top of positive effects of reverse cholesterol transport. Individuals with high HDL-cholesterol (HDL-C) levels show increased endothelial progenitor cells (EPCs) colony forming units and HDL-C is believed a strong determinant of EPCs number and function.
Materials and methods: To gain further insights on the effect of HDL-C we have characterized in vitro function of circulating EPCs of type 2 diabetic subjects (T2DM) with low (34.7±7.9 mg/dl; N=57, M/F 70/30%; age 61.8±7.8 years; BMI 30.6±4.7 kg/m2; HbA1c 7.3±1.0%) and high (74.4±12.9 mg/dl; N=48, M/F 46/54%; age 65.8±8.3 years; BMI 27.3±5.6 kg/m2; HbA1c 7.3±0.8 %) HDL-C. After an overnight fast, venous blood was drawn in EDTA tubes and processed within 2-hrs from sampling. Peripheral blood mononuclear cells (PBMCs) were fractionated using Biocoll density-gradient centrifugation; after 3-day culture, non-adherent cells were discarded and adherent cells positive for Dil-ac-LDL/Lectin dual fluorescent staining were identified as EPCs. After 5-7 day culture in EBM-2 medium, adherent cells were evaluated for viability/proliferation (MTT assay), senescence (beta-galactosidase activity detection), migration (modified Boyden chamber using VEGF as chemoattractant), adhesion capacity (on fibronectin-coated culture dishes) and ROS production (ROS-sensitive fluorescent probe CM-H2DCFDA). Data

have been analyzed as a function of HDL levels, as well as anthropometric features and glycaemic control.
Results: EPCs cells from low HDL-C T2DM had mean 26% lower viability as compared to high HDL-C T2DM (100±30 vs. 74±29; p=0.0001). Four hours H2O2 exposure impaired cell viability to a similar extent in both groups (100±27 vs. 69±25 in high HDL, p<0.0001; 100±24 vs. 81±19 in low-HDL, p=0.007). EPC senescence was comparable in the two groups (100±28 vs. 98±22; p=0.774) and was not significantly modified by exposure to H2O2. There was no difference in the migration capacity between the two groups (100±38 vs. 110±35; p=0.442), while cell adhesion was 25% impaired in low compared to high HDL-C (100±23 vs. 75±15; p=0.0001). Finally, ROS production was slightly (12%) higher in low- (n=27) than in high-HDL (n=18, +12±29; p<0.426). These findings persisted after adjustment for gender, age, BMI and HbA1c.
Conclusion: Our data suggest that in type 2 diabetic subjects HDL-C is a determinant of circulating EPCs function contributing through this mechanism to CV protection.

228

Hypoxia exacerbates the up-regulatory effect of electronegative LDL on cardiomyocyte intracellular triglyceride accumulation
V. Llorente-Cortés[1], R. Cal[1], L. Nasarre[1], M. Estruch[2], S. Benitez[2], J. Sanchez-Quesada[2];
[1]Cardiovascular Research Center, CSIC-ICCC, [2]Biochemistry Department, IIB-SantPau, Barcelona, Spain.

Background and aims: In diabetes, the development of cardiomyopathy is linked to increased myocardial neutral lipid content, in particular to myocardial triglyceride accumulation. Plasma lipoproteins are a source of neutral lipids for cardiomyocytes. By overexpressing certain lipoprotein receptors, these cells have increased capacity to take up neutral lipids from lipoproteins under hypoxic conditions. Electronegative LDL [LDL(-)], a subfraction of LDL with oxidative characteristics, is increased in subjects with diabetes mellitus. Among other features, LDL(-) is characterized by increased content of triglyceride (TG) and non-esterified fatty acids (NEFA). Our aim was to study the capacity of LDL(-), compared to native LDL (nLDL), to alter intracellular cholesteryl ester (CE) and TG content of cardiomyocytes exposed to normoxic and hypoxic conditions.
Materials and methods: LDL(-) was isolated from total LDL by anion-exchange chromatography. HL-1 cardiomyocytes were exposed to increasing nLDL or LDL(-) dose under normoxic (21% O_2) or hypoxic (1% O_2) conditions. Cardiomyocytes were then collected and subjected to thin layer chromatography after lipid extraction.
Results: In normoxic conditions, LDL(-) (0, 50,100 and 200 μg/mL) increased intracellular TG content from 0.25±0.06 to 21.92±1.7 μg TG/mg cell protein. Hypoxia promoted intracellular TG accumulation to 11.28±1.18 μg TG/mg cell protein, in absence of LDL. Remarkably, hypoxia strongly exacerbated LDL(-)-derived intracellular TG accumulation to 51.17±1.7 μg TG/mg cell protein. nLDL did not exert any significant effect on intracellular TG accumulation either under normoxic or hypoxic conditions. LDL(-) and nLDL showed similar ability to accumulate cardiomyocyte intracellular CE. This effect was stimulated under hypoxic conditions.
Conclusion: LDL(-) potentiates cardiomyocyte triglyceride accumulation and this effect is exacerbated under hypoxic conditions. These results suggest that electronegative LDL contributes to myocardial steatosis in diabetes and especially in the context of myocardial ischemia.

OP 40 Beta cell function in vivo

229

Effects of a small protein and lipid preload on oral glucose tolerance in subjects with normal and impaired glucose tolerance
D. Trico'[1,2], A. Tulipani[2], S. Baldi[2], S. Trifiro'[2], S. Frascerra[2], M.P. Macedo[3], A. Mari[4], E. Ferrannini[2], A. Natali[2];
[1]Scuola Superiore Sant'Anna, Pisa, [2]Dipartimento di Medicina Clinica e Sperimentale, Università di Pisa, Italy, [3]Universidade NOVA de Lisboa, Portugal, [4]CNR, Padova, Italy.

Background and aims: In normal subjects, a protein preload has been shown to reduce the AUC of plasma glucose following glucose ingestion by reducing hepatic insulin extraction. In type 2 diabetic patients, a preload of either proteins or lipids has been shown to improve the plasma glucose response to carbohydrate ingestion by slowing gastric emptying and stimulating GLP-1 release. In those studies, the preload was either oil or a protein formula, neither glucose fluxes nor insulin sensitivity or ß-cell function were evaluated and the degree of glucose intolerance was not taken into account. Our aim was to evaluate the effects on glucose fluxes, insulin secretion and peripheral insulin sensitivity of a small mixed protein/lipid preload in subjects with normal (NGT) and impaired (IGT) glucose tolerance.
Materials and methods: Twenty-five volunteers (12 NGT and 13 IGT) were enrolled (13 males, age 38±3 years, BMI 25.7±1.0 kg/m^2). On two separate days, after an overnight fast, subjects were randomised to a preload of either 500 ml of water (control) or Parmesan cheese (50 g) plus a boiled egg with 300 ml of water; 30 min later, they underwent a standard 75 g OGTT. Timed arterialised blood samples were collected to measure plasma glucose, insulin, C-peptide, GLP-1, GIP, glucagon, NEFA and pancreatic polypeptide (PP). Two stable glucose tracers were administered ([6,6-$^2H_2$]glucose *i.v.* and [U-13C]glucose *per os*) to measure ingested glucose appearance (RaO) and endogenous glucose production (RaE). Three major components of ß-cell function, namely ß-cell glucose sensitivity (ßGS), rate sensitivity (ßRS) and potentiation (POT) were evaluated by modeling insulin secretion (estimated from C-peptide deconvolution) and plasma glucose values according to Mari and Ferrannini. Insulin sensitivity was estimated using the OGIS method and AUC of glucose clearance.
Results: In healthy subjects, the mixed protein/lipid preload decreased plasma glucose peak levels at 60 min into the OGTT (6.3±0.2 *vs* 7.7±0.3 mmol/L, $p<0.001$). In the IGT group, it decreased 2-h plasma glucose levels from 8.9±0.3 to 7.8±0.4 mmol/L ($p<0.01$) as well as the whole glucose profile (AUC, $p<0.00001$). In both groups, this improvement in glucose tolerance, which was proportional to the degree of its derangement (AUC *vs* AUC change, r=0.60, $p<0.002$), was associated with an enhancement of ßRS ($p<0.02$), a reduction in oral glucose appearance (RaO, $p<0.01$ only in IGT), a leftward shift of ßGS ($p<0.002$), a small increment in insulin sensitivity as estimated by both OGIS ($p<0.05$) and by tracer-determined glucose clearance ($p<0.04$). Endogenous glucose production similarly declined during the two OGTTs in both groups ($p<0.006$). In neither group were the glucagon, NEFA, PP and GLP-1 responses affected by the preload, while GIP secretion was increased ($p<0.001$) in both.
Conclusion: A small mixed protein/lipid preload significantly improves glucose tolerance, especially in subjects with IGT. This effect results from the combination of a reduction in glucose absorption and a minor improvement in both insulin secretion and peripheral insulin sensitivity. Simple dietetic recommendations have the potential to produce a significant reduction of postprandial hyperglycaemia in pre-diabetic patients.

Metabolic shift with impaired perfusion of pancreas in type 2 diabetes: positron emission tomography study

H. Honka[1], J.C. Hannukainen[1], H. Karlsson[1], V. Lepomäki[1], M. Soinio[2], P. Salminen[3], V. Oikonen[1], R. Parkkola[1,4], N. Kudomi[5], A. Mari[6], P. Iozzo[6,7], P. Nuutila[1,2];
[1]Turku PET Centre, [2]Department of Endocrinology, Turku University Hospital, [3]Division of Digestive Surgery and Urology, Turku University Hospital, [4]Department of Radiology, University of Tampere, Finland, [5]Kagawa University, Japan, [6]Institute of Biomedical Engineering, National Research Council, Padua, [7]Institute of Clinical Physiology, National Research Council, Pisa, Italy.

Background and aims: Glucolipotoxicity and impaired pancreatic blood flow are suggested mechanisms behind β-cell exhaustion in obesity, leading to type 2 diabetes mellitus. The present study was conducted to reveal whether these phenomena exist in humans and if so, their clinical relevance. Positron emission tomography (PET) offers a non-invasive method of studying organ metabolism and blood flow. We have previously validated the use of fluorine-18 labeled radiotracers for the measurement of pancreatic metabolism.
Materials and methods: A total of 47 morbidly obese subjects (20 NGT, 10 IGT, 17 T2DM) with BMI 43±4kg/m^2 and 25 age-matched healthy subjects participated in the study. Pancreatic glucose uptake, fatty acid uptake and perfusion were studied after an overnight fast using [^{18}F]FDG, [^{18}F]FTHA, and [^{15}O]H_2O with PET or PET-CT. Moreover, abdominal MRI and standard OGTT were performed. Regions-of-interest (ROIs) were drawn on head, body, and tail of pancreas. Pancreatic fat index was calculated from in- and outphase MR images. Glucose and fatty acid uptake were calculated using fractional uptake rate (FUR) and blood flow using one-tissue compartment model. The total splanchnic flow was calculated using validated gut compartment model.
Results: As compared to healthy subjects, obese ones had elevated pancreatic fatty acid uptake (1.1±0.3 *vs.* 0.6±0.2μg/100g/min, p<0.0001), lower glucose uptake (1.6±0.5 *vs.* 2.1±0.5μg/100g/min, p<0.03) and perfusion (1.1±0.3 *vs.* 1.7±0.6ml/ml/min p<0.001), and had significantly higher pancreatic fat index (18±21 *vs.* 2.2±5.7, p=0.01). Between obese subgroups no difference was found in previous parameters. Pancreatic blood flow correlated with total splanchnic flow (r=0.35, p=0.04), and both of these parameters were independently associated with higher glucose area under the OGTT curve (r=-0.45, p<0.01 and r=-0.38, p=0.02 for pancreatic and splanchnic blood flow, respectively). Obese subjects were insulin resistant (IR_{HOMA} 0.8±0.9 *vs.* 0.2±0.2, p=0.002), and had higher plasma free fatty acid levels (0.8±0.2 *vs.* 0.5±0.2mmol/l, p=0.0002). No differences were found in GLP-1 levels between the groups but subjects with type 2 diabetes had higher plasma GIP levels compared to controls (22±14 *vs.* 14±6.1ng/ml p<0.01).
Conclusion: This study shows that in obesity the pancreatic metabolism is shifted from glucose to fatty acid utilization in parallel with impairment in organ blood flow and triglyceride accumulation. The association between pancreatic and splanchnic blood flow and mean incremental glucose links blood flow with the regulation intermediary metabolism.
Clinical Trial Registration Number: NCT00793143, NCT01373892

Pancreatic islet cell function before and after Roux-en-Y gastric bypass in glucose tolerant individuals

C. Dirksen[1], K.N. Bojsen-Møller[1], N.B. Jørgensen[1], S.H. Jacobsen[1], V.B. Kristiansen[2], L.S. Naver[2], D.L. Hansen[1], D. Worm[1], J.J. Holst[3], S. Madsbad[1];
[1]Endocrinology, Hvidovre Hospital, [2]Surgical Gastroenterology, Hvidovre Hospital, [3]Biomedical Sciences, University of Copenhagen, Denmark.

Background and aims: Roux-en-Y gastric bypass (RYGB) increases postprandial insulin and glucagon secretion. This change in pancreatic islet cell function is in part explained by altered extrinsic regulation from gut hormones, in particular an exaggerated glucagon-like peptide-1 (GLP-1) meal response. To investigate the influence of changes in intrinsic islet cell regulation, we comprehensively assessed postoperative insulin and glucagon secretion in response to intravenous stimulation including the responsiveness of the islet cells to GLP-1 and glucose-dependent insulinotropic polypeptide (GIP) during stable hyperglycaemia, and compared the results with concomitant changes in response to an oral glucose load.
Materials and methods: Eleven severely obese glucose tolerant individuals (6 women and 5 men; age 40.9 ± 3.3 (SEM) years; preoperative BMI 41.6 ± 1.5 kg/m2) underwent 3 hyperglycaemic clamps (60 min; plasma glucose 9 mmol/L) with bolus injection of arginine at 45 min and primed co-infusion of GLP-1 (1.0 pmol/kg/min), GIP (1.5 pmol/kg/min) or saline, before, 1 week and 3 months after RYGB. In addition, an OGTT was performed before and 3 months after surgery. Acute insulin response to glucose from 0-10 min (AIRg), second phase insulin response from 20-40 min (2nd phase), acute insulin response to arginine (AIRarg), as well as glucagon response to glucose (iAUCglucagon) and arginine (AGRarg) were calculated from the clamp data. Insulinogenic index (IGI) and incremental insulin and glucagon responses were calculated from the OGTT data.
Results: In response to the hyperglycaemic saline clamps, insulin stimulation and glucagon suppression were largely unaltered after RYGB, except for a transient increase in AIRg and AGRarg at 1 week (AIRg: before 9.9 ± 1.1 pmol kg-1 min-1, 1 week 11.3 ± 1.5 P = 0.035, and 3 months 10.1 ± 1.4 P = 0.905; 2nd phase: 4.6 ± 0.6 pmol kg-1 min-1, 3.8 ± 0.5 P = 0.082, and 4.7 ± 0.7 P = 0.941; AIRarg: 47.0 ± 7.7 pmol kg-1 min-1, 33.7 ± 1.9 P = 0.145, and 38.2 ± 3.3 P = 0.210; iAUCglucagon: -270 ± 65 pmol/L min, -414 ± 87 P = 0.104, and -286 ± 53 P = 0.675; and AGRarg: 49.8 ± 10.4 pmol/L, 69.2 ± 14.2 P = 0.009, and 44.6 ± 9.3 P = 0.095). GLP-1 and GIP infusions stimulated insulin responses to glucose and weakly inhibited glucagon release preoperatively, and these effects were unchanged after surgery. In response to the OGTTs, insulin secretion increased and hypersecretion of glucagon was seen at 3 months (IGI: before 3.73 ± 0.63 pmol kg-1 min-1 mmol/L-1 and 3 months 5.90 ± 1.06 P = 0.045; incremental insulin response: 881 ± 68 pmol kg-1 and 1321 ± 100 P = 0.005; incremental glucagon response: -530 ± 174 pmol/L min and 584 ± 75 P < 0.001). Further, GLP-1, but not GIP, secretion during the OGTT increased after RYGB and the glucose profile was altered with a substantial reduction in 2 h plasma glucose.
Conclusion: After RYGB, changes in insulin and glucagon secretion are linked to the oral, but not intravenous, route of delivery, and the insulinotropic and glucagonostatic actions of the incretin hormones are unaltered, highlighting the importance of the gut for the changes in pancreatic islet function.

Beta cell function and insulin sensitivity after Roux-en-Y gastric bypass in patients with type 2 diabetes and normal glucose tolerance

K.N. Bojsen-Møller[1], C. Dirksen[1], S.H. Jacobsen[1], N.B. Jørgensen[1], D. Worm[1], D.L. Hansen[1], A.K. Serup[2], J.J. Holst[3], E.A. Richter[2], S. Madsbad[1];
[1]Department of Endocrinology, Hvidovre Hospital, [2]Department of Exercise and Sport Sciences, University of Copenhagen, [3]Department of Biomedical Sciences, University of Copenhagen, Denmark.

Background and aims: Roux-en-Y gastric bypass (RYGB) improves glucose metabolism within days after surgery. We examined changes in beta-cell function after intravenous and oral challenges as well as changes in peripheral and hepatic insulin sensitivity after RYGB to elucidate the physiological mechanisms responsible for the improved glycemic control.
Materials and methods: We studied 10 obese subjects with type 2 diabetes (T2D) (BMI 38.1±1.8 kg/m^2 mean ± sem) and 10 obese subjects with normal glucose tolerance (NGT) (BMI: BMI 40.2±0.8 kg/m^2) before, 1 week, 3 months and 1 year after RYGB using intravenous glucose glucagon tests (GGTs) and 4 hour hyperinsulinemic (40 mU/m^2/min) euglycemic (5.5 mmol/l) clamps with [6,6-$^2H_2$]-glucose co-infusion. OGTTs (75 g in 5 min) were performed before, 3 months and 1 year after surgery. Acute insulin response (AIR=ΔC-peptide$_{0\text{-}max}$) to GGT and insulinogenic index (IGI = ΔC-peptide$_{0\text{-}30}$/ΔGlucose$_{0\text{-}30}$) from OGTT were used to assess beta-cell function while peripheral and hepatic insulin sensitivity (HISI) were estimated as Rd$_{Clamp}$/Insulin$_{Clamp}$ and $10^5\times$(Ra$_{Basal}\times$Insulin$_{Basal}$)$^{-1}$, respectively.
Results: Glycemic control improved after RYGB in patients with T2D despite cessation of all anti-diabetic medication from the time of surgery (HbA1c T2D: pre 7.0±0.3%, 3 mo 5.9±0.2 p<0.05, 1y 5.8±0.2 p<0.05, NGT: 5.4±0.1, 5.3±0.1 p=ns, 5.3±0.1 p=ns). Insulin secretion after the intravenous challenge was unchanged after RYGB in patients with T2D (AIR: pre 1463±279 pM, 1 wk 1502±440 p=ns, 3 mo 1799±396 p=ns, 1y 1572±395 p=ns) and decreased in NGT at 3 months and 1 year (AIR: 4117±772, 3040±668 p=ns, 3167±748 p<0.01, 3022±804 p<0.05). In response to the oral glucose, insulin secretion increased in T2D after RYGB (IGI: pre 189±60 pM/mM, 3 mo 341±60 p<0.01, 1y 266±55 p<0.05) and was unchanged in NGT (IGI: 788±79, 747±119 p=ns, 770±93 p=ns). Hepatic insulin sensitivity improved equally in both groups

from 1 week postoperatively with further improvements at 3 months and remained elevated at 1 year (HISI T2D: pre 8±2, 1 wk16±6 p<0.01, 3 mo 22±4 p<0.01, 1y 21±6 p<0.01; NGT: 9±1, 16±2 p<0.01, 25±3 p<0.01, 33±8 p<0.01), whereas peripheral insulin sensitivity was unchanged at 1 week but improved at 3 months and 1 year in the two groups (Rd/I T2D: pre 14±2 μg/kg_{ffm}/min/pmol/l, 1 wk 16±3 p=ns, 3mo 25±3 p<0.01, 1y 26±7 p<0.01; NGT: 22±3, 18±2 p=ns, 30±3 p<0.01, 33±5 p<0.01).

Conclusion: Insulin secretion increases after RYGB, but only in patients with type 2 diabetes and only in response to an oral challenge. In patients with NGT, insulin secretion after an intravenous challenge is decreased after RYGB, possible as an adaptation to improved insulin sensitivity. Hepatic insulin sensitivity is equally improved in patients with type 2 diabetes and NGT already from 1 week after surgery while peripheral insulin sensitivity is not increased until 3 months postoperatively in either group. Thus, after RYGB the progressive improvement in glycemic control in patients with type 2 diabetes can be explained by a fast improvement in hepatic insulin sensitivity, a slower increase in peripheral insulin sensitivity and an improved beta-cell function in response to an oral challenge.

The effect of frequency of meals on beta cell function in subjects with type 2 diabetes

H. Kahleova[1], L. Belinova[1], A. Tura[2], M. Hajek[3], M. Dezortova[3], M. Hill[4], T. Pelikanova[1];
[1]Diabetes Centre, Institute for Clinical and Experimental Medicine, Prague, Czech Republic, [2]Institute of Biomedical Engineering, National Research Council, Padova, Italy, [3]Institute for Clinical and Experimental Medicine, Prague, [4]Institute of Endocrinology, Prague, Czech Republic.

Background and aims: The aim of our study was to compare the effect of six vs. two meals a day with the same caloric restriction on β-cell function in subjects with type 2 diabetes (T2D).

Materials and methods: In a randomized, crossover study, we assigned 54 patients with T2D to follow two regimens of a hypocaloric diet (-500 kcal/day), each for 12 weeks: six meals a day (A), and two meals a day, breakfast and lunch (B). The diet in both regimens had the same macronutrient and energy content. All subjects were examined at weeks 0, 12 and 24. Insulin secretory rate (ISR) and β-cell function were assessed during the standard meal tests. ISR was calculated by C-peptide deconvolution, and β-cell function was quantified with a mathematical model that describes ISR as a function of absolute glucose levels (insulin secretory tone and glucose sensitivity), and of glucose rate of change (rate sensitivity), as well as a potentiation factor. Insulin sensitivity (OGIS) was calculated, which quantifies glucose clearance per unit change of insulin. Hepatic fat content was measured by the proton magnetic resonance spectroscopy performed by 3T MR scanner (Magnetom - Trio Siemens). For statistical analysis, 2x2 crossover ANOVA was used.

Results: Insulin secretion at the reference level and glucose sensitivity increased (p<0.05) comparably in both regimens. OGIS increased in both regimens (p<0.01), more in B (+8.2; 95% CI +3.4 to +13.1 ml.min−1m−2 in A vs. +21.0; 95% CI +16.1 to +26.0 ml.min−1m−2 in B; p<0.01). Body-mass-index (BMI) decreased in both regimens (p<0.001), more in B (-0.82; 95% CI -0.94 to -0.69 kg.m-2 in A vs. -1.23; 95% CI -1.4 to -1.17 kg.m-2 in B; p<0.001). Hepatic fat content decreased in response to both regimens (p<0.001), more in B (-3.4; 95% CI -3.8 to -3.1 % in A vs. -4.2; 95% CI -4.5 to -3.8% in B; p=0.03). Changes in glucose sensitivity and OGIS correlated negatively with changes in hepatic fat content (r=-0.28; p=0.02 and r=-0.47; p<0.001, respectively). After adjustment for changes in BMI the correlations were no longer significant.

Conclusion: Two meals a day led to a greater decrease in BMI and hepatic fat content and a greater increase in OGIS compared to six meals a day. Insulin secretion at the reference level and glucose sensitivity increased comparably in both regimens. The association between changes in glucose sensitivity, OGIS and HFC was dependent on changes in BMI. Our data suggest that eating fewer larger meals may be more beneficial than more frequent meals during the day for patients with T2D.

The effect of carbohydrate intake on glycaemic control in patients with type 1 diabetes treated with insulin pumps

M.L. James[1], L. Green[2], S.A. Amiel[1], P. Choudhary[1];
[1]Diabetes and Nutritional Sciences, [2]Diabetes, King's College Hospital, London, UK.

Background and aims: Modern regimens for flexible insulin therapy in Type 1 Diabetes advocate dietary freedom, whereby patients vary insulin doses according to anticipated carbohydrate (CHO) intake. However, there is concern that large variations in CHO intake and in particular high CHO meals may still be detrimental to glucose control and differences in CHO intake may underlie variations in glycaemic outcome between patients and between national diabetes education programmes. We explored the relation between CHO intake and glycaemic control from the routine data downloads of a cohort of insulin pump treated patients with type 1 Diabetes.

Materials and method: Data involving insulin doses, CHO intake and finger-prick blood glucose (BG) measurements were collected from pump downloads. Those from all adult patients using continuous subcutaneous insulin

infusion (CSII) at a single centre were considered (n=467). Inclusion criteria included CSII duration of ≥6 months, at least 2 weeks data from a Medtronic download with bolus wizard usage of ≥80% and ≥3 finger-prick BG tests per day, since January 2011. 148 patients' downloads met the criteria. HbA1c values were obtained concurrent to the download. In a subset of 105 patients, individual mealtime data including pre- and post-meal BG, CHO intake and insulin bolus were collected (4129 meals in total).

Results: Our cohort was 65.5% women, of mean (±SD) age 43 (±13) years and duration of CSII 48 (±30) months, of whom 92.7% had completed a structured education course. Mean HbA1c was 7.8% [62mmol/mol] (±0.93) and range was 5.2-11.0% [33-97mmol/mol]. Mean daily CHO intake was 166g (±71) and median (IQR) was 158g (109-206). There was no association with HbA1c for daily CHO intake (r^2=0.033), mean CHO content per meal (r^2=0.039) or number of meals per day (r^2=0.137). Inter-day variability of daily CHO intake did not affect HbA1c (r^2=4.335E-4) or variability of daily mean BG (r^2=0.004). There was no relationship between meal CHO content and change in BG for post-prandial BG (PPG), either 1-3 or 4-7 hours later. When pre-prandial BG was within target (and no correction dose required), there was no significant association between meal CHO content and the percentage of 1-3 hour (p=0.275) or 4-7 hour (p=0.414) PPG readings that fell within the categories <4, 4-10 and >10mmol/L. For meals containing <40, 40-79 and >79g of CHO, 67, 57 and 59% of 1-3 hour PPG readings were within 4-10mmol/L, respectively. For 4-7 hour PPG readings, meals containing <40, 40-79 and >79g of CHO resulted in 65, 65 and 62% of PPG readings within 4-10mmol/L, respectively. There was a significant association between pre-prandial BG and PPG, both 1-3 (n=1993, p<0.001) and 4-7 (n= 1502, p<0.001) hours later, as determined by chi-squared tests.

Conclusion: These data suggest that at least following structured education and using best technology for insulin delivery (pumps and bolus calculators), people with type 1 diabetes can accommodate a flexible diet with variable, sometimes high, CHO intake, without detriment to their glucose control. Pre-meal BG is a major determinant of post-meal BG, regardless of meal CHO content, suggesting a very important role for correct basal insulin replacement between meals. These data support dietary freedom in well-educated and well-motivated patients.

Effect of whey protein concentrate on blood glucose, insulin and C-peptide serum levels following a high glycaemic index breakfast in patients with type 2 diabetes

D. Jakubowicz, M. Boaz, Z. Landau, Z. Matas, T. Ganz, M. Efremashvili, J. Wainstein;
Diabetes Unit, E.Wolfson Medical Center, Holon, Israel.

Background and aims: Whey proteins have insulinotropic effects and reduce postprandial glycemia in healthy subjects. The mechanism is not known, but insulinogenic amino acids and the incretin hormones seem to be involved. To evaluate whether supplementation with whey protein concentrate (WPC) administered before consumption of a high glycemic index (high-GI) breakfast may decrease the postprandial glucose and increase posprandial serum insulin and C- peptide in patients with type 2 diabetes.

Materials and methods: The protocol included 15-controlled type 2 diabetic patients (9 male), duration of known diabetes 7.9 ± 6.0 years, who attended the laboratory after an overnight fast on 2 separate occasions. At the first visit, 15 type 2 diabetic subjects were randomized to consume either 50 gm WPC dissolved in 250 ml water sweetened with artificial sweetener (WPC) or 250 ml water sweetened with artificial sweetener (placebo). Twenty minutes later, subjects were served a high-GI breakfast (3 slices or 90 gr white bread + 15 gm jelly). Venous blood samples were drawn 15 min prior to consuming WPC or P, 15 min after to consuming it, then15 min after breakfast and thereafter every 30 min until 180 min after breakfast. Glucose, insulin and C- peptide were measured at each time point and area under the curve (AUC) was calculated. At the second visit, the same procedure was repeated, with each subject now crossed over to the opposite treatment (WPC to P and P to WPC).

Results: The subjects were aged 64 ± 5.5 years; BMI 26.9 ± 4.6 kg/m2; and HbA1C 6.7 ± 0.7%. AUC for blood glucose was significantly reduced in WPC vs. P: 745.66 ± 169.98 mg/dl*min vs. 1026.90 ± 291.90 mg/dl*min respectively, p< 0.001. AUC for insulin was significantly greater in WPC than P condition: 367.90 ± 218.15 mIU/ml*min vs. 178.95 ± 112.22 mIU/ml*min respectively, p< 0.003. AUC for C peptide was significantly greater in WPC than P: 40.45 ± 13.32 ng/ml*min vs. 28.44 ± 9.94 ng/ml*min respectively, p< 0.009.

Conclusions: Consumption of WPC short time prior to consuming a high glycemic index breakfast reduces glucose while simultaneously increasing insulin and C-peptide Whey protein may represent an adjuvant treatment for patients with type 2 diabetes.

Clinical Trial Registration Number: NCT01571622

Dietary sodium intake and incidence of diabetic complications in Japanese patients with type 2 diabetes: analysis of the Japan Diabetes Complications Study (JDCS)

C. Horikawa[1,2], Y. Yoshimura[3], C. Kamada[3], S. Tanaka[4], S. Tanaka[4], T. Yamada[1], A. Suzuki[1], O. Hanyu[1], A. Araki[5], A. Tanaka[6], Y. Ohashi[7], Y. Akanuma[8], N. Yamada[2], H. Sone[1], The Japan Diabetes Complications Study (JDCS);
[1]Niigata University, [2]University of Tsukuba, [3]Shikoku University, Tokushima, [4]Kyoto University, [5]Tokyo Metropolitan Geriatric Hospital, [6]Kagawa Nutrition University, Sakato, [7]University of Tokyo, [8]Institute for Adult Diseases Asahi Life Foundation, Tokyo, Japan.

Background and aims: Many guidelines recommend that patients with (T2DM) should reduce their dietary intake of salt. However, the relationship between dietary sodium intake and incidence of diabetic complications in patients with T2DM has not been explored. Therefore, we investigated these relationships in our nationwide prospective cohort comprised of Japanese with T2DM.

Materials and methods: The present analysis was conducted as part of JDCS, a multicenter prospective study on the incidence of and risk factors for macro- and microvascular complications among Japanese patients with T2DM from outpatient clinics in 59 universities and general hospitals. Eligible were previously diagnosed patients with T2DM aged 40-70 y whose HbA1C levels were ≥6.5%. After excluding non-responders to a dietary survey, 1588 patients were analyzed. Baseline dietary intake was assessed by the Food Frequency Questionnaire based on food groups. Primary outcomes were times to cardiovascular disease (CVD), overt nephropathy, and diabetic retinopathy. Hazard ratios (HRs) for dietary intake were estimated by Cox regression adjusted for age, gender, body mass index (BMI), HbA1C, diabetic duration, serum lipids, lipid-lowering agents, smoking, energy intake, and physical activity.

Results: Mean daily dietary sodium intake in quartiles ranged from 2.8 to 5.9 g and mean energy intake ranged from 1470 to 2010 kcal. HbA1C, BMI, triglycerides, and systolic blood pressure were well controlled. During the 8-y follow-up, HR for CVD in patients in the 2nd, 3rd, and 4th quartiles of sodium intake compared with the 1st quartile were 1.70 (95% confidence interval, 0.98 to 2.94), 1.47 (0.82 to 2.62), and 2.07 (1.21 to 3.90), respectively (trend p <0.01). This association remained substantially unchanged even after further adjustment for systolic blood pressure and antihypertensive agents. In addition, among patients who had high HbA1c levels ≥9.0%), HR for CVD in patients in the top vs. bottom tertile of sodium intake was dramatically elevated compared with patients with HbA1c levels <9.0% (1.54 (0.80 to 2.99) and 10.29 (2.02 to 52.30), respectively, interaction term, P=0.03). There were no significant associations of sodium intake with overt nephropathy and diabetic retinopathy.

Conclusion: Findings suggested that high dietary sodium intake is associated with elevated incidence of CVD in patients with T2DM and is a possible risk co-factor increasing the risk in patients with HbA1c levels ≥ 9.0%. It is suggested that dietary salt restriction as medical nutritional treatment would be useful to prevent complications of diabetes in patients with T2DM.

AAV8-mediated Sirt1 overexpression in the liver prevents high-carbohydrate diet induced NAFLD

L. Vilà[1,2], I. Elias[1,2], C. Roca[1,2], A. Ribera[1,2], A. Casellas[1,2], R. Lage[1,2], T. Ferré[1,2], F. Bosch[1,2];
[1]Center of Biotecnology and Gene Therapy, Universitat Autònoma de Barcelona, Bellaterra, [2]CIBER de Diabetes y Enfermedades Metabólicas Asociadas (CIBERDEM), Barcelona, Spain.

Background and aims: Non Alcoholic Fatty Liver Disease (NAFLD), is characterized by an aberrant lipid liver accumulation and is strongly related with insulin resistance and the metabolic syndrome. It is well known that caloric restriction (CR) is an important method to reduce lipid accumulation. Recent studies demonstrate that Sirt1 is one of the key genes involved in numerous effects during CR. Sirt1 is a protein deacetylase that acts by up-regulating the oxidative metabolism and by down-regulating processes like lipogenesis and inflammation. We therefore hypothesize that an increase in hepatic Sirt1 expression may protect the liver from diet-induced NAFLD. Thus, adeno-associated viral (AAV) vectors that overexpress Sirt1 specifically in the liver were injected to mice fed with a high carbohydrate diet.
Materials and methods: AAV8 vectors encoding the murine Sirt1 gene under the control of the hAAT (human α1 antitrypsin) liver specific promoter were generated. AAV8-hAAT-null (CT mice) or AAV8-hAAT-Sirt1 (Sirt1 mice) vectors were injected to three-month old C57Bl6 male mice at a dose of $5x10^{11}$vg/mice by tail vein injection. One week later the high carbohydrate diet was administered. During the diet, body weight and food intake were measured weekly and an insulin tolerance test was performed. At week 15, mice were euthanized for tissue sampling.
Results: During diet, no differences were observed in body weight gain and food intake between the Sirt1 and CT mice. However, a slight amelioration during the ITT was detected in the Sirt1 mice, suggesting that insulin sensitivity was improved. As expected, Sirt1 protein overexpression (3 fold change, $p<0.05$) was only detected in the livers of the AAV8-hAAT-Sirt1 injected animals. Sirt1 mice showed a reduction in the liver triglyceride content (-43%, $p<0.05$) and a reduction in the liver weight compared with CT mice. This reduction could be explained by the rise in liver PGC1α, Sirt3, Sirt6, LCAD and VLCAD mRNA levels. Moreover, an increase in hepatic PGC1α protein levels was also observed in Sirt1 mice. MAC-2 immunohistochemistry in liver showed a reduction in macrophage infiltration in Sirt1 mice that was corroborated by a reduction in CD68 and F4/80 mRNA levels. Furthermore, Sirt1 mice showed a reduction in epididymal WAT (eWAT) adipocyte size and a decrease in leptin expression levels. The mRNA levels of cytokines like MCP-1 and iNOS and also the HIF1α levels were diminished in the eWAT of Sirt1 mice, suggesting a reduction in adipose tissue inflammation and hypoxia. On the other hand, Sirt1 mice showed a trend to accumulate less triglycerides in the skeletal muscle (-30%, $p=0.09$), suggesting that ß-oxidation activity could be up-regulated. In agreement, UCP2, PPARδ and PDK4 mRNA levels were increased in Sirt1 mice. Furthermore, the ratio AMPK-P/AMPKtotal was also increased in the skeletal muscle of Sirt1 versus CT mice.
Conclusion: All these data suggest that long-term AAV8-mediated hepatic Sirt1 overexpression prevents the development of NAFLD induced by a high carbohydrate diet and improve whole body metabolism.

MicroRNA-34a in obesity reduces NAD^+ levels and SIRT1 activity by directly targeting NAMPT and SIRT1 genes

S. Choi[1,2], T. Fu[2], S. Seok[2], D.-H. Kim[2], K.-W. Lee[1], Y. Kang[1], B. Kemper[2], J. Kemper[2];
[1]Ajou University Hospital, Suwon-si, Republic of Korea, [2]University of Illinois, Urbana-Champaign, USA.

Background and aims: SIRT1 is an NAD^+-dependent deacetylase that connects nutrient availability to homeostatic responses by modulating the acetylation status and activity of transcriptional regulators and enzymes. Importantly, NAD^+ bioavailability critical for SIRT1 activity were decreased in obesity and the aged.
Materials and methods: To determine whether NAMPT is a direct target of miR-34a, the wild type (WT) or a mutated sequence of the predicted miR-34a site in the NAMPT 3'UTR was inserted into a luciferase reporter and then checked luciferase activity. To explore the effect of miR-34a on NAMPT and SIRT1 in vivo, miR-34a or anti-miR34a were overexpressed in lean mice or HFD mice via tail vein injection of adenoviral vectors.
Results: We show that hepatic microRNA-34a (miR-34a), highly elevated in obese mice and steatosis patients, reduces NAD^+ levels by inhibiting both NAMPT, the rate-limiting enzyme for NAD^+ biosynthesis, and SIRT1 expression. Hepatic verexpression of miR-34a reduced NAMPT/SIRT1/NAD^+ levels and increased acetylation of SIRT1 target transcriptional regulators, PGC-1α, SREBP-1c, and NF-κB, resulting in obesity-mimetic transcriptional and metabolic outcomes. Conversely, antagonism of miR-34a in dietary obese mice increased NAMPT/SIRT1/NAD^+ levels and alleviated steatosis, inflammation, and glucose intolerance. Anti-miR-34a-mediated increases in NAD^+ levels and lipid-lowering gene expression patterns were largely attenuated when NAMPT was downregulated in hepatocytes from dietary obese mice.
Conclusion: This study highlights an unexpected role of miR-34a in reducing NAD^+ levels, revealing therapeutic options of targeting miR-34a for SIRT1-related diseases of obesity and aging.

Lack of SIRT1 attenuated the effect of Exenatide to ameliorate liver steatosis in mice

F. Xu, Z. Li, H. Liu, H. Liang, Z. Chen, J. Weng;
Department of Endocrinology and Metabolism, the Third Affiliated Hospital of Sun Yat-Sen University; Key lab of Diabetology of Guangdong Province, Guangzhou, China.

Background and aims: Growing evidence suggests that Glucagon-like peptide 1 (GLP-1) receptor agonist Exenatide could relieve hepatocyte steatosis both in vivo and in vitro. Our previous study found that lack of SIRT1 (sirtuin 1) could lead to liver steatosis in mice. It prompted us to wonder whether GLP-1 receptor agonist improving liver steatosis is mediated by SIRT1.
Materials and methods: In this study, 7-8 weeks male SIRT1 heterozygous knockout mice with C57BL/6J background ($SIRT1^{+/-}$) and their wild type littermates mice (WT) were randomly divided into WT+chow diet, WT+HFD(high fat diet), and $SIRT1^{+/-}$+HFD groups and fed for 12 weeks. After the diet induction, animals were randomly divided into WT+chow diet, WT+HFD+saline, WT+HFD+Exenatide, $SIRT1^{+/-}$+HFD+saline and $SIRT1^{+/-}$+HFD+Exenatide groups for another 8 weeks. Systemic evaluations were as follows: body weight, fasting blood glucose, cholesterol and triglyceride both in serum and liver was measured. Livers were collected and weighed, and histology study was carried out such as HE and Oil-Red O staining. Western blot were used to detect protein expression in the liver.
Results: The results showed that the body weight, fasting blood glucose, liver weight, cholesterol and triglyceride level both in serum and in liver were significantly decreased after Exenatide treatment compared with saline control in WT+HFD group. However, no statistically changes were observed in $SIRT1^{+/-}$+HFD group after Exenatide treatment compared with $SIRT1^{+/-}$+HFD+saline group. Meanwhile, significant reduction of hepatic lipid accumulation was shown in WT+HFD+Exenatide group according to the histology results, but after heterozygous knockout of SIRT1, no difference was observed in the liver histology between $SIRT1^{+/-}$+HFD+Exenatide and $SIRT1^{+/-}$+HFD+saline groups. Western blot indicated the expression of SIRT1 was up-regulated, both SREBP-1 and PNPLA3 were significantly decreased in WT+HFD+Exenatide group as compared with WT+HFD+saline group. However, none of the difference above was observed in $SIRT1^{+/-}$+HFD group after Exenatide treatment compared with $SIRT1^{+/-}$+HFD+saline group.
Conclusion: Our data suggested that GLP-1 receptor agonist Exenatide could improve hepatic steatosis through up-regulating SIRT1 expression and then inhibit lipogenesis, while lack of SIRT1 attenuated the effect of Exenatide to ameliorate liver steatosis in C57BL/6J background mice.

High-fat diet-induced impairment of skeletal muscle insulin action is not prevented by SIRT1 overexpression

S. Schenk, A.T. White;
University of California, San Diego, La Jolla, USA.

Background and aims: SIRT1 has been implicated in the regulation of skeletal muscle metabolism in response to changes in nutrient availability, though its role in the modulation of skeletal muscle insulin action remains to be completely defined. Previous studies have demonstrated that SIRT1 expression decreases under insulin-resistant conditions, such as those induced by a high-fat/hypercaloric diet (HFD). Furthermore, pharmacological activation of SIRT1 reverses HFD-induced impairments in insulin sensitivity. Thus, the purpose of this study was to determine whether constitutive activation of SIRT1 in mouse skeletal muscle prevents the deleterious effects of HFD on skeletal muscle insulin sensitivity.
Materials and methods: Mice with muscle-specific overexpression of SIRT1 (mOX) and their wildtype (WT) littermates were fed a low-fat diet (LFD; 10% calories from fat) or a HFD (60% of calories from fat) for 12 weeks beginning at 10 weeks of age. Magnetic resonance imaging and indirect calorimetry were used to measure body composition and energy expenditure, respectively. Basal and insulin-stimulated (0.36 nmol/L [60 μU/mL]) glucose uptake were measured using a 2-deoxyglucose uptake assay (2DOGU) in isolated soleus and extensor digitorum longus (EDL) muscles.
Results: SIRT1 protein abundance was ~50-300-fold higher in soleus and EDL muscles from mOX vs. WT mice. As expected, HFD increased body weight and percent body fat by 30% and 300%, respectively, while there was no effect of genotype on these parameters. In addition, energy expenditure was not affected by diet or genotype, though HFD significantly increased the contribution of fat to total EE. Importantly, 12 weeks of HFD decreased insulin-stimulated glucose uptake in WT soleus (LFD: 0.29±.04 vs. HFD: 0.14±0.03 μmol/20 min/g muscle, p<0.05) and EDL (LFD: 0.25±.04 vs. HFD: 0.13±0.02 μmol/20 min/g muscle, p<0.05), and interestingly, this impairment was not prevented in mOX soleus (LFD: 0.25±.05 vs. HFD: 0.09±0.02 μmol/20 min/g muscle, p<0.05) or EDL (LFD: 0.25±.04 vs. HFD: 0.10±0.03 μmol/20 min/g muscle, p<0.05). These impairments in insulin action were paralleled by decreased insulin-mediated activation of Akt and its downstream substrate, glycogen synthase kinase 3β.
Conclusion: The present results demonstrate that upregulation of SIRT1 activity in skeletal muscle does not prevent HFD-induced impairments in skeletal muscle insulin action. Thus, the improvement in muscle insulin sensitivity in rodent models of insulin resistance following treatment with a pharmacological activator of SIRT1, likely occurs secondary to SIRT1 activation in tissue(s) other than skeletal muscle.

Inadequate plasma adiponectin response characterises non-responsiveness to pioglitazone in individuals with impaired glucose tolerance: results from the ACT NOW study

D. Tripathy[1], D.C. Schwenke[2], M. Banerji[3], G.A. Bray[4], T.A. Buchanan[5], S.C. Clement[6], R.R. Henry[7], A.E. Kitabchi[8], S. Mudaliar[7], R.E. Ratner[9], F.B. Stentz[8], N. Musi[1], P.D. Reaven[2], R.A. DeFronzo[1];
[1]Medicine, University of Texas Health Science Center at San Antonio, [2]Phoenix VA Health Care System, [3]Suny Health Science Center at Brooklyn, [4]Pennington Biomedical Research Center, Baton Rouge, [5]University of Southern California Keck School of Medicine, Los Angeles, [6]Georgetown University, Washington, [7]VA San Diego Healthcare System, [8]Division of Endocrinology, Diabetes and Metabolism, University of Tennessee, Memphis, [9]Medstar Research Institute, Hyattsville, USA.

Background and aims: Several studies have shown that thiazolidinediones (TZDs) delay/prevent onset of diabetes in subjects with IGT. However, a significant number of IGT individuals fail to respond to TZDs. We examined factors that predict lack of response to Pioglitazone in ACT NOW.
Materials and methods: ACT NOW is a randomized double-blind, placebo-controlled study to test whether pioglitazone (PIO, 45 mg/day) can prevent/delay development of type 2 diabetes mellitus (T2DM) in persons with IGT (n= 602, FPG =105, 2-h PG [OGTT]=168 mg/dL). Indices of insulin secretion and insulin sensitivity were derived from plasma glucose, insulin, and C peptide concentrations during OGTT; plasma adiponectin was measured before and at study end (median = 2.4 yrs).
Results: Diabetes developed in 50 PLAC-treated vs. 15 PIO-treated subjects (hazard ratio=0.28: 95% CI= 0.16,-0.49; p<0.001). Of the 213 PIO-treated subjects who completed the study, 101 (47%) reverted to NGT (responders) and 112 (53%) either remained IGT or developed diabetes (non-responders, p<0.005 vs PLAC). 2-h PG was slightly higher in non-responders (172 vs 167 mg/dl, p=0.03); there was no difference in FPG, Matsuda index (MI) of insulin sensitivity, and plasma adiponectin between responders and non-responders at baseline, while indices of beta cell function ($\Delta I_{0\text{-}120}/\Delta G_{0\text{-}120}$ x MI [3.57 ± 0.2 vs. 2.90 ± 0.2, p=0.002], AIR [415± 39 vs 312±27, p=0.03] and disposition index from IVGTT [908± 69 vs 684±72, p=0.02]) were lower in non-responders compared to those who reverted to NGT. Plasma adiponectin increased by approximately 2.5 fold (12± 0.7 to 32±2.0 μg/ml) in non-responders; however, a much greater ~4 fold (11± 0.5 to 46± 4.0 μg/ml) increase was observed in responders (p<0.001). The increase in adiponectin correlated with improvement in FPG (r=0.322, p<0.001), 2-h PG (r=0.281, p<0.001), Matsuda index (r=0.526, p<0.005), and $\Delta I_{0\text{-}120}/\Delta G_{0\text{-}120}$ x MI (r=0.306, p<0.005). When categorized into quartiles of change in plasma adiponectin concentration, individuals in the highest quartile had a markedly lower FPG and 2-h PG, and higher Matsuda insulin sensitivity index and $\Delta I_{0\text{-}120}/\Delta G_{0\text{-}120}$ x MI versus those in the lowest quartile (all p<0.01).
Conclusion: Inadequate rise in adiponectin and markedly reduced β-cell function (IS/IR index) characterize non-responsiveness to PIO in IGT subjects. In individuals with poor adiponectin response to PIO, additional pharmacologic agents may be considered

The efficacy of metformin-based OAD is not inferior to insulin glargine in newly diagnosed type 2 diabetes mellitus patients with severe hyperglycaemia after short-term intensive insulin therapy

Y. Shumin, Q. Cheng, C. Zhao, P. Ye, Q. Li, Z. Liu;
Endocrinology, the First Affiliated Hospital of Chongqing Medical University, Chongqing, China.

Background and aims: In newly diagnosed type 2 diabetic patients with severe hyperglycemia, insulin therapy should be strongly considered from the outset. However, once the metabolic state becomes stabilized, should insulin treatment be continued or transferred to an oral anti-diabetic drug (OAD) therapy is unclear. An open, parallel, randomized trial was conducted to compare the efficacy and safety of metformin-based OAD with glargine in newly

diagnosed type 2 diabetic patients with severe hyperglycemia after short-term insulin therapy.

Materials and methods: All subjects were hospitalized and treated with intensive insulin therapy for 10-14 days. At discharge, patients were randomized into the glargine group (n=21) and the metformin-based OAD group (n=26) for a six-month intervention. Glargine and OAD doses were adjusted aiming for a fasting plasma glucose concentration of 4.4-7.2mmol/l. After the six-month intervention, the glargine group was changed to metformin-based OAD therapy while medication of the OAD group remained unchanged. These patients continually followed up for another six months. Subjects received an oral glucose tolerance test after the intensive insulin therapy, at the end of both the 6th and 12th month. The primary outcome was the HbA_1c change. The secondary outcomes included β-cell function, insulin sensitivity, hypoglycemia episodes, weight change, treatment satisfaction and quality of life.

Results: Of the 108 patients who were eligible, 47 newly diagnosed type 2 diabetic patients with severe hyperglycemia were randomized. HbA_{1c} was reduced by a similar amount in the two treatment groups at the end of the six-month intervention (glargine: 11.81±1.70 vs. 6.48±0.79%; P<0.001; OAD: 11.71±1.89 vs. 6.16±0.52%; P<0.001). At the end of the 12th month, HbA_{1c} was still kept at a comparable and near optimal level in the metformin-based OAD group and the glargine group (6.25±0.60 vs. 6.42±0.72%, P=0.45). HOMA-β increased similarly in the two groups (glargine: 2.78±0.77 vs. 3.90±0.64; P<0.001; OAD: 2.96±0.77 vs. 3.54±0.58; P=0.02) after the six-month intervention. There were no significant differences between the two groups in insulin sensitivity improvement, hypoglycemia episodes, weight change, treatment satisfaction and quality of life after the six-month intervention.

Conclusion: The effects of metformin-based OAD therapy on glycemic control and β-cell function improvement are not inferior to glargine in newly diagnosed type 2 diabetic patients with severe hyperglycemia after short-term intensive insulin therapy.

Table . Parameters of glycemia and insulin secretion before and after the six-month intervention

	Before intervention		After intervention	
	OAD	Glargine	OAD	Glargine
Number (male : female)	26 (16 : 10)	21 (15 : 6)	24 (14 : 10)	20 (14 : 6)

Initiation of new injectable treatment introduced after anti-diabetic therapy with oral-only regimens (INITIATOR) study: an interim analysis

J. Chu[1], W. Wei[2], E. Buysman[3], S. Thayer[3], L. Brekke[3], W.H. Crown[3], M. Grabner[4], S. Raparla[4], R.A. Quimbo[4], M.J. Cziraky[4], W. Hu[2], A. Vlajnic[2], P. Levin[5];
[1]Monterey Endocrine & Diabetes Institute, Monterey, [2]Sanofi U.S., Bridgewater, [3]OptumInsight, Eden Prairie, [4]HealthCore, Inc., Wilmington, [5]MODEL Clinical Research, Baltimore, USA.

Background and aims: Patients with T2DM failing oral antidiabetic drugs (OADs) may initiate injectable therapy with insulin or a glucagon-like peptide 1 (GLP1) analogue. However, real-world data are limited. The INITIATOR study is an observational longitudinal cohort study using both medical chart and health claims data from two of the largest US commercial health insurers, aimed at providing a comprehensive understanding of patients' characteristics, treatment patterns, and associated outcomes. This analysis reports the interim results of the study.

Materials and methods: T2DM patients aged ≥ 18 years, previously on OADs only with HbA1c ≥ 7%, who initiated either insulin glargine SoloSTAR® pen (GLA) or GLP1 analogue liraglutide (LIRA) between 2010-2011 were included. Patients were enrolled in one of the two health insurance plans, with continuous healthcare coverage during the 6 months before (baseline), and 12 months after initiation (follow-up). Health claims and medical chart data from eligible enrolled patients were extracted by OptumInsight™ (OI) and HealthCore® (HC) from respective health plans. Differences in baseline characteristics, treatment patterns, clinical outcomes at follow-up and change in costs from baseline to follow-up were assessed descriptively.

Results: A total of 1,417 patients were included. At baseline, patients had a mean age of 53.2 years and were on 2 OADs. Compared to patients initiating LIRA, patients initiating GLA had poorer health status, as indicated by higher Charlson Comorbidity Score, and higher HbA1c, but lower weight (Table). After 1 year follow-up, treatment persistence was higher for GLA users than LIRA users. Despite higher HbA1c at entry, GLA patients had experienced greater HbA1c reduction but also slight weight gain, while LIRA patients lost weight. Although rates were low, hypoglycaemia was more common in GLA patients. A significant increase in diabetes-related cost was observed in the LIRA group, but not the GLA group, mainly driven by increasing diabetes drug costs (Table).

Conclusion: The interim analysis from this real world study showed significant baseline differences between T2DM patients initiating LIRA and GLA. Results suggest that GLA and LIRA are being used to treat different patient groups. Although each treatment has clinical advantages, significant healthcare cost increases were observed in the LIRA group, warranting further cost-effectiveness analysis.

Initial triple combination therapy is more effective and safer than stepwise add on conventional therapy in newly diagnosed type 2 diabetes mellitus

R.A. DeFronzo, C. Puckett, J. Adams, E. Cersosimo, C. Triplitt, M. Abdul-Ghani;
Medicine, University of Texas Health Science Center at San Antonio, San Antonio, USA.

Background and aims: To compare the efficacy and safety of initiating therapy in new onset T2DM with triple therapy (metformin/pioglitazone/exenatide) versus metformin followed by sequential addition of sulfonylurea and basal insulin.

Materials and methods: 144 newly diagnosed T2DM (age = 45±1 y; BMI=36±0.5; HbA_{1c} = 8.6±0.1%; diabetes duration = 5.6±0.5 mo) were randomized to receive metformin (1000→2000 mg/d) plus pioglitazone (15→45 mg/d) plus exenatide (5→10 μg BID) (Triple Therapy, n=71) or escalating dose of metformin (1000→2000 mg/d) followed by sequential addition of sulfonylurea (glipizide, 20 mg/d) and basal insulin to maintain HbA_{1c} < 6.5 (Conventional Therapy, n = 73).

Results: In subjects receiving Triple Therapy, HbA_{1c} decreased from 8.6 to 6.1% at 6 mo and to 5.9% at month 24. In the Conventional Therapy arm, HbA_{1c} declined to 6.3% at 6 mo and subsequently increased to 6.6% at mont 24. More subjects in the conventional arm failed to achieve the treatment

HbA1c goal <6.5% (35 vs 16%, respectively, p<0.0001). Moreover, as the Box plot below demonstrates, >90% of subjects receiving the triple therapy maintained HbA1c <7.0% at 2 years compared to <75% of subjects in the conventional therapy arm. Despite significantly lower HbA_{1c}, subjects in Triple Therapy arm experienced a 13.6-fold lower rate of hypoglycemia compared to subjects receiving Conventional Therapy. Lastly, subjects in the Triple Therapy arm experienced mean weight loss of 1.2 kg compared to mean weight gain of 3.6 kg (p=0.02) in subjects in the Conventional Therapy arm.
Conclusion: The present results demonstrate that antidiabetic therapy targeting the core metabolic pathophysiologic disturbances (insulin resistance and beta cell dysfunction) responsible for hyperglycemia is more effective and safer than therapy simply aimed at lowering the plasma glucose concentration without correcting the underlying metabolic abnormalities present in T2DM.

Brain glutamate falls during hypoglycaemia in controls but not in type 1 diabetes mellitus subjects with hypoglycaemia associated autonomic failure

E.R. Seaquist[1], M. Terpstra[2], A. Moheet[1], A. Kumar[1], L. Eberly[3], G. Oz[2]; [1]Medicine, University of Minnesota, Minneapolis, [2]Radiology, University of Minnesota, Minneapolis, [3]Biostatistics, University of Minnesota, Minneapolis, USA.

Background and aims: Patients with type 1 diabetes (T1D) who experience recurrent hypoglycemia (HG) as a result of insulin treatment are at risk for developing hypoglycemia associated autonomic failure (HAAF), the syndrome where the first symptom of HG is unconsciousness due to an impaired counterregulatory hormonal response. The mechanism for HAAF is unknown. Bischoff et al (2006) observed lower glutamate-to-creatine in the occipital cortex at moderate hypoglycemia in controls, but not in patients with T1D and blunted glucose counterregulation. However, it was not clear if this difference was due to diabetes or HAAF. Here we test the hypothesis that glutamate (GLU) levels in the occipital cortex will decrease in response to moderate hypoglycemia in healthy controls and in T1D without HAAF, but not in T1D with HAAF.
Materials and methods: 10 subjects with T1D (3M/7F, age 42±14 yrs.) and 5 healthy controls (1M/4F, age 32±4 yrs.) completed the study. Subjects underwent a 2-step hyperinsulinemic euglycemic hypoglycemic clamp in a 7 Tesla scanner; blood glucose was first maintained at 90 mg/dL, then dropped to ~50 mg/dL and maintained at this level. Epinephrine was measured during hypoglycemia. T1D with mean epinephrine < 100 pg/ml were categorized as having HAAF. ^{1}H MR spectra were collected from a 22x22x22 mm^3 occipital cortex voxel using STEAM (TE = 8 ms). CNS metabolites were quantified using LCModel.
Results: High spectral quality was consistently achieved, allowing the quantification of 13 neurochemicals including aspartate, ascorbate/vitamin C, total choline, total creatine, GABA, glutamine, glutamate, glutathione, myo-inositol, lactate, total N-acetylaspartate, scyllo-inositol and taurine with mean CRLB ≤ 20 %. During HG, GLU dropped in controls and T1D without HAAF, but not in T1D with HAAF (see table). In addition, myo-inositol and scyllo-inositol increased in all groups and aspartate increased and lactate decreased in T1D without HAAF (p≤0.03) during HG vs. euglycemia.
Conclusions: We found brain GLU significantly drops in controls and in T1D without HAAF, likely due to glutamate oxidation as demonstrated in healthy rodent brain during HG, but not in T1D with HAAF. This suggests higher glucose and/or alternative fuel availability to the brain in HAAF, eliminating the need to oxidize glutamate. Interestingly, lactate utilization and aspartate increase were also observed in the healthy rodent brain in response to hypoglycemia.

Epinephrine and GLU responses during HG

Group	Epinephrine response durng HG (pg/ml)	GLU during Euglycemia (μmol/g ww)	GLU during HG (μmol/g ww)	% GLU drop	p for GLU drop

Myocardial glucose metabolism: impact of GLP-1 in healthy men during normo- or hypoglycaemia

M. Gejl[1], S. Lerche[1], B. Brock[1], N. Møller[2], J.J. Holst[3], A. Gjedde[4], H.E. Bøtker[5], S.B. Hansen[4], J. Rungby[1];
[1]Inst. of Biomedicine - Pharmacology, Aarhus University, [2]Department of Endocrinology, Aarhus University Hospital, [3]Department of Biomedical Sciences, University of Copenhagen, [4]The PET Center, Aarhus University Hospital, [5]Department of Cardiology, Aarhus University Hospital, Denmark.

Background and aims: Glucagon-like peptide-1 (GLP-1) and GLP-1 receptor agonists provide beneficial cardiovascular effects by protecting against ischemia and reperfusion injury. Type 2 diabetes mellitus (T2DM) patients have reduced glycolysis in the heart. Thus, a mechanism of enhancing myocardial energetic efficiency by increasing glucose availability and utilization reducing beta-oxidation and increasing cardioprotection may exist. Of interest, GLP-1 seems to increase myocardial glucose uptake (MGU) in dogs but not in subjects with T2DM. Thus, our aim was to assess the effects of the GLP-1 receptor (GLP-1r) activation on myocardial glucose metabolism in healthy subjects during normo- and hypoglycemia.
Materials and methods: We conducted two randomized, double-blinded, placebo-controlled cross-over studies including ten healthy men with normoglycemia and eight healthy men with hypoglycemia in order to assess the effect of GLP-1 on myocardial glucose metabolism using positron emission tomography to determine glucose uptake (MGU) during pituitary-pancreatic normo- and hypoglycemic clamps (plasma glucose 4.5 and 3.0 mM) and 18fluoro-deoxy-glucose (FDG) as tracer.
Results: GLP-1 did not affect MGU (during normoglycemia: 0.15 +/- 0.04 and 0.16 +/- 0.03 micromol/g/min, P=0.46 and during hypoglycemia: 0.16 +/- 0.03 and 0.13 +/- 0.04 micromol/g/min, P=0.14). However, regression analysis revealed that the effect of GLP-1 was negatively correlated to baseline MGU in both normo- and hypoglycemia, (P = 0.007 and 0.02, respectively) and positively correlated to the level of insulin resistance in the hypoglycemia study, P=0.04. Except from a GLP-1 mediated increase in glucagon levels and increased glucose infusion rates during hypoglycemia, no differences in circulating hormones and metabolites (catecholamines, free fatty acids, insulin, growth hormone, cortisol and P-glucose) were found.
Conclusion: While GLP-1 does not seem to enhance MGU during normo-nor hypoglycemia, the GLP-1 induced effect on MGU seems to be positive in subjects with low baseline MGU and negative in subjects with high baseline MGU regardless of glycemia level. In the hypoglycemia study the most insulin resistant subjects gained positive effect as expected from the literature.

Glucose-dependent insulinotropic polypeptide protects against hypoglycaemia in type 1 diabetes

A.H. Sparre-Ulrich[1,2], M. Christensen[1,3], S. Calanna[1], P.L. Kristensen[4], F. Purrello[5], J.J. Holst[6], T. Vilsbøll[1], F.K. Knop[1,3];
[1]Diabetes Research Division, Department of Medicine, Copenhagen University Hospital Gentofte, Hellerup, [2]Department of Neuroscience and Pharmacology, Panum Institute, University of Copenhagen, [3]Department of Biomedical Sciences, Panum Institute, University of Copenhagen, [4]Department of Cardiology, Nephrology and Endocrinology,, Copenhagen University Hospital Hillerød, Denmark, [5]Department of Clinical and Molecular Biomedicine, University of Catania, Italy, [6]Department of Biomedical Sciences, Panum Institute, University of Copenhagen, Hellerup, Denmark.

Background and aims: Significant glucagon releasing properties of glucose-dependent insulinotropic polypeptide (GIP) during insulin-induced hypoglycaemia have been demonstrated in healthy individuals and patients with type 2 diabetes. Thus, GIP could potentially increase the glucagon counter-regulatory response also in patients with type 1 diabetes. Glucagon-like peptide 1 (GLP-1) receptor agonists are being explored as add-on treatment to insulin in patients with type 1 diabetes. Owing to inhibitory effects on glucagon secretion demonstrated in healthy individuals and patients with type 2 diabetes, GLP-1 could potentially reduce the glucagon counter-regulatory responses in patients with type 1 diabetes. We sought to evaluate the effects of GIP and GLP-1 on counter-regulatory glucagon responses and endogenous glucose production in patients with type 1 diabetes.
Materials and methods: Ten male subjects with type 1 diabetes (C-peptide negative after 5 g-*iv* arginine test, age: 26±1 years (mean±SEM); BMI: 24±0.5 kg/m^2; HbA_1c: 7.3±0.2%) were studied on 3 separate days. In a randomised double-blinded cross-over study, saline or supraphysiological doses of GIP (4 pmol×kg^{-1}×min^{-1}) or GLP-1 (1 pmol×kg^{-1}×min^{-1}) were administered *iv* for 2 hours. The first hour plasma glucose was lowered by exogenous insulin infusion, thereafter insulin infusion was stopped and plasma glucose was followed for another hour.
Results: GIP infusions elicited larger glucagon responses during the second hour of the study (1.7±0.3 (GIP) vs. 0.4±0.2 (GLP-1) vs. 0.7±0.1 (saline) nmol/l×min, $p<0.0001$). There was no significant difference in glucagon responses between GLP-1 and saline days. During GIP infusions significantly less glucose was needed to keep identical glucose excursions and plasma glucose above 2 mmol/l (156±35 (GIP) vs. 234±41 (GLP-1) vs. 214±56 (saline) mg×kg^{-1}, $p<0.05$). There was no significant differences in glucose infusions between GLP-1 and saline days. Insulin levels were similar on all study days. Hypoglycaemia symptoms score and cognitive tests during hypoglycaemia did not differ significantly between days.
Conclusions: Our results suggest that GLP-1 receptor agonists do not reduce counter-regulatory responses to hypoglycaemia in patients with type 1 diabetes and that exogenous GIP could be exploited in preventing hypoglycaemia in C-peptide negative patients with type 1 diabetes.

DPP-4 inhibition protects from insulin-induced hypoglycaemia: results from a novel graded hyperinsulinaemic hypoglycaemic clamp in mice

S. Malmgren, B. Ahrén;
Department of Clinical Sciences Lund, Lund University, Sweden.

Background and aims: Glucose lowering therapies in type 2 diabetes (T2D) may increase the risk of hypoglycemia, which is associated with acute unpleasant consequences and increased long-term risk for cardiovascular diseases. A major defense mechanism to combat hypoglycemia is glucagon counter-regulation; however, this mechanism is compromised in some patients with T2D. Therefore, there is a need to develop glucose-lowering therapies which sustain the endogenous counter-regulations to hypoglycemia. To enable such development, we have developed a graded hypoglycemic clamp technique in mice for careful and detailed examination of insulin-induced hypoglycemia and its counter-regulation *in vivo*. The aim of this study was to use this novel technique in combination with a meal challenge to explore the influence of DPP-4 inhibition, a relatively novel treatment strategy for T2D associated with a low risk for hypoglycemia, on hypoglycemia and glucagon counter-regulation.
Materials and methods: Anesthetized C57BL/6 mice were simultaneously infused with 15 mU/kg/min of insulin and variable rates of glucose to target a steady state blood glucose of 2.5, 3.5, 4.5 or 6 mmol/L for 30 min between min 60 and 90 of the graded hyperinsulinemic hypoglycemic clamp. To explore the influence of DPP-4 inhibition, mice were given a 0.285 kcal mixed meal with or without the DPP-4 inhibitor NVPDPP728 (NVP) 45 min prior to infusion followed by a hypoglycemic clamp targeting a steady state glucose of 2.5 mmol/L. Glucose and glucagon levels were measured and glucose infusion rate (GIR) during the clamp was estimated.
Results: Steady state glucose levels obtained were 2.7±0.1, 3.4±0.1, 4.4±0.1 and 6.0±0.3 mmol/L. This resulted in a hypoglycemia-dependent and gradual increase in glucagon levels with decreasing glucose. The relation between steady state glucose and glucagon counter-regulation was a highly significant inverse hyperbolic regression (see Figure). The method revealed a clear difference between glucagon levels after clamp at 2.5 or 3.5 mmol/L of glucose (131.9±10.0 and 61.8±8.7 pg/ml respectably, p=0.0022). After a mixed meal with NVP, there was a partial resistance to hypoglycemia, thus, GIR was only 0.6±0.5 mg/kg/min after NVP compared to 4.9±0.9 mg/kg/min (p=0.0095) in controls, even though blood glucose was not suppressed below 3.2±0.4 mmol/l after NVP compared to 2.6±0.1 mmol/L (p=0.04) in controls. Glucagon did not differ between the NVP treated group and control after the hypoglycemic clamp (64.3±9.1 and 83.3±12.0 pg/ml respectably, p=0.25).
Conclusion: We developed a novel *in vivo* technique in mice to enable exploration of glucose-lowering therapies on hypoglycemia and glucagon counter-regulation. Using this, we demonstrate a hypoglycemia-dependent gradual increase in glucagon counter-regulation within the hypoglycemic range along an inverse hyperbolic regression. Finally, we show that DPP-4 inhibition partially protects against severe hypoglycemia.

The novel adipokines BMP4 and BMP7 promote browning of primary human adipose-derived stem cells

M. Elsen[1], S. Raschke[1], H. Sell[1], N. Tennagels[2], T. Romacho[1], J. Eckel[1];
[1]German Diabetes Center, Duesseldorf, [2]Sanofi, Frankfurt, Germany.

Background and aims: White adipose tissue (AT) is an energy storage depot and a real endocrine organ, while brown AT is specialized in energy dissipation and has recently been shown to be present in adult humans. UCP1-expressing adipocytes, with a different origin from classical brown adipocytes, have been found in white AT. These "beige" adipocytes may represent a therapeutic target to fight obesity. Bone morphogenetic proteins (BMPs) have been shown to play an important role in adipogenesis. While BMP4 induces stem cell commitment to the white adipocyte lineage, BMP7 promotes brown adipogenesis. We have previously demonstrated that BMP4 and BMP7 are secreted from human AT and represent novel adipokines. Thus, we aimed to investigate the role of BMP4 and BMP7 in the white-to-brown shift in human adipose-derived stem cells (hASCs).
Materials and methods: hASCs were isolated from human subcutaneous adipose tissue from lean or moderately overweight females. hASC were chronically challenged with BMP4 or BMP7 (50 ng/ml) during the differentiation period (14 days). Lipid accumulation was assessed by Oil Red O staining. PPARγ, C/EBPα, UCP1 and Tcf21 expression was analysed by PCR. Mitochondrial biogenesis was studied with an OXPHOS antibody by Western Blot.
Results: Lipid accumulation was increased in BMP4 and BMP7 treated hASCs (2.5 and 2.6-fold, respectively), as assessed by Oil Red O Staining. Chronic BMP4 and BMP7 treatment increased PPARγ (4.0 and 3.9 fold, respectively) and C/EBPα (7.7 and 6.1-fold, respectively) mRNA levels. Surprisingly, both BMP4 and BMP7 increased UCP1 expression (6.2 and 7.7-fold, respectively). Moreover, both adipokines significantly decreased 50% the levels of the white-specific marker Tcf21. Interestingly, the ability to induce UCP1 in response to BMP4/7 was highly variable between donors. Thus, donors with the strongest UCP1 upregulation displayed higher levels of the recently identified "beige" adipocyte marker CD137. Moreover, BMP4/7 treatment upregulated the mitochondrial OXPHOS complexes in a subset of donors, as determined by Western Blot.
Conclusion: In summary, we showed for the first time that not only BMP7, but also BMP4 is able to induce a white-to-brown transition in hASCs. Therefore, the novel adipokines BMP4 and BMP7 arise as potential therapeutic targets to counteract obesity in humans in an auto/paracrine manner.

Role IGF1R in the regulation of brown fat function and energy balance

V. Viana-Huete[1,2], I. Nieto-Vazquez[1,2], A. Talavera-Pardo[1],
G. Garcia-Gomez[1,2], M. Benito[1,2];
[1]Biochemistry and Molecular Biology II, School of Pharmacy, Complutense University of Madrid. ISCIII, [2]CIBER of Diabetes and Associated Metabolic Disorders, Madrid, Spain.

Background and aims: Excess of visceral adiposity and overweight is associated with the development of metabolic disorders such as type 2 diabetes, hyperlipidemia, and fatty liver and cardiovascular disease. Fat storage results from an imbalance between food intake and energy expenditure. White adipose tissue (WAT) is the main energy storage organ in the body, whereas brown adipose tissue (BAT) is an essential component of non-shivering thermogenesis and energy expenditure by dissipating energy as heat through uncoupled respiration mediated by uncoupling protein 1, a BAT specific mitochondrial protein. Insulin-like growth factor 1 (IGF1) has an important role in brown adipocyte proliferation and also in its adipogenic and thermogenic differentiation together with insulin itself, BMP-7 signaling and sympathetic innervations through beta-adrenoreceptors. However, the implication of IGF1 receptor (IGF1R) and its signaling in the mechanisms controlling the regulation of BAT thermogenesis and energy expenditure and how its dysregulation could affect BAT functionality, remains to be investigated. Thus, the aim of this work was to assess the role of IGF1R in BAT development and thermogenesis and their potential metabolic complications.
Material and methods: We have generated BAT-specific knockout mice of IGF1R (BATIGF1RKO) to eliminate IGF1R expression and signaling in brown adipocytes. Whole-body glucose and insulin tolerance, circulating lev-

els of important mediators, regulation of insulin and BMP-7 signaling pathways, brown fat cell differentiation, BAT functionality, energy expenditure and body fat mass/body weight were studied.
Results: BATIGF1RKO mice displayed higher fasting hyperglycemia and whole-body white fat mass upon ageing. However, KO mice showed a decrease in brown fat mass. Histological analysis of BAT showed a deteriorated morphology in BATIGF1RKO as compared to wild-type mice (WT), which is correlated with a lower basal core temperature. BAT from IGF1RKO mice showed a decrease in gene expression of thermogenic related genes *vs.* controls. Accordingly, BATIGF1RKO mice showed worse thermogenic capacity and exhibited a less oxidative phenotype than WT littermates. Finally, IGF1R deletion in fetal brown adipocytes assessed the essential role played by IGF1R in BAT differentiation and function.
Conclusion: Overall, our data identify IGF1R as an important negative regulator of brown fat activity, key to the maintenance of thermogenesis and body weight, which may have important therapeutic implications for the treatment of obesity and associated metabolic disorders.

Presence of brown adipocytes in white adipose tissue and its role in obesity resistance and insulin sensitivity
A.-L. Poher[1], C. Veyrat-Durebex[1], X. Montet[2], A. Caillon[1], J. Altirriba[1], F. Rohner Jeanrenaud[1];
[1]PHYME, Centre Médical Universitaire de Genève, [2]Radiologie, Hopitaux Universitaires de Genève, Switzerland.

Background and aims: Brown adipose tissue (BAT), characterised by uncoupling protein 1 (UCP1) expression, has recently been described as metabolically active in humans. It induces an increase in energy expenditure by increasing thermogenesis. Lou/C rats which originate from the Wistar strain are resistant to obesity induced by either age or a high fat diet. In inguinal white adipose tissue (WATi) of Lou/C rats, we previously demonstrated the presence of ectopically expressed UCP1, as well as of an overexpression of the β3-adrenoreceptor which controls UCP1 expression. The aim of the present study was to investigate the role of UCP1 in the metabolic regulation of Lou/C rats, including the control of body weight gain and the improvement of insulin sensitivity.
Materials and methods: A β3 agonist treatment (CL-316243, s.c, 1mg/kg/day) was administered in 3 month-old Wistar and Lou/C rats for 2 weeks. Several metabolic parameters were measured. In particular, glucose and cold tolerance, fat mass repartition, overall and tissue-specific insulin sensitivity, as well as energy expenditure were determined.
Results: The treatment induced lower food efficiency, a decreased fat volume (Wistar control =19.08 cm^3±1.3, Wistar treated =7.91±0.6, Lou/C control =4.83±0.9, Lou/C treated =2.27±0.2 $p<0.001$) and enhanced energy expenditure (W=7.09±0.1 kcal/h/$kg^{0.75}$, Wt=9.04±0.1, L=8.68±0.05, Lt=11.23±0.3, $p<0.001$) in both strains. It also similarly increased overall insulin sensitivity (GIR: W=22.3±1.1, Wt= 32.6±0.8, L=31.8±1.3 Lt=40.6±0.5, $p<0.001$), as determined using the euglycemic hyperinsulinemic clamp technique. However and interestingly, muscle glucose uptake, measured with labelled 2-deoxy-glucose, was unaltered by the treatment in both groups of animals. On the contrary, insulin-stimulated glucose uptake in different white adipose tissue depots was highly increased by the β3 adrenoceptor treatment in the Lou/C group only (L=1.6±0.3 ng gluc/mg tissues, Lt=19.7±1.2, $p<0.001$), an increase that correlated with the expression of UCP1 in these tissues. Regarding this gene, the treatment induced its overexpression in the Lou/C group only. In this group, such overexpression was observed in WATi (164 fold increase, $p<0.01$) and was even more marked in epididymal white adipose tissue (WATe) (28864 fold increase, $p<0.01$). These results were confirmed by Western blot analysis. In BAT, UCP1 increased to a similar extent in Wistar and Lou/C rats in response to the treatment (3 fold increase in both groups, $p<0.001$).
Conclusion: A β3 adrenoceptor treatment has similar beneficial effects in Wistar and Lou/C rats on food efficiency through a stimulation of energy expenditure, as well as on overall insulin sensitivity. However, the treatment-induced increase in white adipose tissue insulin sensitivity is more marked in Lou/C than in Wistar rats, as a likely result of UCP1 overexpression in this tissue. This could be one of the mechanisms responsible for the maintenance of the lean phenotype in Lou/C rats.

18F-fluorodeoxyglucose uptake in brown adipose tissue during insulin-induced hypoglycaemia in non-diabetic adults
F. Holleman[1], J.E. Schopman[1], W.M. Admiraal[1], B.M. Frier[2], H.J. Verberne[3], J.B.L. Hoekstra[1];
[1]Internal Medicine, Academic Medical Centre, Amsterdam, Netherlands, [2]The Queen's Medical Research Institute, Edinburgh, UK, [3]Nuclear Medicine, Academic Medical Centre, Amsterdam, Netherlands.

Background and aims: Hypothermia has been associated with acute hypoglycaemia since the earliest use of insulin to treat diabetes. In humans, the capacity to generate heat resides principally in two organs: skeletal muscle and brown adipose tissue (BAT). Hypoglycaemia inhibits muscle shivering and hence suppresses muscle thermogenesis. However, an unexplained persistence in hypoglycaemia induced heat production has been noticed. Hypoglycaemia is characterised by acute sympatho-adrenal activation causing profuse catecholamine secretion which stimulates BAT activity. This study aimed to investigate the effects of hypoglycaemia on the activity of BAT in adult humans to elucidate the counterintuitive increase in heat production that occurs during hypoglycaemia.
Materials and methods: Nine healthy lean male volunteers (age range 19-30 years; body mass index range 20-23 kg/m2) underwent hyperinsulinaemic glucose clamps (insulin infusion rate 1.5 mU/kg/min) on two separate occasions in a cold environment (17-18°C) followed by a 18F-FDG PET-CT scan as a measure of BAT activity. Arterialised blood glucose level was maintained at 4.5 mmol/L for 30 minutes, and either continued at this level (euglycaemia condition) or lowered to 2.5 mmol/L (hypoglycaemia condition) over 20 minutes. An hour after the start of the glucose clamp, when the subjects during the hypoglycaemic condition were hypoglycaemic for at least 15 minutes, 200 MBq of 18F-FDG was administered intravenously and exposure to the specific glycaemic condition was continued for a second hour. The maximal standardized uptake values (SUVmax), defined as the activity in Bq/ ml within the region of interest (cervical, supraclavicular, superior mediastinal fat depots and muscle) divided by the injected dose in Bq/g (body weight), were determined. Counterregulatory hormones were measured at baseline, 50, 70, 90 and at 110 minutes. Results were analysed by means of the non-parametric Wilcoxon signed-rank test and Spearman's rank correlation coefficient.
Results: BAT activity was observed in all volunteers. No difference was observed in the standardised uptake value SUVmax measured during either condition: euglycaemia (median (range) 4.2 g/ml (1.0-7.7); hypoglycaemia 3.1 g/ml (2.2-12.5); (p=0.7). Further, no difference was found for the SUVmax in skeletal muscle between the conditions: 4.1 (2.2-6.5) vs. 3.4 (1.7-5.5) g/mL (p=0.3). A greater fall in temperature was observed during hypoglycaemia when compared to euglycaemia 80 min from baseline (after 40 min of hypoglycaemia): -0.1 (-0.5-0.8) °C during euglycaemia vs. -0.3 (-1.1-0.1) °C (p=0.02) during hypoglycaemia and this difference continued at 90, 100 and 110 min after. No correlations existed between the SUVmax of 18F-FDG in BAT and levels of counterregulatory hormones.
Conclusion: This study shows that there is a similar amount of 18F-fluorodeoxyglucose uptake in brown adipose tissue during hypoglycaemia when compared to euglycaemia. It is therefore not likely that brown adipose tissue activity is a major determinant of the increased heat production that occurs during hypoglycaemia.

Pro-apoptotic Bax and Bak control beta cell death and early ER stress signalling under glucolipotoxic stress

S.A. White, L. Zhang, J.D. Johnson, D.S. Luciani;
The University of British Columbia, Vancouver, Canada.

Background and aims: Loss of functional pancreatic beta-cells is a critical event in the pathogenesis of diabetes and mounting evidence suggests that chronic endoplasmic reticulum (ER) stress contributes to beta-cell dysfunction and apoptotic death. Two core pro-apoptotic proteins from the Bcl-2 family, Bax and Bak, mediate the execution of mitochondrial apoptosis and have also been suggested to regulate aspects of ER physiology and the unfolded protein response (UPR) induced by ER stress. In this study we aimed to determine the relative importance of Bax and Bak in beta-cell death under glucolipotoxic stress and examine their putative involvement in beta-cell ER stress signaling.
Materials and methods: We established a mouse line in which single or combined knockout of Bax and/or Bak can be induced in pancreatic beta-cells by crossing $Bax^{flox/flox}$:$Bak^{-/-}$ mice with Pdx1-CreER mice. Ablation of islet Bax was achieved by injecting all animals with 3 mg/40 g of tamoxifen for 4 consecutive days. Bax and Bak single knockout (SKO), double knockout (DKO), and wild-type (WT) islet cells were assayed for total cell death by kinetic image analysis of propidium iodide (PI) incorporation following treatment with 1.5 mmol/L palmitate (lipotoxicity), palmitate in combination with 25 mmol/L glucose (glucolipotoxicity), and the chemical apoptosis inducer staurosporine (1 μmol/L). To examine ER stress, Chop and spliced Xbp1 were assayed by real-time PCR in islets exposed to either glucolipotoxicity or the chemical ER stress inducer thapsigargin (0.1 μmol/L).
Results: Tamoxifen administration lead to >80% Bax knockout in $Bax^{flox/flox}$ islet cells (87±0.03%, p<0.05). No significant differences in islet function were observed among all genotypes under physiological conditions, with respect to *in vivo* glucose tolerance and *in vitro* analysis of insulin content and glucose stimulated insulin secretion. Kinetic cell death analysis demonstrated the expected protection of single and double Bax-Bak knockout beta-cells from mitochondrial apoptosis induced by staurosporine compared to WT littermate controls (cell death at the 36h time-point: WT 78±6%, Bax SKO 44±5%, Bak SKO 42±8%, Bax-Bak DKO 26±5%, p<0.05) . Bax-Bak DKO beta-cells were partially protected from cell death induced by glucolipotoxicity (Bax-Bak DKO 69±4% relative to WT 100%, p<0.05), while single Bax or Bak knockout beta-cells showed no significant protection compared to WT littermate controls. ER-stress induced by either thapsigargin or glucolipotoxicity revealed a time-dependent increase in Chop expression, with no significant differences between the genotypes. Interestingly, spliced Xbp1 was significantly increased in Bax-Bak DKO islets under early stages of ER stress compared to WT littermate control islets (12h thapsigargin: Bax-Bak DKO 4.1-fold±0.3, WT 2.6-fold±0.3 relative to DMSO control, 24h glucolipotoxicity: Bax-Bak DKO 2.1-fold±0.3, WT 1.2-fold±0.1 relative to 25 mmol/L glucose control, p<0.05).
Conclusion: Together, our data suggests that Bax and Bak have individual roles in mediating mitochondrial apoptosis induced by staurosporine but may be redundant in the execution of beta-cell death under chronic glucolipotoxicity. Furthermore, our findings show that Bax and Bak regulate early activation of the UPR in the beta-cell, suggesting these core apoptotic proteins play important roles in pancreatic beta-cell stress signaling upstream of their canonical roles regulating apoptosis execution.

The transcription factor JunB protects pancreatic beta cells from lipotoxicity by induction of the ER stress response gene XBP1 and AKT signalling

D.A. Cunha[1], E.N. Gurzov[1], F. Ortis[1], N. Naamane[1], M. Bugliani[2], P. Marchetti[2], D.L. Eizirik[1], M. Cnop[1];
[1]Experimental Medicine, Université Libre de Bruxelles, Belgium, [2]Endocrinology and Metabolism, University of Pisa, Italy.

Background and aims: Environmental factors such as diets rich in saturated fats contribute to the loss of pancreatic β-cells in type 2 diabetes. JunB, a member of the AP1 transcription factor family, promotes β-cell survival in models of type 1 diabetes. We have previously shown that GLP-1 agonists and induction of cellular cAMP protect β-cells from lipotoxicity partially via JunB induction. In this study we interrogated the molecular mechanisms involved in JunB-mediated β-cell protection from lipotoxicity.
Materials and methods: Apoptosis was detected by Hoechst 33342/propidium iodide staining, mRNA expression by qPCR, protein expression or phosphorylation by Western blot. Gene silencing was done by siRNA and overexpression by adenovirus infection. Affymetrix microarray analysis was performed in JunB-deficient INS-1E cells.
Results: JunB knockdown (KD) potentiated palmitate-induced apoptosis in INS-1E cells (from 26 ± 1 to 38 ± 3%, p<0.05), primary rat β-cells (from 24 ± 2 to 33 ± 3%, p<0.05) and dispersed human islets (from 31 ± 3 to 43 ± 5%, p<0.05), while its overexpression protected from lipotoxicity (from 26 ± 2 to 18 ± 2% apoptosis, p<0.05). By array analysis we found that JunB KD downregulates the endoplasmic reticulum (ER) stress response gene XBP1 (by 50 ± 7%, p<0.05) and inhibits AKT signalling. We therefore investigated whether these pathways are involved in JunB-mediated β-cell protection. XBP1 overexpression rescued cell viability in JunB-deficient cells (from 41 ± 2% in JunB KD cells to 27 ± 2% in JunB KD and XBP1 overexpressing cells, p<0.05). Downstream of JunB, c/EBPδ mediates the induction of XBP1 since: 1) the XBP1 promoter has a c/EBP binding site; 2) JunB siRNA decreased c/EBPδ expression (by 62 ± 2%, p<0.05) and 3) c/EBPδ KD decreased palmitate-induced XBP1 expression (by 52 ± 6%, p<0.05). JunB KD decreased AKT activation (by 50 ± 7%, p<0.05) and activated the proapoptotic Bcl2 protein BAD via its dephosphorylation (48 ± 9%, p<0.05). BAD KD reversed lipotoxic β-cell death potentiated by JunB siRNA (from 39 ± 6% in palmitate-treated JunB-depleted cells to 27 ± 5% in palmitate-treated cells double KD for JunB and BAD, p<0.05). Interestingly, XBP1 links JunB and AKT signaling since XBP1 KD also reduced AKT phosphorylation (by 56 ± 7%, p<0.05). We next investigated whether the XBP1-AKT axis mediates the previously shown JunB-dependent protection of β-cells by GLP-1 agonists. Forskolin, an inducer of intracellular cAMP, increased AKT phosphorylation (by 2.3 ± 0.5 fold, p<0.05) and this was partially prevented by JunB or XBP1 KD (by 32 ± 5% and 44 ± 1%, respectively, p<0.05) or by inhibition of XBP1 expression using the IRE1 inhibitor 4μ8C (by 46 ± 7%, p<0.05). β-Cell protection from lipotoxicity by forskolin (from 28 ± 1 to 19 ± 0% apoptosis, p<0.05) was abrogated by chemical inhibition of AKT.
Conclusion: JunB modulates the β-cell ER stress response and AKT signaling via the induction of XBP1. The activation of the JunB gene network and the crosstalk with the ER stress and AKT pathways constitutes a crucial defense mechanism mediated by GLP-1 agonists to protect β-cells from lipotoxicity. These findings elucidate novel β-cell protective signal transduction in type 2 diabetes.

Involvement of Pannexin-2 in the regulation of pancreatic beta cell function and apoptosis

L.A. Berchtold[1], S.V.H. Pedersen[2], M. Miani[3], D.L. Eizirik[3], R. Bergholdt[2], F. Pociot[1], J. Størling[1];
[1]Glostrup Research Institute, [2]Hagedorn Research Institute, Gentofte, Denmark, [3]Universite Libre de Bruxelles, Belgium.

Background and aim: We recently constructed biological protein networks relevant for islet function in Type 1 Diabetes (T1D) based on genome-wide association data, protein interaction data and human islet gene expression profiles. Pannexin2 (Panx2), a membrane protein primarily described in the central nervous system, emerged in one of these functional networks. Recent studies illustrate that proteins of the Pannexin family are involved in immune functions and cell death signalling in neurons. However, little is known about the expression of Panx2 in pancreatic islets and the potential functional role of Panx2 in beta cells remains to be addressed. Aim: To evaluate the expression and function of Panx2 in beta cells and to investigate whether Panx2 might be involved in deleterious beta cell processes seen in T1D.
Methods and results: We found that Panx2 transcripts were present in both insulin-secreting INS1 cells, in primary rodent beta cells and in human pancreatic islets, quantified by realtime-PCR. In addition, Panx2 transcripts were significantly downregulated in INS1 cells and primary rat beta cells after stimulation with pro-inflammatory cytokines (IL-1β + IFNγ) known to induce beta cell failure in T1D. RNAi knockdown experiments in INS1 cells and primary rat beta cells (~70% knockdown efficiency) demonstrated that knockdown of Panx2 aggravates cytokine-induced apoptosis as quantified by ELISA detection of cytosolic histone-DNA complexes and by Hoechst/PI stainings, respectively. In line with this, we found that knockdown of Panx2 in

INS1 significantly increased cytokine-induced caspase 3/7 activity compared to control cells. Islets isolated from Panx2 -/- mice showed significantly increased levels of apoptosis compared to age-matched wild-type islets, quantified by the cytosolic histone-DNA complexes. Moreover, glucose-stimulated insulin secretion was significantly decreased in Panx2 knockout islets compared to controls.
Conclusion: The data obtained indicates that Panx2 may have important anti-apoptotic properties in beta cells and that differential regulation of Panx2 could influence beta cell failure in T1D.

Contribution of long non-coding RNAs to beta cell dysfunction in type 1 diabetes
A. Motterle[1], S. Gattesco[1], D. Caille[2], P. Meda[2], R. Regazzi[1];
[1]Department of Fundamental Neuroscience, University of Lausanne, [2]Department of Cell Physiology and Metabolism, University of Geneva, Switzerland.

Background and aims: Recent transcriptome analysis revealed that the vast majority of the mammalian genome is transcribed and produces different classes of non-coding RNAs, including a large number of long non-coding RNAs (lncRNAs). Only very few of these lncRNAs have been functionally characterised, and little is known about their role in pancreatic β-cells. The aim of this project is to identify and functionally characterise the lncRNAs differentially expressed in pathophysiological conditions that favour the development of Type 1 Diabetes (T1D).
Materials and methods: The expression of lncRNAs in the mouse β-cell line MIN6 exposed to proinflammatory cytokines (IL-1β, TNFα, IFNγ), a treatment that mimics the conditions occurring during the development of T1D, was determined by microarray. Differential lncRNA expression was confirmed by quantitative real-time PCR. The changes induced by cytokines were subsequently verified in primary mouse islets and in islets derived from NOD mice, a well-known model of T1D. The lncRNAs of interest were overexpressed in MIN6 cells to investigate their impact on cell survival and insulin secretion.
Results: MIN6 cells were found to express approximately 15000 previously annotated non-coding RNA transcripts. About 470 of them were up-regulated and 224 were downregulated. The changes in four upregulated lncRNAs (lncRNA-1, lncRNA-2, lncRNA-3, lncRNA-4) were confirmed by qPCR. These lncRNAs were almost undetectable in untreated cells and their expression raised 209±75 (p=0.0471), 3.8±1.1 (p=0.0402), 1072±319 (p=0.0215), 148±39 (p=0.0062) fold respectively, in the presence of cytokines. Similar results were obtained with primary mouse islets where lncRNA-1 increased 36±9 (p=0.0044) fold, lncRNA-2 3.6±0.6 (p=0.0028), lncRNA-3 520±214 (p=0.0412) and lncRNA-4 26.2±4.7 (p=0.0007). The expression of all these genes was mainly triggered by INFγ but was further potentiated by IL-1β and TNFα. The expression of lncRNA-1, -3 and -4 was also increased in islets of NOD mice concomitantly with the development of insulitis and T1D. LncRNA-1 and lncRNA-2 overexpression in MIN6 cells increased apoptosis, whereas lncRNA-3 and lncRNA-4 overexpression triggered apoptosis only in combination with either IL-1β or TNFα. LncRNA-3 and -4 overexpression did not affect insulin secretion.
Conclusion: Our study shows that lncRNAs are substantially modulated by exposure to proinflammatory cytokines, a treatment that mimics the pathophysiological conditions associated with the development of T1D. Indeed, some of these lncRNAs, display analogous changes in the islets of prediabetic NOD mice. Overexpression of these lncRNAs sensitises β-cells to apoptosis, suggesting that they may contribute to β-cell failure during the initial phases of T1D.

Genes associated with obesity or type 2 diabetes display altered levels of DNA methylation in human adipose tissue in response to exercise
T. Rönn[1], P. Volkov[1], A.H. Olsson[1], E. Hall[1], T. Dayeh[1], M. Dekker Nitert[2], K.-F. Eriksson[3], L. Groop[3], C. Ling[1];
[1]Epigenetics & Diabetes, Clinical Sciences, Malmö, Sweden, [2]The University of Queensland, Brisbane, Australia, [3]Clinical Sciences, Malmö, Sweden.

Background and aims: Obesity is a predictor for type 2 diabetes (T2D), which in combination with genetic and life-style factors suggests a central role for adipose tissue in the pathogenesis of T2D. Environmental factors potentially alter the epigenome and recent studies point towards epigenetic mechanisms to be involved in the regulation of genes important for glucose metabolism and the pathogenesis of T2D. Here we describe the DNA methylation pattern in candidate genes for T2D and obesity, in human adipose tissue from healthy men before and after a six months exercise intervention.
Materials and methods: A supervised exercise intervention was performed in 23 men with a mean age of 37.4 years and BMI of 27.8 kg/m^2 at inclusion. Subcutaneous fat biopsies were obtained before and after the intervention. DNA methylation was analysed using Infinium HumanMethylation450 BeadChip (Illumina), containing 485,577 probes (99% RefSeq genes). mRNA was analysed using HumanGene 1.0ST array (Affymetrix). DNA methylation data before vs. after the six month exercise intervention was analysed using a paired non-parametric test, whereas a paired t-test was used to compare the mRNA expression. False discover rate analyses were used to correct for multiple testing.
Results: The clinical and metabolic outcomes of the exercise intervention was a significant decrease in waist circumference, waist/hip ratio, diastolic blood pressure and resting heart rate, whereas a significant increase was seen for VO_{2max} and HDL. For the 476,753 CpG sites analysed on the Infinium HumanMethylation450 BeadChip and passing quality control, we found a total of 17,975 individual CpG sites, corresponding to 7,663 unique genes, with altered levels of DNA methylation in adipose tissue after the exercise intervention (q<0.05). Additionally, among all 476,753 analysed CpG sites, 1,351 sites mapped to 53 genes suggested to contribute to obesity, and 1,315 sites mapped to 39 genes suggested to contribute to T2D based on previous genome-wide association studies. We found 24 CpG sites located within 18 of the candidate genes for obesity with a difference in DNA methylation in adipose tissue in response to the exercise intervention (q<0.05). Additionally, two of those genes (*CPEB4* and *SDCCAG8*) showed concurrent inverse change in mRNA expression after exercise (q<0.05). Among the T2D candidate genes, 45 CpG sites in 21 different genes were differentially methylated (q<0.05) in adipose tissue before vs. after exercise. Of note, 10 of these CpG sites mapped to *KCNQ1* and 6 sites mapped to *TCF7L2*. A simultaneous change in mRNA expression was seen for four of the T2D candidate genes where mRNA expression decreased while DNA methylation increased in adipose tissue in response to exercise (q<0.05).
Conclusion: We present a link between exercise and altered adipose tissue DNA methylation in candidate genes for obesity or T2D. This study highlights the dynamic feature of DNA methylation, described using a genome-wide analysis in human adipose tissue before and after exercise.

Methylation of SCD gene promoter and LINE-1 repeat region are associated with weight gain: a study of primary prevention of diabetes
S. Morcillo[1,2], G.M. Martín-Núñez[3,2], R. Cabrera-Mulero[3], G. Rojo-Martínez[3,2], E. García-Escobar[2], S. Valdés[3,2], L. Castaño[1,2], F. Soriguer[3,2];
[1]Hospital Cruces, Bilbao, [2]CIBERDEM, Barcelona, [3]Hospital Carlos Haya, Málaga, Spain.

Background and aims: In the last years, several studies are emerging showing the role that epigenetic modifications could have in the etiology of complex human diseases, such as Type 2 Diabetes Mellitus, obesity, etc. Epigenetic changes are dynamics and are known to vary with cell age, development and differentiation. These epigenetic processes may also be affected by envi-

ronmental factors (diet and exercise). DNA methylation is one of the most common epigenetic marks studied. DNA methylation measured in LINE-1 elements (long interspersed nucleotide element-1) has been correlated with global DNA methylation. On the other hand, Stearoyl CoA desaturase (SCD) is a key enzyme in the synthesis of monounsaturated fatty acids from saturated fatty acids. Variations in SCD activity may be involved in various processes that can lead to diseases such as obesity or other related metabolic disorders. The aim of this study was to analyze whether the patterns of global and specific DNA methylation are involved in the different response to dietary intervention program in a population-based cohort study.
Materials and methods: Cohort study (prospective) and intervention with control group. Subjects: After an OGTT, those subjects with a carbohydrate metabolism disorder were selected (200 control subjects and 200 intervention group). Intervention program consisted of intensive program with regular controls to achieve goals for dietary habits, exercise and weight within the Mediterranean dietary pattern. After a year of nutritional intervention, a blood sample was taken at baseline and after an OGTT in both cohorts. Methods: We collected phenotypic, anthropometric, biochemical and nutritional information of all subjects. DNA methylation was quantified by pyrosequencing technology. Previously DNA was extracted from peripheral blood sample and treated with bisulphite. Global methylation was measured by LINE1 elements and specific methylation was measured from a region of Stearoyl Coa Desaturase (SCD) gene promoter.
Results: DNA methylation patterns (LINE and SCD promoter) were similar at the beginning of the study in both populations, whereas after a year these profiles were significantly greater in control group than in intervention group ($p<0.001$). We observed intra-individual change in global DNA methylation in both groups (Control: 64.2% *vs* 66.9%, $p<0.001$; Intervention group: 64.1% *vs* 63.6%, $p<0.001$) whereas SCD promoter methylation only changed in control group (1.4% *vs* 2.4%, $p<0.001$). Global DNA methylation was statistically lower in women in both baseline ($p=0.018$) and after of the intervention program ($p<0.001$). Regarding to weight gain, subjects from intervention group lose more weight than control group (-2.5 ± 4.8 kg vs -0.7 ± 3.5 Kg; $p=0.001$). We found a significant association between weigh gain and SCD promoter methylation levels in the intervention group ($p= 0.013$) in a linear regression model (adjusted for age, sex and physical activity).
Conclusion: Intra individual changes in global DNA methylation vary over time and these levels are different according to gender. Changes in DNA methylation of SCD promoter gene could be involved in the different response to dietary intervention program in a population-based cohort study.

Intrauterine undernutrition alters patterns of DNA methylation in the next generation offspring through the male line
D. Martinez[1], T. Pentinat[1], C. Davidaud[2], S. Ribo[1], J. Cebria[1], R. Diaz[1], J. Tost[2], J.C. Jimenez-Chillaron[1];
[1]Endocrinology, Fundacio per la Recerca Sant Joan de Deu, Esplugues, Barcelona, Spain, [2]Centre National de Génotypage, Evry, France.

Background and aims: Human and experimental data show that malnutrition during early development may increase diabetes risk into the second generation offspring. These transgenerational effects might be mediated by epigenetic mechanisms. We have previously reported a mouse model of intrauterine growth restriction (IUGR) by reducing to 50% global caloric availability to pregnant females. IUGR mice developed metabolic syndrome with ageing. Strikingly, the diabetic phenotypes progressed to the next generation offspring (IUGR-F2) through the paternal lineage, despite IUGR-F2 mice had not been exposed to nutritional stress during their development. Here we aim to test: *a)* whether *in utero* malnutrition influences the epigenome in the next generation offspring and *b)* whether such transgenerational effects are mediated by epigenetic modifications inherited through the gametes (sperm).
Materials and methods: Here we analyzed global DNA methylation patterns in liver samples from control and IUGR-F2 mice (385K, Roche-NimbleGene). Next, we validated positive *loci* identified in the array by PyroSequencing (liver and sperm).
Results: In utero undernutrition altered the methylation of 1,207 regions in livers from IUGR-F2 mice. Bioinformatics analysis showed enrichment in loci belonging to the Wnt ($P= 0.01$) and Hedgehog signaling pathways ($P= 0.04$). Remarkably, no statistic enrichment in loci belonging to metabolic pathways was observed. Next, we confirmed a set of positive candidate genes from the array (Wnt2b, Wnt7a, Wnt9a, Sfrp1 and Gsk3b) by Pyrosequencing. These epigenetic modifications might be inherited from their progenitors (IUGR-F1) through the germ line or develop as a consequence of progressive metabolic dysfunction. To address this, we analyzed DNA methylation of the candidate loci in sperm samples from IUGR-F1 mice. Strikingly, the epigenetic signatures for Wnt2b and Wnt7a were already present in sperm samples from IUGR-F1 male mice, thus suggesting that early nutritional stress may cause transgenerational epigenetic inheritance of epigenetic marks.
Conclusion: Early malnutrition may induce epigenetic modifications in cells from the germ line. Next, these alterations remain stable during gametogenesis and can be inherited into the following generation offspring thus influencing disease risk.

Repeated measurements of 25-hydroxyvitamin D and vitamin D-binding protein throughout pregnancy and risk of type 1 diabetes in the offspring
I.M. Sørensen[1], G. Joner[1,2], P.A. Jenum[3], A. Eskild[4,5], C. Brunborg[6], P.A. Torjesen[7], L.C.M. Stene[8];
[1]Dept. of Paediatrics, Oslo University Hospital, Ullevål, [2]Dept. of Health Management and Health Economics, University of Oslo, [3]Dept. of Medical Microbiology, Vestre Viken Hospital Trust, Bærum, [4]Dept. of Obstetrics and Gynaecology, Akershus University Hospital, Lørenskog, [5]University of Oslo, [6]Dept. of Biostatistics and Epidemiology, Oslo University Hospital, [7]Hormone Laboratory, Oslo University Hospital, Aker, [8]Division of Epidemiology, Norwegian Institute of Public Health, Oslo, Norway.

Background and aims: We have previously reported that low maternal levels of 25-hydroxyvitamin D (25-OH D) in late pregnancy was associated with higher risk of type 1 diabetes in the offspring, whereas a Finish study did not find this relation with early pregnancy samples. No previous study in this context have to our knowledge observed Vitamin D binding protein (VDBP), which is known to increase during pregnancy. We aimed to test whether levels of repeated measurements of 25-OH D and VDBP throughout pregnancy differed from women whose offspring later developed type 1 diabetes compared to controls in a case control study nested within a large cohort.
Materials and methods: Serum samples drawn at 1-4 time points in pregnancy were analysed for total 25-OH D and VDBP in 113 women delivering a child who developed type 1 diabetes during childhood (cases), and from 221 randomly selected control women. Both cases and controls were part of a prospective cohort of 29,072 pregnant women who gave birth in Norway 1992-94. Cases were identified by linking the cohort of women and their offspring to The Norwegian Childhood Diabetes Registry. Linear mixed models with case/control status as the independent variable, and logistic regression with case/control status as dependent variable were used for statistical analyses.
Results: Estimated mean difference in 25-OH D between case- and control women was 5.75 nmol/l (95% CI 1.25-10.24), p=0.012, and in VDBP 0.36 µmol/l (95% CI 0.04-0.67), p=0.025. In third trimester of pregnancy lower maternal levels of 25-OH D was associated with increased risk of type 1 diabetes development in children, OR 2.68 (95% CI 1.16-6.16), test for trend; p=0.013 for lowest vs. highest quartiles of 25-OH D. The association was still present after adjustments for VDBP. In first and second trimester, no such associations were found. The mean levels of 25-OH D and VDBP significantly increased during the progression of pregnancy in both cases and controls, $p<0.001$. Mean increase in 25-OH D and VDBP pr week of gestation tended to be slightly lower in case mothers compared to controls (p=0.003 and p=0.025 respectively) but the interaction between case/control status and week of gestation at blood sampling was not statistically significant.
Conclusion: In this first study of repeated measures of 25-hydroxyvitamin D and vitamin D binding protein during pregnancy and risk of type 1 diabetes in offspring, we found inverse significant associations with both, and differences tended to be greater towards late pregnancy.

In vivo inhibition of Nuclear Factor of Activated T cells (NFAT) leads to atherosclerotic plaque regression in diabetic IGF-II/LDLR$^{-/-}$ApoB$^{100/100}$ mice

F. Blanco[1], S. Heinonen[2], E. Gurzeler[3], L.M. Berglund[1], A.-C. Jönsson-Rylander[2], S. Ylä-Herttuala[3], M.F. Gomez[1];
[1]Department of Clinical Sciences, Lund University, Malmö, [2]Bioscience, Astra Zeneca, Mölndal, Sweden, [3]Department of Biotechnology & Molecular Medicine at A.I. Virtanen Institute for Molecular Sciences, University of Eastern Finland, Kuopio, Finland.

Background and aims: Despite the vast clinical experience linking diabetes and atherosclerosis, it is still unclear what molecular mechanisms are involved. We recently showed that hyperglycemia activates the transcription factor NFAT in the arterial wall. Here we tested whether NFAT is involved in diabetes-driven atherosclerosis and explored the potential benefit of therapeutic inhibition of NFAT.
Materials and methods: A recently developed mouse model of type 2 diabetes, generated by the crossbred of the LDL receptor deficient mice that synthesize only apolipoprotein B100 (LDLR$^{-/-}$ApoB$^{100/100}$) and transgenic mice over-expressing insulin-like growth factor-II (IGF-II) in pancreatic β cells was used. Mice have hyperglycemia, mild hyperinsulinemia and develop calcified and complex atherosclerotic lesions. Young (4 months, n=10) and old (12-16 months, n=17) diabetic IGF-II/LDLR$^{-/-}$ApoB$^{100/100}$ mice were studied. Four weeks after the introduction of a high fat Western diet, mice were treated with daily i.p. injections of the NFAT blocker A-285222 (0.29 mg/kg body weight) or vehicle (saline) for 4 weeks. Body weight, fasting blood glucose and total plasma cholesterol and triglycerides were measured before, during and after treatment. Brachiocephalic and aortic plaque size was assessed non-invasively by ultrasound biomicroscopy before and after treatment. Histological determination of plaque size was performed after termination.
Results: Non-invasive ultrasound measurements revealed that *in vivo* treatment with the NFAT blocker A-285222 significantly reduced plaque size in the brachiocephalic arteries of young mice, both compared to plaque size in vehicle treated control mice (0.0405 ± 0.0056 mm^2 vs. 0.0818 ± 0.016 mm^2; *p=0.0218) and to the same animals prior treatment (0.0405 ± 0.0056 mm^2 vs. 0.0643 ± 0.0063 mm^2; *p=0.0182). No significant effects were observed in the brachiocephalic arteries of old mice. In the ascending aortas of both young and old mice, a trend towards decreased plaque progression was observed after NFAT inhibition. Results from the histological assessment at termination is in line with the ultrasound data, revealing also decreased brachiocephalic plaque size in old mice, which was not evident by ultrasound.
Conclusion: Our results provide evidence for the involvement of NFAT in the development of macrovascular complications in diabetes. Inhibition of NFAT signaling in diabetic IGF-II/LDLR$^{-/-}$ApoB$^{100/100}$ mice not only limits the progression of atherosclerosis in the brachiocephalic artery, a particularly disease prone vascular segment in mice, but more importantly, it leads to atherosclerosis plaque regression.

Circulating myeloid calcifying cells have anti-angiogenic activity via thrombospondin-1 overexpression

L. Menegazzo[1,2], M. Albiero[2], R. Milioni[1,3], S. Tolin[2,3], G. Arrigoni[2,3], N. Poncina[1,2], P. Tessari[1], A. Avogaro[1,2], G. Fadini[1,2];
[1]Department of Medicine, University of Padua, [2]Venetian Institute of Molecular Medicine, [3]Proteomic Center of Padova University, Padova, Italy.

Background and aims: We have recently identified myeloid calcifying cells (MCCs) as a subpopulation of human monocytes with circulating procalcific potential, characterized by co-expression of osteocalcin (OC) and bone alkaline phosphatase (BAP). Herein, we tested the angiogenic activity of MCCs.
Materials and methods: Human OC+BAP+ MCCs were quantified in diabetic and non diabetic patients by flow cytometry. An in-depth proteomic investigation of MCCs based on FACS, protein extraction and digestion, iTRAQ labelling, peptide fractionation and double mass spectrometry analysis on MALDI-TOF/TOF and LTQ-Orbitrap was performed on human OC+BAP+ MCCs and control OC-BAP- cells. Angiogenesis was assayed in vitro using the Matrigel tubulization assay and in vivo using the Matrigel plug assay and hind limb ischemia. Thrombospondin-1 neutralization was achieved using a blocking antibody.
Results: The proteomic analysis of MCCs identified and quantified more than 700 proteins and revealed pathways activated in OC+BAP+ MCCs compared to OC-BAP- cells. Among proteins referable to angiogenesis, the thrombospondin-1 pathway was markedly upregulated in MCCs vs control cells. Using in vitro and in vivo angiogenesis assays, we found that freshly isolated MCCs and cultured MCCs display an anti-angiogenic function by means of both paracrine activity (conditioned medium) and altered spatial localization in co-cultures with endothelial cells. Treatment with a neutralizing antibody against thrombospondin-1 restored the angiogenic activity of OC+BAP+ MCCs toward normal values, without affecting the function of OC-BAP- monocytes, and abolished the anti-angiogenic effects of MCCs conditioned medium.
Conclusion: These data indicate that circulating MCCs exert an anti-angiogenic activity by virtue of their overexpression of thrombospondin-1. The study also highlights the successful identification and validation of a pathogenic pathway by a gold standard proteomic analysis of blood cells.

263

Myeloid calcifying cells promote atherosclerotic calcification in apolipoprotein-E knock-out mice

M. Albiero[1], M. Rattazzi[2], L. Menegazzo[1,2], E. Boscaro[2], R. Cappellari[2], E. Pagnin[2], E. Bertacco[2], N. Kraenkel[3,4], U. Landmesser[3,4], C. Agostini[1,2], A. Avogaro[1,2], G. Fadini[1,2];
[1]Venetian Institute of Molecular Medicine, Padova, [2]Department of Medicine, University of Padova, Italy, [3]Cardiovascular Research, University of Zurich, [4]Department of Cardiology, University Hospital Zurich, Switzerland.

Background and aims: Several cell types contribute to atherosclerotic calcification. Myeloid calcifying cells (MCCs) are a monocyte subpopulation expressing osteocalcin (OC) and bone alkaline phosphatase (BAP), with ability to calcify in vitro and in vivo. Herein, we tested whether MCCs promote atherosclerotic calcification in vivo.
Materials and methods: Human OC+BAP+ MCCs were quantified in diabetic and non diabetic patients by flow cytometry. In mice, MCCs were characterized by cell culture, flow cytometry and in vivo calcification assay. Migration of human OC+BAP+ MCCs and control OC-BAP- cells was assessed using a modified transwell system. Induction of calcification was studied by transplanting GFP+ OC+BAP+ MCCs and control OC-BAP- cells into young and old ApoE-/- mice sacrificed 24 and 2 weeks later respectively. The pro-calcific potential of MCC conditioned medium was tested on cultured smooth muscle cells.
Results: Circulating MCCs levels were about 2-fold increased in diabetic versus non-diabetic subjects. We show that OC+BAP+ cells had a selective transendothelial migration capacity, suggesting that MCCs are prone to enter the vessel wall. The spleen of C57Bl/6 mice contained OC+BAP+ cells with a phenotype similar to human MCCs, a high expression of adhesion molecules, and capacity to calcify in vitro and in vivo. Injection of GFP-expressing OC+BAP+ cells into 8- or 40-week ApoE-/- mice led to more extensive calcifications in atherosclerotic areas after 24 or 2 weeks, respectively, compared to injection of control OC-BAP- cells. Tracking of the GFP signal identified a

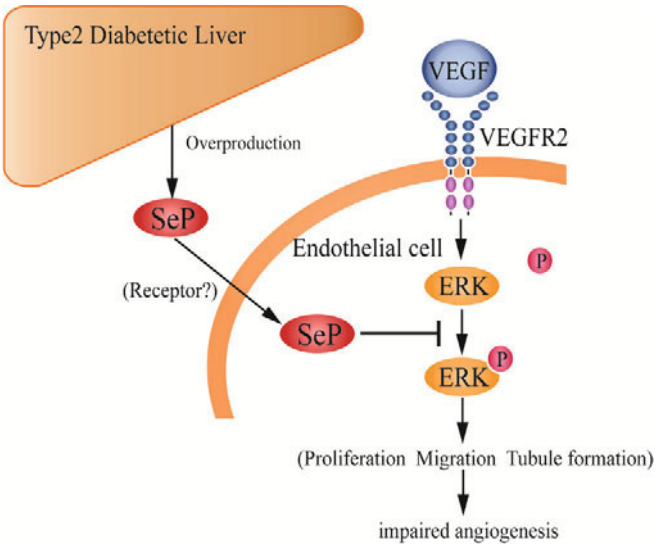
small numbers of injected cells within atherosclerotic areas, suggesting a paracrine effect. Conditioned medium of OC+BAP+ cells promoted calcification of vascular smooth muscle cells in vitro significantly more than conditioned medium of control OC-BAP- cells.
Conclusion: Murine OC+BAP+ cells correspond to human MCCs and promote atherosclerotic calcification in ApoE-/- mice, prevalently through paracrine activity and modulation of resident cells.

264

Selenoprotein P as a diabetes-associated hepatokine that impairs angiogenesis by inducing VEGF resistance in vascular endothelial cells

K. Ishikura[1], H. Misu[1], M. Kumazaki[2], H. Takayama[1], H. Ando[2], Y. Takeshita[1], K. Kato[1], S. Kaneko[1], T. Takamura[1];
[1]Department of Disease Control and Homeostasis, Kanazawa University Graduate School of Medical Science, Kanazawa, [2]Division of Clinical Pharmacology, Department of Pharmacology, Jichi Medical University, Tochigi, Japan.

Background and aims: Impaired angiogenesis is associated with the development of various vascular complications in people with type 2 diabetes. A defect of vascular endothelial growth factor (VEGF)-related signal transduction has been postulated for the diabetic dysregulated angiogenesis, but its molecular mechanism is not fully understood. We have recently identified selenoprotein P (SeP), encoded by the *SEPP1* gene in human, as a liver-derived secretory protein that causes insulin resistance in type 2 diabetes. We reported that levels of serum SeP and hepatic expression of *SEPP1* are elevated in type 2 diabetes approximately twice. Here, we investigated the effects of SeP on VEGF signaling and angiogenesis.
Materials and methods: (i) Human vascular endothelial cells (HUVECs) were pretreated with physiological concentrations of SeP (5 μg/ml as the normal group, 10 μg/ml as diabetes) to examine its effects on angiogenic ability. After 2 hr of starvation, HUVECs were stimulated with VEGF (20 ng/ml) for 15 min. The effects of SeP on VEGF signal transduction was investigated by western blotting. (ii) Mice with hepatic SeP over-expression were made using a hydrodynamic injection technique. We evaluated wound healing of the mice. (iii) SeP-heterozygous knockout mice were operated with hindlimb ligation as an ischemic event. The recovery of blood flow after ischemia was evaluated by using a laser-Doppler perfusion scanner. Two weeks after ischemia, angiogenesis was quantified by CD31 staining of lower limb tissue in the mice.
Results: (i) SeP inhibited VEGF-stimulated cell proliferation by 26%, tubule formation by 28%, and migration by 30% in HUVECs. SeP inhibited VEGF-induced phosphorylation of VEGFR2 and ERK 1/2 in HUVECs, whereas phosphorylation of p38MAPK and Akt (Ser473) was not affected. (ii) In the mice overexpressing *Sepp1*, wound closure was impaired by 23% in 7 days after injury. (iii) *Sepp1*-heterozygous knockout mice exhibited a 1.7-fold acceleration of blood flow recovery and a 2.6-fold increase of vascular endothelial cell numbers in the ischemic hindlimb area.
Conclusion: The present study indicates that diabetes-associated hepatokine SeP, elevated in type 2 diabetes, impairs angiogenesis in vitro and in vivo by inducing VEGF resistance in endothelial cells. It might be possible that SeP affects VEGF-stimulated reactive oxygen species (ROS) generation required for VEGF signal transduction. We are researching the effect of SeP to ROS burst caused by growth factors including VEGF. Furthermore, the identification of SeP receptor(s) in endothelial cells would provide more insight into the molecular mechanism and a novel therapeutic target for treatment of impaired angiogenesis in type 2 diabetes.



PS 001 Managing and monitoring diabetes: who does well and who doesn't?

Metformin - a therapeutic option for prevention of type 2 diabetes in persons with normal glucose tolerance, metabolic syndrome and hyperinsulinaemia

P. Kamenova, I. Atanasova, G. Kirilov;
Department of Diabetology, Clinical Center of Endocrinology and Gerontology, Medical University, Sofia, Bulgaria.

Background and aims: Metabolic syndrome (MS) is a risk factor for type 2 diabetes (T2D) and cardiovascular disease (CVD). Hyperinsulinaemia is the earliest stage in the development of T2D and a strong CV risk factor. Metformin is a first line therapy for T2D and reduces the risk of T2D in individuals with impaired fasting blood glucose and impaired glucose tolerance. The aim of the present study was to establish the effect of metformin on cardiometabolic risk factors in persons with metabolic syndrome, normal glucose tolerance and hyperinsulinaemia.
Materials and methods: 52 individuals (32 females, 20 males) of mean age 40.1±14.2 yrs with MS (IDF Definition), normal glucose tolerance during oral glucose tolerance test (OGTT) defined as fasting plasma glucose < 6.1 mmol/l and 2-h plasma glucose < 7.8 mmol/l and hyperinsulinaemia- fasting serum insulin > 25 mIU/l and/or 2- h post glucose challenge serum insulin > 3 times from baseline (IRMA, reference range 2-25 mIU/l) were included in a prospective one year observational clinical study. Body weight, body mass index, waist circumference, serum lipids, blood pressure, OGTT and homeostasis model assessment of insulin resistance (HOMA-IR) at three month intervals were followed. Metformin was applied at an initial dose of 500 mg titrated to the maximal 3 g, the mean dose was 2.55±0.2 g daily.
Results: Body weight (BW), body mass index (BMI) and waist circumference (WC) decreased significantly at 6 month of metformin treatment and this effect continued to the end of the observation and it was no more pronounced at 1 year compared to the 6 month. BW 97.5±18.5 kg decreased to 89.8±16.9 kg at 6 month (p=0.028) and to 85.3±16.7 kg at 1 year (p=0.001), BMI 32.3±5.2 kg/m^2 decreased to 29.9±4.8 kg/m^2 at 6 month (p=0.012) and to 28.4±5.0 kg/m^2 at 1 year (p=0.0004), WC 102.8±14.3 cm decreased to 95.3±12.2 cm at 6 month (p=0.004) and to 90.9±12.5 cm at 1 year (p<0.0001). The significant effect of metformin on triglycerides (TG), LDL cholesterol (LDL-C), systolic blood pressure (SBP) and diastolic blood pressure (DBP) was observed at 9 month. At 1 year of metformin treatment TG reduced from 2.60±1.74 mmol/l to 1.44±0.53 mmol/l (p=0.0004), LDL-C reduced from 3.61±0.76 mmol/l to 2.74±0.94 mmol/l (p=0.001), SBP reduced from 131±18 mmHg to 119±12 mmHg (p=0.0006) and DBP reduced from 85±11 mmHg to 76±6 mmHg (p<0.0001). HDL-C significantly increased at 1 year of metformin treatment from 1.10±0.34 mmol/l to 1.44±0.28 mmol/l (p=0.0005). Fasting serum insulin 24.1±15.3 mIU/l decreased significantly at 6 month 17.2±8.8 mIU/l (p=0.012) and at 1 year was 11.6±6.0 mIU/l (p<0.0001), 1-h post glucose insulin (PGI) 136.8±67.6 mIU/l decreased significantly at 3 month 94.9±52.2 mIU/l (p=0.009) and at 1 year was 54.5±51.4 mIU/l (p<0.0001), 2-h PGI 62.6±43.2 mIU/l decreased significantly at 3 month 45.1±26.6 mIU/l (p=0.04) and at 1 year was 27.6±21.6 mIU/l (p<0.0001), 3-h PGI 23.2±11.7 mIU/l decreased significantly at 6 month 13.3±7.1 mIU/l (p<0.0001) and at 1 year was 9.7±5.8 mIU/l (p<0.0001). HOMA-IR 5.74±3.77 was significantly reduced at 6 month of metformin treatment 4.01±2.13 (p=0.001) and at 1 year was 2.58±1.40 (p<0.0001).
Conclusion: Metformin reduces cardiometabolic risk factors and restores physiological insulin secretion in normal glucose tolerant persons with metabolic syndrome and hyperinsulinaemia and could be applied for prevention of type 2 diabetes and cardiovascular disease.

266

Reasons for non-intensification of therapy in type 2 diabetes patients uncontrolled by oral monotherapy in general practice in France: the DIAttitude study

B. Balkau[1], S. Halimi[2], J. Blickle[3], C. Attali[4], A. Avignon[5], E. Amelineau[6], I. Chartier[7], M.-A. Geoffroy[8], B. Verges[9];
[1]Inserm U 1018, Villejuif, France, [2]Pavillon Les Ecrins, Endocrinologie Diabete Nutrition, Grenoble, [3]Hopitaux Universitaires, Strasbourg, [4]Medecine Generale, Epinay-sous-Senart, [5]CHU La Peyronnie, Montpellier, [6]Bristol-Myers Squibb, Rueil-Malmaison, [7]Aixial Pharma, Levallois-Perret, [8]Docs, Sèvres, [9]CHU Dijon, Dijon, France.

Background and aims: The ENTRED 2007 study, initiated by the French Health Authority, showed that in T2D patients, intensification of therapy as recommended by national guidelines, was imperfectly followed. The DIAttitude non-interventional study (2010-2012), aimed to describe therapeutic management by French general practitioners (GPs), of T2D patients treated with oral hypoglycaemic agents (OHA) and to identify the major reasons for not intensifying treatment.
Materials and methods: The DIAttitude study included three parts and all aimed to characterize treatment in orally treated T2D patients, who were enrolled by GPs, members of a representative panel of office-based physicians. The first part of DIAttitude analyzed retrospective data from 17 493 orally treated T2D patients. The second part was a non-interventional cross-sectional study. The third part presented here, was a 1-year longitudinal follow-up of the T2D patients treated by OHA monotherapy. The criteria for treatment intensification was defined by two consecutive HbA1c ≥ 7% separated by at least 3 months. Major reasons for non-intensification were recorded every 3 months by the GPs.
Results: In total, 937 patients treated by OHA in monotherapy were included; they were enrolled by 198 GPs, and were followed over 1 year. Among the 916 patients having at least two HbA1c values available, 175 (19%) required treatment intensification: men 61%; mean age 67 years; mean duration of diabetes 8 years; mean HbA1c 7.7%; 45% had HbA1c between 7.0 and 7.5%, 55% over 7.5%; at least one macrovascular complication 23%; at least one microvascular complication 29%; overweight or obese 84%; OHA at inclusion: biguanides 49%, sulfonylureas 39%, other 12%; uncontrolled for more than 12 months 37%. There was no treatment intensification for 81 of the 175 patients (46%). Their baseline characteristics were similar to those requiring treatment intensification, except they had lower HbA1c levels: between 7.0 and 7.5% there were 58% *vs* 45%, for HbA1c over 7.5%, 42% *vs* 55%. Reasons for non intensification were reported for 76 patients: 49% current HbA1c satisfactory, 21% lifestyle and dietary advice the priority, 9% other reasons related to the patient, 8% medical priority other than diabetes, 8% HbA1c decreased since previous visit, 5% decision postponed until next visit. The distribution of these patterns was constant during follow-up.
Conclusion: Therapeutic inertia remains common in T2D patients treated by OHA in monotherapy in France: 46% patients who met the criteria for treatment intensification during a 1-year period did not have additional treatment, while 38% of these patients required intensification for at least one year. The most common reason was GP-defined acceptable HbA1c (49%), in spite of 42% having ≥ 7.5%. Data are available with a 6.5% HbA1c threshold which obviously strengthens the finding of therapeutic inertia.

C-peptide levels not affected by duration of diabetes in a telemedicine based long-term follow up programme

G. Krishnan, P.S. Pillai, A. Shankar, S. Jothydev, J. Kesavadev;
Jothydev's Diabetes and Research Center, Trivandrum, India.

Background and aims: In the natural history of progression of type 2 diabetes the initial hyperinsulinaemia culminates in near total decline in the beta cell function. The eventual loss of beta cell function and associated insulin secretary deficiency is more rapid with higher HbA_{1c} levels. In our center, subjects registered under telemedicine based long term follow up care Diabetes Tele Management System (DTMS*) maintains near normal metabolic targets being followed up frequently via a multi disciplinary trained diabetes team. The follow up program via the telephone or internet as published elsewhere precludes physical visits to the hospital and has been proven cost effective and helps maintain HbA_{1c} targets without significant hypoglycaemia. We hypothesized the correlation between C-peptide levels, duration of diabetes,

HbA1c and the effects of a long term follow up program on these parameters if subjects maintain desirable glycaemic targets.
Materials and methods: A cross-sectional analysis of 2076 T2DM patients aged above 20 years was performed. 37% were female. Mean age was 51.7 year SD 11.9 and C-peptide mean was 2.725 SD 1.7.A1c mean was 8.8 SD 2.1.
Results: 829 patients with duration of follow-up more than 1 year and 1247 patients with duration of follow-up less than 1year were included in the analysis. Age and gender distribution were similar among the two groups. Group with more than 1 year follow up (M=8.4, SD-1.8) had significantly lower A1c compared to new patients with less than 1 year follow-up (M=9.1%, SD=2.2), t(2009) = 7.25, p < .0001. Regression analysis also indicated that A1c tends to be lower with higher C-peptide (R2=0.01,F(4,819)=2.7,p=0.02). Linear regression also showed no significant change of C-peptide levels with duration under care.(Fig.1)
Conclusion: In patients on long term follow up and low HbA1c value when compared with newly enrolled patients, there was no decline in C-peptide levels in DTMS® based follow up care. Maintaining near normal glycaemic targets in type 2 diabetes patients may help preserve the beta cell function even after decades of onset of diabetes.

Accuracy of self-measured blood glucose (SMBG) in 11317 adult diabetes patients based on Clark Error Grid, Parkes Error Grid, ISO 15197 and Bland-Altman-plot

M. Flechtner-Mors[1], C. Boettcher[2], K. Doering[3], A. Dost[4], D. Krakow[5], E. Molz[6], C. Wagner[7], A. Zimmermann[8], R.W. Holl[1], for the DPV Initiative and the BMBF Competence Network Diabetes;
[1]Institute of Epidemiology and Medical Biometry, University Ulm, [2]Division of Pediatric Endocrinology and Diabetology, Justus Liebig University, Giessen, [3]St.-Antonius-Hospital, Kleve, [4]Department of Pediatrics, University Jena, [5]Diabetes Center Forchheim, [6]University Ulm, [7]Diabetes Center Surheim, [8]Diabetes Center Bad Aibling, Germany.

Background and aims: Accuracy of SMBG is essential for correct adjustment of insulin dose, for early detection of hypoglycaemia and for adequate assessment of metabolic control. In this study, the agreement between patient SMBG and simultaneous laboratory/POCT measurement is analyzed, together with the effect of SMBG accuracy on metabolic control.
Methods and subjects: The Diabetes Quality Management System (DPV) is a standardized, electronic longitudinal documentation for institutions specialized in diabetes care. Since 2004, data from 11317 patients >18 years of age with parallel measurements of SMBG and laboratory blood glucose were documented (most recent patient year). International Organisation of Standardization criteria (ISO 15197, current and new criteria) were used to quantify accuracy of SMBG. In addition, the percentage of values within region A according to Clarke or Parkes Error Grid is given and Bland-Altman-plot is visualized. HbA1c-concentration is stratified among patients with SMBG results as much too high (Q1), too high (Q2), too low (Q3) or much too low (Q4) compared to the laboratory measurement. SAS9.3 was used for data analysis.
Results: Diabetes onset was at a mean age of 46.0±18.8 years and diabetes duration was 10.7±9.9 years. 75.7% of patients had type 2 diabetes and 24.3% had type 1. According to ISO 15197 2003, 96.3% of measurements were within target. No difference was found between type 1 and type 2 diabetes, between males and females, and between patients on insulin injections or insulin pumps. SMBG accuracy was highest during the first year of diabetes (p<0.01). Based on the newly proposed ISO standard, only 92.2 % of measurements were within target (minimum requirement 95%). Clarke or Parkes Error Grid analysis resulted in 96.5% and 96.2% of values in zone A. Bland-Altman-plot shows a symmetric distribution of blood glucose differences, with higher variation for elevated blood glucose values. In insulin-treated patients (n=8449), after adjustment for age, sex, diabetes duration and year of treatment, higher deviation of SMBG from laboratory values (Q1: much too high or Q2: too low) is associated with higher HbA1c values (p<0.02).
Conclusion: In this large, multicenter, heterogeneous group of patients, using different blood glucose monitoring systems, current ISO 15197 standards were met, but not the proposed new specifications. Lower accuracy of SMBG is associated with worse metabolic control in insulin-treated subjects.

Monitoring and management of type 2 diabetes patients with renal disease: gap between knowledge and real-life practices

S. Dejager[1], J.-F. Blicklé[2], B. Fiquet[1], A. Penfornis[3];
[1]Clinical Affairs, Novartis Pharma SAS, Rueil Malmaison, [2]Internal Medicine & Diabetology, Strasbourg University Hospital, [3]Diabetology & Endocrinology, Jean Minjoz Hospital, Besançon, France.

Background and aims: To evaluate management of T2DM in patients with/without CKD included by GP and diabetologists (DB) in a transversal study in 2012 in France.
Materials and methods: 3704 patients were recruited in 2 cohorts (2/3 considered to have renal disease [CKD patients] and 1/3 considered not to [no-CKD patients]) by 813 GP [recruiting 81% of patients] and 155 DB. Regardless of inclusion in CKD/no-CKD cohorts, patients were classified by their actual eGFR status in normal RF [≥ 60 mL/min/1,73m²], moderate RI [30-60] and severe RI [< 30]. After recording patients' data, physicians received a general questionnaire about their practice.
Results: For both DB and GP, CKD vs no-CKD patients were significantly older (71 vs 63 yrs). DB patients had longer disease history (18 & 13 yrs in CKD/no-CKD vs 12 & 8 yrs respectively for GP) and more micro- and macrovascular complications. Mean eGFR were similar in DB and GP patients in both cohorts: 46 vs 49 ml/min/1.73m² in CKD and 91 vs 88 ml/min/1.73m² in no-CKD. In 80 and 88% of GP and DB patients, eGFR was known (CG formula more frequently used by GP -38% vs 18% by DB- while MDRD was used by 75% of DB vs 52% of GP). Proteinuria was more often available in DB than GP patients (82 vs 69%). Mean A1c was higher in DB (7.8%) than GP patients (7.4%) in CKD, as well as in no-CKD patients (7.3 vs 7.1%). Therapeutic management of patients included by DB significantly differed to that of GP, especially in the CKD cohort: DB patients were prescribed less metformin (42%) and more insulin (68%) (no-CKD metformin 88% & insulin 30%) and GP patients more metformin (66%) and much less insulin (34%) (no-CKD 86% metformin & 13% insulin). However, doses of metformin were not reduced in DB or GP CKD patients (mean of 1.9 & 2.1 g/d respectively, with 30 and 33% of the DB and GP patients receiving >2g/d, and 21 and 23% receiving 3g/d). Use of SU by DB patients clearly decreased with RF (26% of CKD and 41% of no-CKD patients), while it remained stable across RF in GP patients (31 and 29% in CKD/no-CKD patients). Conversely, use of glinides by DB patients increased in CKD (24% vs 12% in no-CKD) as well as by GP patients (12% vs 6% in no-CKD). DPP4-i were used by DB in 25 and 46% of CKD/no-CKD patients, while they were more frequently used by GP (38% and 45% respectively). Of note, in patients with severe RI, metformin was still prescribed in 16% of DB and 37% of GP patients. In this population, DB patients were also prescribed SU (6%) and DPP4i (6%) less often than GP patients (respectively 23% and 31%) and insulin more often (88 vs 54%). Decision to decrease/stop metformin at the end of the visit occurred in 85% of DB and 33% of GP patients. In contrast, based on the general questionnaire fulfilled afterwards, both GP and DB declared decreasing metformin doses at a mean threshold of 54 mL/min/1.73m² and stopping its use at 35 and 32 mL/min/1.73m². In patients with severe RI, respectively 15, 4, 52 and 32% of the DB declared using metformin, SU, glinides and DPP4i (vs 14, 19, 15 and 58% of the GP) and a similar % of DB and GP declared using insulin (64%).
Conclusion: While treatment of T2DM was clearly distinct in CKD vs no-CKD patients and by GP vs DB, the use of metformin differed in practice from theoretical knowledge in both GP and DB. Use of eGFR for adapting antidiabetics' prescriptions and doses is insufficient. Prescription adjustment is more likely to be done after DB visit.

Meta-analysis of studies examining medication adherence to oral antihyperglycaemic agents in type 2 diabetes

K. Tunceli[1], S.E. Cartier[2], V.M. Rosen[2], V. Zarotsky[2], K. Iglay[1], S.N. Rajpathak[1], L. Radican[1];
[1]Merck Sharp & Dohme Corp., Whitehouse Station, [2]Optum, Eden Prairie, USA.

Background and aims: Medication adherence among patients with type 2 diabetes mellitus (T2DM) has been examined in numerous studies showing substantial variation in the estimated medication adherence rates. The purpose of this meta-analysis was to estimate the overall rates of adherence to oral antihyperglycemic agents (OAHAs) for patients with T2DM by combining results of published studies.
Materials and methods: A systematic literature review was conducted to identify articles published in English over the last 10 years evaluating the use of OAHAs for the treatment of T2DM. Databases searched included PubMed/MEDLINE, EMBASE, and The Cochrane Library. Forty observational studies reporting adherence were identified. Two reviewers independently selected studies for inclusion, performed data extraction, and assessed study quality. Of the studies identified, 18 reported at least one relevant endpoint for analysis. Meta-analyses were weighted using the inverse variance method and examined 1) mean adherence rate defined as the average medication possession ratio (MPR) (sum of days' supply for all fills in period / number of days in period) assessed over a period of 6 to 12 months; and 2) proportion of adherent patients defined as those with an MPR ≥80% assessed over a period of 6 to 12 months. The random effects models incorporated a multilevel structure to account for multiple observations reported in some studies. Subgroup and regression analyses were conducted to investigate if study and patient attributes impact adherence. Heterogeneity was assessed for each analysis using I^2 values.
Results: The pooled mean medication adherence rate (SE) across 12 studies was 74.9% (3.2%) (range: 52-88%). The proportion of adherent patients was 67.2% (4.1%) (range: 44.4-89.8%; n=11). Both I^2 values were greater than 90% indicating significant heterogeneity across studies. Meta-regression showed positive associations between mean age and both outcomes. When centering the covariate for mean age, the meta-regression estimated a mean adherence of 74.3% (3.8%) for the baseline mean age of 54.4 years, and a proportion of patients who were adherent of 64.4% (3.2%) for the baseline mean age of 56 years. Analyses restricted to monotherapy regimens, and separately to treatment naïve patients, both produced estimates for the mean adherence rate and proportion of adherent patients that were similar to the overall results. There were variations in the definitions of MPR across studies, both in what it captured and its method of calculation. In some studies MPR was measured for any OAHA in the index period while in others it was limited to the index therapy (or index class). The estimates for mean adherence rate and proportion of adherent patients to the index therapy were 70.1% (4.4%) and 69.6% (4.8%), respectively; versus 81.6% (2.2%) and 65.8% (5.7%) respectively, for any OAHA received.
Conclusion: This meta-analysis supports the notion that medication adherence to OAHAs is suboptimal. Furthermore, adherence to OAHA medication may vary as a function of patient attributes such as age and therapies examined (index therapy only vs. any OAHA). Additional research is needed to further investigate the factors that impact adherence to OAHAs and examine whether differences in adherence could relate to differences in health outcomes and healthcare costs among patients with diabetes.

271

How are patients with type 2 diabetes and renal disease monitored and managed in France? Results from the OreDia 2012 survey

J.-F. Blicklé[1], A. Penfornis[2], B. Fiquet[3], S. Dejager[3];
[1]Department of Internal Medicine & Diabetology, Strasbourg University Hospital, [2]Department of Endocrinology-Metabolism and Diabetology-Nutrition, Jean Minjoz Hospital, Besançon, [3]Clinical Affairs, Novartis Pharma SAS, Rueil Malmaison, France.

Background and aims: Chronic kidney disease (CKD) is frequent in patients with T2DM. This study aimed to assess in real-life the therapeutic management of T2DM patients with and without CKD.
Materials and methods: 3704 patients were recruited in 2 cohorts (2/3 considered to have renal disease [CKD patients] and 1/3 not to [no-CKD patients]) by 968 Physicians (81% by GPs) in a nation-wide, transversal study from June 2012 to January 2013. Regardless of inclusion in CKD/no-CKD cohorts, patients were also classified by their actual eGFR status in normal renal function (RF) [eGFR ≥ 60 mL/min/1.73m²], moderate renal impairment (RI) [eGFR 30-60 mL/min/1.73m²] and severe RI [eGFR < 30 mL/min/1.73m²].
Results: CKD vs no-CKD patients were significantly older (71 vs 63 yrs; 40% vs 15% ≥ 75 yrs) with longer diabetes history (13 vs 9 yrs; 38% vs 18% ≥ 15 yrs) but similar sex-ratio (62% M) and BMI (29.3 kg/m²). CV risk factors were highly prevalent overall (98 and 90%) driven by hypertension (91 and 71%) and dyslipidaemia (79 and 65%). Diabetic complications were more prevalent in CKD (84 vs 29%) driven by nephropathy (71 vs 4.5%), cardiovascular disease (40% vs 17%) and retinopathy (20% vs 8%). Creatinine levels < 1 yr were available in all patients (mean of 144 and 80 µmol/L, respectively) and results for eGFR in 82% (mean of 49 vs 90 mL/min/1.73m²). 15% of CKD patients had severe RI (vs 0.4% no-CKD) and 66% moderate RI (vs 7.7% no-CKD) with only about 19% of CKD patients with normal RF. Overall 70% of patients were screened for proteinuria and only 21% of CKD (vs 86% of no-CKD) had normal albumin excretion rate. Glycemic control was worse in CKD patients (mean A1C 7.5% vs 7.1%; with 25% of CKD patients ≥ 8% vs 15%). Therapeutic management of T2DM was clearly distinct in the 2 cohorts, with less use of metformin in CKD patients (62% vs 86%) but without a reduction in daily doses (mean of ~2g/d) and with similar proportions treated with high doses (3g/d: 22.5% and 20% respectively of CKD/no-CKD patients). When classified by their actual eGFR status, the groups with moderate and severe RI included 95 and 99% of patients from the CKD cohort. Metformin was used by 86% of patients with normal RF, 63 and 33% of those with moderate and severe RI. For other OADs, a distinct pattern of use was also seen across renal function, except for IAG which were used in about 5% of patients regardless of RF. SU use decreased with RF (32, 31 and 20% respectively in normal RF, moderate and severe RI), while that of glinides increased (8, 14 and 18% respectively in normal RF, moderate and severe RI) and DPP4-i decreased (41, 36 and 25% in normal RF, moderate and severe RI). Patients in the CKD cohort were more frequently treated with insulin (40% vs 16% of no-CKD) when assessed across RF by eGFR, insulin was used in 19, 39 and 61% of patients respectively with normal RF, moderate and severe RI. Treatment was modified at the end of the visit in only 34% of CKD patients, primarily to stop or reduce metformin. However, metformin was stopped in only 40% of the severe RI patients.
Conclusion: In clinical practice, despite a fairly good screening of renal complications in patients with T2DM, RI is insufficiently taken into account for adjustng anti-diabetic treatment.

Prevalence of inadequate metabolic control: results from a provincial wide survey in 1,461 patients with type 1 diabetes in China

D. Yang, J. Li, J. Yan, J. Weng;
Department of Endocrinology and Metabolic Disease, The Third Affiliated Hospital of Sun Yat-sen University, Guangzhou, China.

Background and aims: Type 1 diabetes mellitus (T1DM) requires comprehensive management of glycaemia, blood pressure and blood lipids. However, data of metabolic control status in Chinese T1DM patients is still lacking to date. In this study, we sought to investigate the current status of metabolic control in Chinese T1DM patients, aiming to provide better public health messages.
Materials and methods: This multicenter, cross-sectional study investigated patients with established T1DM between January 1, 2000 and March 31, 2012 from 21 cities in Guangdong, China. Data entry forms were used to collect patients' clinical information, and HbA_{1c}, LDL-C, HDL-C and triglyceride (TG) were measured centrally. HbA_{1c}, blood pressure, blood lipid levels and target levels achieving rates were calculated.
Results: A total of 1,461 patients were enrolled (51.5% female). The age was 29.5 years (20.6-40.0) [median (interquartile range)], duration of T1DM was 3.7 years (1.6 -7.8), age at diagnosis was 24.4 years (15.9-34.9). Proportions of overweight/obese and underweight patients were 11.4% and 23.9%, respectively. Of patients ≥ 18 years, 21% were with abdominal obesity. HbA_{1c} level was 8.7 % (7.1%-11.1%), and 24.7% of patients achieved the age-specific target level. Highest $HbA1_c$ level (10.2%), as well as lowest target level achieving rate (14.2%), were observed in adolescence (13-19 years). Systolic blood pressure (SBP) and diastolic blood pressure (DBP) were 113 mmHg (105-122.5) and 71.5 mmHg (66-78.5), respectively. A total of 69.7% patients achieved target blood pressure level, female higher than male (72.4% vs. 67.0%, P=0.04). LDL-C,HDL-C and TG levels were 2.5 mmol/L (2.0-3.2), 1.4 mmol/L (1.1-

1.7) and 1.1 mmol/L (0.8-1.7), respectively, with 55.3%, 75.5% and 76.7% patients achieving the target levels, respectively. Only 16.2% achieved the target levels of both blood sugar and blood pressure, 12.7% achieved the target levels of both blood sugar and blood lipids, and 9.0% achieved all target levels of blood sugar, blood pressure and blood lipids.
Conclusion: There is a giant gap between current status and the target levels. Our data demonstrated urgent need for a more comprehensive management for these patients.

Sex differences in glycaemic control among people with type 1 diabetes
S. Wild, International quality of care for type 1 diabetes group; University of Edinburgh, UK.

Background and aims: There are limited data describing whether control of type 1 diabetes differs between the sexes. Our aim was to investigate this issue using a large international dataset.
Materials and methods: This analysis represents an international collaboration based on data for 142,260 children and adults with type 1 diabetes, defined using the best available criteria for each country, from 12 countries in total (Austria, Denmark, Germany, Italy, Latvia, New Zealand, Norway, Scotland, Slovenia, Sweden, Ukraine, United States) on glycaemic control over the previous 12 to 24 months derived from both population-based registers and clinic databases. Logistic regression was used to generate odds ratios (ORs) and 95% confidence intervals (CI) for HbA_{1c} ≥7.5% (58 mmol/mol) for females compared to males adjusted for age and duration of diabetes within three age strata that broadly represent paediatric (<15 years), young adult (15-29 years) and adult populations (≥30 years).
Results: Proportions of people with HbA_{1c} ≥7.5% (58 mmol/mol) ranged from 64.4% in boys <15 years of age to 74.0% in women of 15-29 years old. In the youngest age strata there was no statistically significant difference in odds of HbA_{1c} ≥7.5% (58 mmol/mol) between boys and girls: adjusted OR 1.05, 95% CI: 1.00-1.10 (n=15304 boys and 14423 girls). In the two older age categories, women had statistically significantly higher adjusted odds ratios (AOR) for HbA_{1c} ≥7.5% (58 mmol/mol) (15-29 years AOR 1.08, 95% CI: 1.02-1.13 (n=19799 men and 17012 women); ≥30 years AOR 1.06, 95% CI: 1.02-1.10 (n=40388 men and 33241 women)).
Conclusion: In this cross-sectional analysis of type 1 diabetes data from several countries females were more likely to have an HbA_{1c} ≥7.5% (58 mmol/mol) than males. Further work is required to investigate explanations for this finding.

274

Glycaemic control is not affected by age and gender: results from a large cohort study (EDGE)
M. Ratzinger[1], H. Brath[2], A. Kautzky-Willer[3], G. Bader[4];
[1]Novartis Pharma GmbH, Vienna, Austria, [2]Health Centre South, Vienna, Austria, [3]Department of Medicine III, Clinical Division of Endocrinology and Metabolism, Medical University of Vienna, Austria, [4]Novartis Pharma AG, Basel, Switzerland.

Background and aims: The Effectiveness of Diabetes control with vildaGliptin and vildagliptin/mEtformin (EDGE) study compared the effectiveness and safety of adding vildagliptin or other oral anti-diabetic drugs (OADs) in patients with type 2 diabetes mellitus (T2DM) inadequately controlled by oral monotherapy. We present the post hoc analysis from this large EDGE study that aimed to investigate whether there were changes in glycaemic control across age classes and gender in patients treated with vildagliptin or sulphonylureas as add-on to metformin.
Materials and methods: Patients became eligible only after the treatment decision on whether to give vildagliptin or other OADs (including any sulphonylurea, thiazolidinedione, glinide, α-glucosidase inhibitor or metformin, but excluding any other dipeptidyl peptidase-4 inhibitor or glucagon-like peptide-1 mimetics/analogues) was finalised by the physician. Glycaemic control comparisons across age and gender between the two groups were performed using the analysis of covariance after adjusting for baseline HbA1c and body weight (p values were adjusted for multiple comparisons).
Results: Overall, 24,854 patients were treated with vildagliptin and 10,858 with sulphonylureas, both as add-on to metformin. The adjusted difference in HbA1c (ΔHbA1c) was -0.20 [95% confidence interval (CI): -0.22, -0.18; p<0.001] in favour of vildagliptin (Table). ΔHbA1c within classes of age in the vildagliptin cohort was not statistically significant, except in patients <40 vs. >80 years who showed a stronger reduction in HbA1c of -0.12 (95% CI: -0.24, -0.00; p<0.05). No difference was found in the sulphonylurea group. ΔHbA1c between treatment groups was statistically significant within each class of age. Vildagliptin showed ΔHbA1c vs. sulphonylureas ranging from -0.12 in the elderly (≥70 years) to -0.26 in the younger classes (≤50 years). There was no difference in HbA1c drop between genders [0.00 (95% CI: -0.01, 0.01; p=0.958)] in either treatment groups.
Conclusion: Treatment with vildagliptin or sulphonylureas, combined with metformin, provides effective HbA1c control regardless of age and gender. Under real-life conditions, vildagliptin lowers HbA1c more effectively than sulphonylureas within each class of age.

	Vildagliptin				Sulphonylureas				Vildagliptin vs. Sulphonylureas

The use of HbA_{1c} to diagnose type 2 diabetes in a multiethnic and diverse socioeconomic population: results from the South London Diabetes study (SOUL-D)

M. Azam[1], L. Marwood[2], K. Ismail[2], T. Evans[3], K. Winkley[2], S.A. Amiel[4];
[1]Diabetes Research Group, King's College London, [2]Department of Psychological Medicine, King's College London, [3]Paxton Green Group Practice, [4]Diabetes & Nutritional Sciences Division, King's College London, UK.

Background and aims: The authorities providing health care to a large area of South London adopted the WHO's recommendations of an $HbA_{1c} \geq 6.5\%$ as a diagnostic tool for type 2 diabetes (T2DM) in May 2012. The South London Diabetes Study (SOUL-D) has been recruiting people with new onset (<6 months) T2DM since 2008. We aimed to estimate the proportion of SOUL-D participants diagnosed with HbA_{1c} <6.5% prior to May 2012 and whether they are significantly different from participants with a higher HbA_{1c} in terms of demographics and their diabetes status.
Materials and methods*:* This was a cross-sectional study in a population-based cohort of individuals with newly-diagnosed T2DM recruited through 6-monthly searches of 96 primary care databases in South East London. Data, including HbA_{1c} at diagnoses, are collected from the participants and the practice records. Participants diagnosed with HbA_{1c} <6.5% were compared with participants diagnosed with $HbA_{1c} \geq 6.5\%$ for age at diagnosis, gender and race using ANOVA and chi-square analysis. Biomedical data including micro/macrovascular complication and medication status were also compared at baseline and after one year between the groups.
Results*:* 1461 participants (55% male, mean age 55.73 years, SD = 11.15, 37.8% Black African/Caribbean ethnicity) were analysed. 338 (23.1%) had an HbA_{1c} <6.5% at diagnosis. Those with diagnostic HbA_{1c} <6.5% were significantly more likely to be white ($p<0.001$) and had an older mean age of onset (58.2 ± 10.81 vs. 54.4 ± 11.20, $p<0.001$) but there were no significant differences in gender compared to the rest ($p=0.98$). The prevalence of retinopathy (7.4% vs. 11.9%, $p=0.21$), nephropathy (16.7% vs. 13.2%, $p=0.15$), Myocardial Infarction (3.0% vs. 2.3%, $p=0.07$) and Stroke (1.0% vs. 1.7%, $p=0.35$) did not differ significantly before enrolment into SOUL-D, except for a higher proportion of patients with sensory neuropathy diagnosed with an HbA_{1c} <6.5% (9.9% vs. 5.8%, $p<0.05$). At one year, there were no significant differences in complication status ($p>0.05$). The number patients on insulin (6.0% vs. 3.4%) and mean difference in HbA_{1c} (6.8 ± 1.17 vs. $6.9 \pm 1.28\%$) at one year did not reach significance ($p=0.08$ for both).
Conclusion: Nearly a quarter of patients with newly diagnosed T2DM in South London did not have a diagnostic $HbA_{1c} \geq 6.5\%$ by WHO guidance and may not receive T2DM diagnosis in the future. These patients may nevertheless have clinically significant disease, as there were little significant difference in biomedical data between them and those with $HbA_{1c} \geq 6.5\%$ at baseline or at one year. Ethnicity may need to be taken into account when using HbA_{1c} levels to diagnose diabetes.

Identification of HbA_{1c} cut-off for pre-diabetes from incidence of diabetes in a Japanese population

T. Yuki[1], T. Nakagami[1], J. Oya[1], Y. Yamamoto[1], Y. Hasegawa[1], M. Kurita[1], Y. Endo[2], Y. Uchigata[1];
[1]Diabetes Center, Tokyo Women's Medical University, Tokyo, [2]Department of Health and Community Medicine, Saitama-ken Saiseikai Kurihashi Hospital, Saitama, Japan.

Background and aims: Pre-diabetes is an intermediate stage between normal glucose and diabetes. It includes impaired fasting glucose on fasting plasma glucose (FPG) (110-125 mg/dL) and impaired glucose tolerance on 2-hour plasma glucose on a 75g oral glucose tolerance test (140-199 mg/dL). Individuals with pre-diabetes have a high risk of developing diabetes mellitus (DM). However, there is no clear cut-off point for HbA1c to define pre-diabetes. The aim of the study was to identify the cut-offs for HbA1c with respect to incidence of DM on HbA1c.
Materials and methods: We registered participants who underwent general health check up at SSK hospital from February 2006 to January 2007 as baseline and followed them for five years until January 2012. 3,826 subjects who had FPG <126 mg/dl (mean follow-up period 4.0 ± 1.4y) and 2,772 subjects who had HbA1c <6.5% (mean follow-up period 4.0 ± 1.4y) were analyzed respectively. Diabetes was diagnosed if HbA1c ≥6.5% (HbA1c-DM) or FPG ≥126 mg/dl (FPG-DM) at least once during the follow-up period. We assessed the risk of developing diabetes according to different stage of glucose tolerance by survival analysis using the Cox proportional hazards model. Receiver operating characteristic (ROC) curve analysis was used to identify the optimal cut-off point for incidence of diabetes on FPG and HbA1c, respectively.
Results: Of the 3,826 subjects with FPG<126mg/dL, 129 (3.4%) developed FPG-DM while of the 2,772 subjects with HbA1c<6.5%, 74 (2.7 %) developed HbA1c-DM. In the survival analysis, hazard ratios (HRs) for incidence of diabetes increased with deteriorating levels of FPG and HbA1c ($p < 0.001$ for both) after adjustment for age at baseline, sex, body mass index, waist circumference, systolic blood pressure, and total cholesterol. In addition, HRs of incidence of FPG-DM for FPG of 100-109 and 110-125 mg/dl were 7.5 (95% confidence intervals: 4.0 -14 .0) and 66.7 (37.6-118.2) compared with FPG < 100 mg/dl. HRs for incidence of HbA1c-DM for HbA1c of 5.6-5.9% and 6.0-6.4% were1.6 (0.4-6.0) and 77.9 (26.8-226.2) compared with HbA1c <5.6%. Area under the ROC curve for FPG and for HbA1c were 0.92 (0.90-0.95) and 0.92 (0.88-0.96), respectively. Sensitivity and specificity were 88% and 99% for FPG of 100mg and 86% and 91% for HbA1c of 6.0%, respectively.
Conclusion: The optimal cut-off value for HbA1c to define pre-diabetes with respect to incidence of diabetes may be 6.0% in a 5-year prospective Japanese cohort study.

277

Phenotypes and biochemical characteristics of new diabetes patients diagnosed based on different criterion: HbA_{1c} recognises people with more advanced diabetic stage

S. Ilhan[1], Y. Tutuncu[1], S. Gedik[1], F. Turker[1], N. Dinccag[1], K. Karsidag[1], B. Omer[2], S. Kalaca[3], A. Telci[2], S. Genc[2], T. Yilmaz[1], B. Cakir[4], J. Tuomilehto[5], The TURDEP-II Study Group;
[1]Endocrinology and Metabolism, Istanbul University, Turkey, [2]Clinical Biochemistry, Istanbul University, Turkey, [3]Public Health, Marmara University, Istanbul, Turkey, [4]Endocrinology and Metabolism, Yildirm Bayezit University, Ankara, Turkey, [5]Center for Vascular Prevention, Danube University, Krems, Austria.

Background and aims: Gycated haemoglobin A1c (A1C), fasting plasma glucose (FPG) and oral glucose tolerance test (OGTT) are universally accepted diagnostic tools to identify people with previously unknown type 2 diabetes (NewDM). However, each test could recognize people with different risk factors, and the agreement between these three tests is not high enough. We aimed to compare phenotypes and biochemical features of NewDM groups identified based on FGP, OGTT, and A1C criterion.
Materials and methods: Data derived from recently completed cross-sectional population-based Epidemiologic Survey on Diabetes, Obesity, Hypertension and Endocrine Disease in Turkey (TURDEP-II) that was included 26,499 people (age: ≥20 years, response rate: 87%, women: 63%). We used all of the diagnostic tools to diagnose NewDM (A1C: ≥6.5% or FPG: ≥126 mg/dL or OGTT-2hPG: ≥200 mg/dL) and compare their characteristics.
Results: The prevalence of NewDM based on FPG was 4.6%, that of OGTT: 3.8%, and A1C: 3.4%. OGTT was the most frequent test without any agreement with the others (isolated OGTT-based NewDM was 76.4% vs. 16.0% isolated A1C-based, and 9.4% isolated FPG-based NewDM, $p<0.001$). A1C was the most frequent test found in agreement with one of the other two (Combined New DM based on A1C plus FPG or OGTT: 68.5% vs. FPG plus OGTT or A1C: 44.7% vs. OGTT plus FPG or A1C: 17.8%). Agreement of all three tests together was 2.2% within FPG, 2.4% within OGTT, and 2.9% within A1C-based NewDM groups. NewDM based on FPG was more prevalent among men ($p<0.001$); these peoples were younger ($p<0.001$ and more smoker ($p<0.001$); they had higher insulin ($p=0.011$) and IGF1 ($p<0.001$) but lower cystatin C ($p<0.001$) levels. Whereas NewDM based on OGTT criterion identified more women ($p<0.001$), more elderly people ($p<0.001$), more people with hypertension (HT) ($p<0.001$). On the other hand, NewDM based on A1C criterion identified more men and more people in middle age ($p<0.001$); family history of DM ($p=0.045$), heavy alcohol use ($p=0.018$), prevalent HT and obesity ($p<0.001$) was more common among these group of people; they had higher BMI, waist and systolic BP ($p<0.001$), higher diastolic BP ($p=0.002$), higher FPG, OGTT-1hPG, OGTT-2hPG and A1C ($p<0.001$),

moderately higher insulin (p=0.001), higher HOMA-IR, lower IGF1, higher IGFBP3, lower eGFR (MDRD), higher triglycerides, lower HDL-chol and higher nonHDL-chol (p<0.001). Among central obese and less physically active people, NewDM was more prevalent based on all three diagnostic tests (p<0.001 for all).

Conclusion: Our results indicated that each diagnostic method identifies NewDM people with different clinical and biochemical characteristics. A1C based method recognizes people in more advanced stage of DM. Therefore, we recommend that these people should be treated more aggressively than those diagnosed with FPG or OGTT-based criterion. This study was funded by The Turkish Scientific and Technical Research Council (No. 109S166), and The Society of Endocrinology & Metabolism of Turkey.

Prediction of diabetes mellitus using HbA_{1c}: Does HbA_{1c} more efficiently predict onset than plasma glucose concentration?

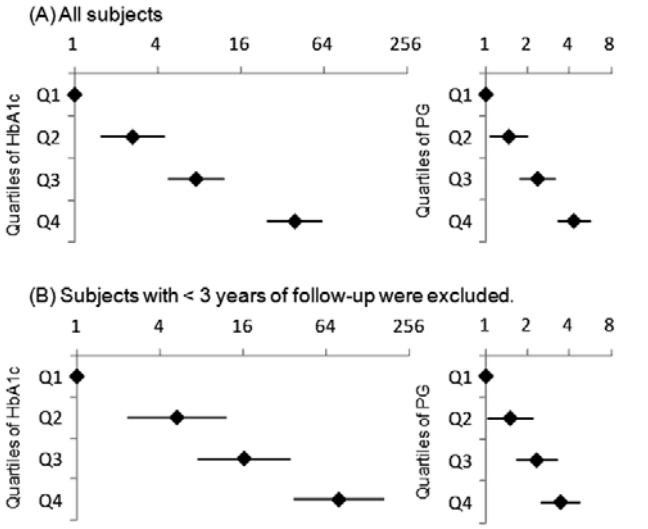
N. Tanabe[1], M. Yamamoto[2], T. Momotsu[2], K. Suzuki[2], K. Sanpei[2], H. Sone[3];
[1]Department of Health and Nutrition, Faculty of Human Life Studies, University of Niigata Prefecture, Niigata, [2]Sado General Hospital, Sado, [3]Division of Hematology, Endocrinology and Metabolism, Department of Internal Medicine, Niigata University Faculty of Medicine, Niigata, Japan.

Background and aims: HbA1c concentration is a reliable indicator of blood glucose control in diabetic patients. HbA1c as well as plasma glucose (PG) concentrations are widely used to identify subjects at high risk of developing diabetes mellitus (DM) in Japan. However, there is limited evidence that HbA1c concentrations comparably or more efficiently predict the risk of DM onset in comparison with PG. This paper evaluated the utility of HbA1c in predicting the risk of DM onset and compared it with that of PG.

Materials and methods: The Sado cohort consists of 8,462 inhabitants, comprising 3,526 men and 4,936 women aged 27-92 years, of Sado City located on Sado Island in the Sea of Japan. The baseline data for 761 participants were obtained in 2002, and for the remaining 7,701 participants in 2003. From those participants, 5,044 DM-free subjects aged 40-89 years and comprising 1,875 men and 3165 women, underwent baseline assessment of HbA1c and PG concentrations and were monitored for the onset of DM until 2011 through annual health check-ups organized by Sado City. A subject was considered to have developed DM when he/she declared to have been diagnosed with DM, or when he/she met any of following criteria: 1) fasting PG ≥ 7.0 mmol/L, 2) casual PG ≥ 11.1 mmol/L or 3) HbA1c ≥ 6.5% (NGSP). The follow-up period was determined on the basis of age at diagnosis or the date of blood sampling. Baseline PG and HbA1c concentrations were assessed in quartiles and the association with the risk of DM onset was evaluated using hazard ratios (HRs) and 95% confidence intervals (CIs) derived from sex- and age-adjusted Cox proportional hazards models. For PG, quartile categories were fasting-interval specific.

Results: During the 29,727 person-years of follow-up, 5.9 years per person in average, 539 instances of DM onset were identified. The annual incidence rate was 18.1/1000/year (21.0/1000/year for men and 16.4/1000/year for women). Although both HbA1c and PG were positively associated with the risk of DM onset, the association was much stronger for HbA1c than for PG (Figure A). The sex- and age-adjusted HR (CI) for DM onset for the highest quartile compared with the lowest quartile was 39.3 for HbA1c (24.9-62.1) and 4.3 (3.3-5.7) for PG. When subjects with a <3-year follow-up period were excluded from the analyses, the HR (CI) for the highest vs. the lowest quartiles of HbA1c was elevated to 78.9 (37.0-168.5), although that of PG was decreased to 3.5 (2.5-4.8) (Figure B).

Conclusion: High HbA1c concentrations more closely associate with a high risk of DM onset than high PG concentrations. The longer the follow-up period, the stronger this association will be for HbA1c but not for PG.



Sex- and age-adjusted hazard ratios for the onset of diabetes mellitus according to quartiles of HbA1c and plasma glucose (PG) concentrations

Average glucose and respective glycated haemoglobin values in patients with type 2 diabetes: reappraisal of the ADAG study

E. Franek[1], J. Rzeszotarski[2], P. Bijos[3], J. Jozwiak[4], A. Zonenberg[5], M. Masierek[6];
[1]Dept of Internal Diseases, Endocrinology and Diabetology, Central Clinical Hospital MSW, Warsaw, [2]10th Military Hospital, Bydgoszcz, [3]Private practice, Warsaw, [4]Czestochowa University of Technology, Czestochowa, [5]Medical Institute of Higher School of Computer Sciences and Business Administration, Lomza, [6]BIOTON SA, Macierzysz, Poland.

Background and aims: The results of ADAG study, recommended by ADA guidelines and widely used for a calculation of HbA1c from average glucose values, were achieved in healthy subjects, patients with type 1 and in only 159 with type 2 diabetes. The aim of the study was to validate those results in a large group of type 2 diabetic patients.

Materials and methods: A prespecified analysis of data from the PROGENS HbA1c study was performed. In 4257 patients with type 2 diabetes (mean age 63.7±9.4 years, mean BMI 30.3±4.5 kg/m2, time from diagnosis 9±5.5 years) treated with premixed insulin with or without oral antidiabetic drugs, HbA1c (using a multitest HbA1c analyser A1cNow+) and average blood glucose from the preceeding 90 days (ABG 90 days), calculated automatically from all values measured by the glucometer, were assessed at visits 2 and 3.

Results: The results of the PROGENS study differ from those from ADAG study by different slope of the regression line (and therefore different glucose values assigned to HbA1c) and broader distribution of the results by lower HbA1c values (Table 1). The probability existence of real HbA1c>7% in patients with ABG 90 days = 140 mg/dl was equal 0.53 (0.51-0.55), with ABG 90 days = 100 mg/dl was still 0.22 (95%CI 0.18-0.25).

Conclusion: Broad use of the results achieved in the ADAG study for the assessment of diabetes control in subjects with no HbA1c value seems to be inappropriate. The probability of wrong assessment of the HbA1c target using only the value calculated from ABG 90 days using ADAG data is high. Therefore HbA1c seems to be necessary for the proper assessment of diabetes control, and average blood glucose estimation as a tool that may replace HbA1c should not be recommended.

Table 1. Comparison of PROGENS HbA1c and ADAG studies

HbA1c [%]	ABG PROGENS (95% CI)	ABG ADAG (95% CI)
6	134,4 (93-175,7)	126 (100-152)
7	149,3 (107,9-190,6)	154 (123-185)
8	164,1 (122,8-205,5)	183 (147-217)
9	179,0 (137,6-220,4)	212 (170-249)
10	193,9 (152,5 -235,3)	240 (193-282)
11	208,8 (182,1-265,2)	269 (217-314)
12	223,7 (195,4-278,9)	298 (240-347)

Relationship between haemoglobin and glycated haemoglobin A_{1c} in a Japanese population

T. Nakagami[1], J. Oya[1], Y. Yamamoto[1], Y. Hasegawa[1], M. Kurita[1], Y. Tanaka[1], T. Kasahara[2], Y. Uchigata[1];
[1]Diabetes Centre, Tokyo Women's Medical University School of Medicine, [2]Josai Hospital, Tokyo, Japan.

Background and aims: The recommendations for the use of hemoglobin A1c (HbA1c) as a diagnostic test is likely increase its use in individuals without a prior history of diabetes. However, HbA1c measurements have several limitations. Plasma glucose molecules attach the hemoglobin (Hb) in erythrocyte through non-enzymatic glycation that results in a small Hb variant of HbA1c. The condition affecting characteristics of Hb, erythrocyte turnover and Hb glycation would influence on HbA1c levels independent from blood glucose levels. Thus, there may be difference in the relation between blood glucose levels and HbA1c values. The HbA1c values are calculated as the ratio of glycated hemoglobin to total Hb, suggesting that Hb may affect HbA1c levels independent from blood glucose levels. Thus, the aim of the study is to assess the relationship between HbA1c and Hb in non-anemic and non-diabetes Japanese population.
Material and methods: Subjects were 31.081 individuals (17,780 men) aged 30 to 75 years old without anemia (men: Hb<13.5 g/dL, women: Hb<11.5 g/dL), Hb with above reference range (men: Hb>17.5 g/dL, women: Hb>15.5 g/dL), self-reported diabetes, fasting plasma glucose (FPG) >=126 mg/dL, HbA1c >=6.5%, or chronic kidney disease (creatinin>1.5 mg/dL) from general health check-up program in Japan. Subjects were classified according to FPG by quintiles (men: <87, 87-90, 91-94, 95-100, >=101 mg/dL, women: <82, 82-85 86-89, 90-94, >=95 mg/dL) and Hb by tertiles (men: <15.1, 15.1-15.7,>=15.8 g/dL, women: <13.1, 13.1-13.7, >=13.8 g/dL), respectively in men and women. Mean HbA1c levels were calculated in FPG quintiles across Hb tertiles. General linear model was used to calculate age- and Hb-adjusted mean HbA1c levels in FPG quintile categories. Multivariate linear regression analysis was performed to analyze factors affecting on HbA1c levels.
Results: HbA1c increased with increase of FPG in both men and women (p<0.001 for both). Subjects with lower Hb had significantly higher HbA1c at given FPG in both sexes (p<0.001). This trend was consistent though FPG quintiles of no-diabetic FPG range (p <0.001), and the difference of mean HbA1c levels at given FPG decreased with deterioration of FPG. Women had lower mean HbA1c levels than men in the same age except for age >=55 years old. Women had higher age-adjusted mean HbA1c levels than men at given FPG across all FPG categories (p<0.001), but had lower age- and Hb-adjusted mean HbA1c levels than men at given FPG across all FPG categories (p<0.001). Older age (beta=0.104 for 10 years, p<0.001), higher FPG (beta=0.306 for 1 mmol/L, p<0.001), women (beta=0.0124, p=0.038) and lower Hb (beta=-0.016 for 1g/dl, p<0.001) were independently related with an increase of HbA1c.
Conclusion: Hb and sex influence on HbA1c values independent from glucose concentrations in non-anemic and non-diabetes Japanese population. This should be considered as one of limitations to use diagnostic criteria for diabetes on HbA1c.

'Tracking' of metabolic parameters in patients with diabetes: Are we making a difference?

J. Sangha, P. Narendran;
School of Clinical and Experimental Medicine, University of Birmingham, UK.

Background and aims: The morbidity and premature mortality associated with type 1 and type 2 diabetes (T1D, T2D) can be improved through optimised metabolic control. Indeed this is a major driver for the regular review of diabetic patients. Previous studies have however demonstrated that glycated haemoglobin (HbA_{1c}) levels 'track' within clinic populations. That is, average values for HbA_{1c} rarely improve over time within a given diabetic population. Our aim was to explore secular trends within a large diabetic clinic for 1) average clinic HbA_{1c} , 2) HbA_{1c} within individual diabetic patients, and 3) lipid and BP at a clinic and individual level.
Materials and methods: We used diabetes clinic data from the our university hospital during the period 2008-2013. At each clinic visit, HbA_{1c} and metabolic parameters (cholesterol, triglycerides, creatinine, BP, BMI) are measured. In total, 1051 T1D patients and 2956 T2D patients visited our clinic during the study period. Linear regression was used to evaluate secular trends in mean clinic parameters (using 6 monthly intervals), and to determine predictors of intra-individual mean parameter levels. To further assess intra-individual tracking, we performed a paired t-test to compare differences in values between first and last clinic visits (analyses were restricted to cases in which the time difference between first and last available visits was over one year). All analyses were performed using SPSS.
Results: Secular trends in mean clinic HbA_{1c} and metabolic parameters. In T1D, average clinic values for HbA_{1c} and all metabolic parameters remained constant during the study period, with the exception of cholesterol levels which rose from 4.19 to 4.70 mmol/L (β = 0.081, p<0.001). In T2D, all parameters remained constant except HbA_{1c} which rose from 65.4 to 66.9 mmol/mol (β = 0.047, p<0.001). Predictors of intra-individual mean HbA_{1c} and metabolic parameters. In T1D for all parameters, the patient's individual mean parameter value (averaged out across all of their clinic visits), was predicted by the parameter value at both the first available and last visit (p<0.001 respectively). This was also evident for all parameters in T2D (p<0.001 respectively). Intra-individual tracking. In T1D, there was no significant difference between the parameter value at the first clinic visit and the parameter value at the last visit for all parameters other than systolic BP, which rose from an average of 134 to 137 mmHg (p<0.01). In T2D, HbA_{1c} (mean difference 1.58mmol/mol, p<0.01), triglycerides (mean difference 0.20mmol/L, p<0.001), and BMI (mean difference 0.24, p<0.05) were all lower on the most recent clinic visit. However, both systolic (mean difference 2.54, p<0.001) and diastolic (mean difference 1.61, p<0.05) BP increased.
Conclusion: We demonstrate intra-individual tracking of HbA_{1c} and all metabolic parameters in T1D. This indicates that those patients with high parameter values will continue to suffer from poor control years later, increasing their risk of long-term complications. Our results support other studies of 'glycaemic tracking', but extend it to an intra-individual level, as well as to other metabolic parameters. Further studies are required to determine whether current medical management in these patients is failing, whether there is a biological underpinning to this tracking, and whether regular clinic attendance provides benefits outside the classical parameters used in our study.

282

The threshold of glycated haemoglobin and diabetic complications: a community-based screening programme in Shanghai

C. Pang[1], X. Hou[1], Y. Bao[1], Y. Zuo[2], S. Jiang[3], W. Jia[1];
[1]Department of Endocrinology and Metabolism, Shanghai Jiaotong University Affiliated Sixth People's Hospital, [2]Shanghai Caoyang health center, [3]Shanghai Huayang Health Center, Shanghai, China.

Background and aims: To determine the association of HbA1c with diabetic complications and whether such relationship supports the previously proposed diagnositc threshold of diabetes (≥6.3%) in Chinese adults.
Materials and methods: A total of 1996 Chinese subjects were recruited from urban communities in Shanghai and screened for diabetic retinopathy, nephropathy, neuropathy and peripheral arterial disease. Diabetes and impaired glucose regulation were diagnosed with a 75g OGTT. Nephropathy was defined as an elevated morning urine albumin-to-creatinine ratio (30 mg/g or higher). The levels of diabetic retinopathy were identified with nonmydriatic

retinal photographs according to the Diabetic Retinopathy Disease Severity Scale. Peripheral neuropathy were assessed with Michigan Neuropathy Screening Instrument (MNSI) and impaired sensation was defined as MNSI scored over 2. Peripheral aterial disease (PAD) was assessed by measuring an ankle-brachial index (ABI) and defined as ABI ≤ 0.9 with an automatic device that incorporates a sphygmomanometer and 2-way Doppler. Stepwise Logistic regression and receiver operating curve (ROC) were performed to evaluate the risk factors for diabetic complications and the threshold of HbA1c.
Results: Excluding 236 participants with ungradable retinal photographys, 1758 subjects were analyzed, as included 616 with diabetes, 542 with IGR, 936 with hyptertension and 84 with obesity. Retinopathy, nephropathy, neuropathy and PAD were determined in 4.8%, 13.9%,13.9% and 5.3% of the analyzed subjects, separately. HbA1c was the only common risk factor for the four complications(OR for retinopathy: 1.66 [95% CI:1.49-1.86], for nephropathy: 1.35 [1.23-1.48], for neuropathy: 1.29 [1.18-1.42], for PAD: 1.19 [1.03-1.36]). Hypertension contributed to retinopathy (2.07 [1.23-3.49]) and nephropathy(2.26 [1.61-3.17]) . Aging was positively related to nephropathy (1.45 [1.26-1.65]), neuropathy (1.83 [1.60-2.09]) and PAD (1.85 [1.51-2.29]). The area under curve for retinopathy was 0.864 (0.707-0.822), nephropathy 0.644 (0.605-0.683), neuropathy 0.630 (0.590-0.670), PAD 0.622 (0.559-0.684). Based on the ROC and the diagnostic value of the different cut-off points, the observed optimal cut-off point was found to be 6.35% for retinopathy (figure 1).
Conclusion: HbA1c was positively associated with diabetic complications. An HbA1c cut-off point of over 6.3% for identifying diabetic retinopathy was supportive of complementary diagnostic criterion for diabetes in Chinese adults.

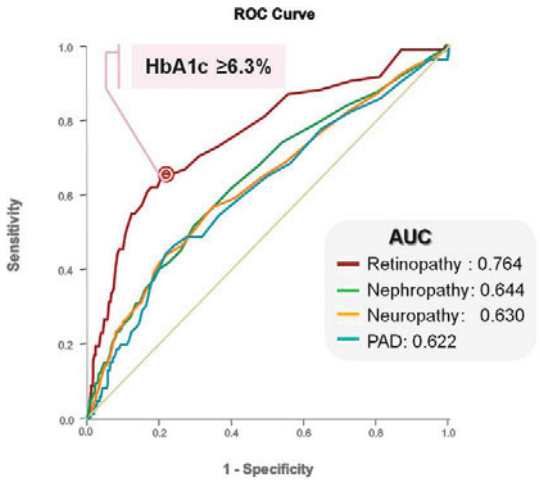

Figure 1. ROC curves for HbA1c (%) and the various diabetic complications

283

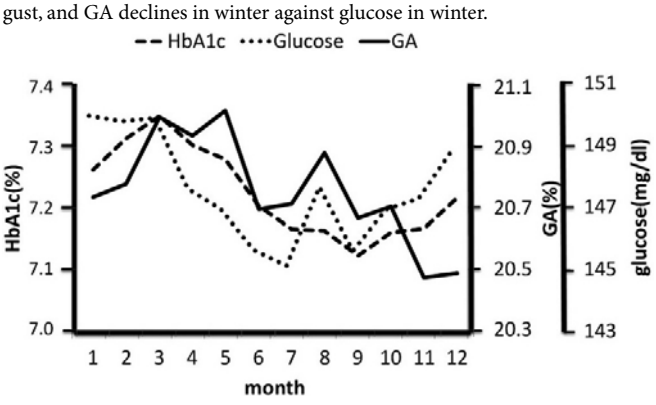
Seasonal variation in haemoglobin A_{1c} in adult Portuguese patients
M.T.R. Pereira, D. Lira, C. Bacelar, A.C. Carvalho;
Division of Endocrinology, Diabetes and Metabolism, Hospital de Santo António - Centro Hospitalar do Porto, Portugal.

Background and aims: Glycated Hemoglobin (HbA1c) reflects average glycemic control of the last 120 days and is used as a predictor of complications of diabetes mellitus. It was suggested that HbA1c seasonal fluctuations can be directly related to different biological, geographical and cultural parameters. The aim of this study was to evaluate of the HbA1c seasonal variation, starting from assays performed in a large cohort of patients over a period of 5 years (2008 to 2012).
Materials and methods: It was performed a retrospective analysis of all HbA1c assays performed to patients evaluated at a tertiary care university hospital during the period between 1st January 2008 and 31st December 2012. Both patients younger than 18 and HbA1c extreme values (<3% and/or >18%) were excluded.
Results: We obtained 62,384 HbA1c measurements during the period defined for the study. It was observed a cyclic seasonal fluctuation consistently repeated over the 5 years. Higher mean HbA1c levels were found in winter months (January-February), while lower mean HbA1c levels were found in the warm summer months (August-September), with an increasing level tendency from October (p <0,0001, Kruskal-Wallis test). There was a significant HbA1c maximal amplitude value of 0.33% (p <0,0001) between February-September, with mean HbA1c values fluctuations between 6.80% and 7.13%.
Conclusion: Seasonal HbA1c patterns were previously described in other studies and the explanation seems to be multifactorial (seasonal and festivities-related high calorie food intake, secondary insulin resistance, thermal effect on the metabolic axis, among others). The clinical importance of our findings is related to their practical implications, particularly regarding the need to improve the interpretation of HbA1c values. Restriction of HbA1c assay to specific times of the year may reduce the seasonal variation of physiological responses.

284

Difference of seasonal variation between glycated albumin and glycated haemoglobin A_{1c}
K. Tanaka, S. Meguro, T. Kawai, M. Tanaka, J. Irie, Y. Saisho, H. Itoh;
Internal Medicine, Keio University School of Medicine, Tokyo, Japan.

Background and aims: Glycated albumin(GA) is a product of the chemical binding of serum albumin and glucose by non-enzymatic oxidation reaction. It reflects 2-3week glycemic control, and has been used as a glycemic control indicator such as glycated hemoglobin A1c (HbA1c). GA potentially has an advantage compared to HbA1c as its measurement is not influenced by disorders of hemoglobin metabolism. It is a well-known fact that HbA1c has seasonal variations. Considering the same use of both GA and HbA1c, we then presume that GA also has seasonal variations like HbA1c.
Materials and methods: Subjects are all diabetic outpatients of our University Hospital from January 2005 to December 2011, whose HbA1c and GA were examined simultaneously. Casual plasma glucose was also measured simultaneously in the most subjects. HbA1c was measured by HPLC, and GA was measured by an enzymatic method. We analyzed monthly means of plasma glucose, GA, and HbA1c each year with monthly average temperature in Tokyo reported by the Japan Meteorological Agency.
Results: The number of outpatient per month was 1665.6 ± 288.4 (mean ± SD), mean age was 64.2 ± 12.5. Our analysis showed that plasma glucose was recorded highest in January and February, lowest in June and July. It then reascended in August, and declined in September. HbA1c was recorded highest in February and March, and lowest in August and September. GA was highest in March, lowest in November. It also reascended in August, then declined in September. GA tended to have a disjunction with plasma glucose in winter. Plasma glucose and HbA1c showed significant inverse correlations with monthly mean temperature in Tokyo (rs = -0.520, p < 0.001, rs = -0.419, p < 0.001, respectively), but GA did not intercorrelation with temprature.
Conclusion: GA and HbA1c have different seasonal variations from each other. They do not necessarily have same relationship with glucose elevation as below graphs show. HbA1c does not respond to glucose elevation in August, and GA declines in winter against glucose in winter.



PS 003 Prevalence and incidence of diabetes

285

Incidence and risk factors of new-onset diabetes mellitus after lung transplantation

S. Thilmany[1], J. Jamart[2], P. Evrard[3], J.E. Donckier[1];
[1]Endocrinology and Diabetes, [2]Biostatistics, [3]Intensive Care Unit, CHU Mont-Godinne - Dinant, Université Catholique de Louvain, Yvoir, Belgium.

Background and aims: New-onset diabetes mellitus after transplantation (NODAT) is a common complication in renal and liver transplant recipients but has been less extensively studied after lung transplantation. The objective of this study was to examine the incidence of NODAT in our centre and its risk factors and complications.
Materials and methods: We reviewed the medical records of 108 patients who received single or double lung transplants from January 1995 to July 2012. Mean (± SD) age was 52.6 ± 11.4 years. Most patients had chronic pulmonary obstructive disease/emphysema but 9 patients had cystic fibrosis. Immunosuppressive therapy consisted in cyclosporine, azathioprine and methylprednisolone in all patients. Tacrolimus was introduced only if there were contraindications or side effects to cyclosporine. NODAT was diagnosed after at least 3 months post-transplant on the basis of fasting plasma glucose ≥ 7 mmol/l or random glucose ≥ 11.1 mmol/l on two or more separate days in association with symptoms of diabetes or HbA1c ≥ 6.5 %.
Results: Fourteen patients were diabetic before transplantation whereas NODAT was diagnosed in 38 patients (40.4 %). Using Kaplan-Meier estimates, the incidence of NODAT was 30 % after one year and 45 % after 5 years, for a mean duration of follow-up of 4.2 ± 0.5 years. A multivariate Cox regression analysis showed that an age ≥ 50 years and cystic fibrosis were independent risk factors for the development of NODAT (p = 0.032 and p = 0.005 respectively). There was a tendency for patients with NODAT to have lower vitamin D levels (p = 0.096). Other factors such as sex, body mass index, type of immunosuppressive therapy, CMV or hepatitis B immune status were unrelated to NODAT. Main complications included rejection episodes in 46 cases, infections in 89, renal failure in 51 and cerebral vascular accidents in 3. NODAT was significantly more common in infected patients (45 % versus 14 % in non infected patients; p = 0.032). Survival rates were not significantly different between diabetic and non diabetic patients.
Conclusion: NODAT was diagnosed in 40.4 % of patients, a figure comparable with other solid organ transplants. The main risk factors for NODAT were an age ≥ 50 years and cystic fibrosis. NODAT was more frequently associated with infections.

286

20 years of type 1 diabetes registry of Catalonia

C. Castell[1], N. Lara[1], A. Daroca[1], R. Milà[2], C. Cabezas[1];
[1]Public Health Agency, [2]Barcelona University, Barcelona, Spain.

Background and aims: Type 1 Diabetes mellitus (DM1) is the most common chronic diseases in childhood and adolescence, particularly in industrialized countries. The Catalan Type 1 diabetes Registry has been recording new cases of type1 diabetes since 1987. Trends in incidence rate during the 24 year period 1989-2010 are described.
Materials and methods: Patients under 30 at diagnosis of DM1, according to WHO criteria, were included in a prospective way. Health professionals and patients association were the primary and secondary sources of ascertainment, respectively. Incidence rates were estimated using Poisson regression models. Completeness of registration was assessed using capture-recapture methodology.
Results: 6310 new cases of DM1: 3713 men, 2597 women under 30 at diagnosis were identified during the period January 1987 - December 2010. There is a similar distribution between the group of 0-14 years (3139) and the group of 15 to 29 years (3171) with a predominance of men in the latter group. The degree of completeness of the registry overall has been estimated at 90.1%. Age and sex -specific rates varied from 11.0 per 100.000 per year (95% CI 9.7-12.3) during 1987-1989 to 8.9 per 100.000 per year (95%CI 7.7-10.2) during 2005-2010. There were no differences between the eight regions of Catalonia.
Conclusion: Incidence rate of Type 1 diabetes in Catalonia is stable. There is no pattern in the geographical distribution in the incidence of type 1 diabetes in Catalonia.

287

The incidence of type 1 diabetes mellitus in Romanian children aged 0-17 years increased significantly between 2002 and 2011

A. Vlad[1], V. Serban[1,2], R. Timar[1], B. Timar[1], A. Sima[1], M. Rosu[1], ONROCAD Study Group;
[1]Diabetes Clinic, University of Medicine and Pharmacy, Timisoara, [2]Medical Center "Cristian Serban", Buzias, Romania.

Background and aims: The epidemiology of type 1 diabetes mellitus (T1DM) is a matter of interest worldwide. Its recent time trends in Romanian children aged between 0 and 17 years have not yet been analyzed. The aim of this work was to reveal the evolution, over a 10-year interval, of the incidence of childhood T1DM in Romania.
Materials and methods: The primary source for incident cases of T1DM was the Romanian Childhood Diabetes Register (RCDR), elaborated each year by ONROCAD (Romanian acronym for "Romanian National Organization for the Protection of Children and Adolescents with Diabetes") since 1996. The secondary source was represented by the medical records from Medical Center "Cristian Serban" from Buzias, a reference center for pediatric diabetes, where T1DM children from all over the country are admitted and treated. Demographic data were retrieved from the National Institute for Statistics. The incidence was calculated per calendar year and 100,000 population at risk in age groups 0-4, 5-9, 10-14, 15-17, and 0-17 years. The statistic methods used were chi-square test, chi-square test for trend, and Wilson's procedure for the 95% confidence interval (CI). Statistical significance was set at $p<0.05$.
Results: A number of 3,196 new cases of type 1 DM (1,696 - 53.1% boys, and 1,500 - 46.9% girls), aged less than 18 years, were found in both sources. The primary source detected 3,144 cases, and the secondary source 964 cases (912 patients were diagnosed by both sources), leading to a level of ascertainment was 96.2% The main data regarding the incidence of T1DM in Romanian children, between years 2002 and 2011, are shown in the table. The estimated average incidence of T1DM during the studied interval was 7.35/100,000/year (95% CI 6.58 - 8.12). It was not significantly (p=0.53) higher in boys (7.62/100,000/year, 95% CI 6.53 - 8.71) than in girls (7.08/100,000/year, 95% CI 5.99 - 8.17), leading to a sex ratio for incidence (boys/girls) of 1.08. The incidence in children 0-17 raised extremely significantly ($p<0.0001$) during the studied interval, being 50.5% higher in 2011 as compared to 2002 (mean annual increase 5.61%). This trend was noticed for age groups 0-4, 5-9, and 10-14 years, but not for children aged 15-17 years.
Conclusion: Romania is a country with an intermediate incidence of T1DM in children that showed a continuous increase over a decade. Children aged 10-14 years have the highest probability of developing T1DM. Boys seem to be more predisposed than girls.

Incidence of T1DM (no. of cases/100,000) in Romanian children aged 0-17 years, between 2002 and 2011

Year	0-4 yrs (T)	5-9 yrs (T)	10-14 yrs (T)	15-17 yrs (T)	0-17 yrs (T)	0-17 yrs (B)	0-17 yrs (G)
2002	3.17	7.41	7.34	6.22	6.18	6.95	5.38
2003	3.58	6.74	8.32	5.78	6.31	6.72	5.87
2004	3.54	8.59	8.07	6.49	6.78	7.65	5.88
2005	4.14	7.40	8.68	6.54	6.79	6.94	6.64
2006	3.97	8.94	9.28	6.42	7.25	7.77	6.70

Undiagnosed diabetes and prediabetes in the Bangladeshi population

M. Das[1,2], K. Islam[3], M. Sahabuddin[3], Z. Hassan[2], M. Khalequzzaman[1], L. Ali[4];
[1]Institute of Biological Sciences (IBSc), Rajshahi University, Rajshahi, [2]Physiology and Molecular Biology, BIRDEM, Dhaka, [3]Biotechnology and Genetic Engineering, Khulna University, Khulna, [4]Biochemistry and Cell Biology, Bangladesh University of Health Sciences (BUHS), Dhaka, Bangladesh.

Background and aims: Due to lack of properly organized health care facilities, there is no systematic screening performed for chronic diseases in Bangladesh. Accordingly, a large number of people remains undiagnosed and silently progress towards complications. The present study was undertaken to find out the proportion of undiagnosed diabetes and prediabetes as well as their determinants in a general population of Bangladesh.
Materials and methods: Under a cross-sectional observational design, a total number of 1303, middle aged (range 35-60 years) healthy subjects, responding to open invitation for health check in three districts of Bangladesh, were recruited in the study (male 58.3% and female 41.7%; mean(±SD) age 42.7(±10.0) and 41.3(±8.9) years respectively. Among the participants 46.2% were from rural and 53.8% from urban areas. A two sample oral glucose tolerance test was performed and anthropometric measurements were taken. Glucose was estimated by glucose-oxidase method and triglyceride, total cholesterol and HDL were measured by enzymatic-colorimetric method. LDL was calculated by using Friedewald's formula. Anthropometric, glucose and lipid abnormalities were defined and classified as per WHO criteria. Data were analyzed using statistical Package for Social Program (SPSS) for Windows version 17.
Results: Among the total subjects, type 2 diabetes was 14.3% and impaired glucose regulation was 17.8% (impaired fasting glucose 3.3%, combined impaired fasting glucose - impaired glucose tolerance 3.1% and impaired glucose tolerance 11.5%). The proportion of type 2 diabetes was more than two times higher in urban (18.5%) compared to the rural (8.0%) areas ($p<0.001$). However, the proportion of impaired glucose regulation was only marginally higher in urban (20.1%) compared to the rural (15.4%) areas ($p<0.05$). Type 2 diabetes ($p<0.001$) and impaired glucose regulation ($p<0.01$) subjects were significantly older compared to the normoglycemic. BMI [type 2 diabetes ($p<0.002$); impaired glucose regulation ($p<0.001$)] and WHR [type 2 diabetes ($p<0.001$); impaired glucose regulation ($p<0.01$)] were significantly higher compared to normoglycemic. Pearson correlation analysis showed positive correlation of fasting glucose with age ($p<0.001$), WHR ($p<0.006$), triglyceride ($p<0.001$), cholesterol ($p<0.001$) and LDL ($p<0.001$), and it showed a negative correlation with HDL ($p<0.03$). Multinomial regression showed significant association of type 2 diabetes subjects with WHR ($p<0.002$), triglyceride ($p<0.001$) and area of residence ($p<0.003$); however, the impaired glucose regulation subjects showed significant association only with WHR ($p<0.033$) and triglyceride ($p<0.031$).
Conclusion: Type 2 diabetes and impaired glucose regulation remain undiagnosed in a high proportion of Bangladeshi population and age, central obesity and urbanization are among the major determinants of type 2 diabetes and impaired glucose regulation in this population.

289

Undiagnosed type 2 diabetes remains an important health problem disproportionately affecting Irish males: the diabetes mellitus and vascular health initiative (DMVhi)

M. Sinnott[1], A. Jackson[1], B. Kinsley[2], C. Walsh[3], T. O'Grady[1], P. Gaffney[4], G. Boran[4], J.J. Nolan[5], C. Kelleher[6], B. Carr[1];
[1]Vhi Healthcare, Dublin, Ireland, [2]Mater Misericordiae University Hospital, Dublin, Ireland, [3]Department of Statistics, Dublin, Ireland, [4]Tallaght Hospital, Dublin, Ireland, [5]Steno Diabetes Center, Copenhagen, Denmark, [6]UCD School of Public Health, Physiotherapy and Population Science, Dublin, Ireland.

Background and aims: Early identification of those with or at greatest risk of developing type 2 diabetes (T2D) is a challenge. Knowledge of local disease burden and epidemiology is important for appropriately targeting healthcare interventions. In the Republic of Ireland, information on undiagnosed T2D is limited and until now has been indirectly estimated or extrapolated from small regional studies. This abstract looks at gender differences in prevalence of undiagnosed T2DM, IGT and IFG in men and women by screening 30 000 people.
Materials and methods: The Diabetes Mellitus and Vascular health initiative (DMVhi) is a prospective, longitudinal study of Irish adults, policy holders in the largest private health insurer, aged 45-75 years without known T2D. At baseline, 29 144 participants completed screening: detailed medical questionnaire; fasting plasma glucose (FPG), lipid profile, blood pressure, weight, height, BMI, waist circumference, and waist:hip ratio were measured. Those with FPG ≥5.6≤6.9mmol/L had an Oral Glucose Tolerance Test (OGTT) performed. Those with a FPG ≥7.0mmol/L had a repeat FPG. Diabetes Risk Score was calculated based on FINRISC.
Results: Abnormal glucose concentrations (T2D, IGT and IFG) were detected in 11.9% of the DMVhi population; prevalence rates were 17.1% in males and 7.8% in females. Prevalence increased with age in both males (10.6%, 18.5%, 21.7% among those aged 45-54, 55-64 and 65-75 years) and females (4.3%, 8.6%, 10.9% respectively). Of the participants with T2D, 69.3% were male, 27.4% exercised ≥5 days/week, 91.4% had a BMI ≥25kg/m^2, 95.3% had abdominal obesity (waist circumference ≥80cm in females, ≥90cm in males), and 46.2% had a family history of diabetes. Risk factors with significant odds ratios of association with T2D included being male, older age, elevated blood pressure, higher BMI, abdominal obesity, family history of diabetes and elevated triglyceride levels. Few gender differences in risk factors were detectable, suggesting that the determinants of disease are similar in males and females. However, proportionally more males than females in our cohort had these risk factors. Compared to DMVhi females, males had a higher BMI (27.5 vs. 26.1 kg/m^2), higher systolic BP (126.4 vs. 123.3 mmHg), more abdominal obesity (79.2% vs. 65.6%), use of anti-hypertensive medication (22.7% vs. 18.9%), consumed alcohol (82.9% vs. 77.3%) and smoked (current and ex-smokers) (47.4% vs. 34.0%).
Conclusion: Undiagnosed T2D and pre-diabetes is an important health problem in Irish adults, particularly in Irish males. A better understanding of why males have a greater prevalence of disease is required. Our data suggest males have proportionally more risk factors for disease than females. Knowledge of risk factors associated with having abnormal glucose from the DMVhi could help focus limited healthcare resources on those at greatest risk of disease development.

290

Regional differences in the incidence of known type 2 diabetes mellitus in 45-74 years old individuals: results from five population-based studies in Germany

S. Schipf[1], T. Ittermann[1], T. Tamayo[2], W. Maier[3], C. Meisinger[4], K.H. Greiser[5], G. Mueller[6], S. Moebus[7], H. Völzke[1];
[1]Institute for Community Medicine, University Medicine Greifswald, [2]German Diabetes Center, Leibniz Center for Diabetes Research at Heinrich-Heine-University, Düsseldorf, Institute of Biometrics and Epidemiology, Greifswald, [3]Helmholtz Zentrum München, German Research Center for Environmental Health (GmbH), Institute of Health Economics and Health Care Management,, Neuherberg, [4]Institute of Health Economics and Health Care Management, Institute of Epidemiology II, Neuherberg, [5]Division of Cancer Epidemiology, German Cancer Research Center (DKFZ), Heidelberg, [6]Institute of Epidemiology and Social Medicine, University of Muenster, [7]Institute for Medical Informatics, Biometry and Epidemiology, University Hospital of Essen, University Duisburg-Essen, Germany.

Background and aims: Regional data on the incidence of type 2 diabetes are scarce. Population-based data are paramount to investigate the long-term course of diabetes, for planning in health care and to evaluate the cost-effectiveness of primary prevention. We analysed regional differences in the incidence of type 2 diabetes within Germany.
Materials and methods: Data of participants aged 45 to 74 years at baseline between 1997-2006 (mean follow-up 2.2 to 7.1 years) from five regional population-based studies were included. Information on the incidence of self-reported type 2 diabetes at follow-up was compared. The incidence rates per 1000 person-years (95% CI) and the cumulative incidence (95% CI) from regional studies were directly standardized to the German population (31 December 2007) and weighted by inverse probability weights for losses to follow-up.
Results: Of 8,814 participants, 526 (6.0%) developed type 2 diabetes corresponding to an incidence rate of 11.4 per 1000 person-years (95%CI 10.4-12.4). The regional incidence was highest in the East and lowest in the South of Germany with 16.9 (95%CI 13.3-21.8) vs. 9.3 (95%CI 7.7-11.3) per 1000 person-years, respectively. The incidence increased with age and was higher in men than in women.
Conclusion: Similarly to the previously reported gradient in the prevalence estimates for type 2 diabetes (Schipf et al. 2012) the incidence shows

a Southwest-to-Northeast gradient within Germany. Our results strengthen the hypothesis that the observed differences may partly linked to prevalence differences in common risk factors for type 2 diabetes.

Figure 1: Regional incidence rates (per 1000 person-years) of type 2 diabetes mellitus (45-74 years at baseline) standardized to the German adult population (31/12/2007).

New estimates of diabetes prevalence in the Netherlands, based on information from 5 million subjects (DUDE-1)

S.T. Houweling[1,2], N. Kleefstra[1,3], M. Meulepas[4], A. Romeijnders[5], M. Klomp[6], H.J.G. Bilo[1,3];
[1]Diabetes Centre, Isala Clinics, Zwolle, [2]Medical Research Group, Langerhans, Zwolle, [3]Internal Medicine, University Medical Center Groningen, [4]Meetpunt Kwaliteit, Eindhoven, [5]Praktijkondersteuning Zuidoost-Brabant, Veldhoven, [6]Landelijke Organisatie Ketenzorg, Utrecht, Netherlands.

Background and aims: In 2009, the Dutch National Institute for Public Health and the Environment (RIVM) published an estimation of the prevalence of diabetes in The Netherlands to be around 817,000 in 2011, and a total of 1.3 million subjects known with DM in 2025. This estimate was performed based on five general practitioner registries which contained almost 500,000 members of the general population. Since then, the LOK (Dutch initiative for shared care organisations) has initiated data collection over larger groups of subjects in the years 2010 and 2011, concentrating on subjects with type 2 diabetes (T2DM), treated in shared care groups within a primary care setting. Therefore, it should be possible to make a more precise estimate of the total number of subjects with DM in the Netherlands.
Materials and methods: Collection of data was performed as part of the quality control initiative of the LOK. All shared care groups were invited to voluntarily submit relevant information to the Landelijke Organisatie Ketenzorg (LOK); 66 out of a total of more than 100 did so. Of these 66, 41 delivered sufficient information not only regarding the subjects with T2DM seen within the shared care environment, but also regarding the total amount of subjects known with DM (both T1DM and T2DM) in primary and secondary health care. Data were analyzed as part of the DUDE-initiative (DUtch Diabetes Estimates).
Results: Results are observational and self-reported, which might lead to bias. Still, in the primary care practices of these 41 shared care groups, a total of 5,185,801 members of the total population were known in 2011. Of these, the total amount of subjects known with DM was 276,739 (5.36%), 251,504 of which with T2DM (4.88%). In 2011, the Netherlands had a population of 16,725,902; this translates into 893,000 subjects known with DM (815,000 with T2DM) in 2011, 9.3% more than the RIVM estimate. Using this information as a base for prediction of DM in 2025, the RIVM estimate of 1.3 million will be surpassed by at least 200,000 more prevalent cases, mainly T2DM.
Conclusion: The prevalence of diabetes, especially T2DM, increases even quicker than recently estimated. When this growth remains unchecked, the prediction of the RIVM of 1.3 million subjects with DM in 2025 will be surpassed by at least 200,000. These new results further emphasize the need for both concerted programs for prevention and treatment of DM. It will also mean an extra disease and financial burden for both individuals and the total community when this growth remains unchecked.

Evaluation of two screening methods for newly diagnosed diabetes in China: a cost-effectiveness study

Y. Zhang[1], J. Sun[2], Z. Pang[2], W. Gao[1], H. Sintonen[1], A. Kapur[3], Q. Qiao[1];
[1]Department of Public Health, Hjelt Instituet, Helsinki, Finland, [2]Department of non-communicable Disease Prevention, Qingdao Municipal Centre for Disease Control and Prevention, Qingdao, China, [3]World Diabetes Foundation, Gentofte, Denmark.

Background and aims: To evaluate the performance and cost-effectiveness of two screening methods to identify undiagnosed diabetes at primary care settings among a Chinese population.
Materials and methods: Two screening methods using a fasting capillary glucose (FCG) test or a Chinese diabetes risk score (DRS) at primary care settings followed by diagnostic tests were compared. The performance of FCG and DRS was evaluated by using receiver operating characteristic (ROC) curve analysis. The main economic outcome measures were the total cost of screening per 1000 persons, proportion of undiagnosed diabetes detected, and the cost per undiagnosed diabetes identified from the societal perspective.
Results: Among all participants, 26.6% (2453/9208) had undiagnosed diabetes defined by fasting plasma glucose≥7.0 mmol/l and/or 2hour plasma glucose≥11.1 mmol/l and/or hemoglobin A1c≥6.5%. At the optimal cutoff point of 6.2 mmol/l for FCG and 14 for DRS, the sensitivity was 42.7% and 62.5%, and specificity was 75.4% and 57.0%, respectively. The area under the ROC curve was 67.7% for FCG and 62.4% for DRS (P<0.001). Based on the input costs, the total cost of screening 1000 persons was ¥56000 ($8000) for FCG and ¥77000 ($11000) for DRS. The cost per case identified was ¥491 ($70) for FCG and ¥463 ($66) for DRS, at the optimal cutoff points.
Conclusion: As a first-line screening tool for undiagnosed diabetes, the FCG test performed slightly better than the DRS in primary care settings in China. The non-invasive and layperson-oriented DRS was more cost-effective and feasible.

293

Screening for people with glucose metabolism disorders within the framework of the Demojuan project in Barranquilla, Colombia

N.C. Barengo[1], T. Acosta[2], A. Arrieta[3], C. Ricaurte[3], D. Mayor[3], J. Tuomilehto[4];
[1]Non-Communicable Diseases, Ministry of Health and Social Protection, Bogotá, Colombia, [2]Hospital Universitario La Paz, Madrid, Spain, [3]Centro de Investigación Sanitaria, Barranquilla, Colombia, [4]Department of Vascular Prevention, Danube-University Krems, Austria.

Background and aims: In Colombia, many people with type 2 diabetes (T2D) patients remain undiagnosed. The aims of this study were to implement the FINDRISC as a screening tool for disorders of glucose metabolism in five catchment areas of the primary health care system in Barranquilla in Colombia using the FINDRISC during 2011 and 2012, and to describe the risk factors for T2D in the population screened.

Materials and methods: This study was screening opportunistically people aged 34-60 years living in five primary health care catchment areas in Barranquilla, Colombia (Camino El Pueblo, Camino Simon Bolívar, Camino El Bosque de María, COOSALUD and Paso Juan Mina) using the Finnish Diabetes Risk Score (FINDRISC). People with 13 or more FINDRISC points were invited to an oral glucose tolerance test (OGTT).
Results: Out of 14193 participants with the FINDRISC, 35% (n=4915) had a score of 13 points or higher (men 23%, women 40%). Out of 14193 participants with the FINDRISC, 35% (n=4915) had a score of 13 points or higher (men 23%, women 40%). Only 46% of men and 35% of women had a BMI of less than 25 kg/m2. Similarly, central obesity using the WHO criteria (≥102 cm and ≥88 cm) was common (women 70% and men 57%). Only 33% of men and 20% of women reported that they reached the recommended 30 min of physical activity daily. The percentage for daily intake of fruits and vegetables was 32% in men and 34% in women. Approximately 40% of the people had family history of T2D.Hypertension was less common; 16% in men and 24% in women reported to use of antihypertensive drugs. The prevalence of screen-detected T2D was 18% in men and 12% in women, respectively. In both sexes the prevalence of isolated IGT, isolated IFG, and IFG and IGT combined were 8%, 11%, and 8%, respectively. />
Conclusion: Implementing the FINDRISC within the primary health care settings in a large city in Colombia helped to identify people with glucose metabolism disorders and T2D risk factors. The FINDRISC served its function of the initial screening tool well; 65% of the population screened had the score 12 points or under, and could be excluded from further procedures and blood testing. Furthermore, a special emphasis should be given not only to identify people at high risk of T2D as early as possible but also to implement population-wide actions in order to decrease the burden of overweight and obesity as well as to increase physical activity.

Prevalence of carbohydrate metabolism disorders in patients with acromegaly
A.V. Dreval[1], I.V. Trigolosova[1], B.H.R. Wolffenbuttel[2], I.V. Misnikova[1], Y.A. Kovaleva[1], R.S. Tishenina[3], I.A. Barsukov[1], A.V. Vinogradova[1]; [1]Endocrinologic department, Moscow Regional Scientific Research Clinical Institute, Russian Federation, [2]Endocrinologic department, University Medical Center, Groningen, Netherlands, [3]biochemical laboratory, Moscow Regional Scientific Research Clinical Institute, Russian Federation.

Background and aims: Early carbohydrate metabolism disorders (ECMDs) and secondary diabetes mellitus (DM) are frequently associated with acromegaly. Several factors may be involved in the development of ECMD and/or progression to diabetes mellitus, amongst others the levels of growth hormone (GH) and/or IGF-1, age and gender of the patient, and duration of acromegaly. The aim of this study was to assess the prevalence of ECMDs in patients with acromegaly and compare the results with prevalence of glucose derangements in two population-based surveys (random sample of the adult population and adult population with a high risk of type 2 diabetes). We also analyzed the factors contributing to the development of glucose derangement.
Materials and methods: 97 acromegaly patients: men - 16, women - 81 (age - 56 [47.5-64.5], duration of acromegaly - 12.5 [7.5 - 20.3] years) were evaluated. As in 24 (24.7%) patients DM was diagnosed before acromegaly, an oral glucose tolerance test was done in the remaining 73 patients to reveal asymptomatic DM or ECMD (IGT and IFG). The activity of acromegaly was assessed by the international 2009 consensus criteria. There were two control groups: (1) a random sample of the adult population (2638 participants) and (2) an adult population with type 2 diabetes risk factors (n=2304). The groups had comparable to age and BMI.
Results: DM was diagnosed in 51 (52.2%) patients among 97 examined acromegalics. It was 3.5 times higher than the prevalence of DM2 in the Moscow county random population sample (14.7%). Newly-diagnosed diabetes was revealed in 27 (37%) patients among 73 acromegalics - it is 8.4 times higher than prevalence newly-diagnosed DM2 in general population (4.4%) and 1.5 times higher than prevalence in the high-risk DM2 group (25.2%). ECMDs were in 25 (34.2%) patients among 73 acromegalic patients - it is 3.4 times higher than prevalence ECMD in general population (9.9%) ($p<0.001$) and 1.3 times higher than ECMDs prevalence in the high-risk DM2 group (25.7%) ($p<0.01$). Peak of the DM and ECMD prevalence in acromegalic patients was observed in age interval 50-60 yrs. Acromegalic patients with ECMD or diabetes were older and more obese, and the proportion of women was highest in the diabetes group. Acromegaly duration was longer in those with diabetes. IGF-1 levels (z-score) were higher in subjects with ECMD or diabetes compared to acromegalic patients with normal glucose levels (5.1[3.3-6.6], 4.5[2.3-6.5] and 2.1[0.7-4.4] accordingly, $p=0.002$). Multinomial logistic regression yielded that the severity of glucose derangement was predicted by age, body mass index, female gender and level of IGF-1.
Conclusion: The prevalence of DM and ECMD among acromegalic patients considerably exceeds the prevalence of DM2 and ECMDs in the general population and in the high-risk DM2 group, and its development depends on age, BMI, gender and IGF1 level.

Antibodies against the Epstein-Barr virus Nuclear Antigen (EBNA-1) in patients with autoimmune diabetes mellitus

E. Sipter, D. Csuka, Z. Prohászka, P. Pánczél, Á. Szilágyi, I. Karádi, G. Füst, N. Hosszúfalusi;
3rd Department of Internal Medicine, Semmelweis University, Budapest, Hungary.

Background and aims: Type 1 diabetes mellitus (T1DM) and latent autoimmune diabetes in adult (LADA) are known as autoimmune types of diabetes mellitus. The etiology of autoimmune diseases is widely studied and environmental factors can contribute to the pathogenesis. The possible role of viral infections is still unclear. Several studies published that Epstein-Barr virus infection is associated with multiple sclerosis, systemic lupus erythematosus, rheumatoid arthritis and myasthenia gravis, but no relevant publication was found with diabetes mellitus. The aim of our study was to find a possible relationship between EBV infection and T1DM and LADA.
Materials and methods: Serum samples were collected at the onset of the disease from 52 patients having T1DM with adult onset (30 male/22 female) and 23 patients with LADA (15 male/8 female). The age range was from 18 to 59 years in T1DM group and from 20 to 63 years in LADA group. The diagnosis of T1DM was based on WHO criteria, and LADA was diagnosed if the patient had islet cell antibody (ICA) and/or glutamic acid decarboxylase antibody (GADA); and insulin therapy was not required in the first six months after the diagnosis. Our study included also sex and age matched healthy control subjects (30 male/22 female; 16-58 years and 15 male/8 female; 17-63 years), in whom any type of diabetes mellitus and autoimmune diseases were excluded. The serum concentration of antibodies against the Epstein-Barr virus nuclear antigen (EBNA-1) was determined using a commercial enzyme-linked immunosorbent assay. The anti-EBNA-1 appears 2-4 months after the infection and can be detected during the whole life.
Results: At the diagnosis of diabetes, 94.2% of the patients with T1DM and 100% of the patients with LADA had at least one autoantibody positive either ICA and/or GADA. The median concentrations of fasting glucose and HbA1C were the following in the T1DM and LADA group, respectively: 8.98 and 8.94 mmol/l, 10.17 and 7.75%. The percentage of seropositive subjects was 92.3% vs 84.6% in the T1DM vs control group, and 86.9% vs 73.9% in the LADA vs control group, the difference was not significant between the groups. The median level of anti-EBNA-1 IgG was 165.50 AU/ml in the T1DM group (25% - 75% percentiles: 48.84-370.30 AU/ml), and 91.16 AU/ml in the control group (33.76-179.60 AU/ml). The median level of anti-EBNA-1 IgG was 77.00 AU/ml in the LADA group (30.93-264.50 AU/ml), and 89.71 AU/ml in the control group (8.58-178.71 AU/ml). The statistical analysis demonstrated significant difference in the concentration of anti-EBNA-1 IgG between the newly diagnosed patients with T1DM and healthy subjects ($p<0.01$), but it did not differ between the patients with LADA and healthy subjects. The level of GAD antibody did not correlate with that of anti-EBNA-1 IgG.
Conclusion: Our study demonstrates that anti-EBNA-1 IgG levels measured in the serum of patients with T1DM at the onset of the disease was higher than in the serum from non-diabetic subjects. We did not find the same correlation between patients with LADA and healthy controls. Our result may suggest a different immunological response to EBV infection, which can reflect a difference in the immune and/or autoimmune responses of patients with T1DM and LADA.

The risk of type 1 diabetes mellitus in offspring of immigrants in Sweden

H.I. Hussen[1], S. Cnattingius[2], M. Persson[3], T. Moradi[1,4];
[1]Institute of Environmental Medicine, Division of Epidemiology, Karolinska Institutet, Stockholm, [2]Department of Medicine, Clinical Epidemiology Unit, Karolinska University Hospital, Stockholm, [3]Department of Clinical Science, Intervention and Technology, Karolinska Institute, Stockholm, [4]Centre for Epidemiology and Social Medicine, Health Care Services, Stockholm County Council, Sweden.

Background and aims: The epidemic of childhood type 1 diabetes (T1DM) is accelerating in many parts of the world. The lowest incidence of T1DM is reported from China and Venezuela and the highest from Finland, Sardinia and Sweden. Investigating the occurrence of T1DM in immigrants and their offspring offers a unique possibility to explore and delineate the gene-environment interaction for the development of type 1 diabetes. We investigated the risk of developing T1DM in offspring of Swedes and immigrants by specific parental migration background.
Materials and methods: Using Swedish nation-wide data we analyzed the risk of developing T1DM in 3,593,765 female and 3,794,477 male offspring born to native Swedes or immigrants. The subjects were between 0 to 30 years of age and born and living in Sweden between 1969 and 2009. We calculated Incidence rate ratios (IRRs) with 95% confidence intervals (CIs) using Poisson regression models.
Results: Compared with Swedes, children (0 to 14 years of age) and young adults (15 to 30 years of age) with only one parent born abroad had about 30% and 15% to 20% lower IRR for T1DM,respectively, after adjustment for age, calendar period and parental education and regardless of sex. Girls and boys with both parents born abroad had about 40% and young adults had about 25% to 30% decreased risk of TIDM compared with children and young adults of Swedes. These reductions in risks in both children and young adults with immigrant parents retained in all ethnic groups except for offspring of Africans in whom the risk was increased. Compared with offspring of Swedes aged 0-30 years, male and female offspring of mothers or fathers born in Africa had about 20% to 40% higher IRR for T1DM. The increased risk was more pronounced in individuals with parents from Eastern Africa, with a 45% to 60% higher risk compared with offspring of Swedes. With a few exceptions, offspring of any parent born in Asia, Europe (except Northern Europe), Latin America and Northern America (except female offspring to fathers from Northern America) had between 35% to 65% lower IRR compared with offspring of Swedes. Offspring of Finnish immigrants and offspring with parents from other parts of Northern Europe had almost similar risks compared with offspring of Swedes.
Conclusion: Ethnic background and its interaction with environmental factors play an important role in the etiology of TIDM. Further studies on offspring of immigrants from African countries, and in particular from Eastern Africa, might improve our understanding on the etiology of the disease.

Non-HLA genes and familial predisposition to autoimmune diseases in families with a child affected by type 1 diabetes

A. Parkkola[1], A.-P. Laine[2], T. Härkönen[1], S.J. Ryhänen[1], J. Ilonen[2,3], M. Knip[1,4], the Finnish Pediatric Diabetes Register;
[1]Scientific Laboratory, Children's Hospital, University of Helsinki, [2]Immunogenetics Laboratory, University of Turku, [3]Department of Clinical Microbiology, University of Eastern Finland, Kuopio, , [4]Folkhälsan Research Center, Helsinki, Finland.

Background and aims: Autoimmunity clusters in individuals and in families. Genetic predisposition could be assumed to be the reason for this clustering but we have recently failed to provide convincing evidence for an increased HLA class II mediated risk in families with clustered autoimmunity. To date, more than 60 loci outside HLA have been associated with type 1 diabetes. As most of these have functions related to the immune system, many of them associate with other autoimmune diseases in addition to type 1 diabetes. Thus, we tested the hypothesis that these non-HLA loci would associate with clustering of autoimmunity in familial type 1 diabetes, in children with multiple autoimmune diseases, or in children with a family history for autoimmune diseases.
Materials and methods: We included 1785 children with type 1 diabetes diagnosed before the age of 15 years (median 7.9, 57% male) from the Finnish Pediatric Diabetes Register. Data on family history of autoimmune diseases in first- and second-degree relatives at diagnosis of the index child were collected with a structured questionnaire. The Sequenom (San Diego, California, USA) platform was used to genotype 40 single nucleotide polymorphisms (SNPs). Statistical analyses were carried out with PLINK v1.07 software package. Three SNPs and 41 individuals failed the missingness tests (call rate >90% and >50%, respectively).
Results: Only 27 children had known multiple autoimmune diseases at diagnosis. This phenotype was associated with rs17388568 (ADAD1, OR 1.74, 95%CI 1.01-3.00) and rs17696736 (C12orf30, OR 0.32, CI 0.30-1.00). Three SNPs; rs2476601 (PTPN22, OR 1.35, CI 1.05-1.74), rs12061474 (PIK3C2B, OR1.31, CI 1.00-1.71), and rs3184504 (SH2B3, OR 0.79, CI 0.63-1.00) associ-

ated with having a first-degree family member with type 1 diabetes (n=180). Having a first-degree family member with another autoimmune disease (n=221) associated with rs9653442 (OR 0.78, CI 0.64-0.96), and with IFIH1 SNPs rs2111485 (OR 0.80, CI 0.64-1.00) and rs1990760 (OR 0.80, CI 0.65-1.00). Being a member of an autoimmune family (>3 autoimmune diagnoses or >2 different autoimmune diseases in the extended family, n=203) associated with rs11711054 (CCR2, OR 0.66, CI 0.52-0.86). Correcting for multiple tests removed statistical significance from all these findings, however.
Conclusion: Some genetic loci reached nominally significant association with clustered autoimmune diseases. PTPN22 was a risk loci for familial type 1 diabetes. These findings did not survive the correction for multiple testing, however. This may be due to the relatively small sample size leading to inadequate power. Larger studies are needed to unravel the possible non-HLA mediated predisposition to clustering autoimmunity. In addition, these findings emphasize the role of environmental factors predisposing to clustering autoimmunity.

Mortality and having offspring in type 1 diabetes
L. Sjöberg[1,2], L. He[3], J. Tuomilehto[2,4], R. Kaaja[5,6], J. Pitkäniemi[3,7];
[1]Dept of General Practice and Primary Health Care, University of Helsinki, Helsinki, Finland, [2]Department of Chronic Disease Prevention, National Institute for Health and Welfare, Helsinki, Finland, [3]Hjelt-institute, University of Helsinki, Finland, [4]Danube University Krems, Austria, [5]Central Hospital of Satakunta, Pori, Finland, [6]University of Turku, Finland, [7]Finnish Cancer Registry, Helsinki, Finland.

Background and aims: Type 1 diabetes is associated with increased mortality compared with the general population, from both acute and long-term diabetic complications. Previous studies have shown that mortality in the general population is higher among women and men who do not have any offspring than among those who have children. Both men and women with childhood-onset type 1 diabetes have fewer offspring than the general population. Our aim was to examine mortality and causes of death among subjects with childhood-onset type 1 diabetes compared to control people, with focus on mortality differences between childless people and those having had offspring.
Materials and methods: The people with diabetes in our study comprise the Finnish DERI cohort (Diabetes Epidemiology Research International). They were all diagnosed with diabetes at 17 years of age or under during 1965-1979 and placed on insulin at diagnosis. 5,162 cases were identified nationwide with an ascertainment rate approaching 100 percent; 2,327 of them were women. Two non-diabetic control persons for each person in the DERI cohort were selected from the database of the national Social Insurance Institution, matched for the year of birth, geographical birth region and gender. This register-based study uses information on the offspring from the national Population Register Centre. All statistical analyses were done using Cox proportional hazards model.
Results: 1,025 people with diabetes and 497 people without diabetes died during the follow-up until the end of 2010. All-cause mortality in people with diabetes was significantly higher than that of control persons, both among men and women ($p>0.01$). All-cause mortality was statistically significantly lower in persons who had offspring ($p<0.01$), among both cases and controls, and in both genders. Among females, having children lowered mortality in a similar way in diabetic persons and controls ($p=0.99$ for interaction). In males, the difference in the shapes of the mortality curves by the number of offspring was statistically significant between diabetic and control people ($p<0.01$ for interaction).
Conclusion: The beneficial effect of having offspring on mortality was observed. It was, however, significantly smaller among men with diabetes than among men in the control group. In women, having offspring was associated with lower mortality in a similar way regardless of the diabetes status. One possible reason for this gender difference is that women with type 1 diabetes are trained and well motivated to achieve better metabolic control during pregnancy and that this motivation may persist also post partum.

Quality of life, age at onset of type 1 diabetes and metabolic control in a cohort of patients followed for 16 years
M. Trevisan[1], E. Coppo[2], A. Raviolo[2], P. Passera[1], M. Zanone[2], F. Cavallo[3], M. Porta[1], M. Trento[1];
[1]Medical Sciences, Laboratory of Clinical Pedagogy, [2]Medical Sciences, Internal Medicine, [3]Public Health and Pediatric Sciences, Public Health, Turin, Italy.

Background and aims: Progressive adaptation to type 1 diabetes (T1DM) is paramount to improve quality of life (QoL) and other psychological dimensions. This study aimed at identifying possible correlations between QoL, Locus of Control (LoC) and clinical variables in patients with T1DM over a 16 year follow up.
Materials and methods: Fifty-nine patients (27 women) with T1DM, age 31.3±2.0, duration of disease 23.0±4.0, part of a cohort of 112 followed since 1996 accepted to participate. Nine patients had completed middle school, 32 high school and 18 had a university degree. HbA1c was 8.8±1.7 at baseline and 8.0±1.2 after 16 years. Patients were divided into those in whom onset of T1DM had been during the first 5 years of life (n=16) or later (n=43). They were also stratified into Worsened (n=7), Stable (n=23) and Improved (n=27), based on whether their HbA1c had increased/decreased by 1 percentage point between baseline and last follow up visit (7.6±1.8 to 9.6±1.9; 7.8±0.8 to 7.7±0.8; and 9.8±1.4 to 7.6±0.8, respectively). QoL was measured by the Diabetes Quality Of Life questionnaire (DQOL), translated into Italian and re-validated. The DQOL includes 46 items that explore 4 dimensions: Satisfaction, Impact, Diabetes Related Worries and Social/Vocational Worries. The LoC was measured by the Peyrot and Rubin specific questionnaire, composed of 18 items that evaluate 3 dimensions of control of disease: Internal Control, Role of Chance, Powerful Others.
Results: Compared with patients who developed T1DM later in life, those in whom onset had been before age 5 had better total DQOL score (69.3±8.3 vs 81.0±18.3, $p=0.022$), due to the Satisfaction dimension (25.0±4.0 vs 30.2±7.8, $p=0.016$), and a tendency to decreased fatalism (Role of Chance, 8.4±3.0 vs 10.5±4.0 $p<0.06$) in adult age. Age of onset higher than 5 and frequent episodes of hypoglycaemia scored the highest ORs (7.6, $p<0.10$ for age of onset and 20.3, $p<0.01$ for frequent episodes of hypoglycaemia) in a multivariate logistic model with HbA1c as dependent variable, dichotomized in 'Worsened' vs all others. All subjects with worsened HbA1c had their diagnosis after 5 years of age and more frequent episodes of hypoglicaemia.
Discussion: Onset of T1DM during the first 5 years of life may result in better QoL and less fatalism in the long term. Presumably, these patients have no memory of disease onset, which may reduce trauma and facilitate adaptation to managing life with diabetes.

300

50 years of childhood type 1 diabetes: clinical characteristics of survivors from the Pittsburgh Epidemiology of Diabetes Complications study (EDC)
T.J. Orchard, R.G. Miller;
Epidemiology, University of Pittsburgh, USA.

Background and aims: More individuals with childhood onset type 1 diabetes are now surviving for 50 years or more after diagnosis. To characterize these survivors, data from the EDC study of childhood onset (<17 years) T1D were examined.
Materials and methods: The EDC study is based on an historical-prospective cohort (n=934) diagnosed between 1950 and 1980 and first seen at Children's Hospital of Pittsburgh within 1 yr of diagnosis. The first examinations and surveys for EDC were conducted between 1986-1988. If they all had lived, 341 would have had a T1D duration of ≥50 yrs by June 1, 2013. Of these, 146 had already died (predeceased) before baseline exam, while 91 died after baseline (1986-1988), and 99 have so far survived.
Results: The predeceased did not differ by age at diagnosis or gender but their mean calendar year of diagnosis was 2 years earlier (1956 vs 1958) than those surviving until baseline ($p<.0001$). As expected, those surviving to ≥50 yrs duration had fewer complications (renal, proliferative retinopathy, distal symmetrical polyneuropathy(DSP), cardiac autonomic neuropathy and coronary artery disease (CAD)) and better anthropometric (weight, BMI), CAD (hypertension, lipids, smoking, white blood cell (WBC)) and diabetes related (HbA1c, insulin dose/kg body weight) baseline risk factors compared to those dying after baseline, except that no differences were seen for gender, weight,

BMI, pulse rate, insulin dose/kg body weight (p values all >0.50), or diastolic blood pressure (p=0.15). Multivariable analyses allowing for age, duration of diabetes and all complications suggested that micro-or-greater-albuminuria (p<0.0001), coronary artery disease (p=0.0006) and distal symmetric polyneuropathy (p=0.01) were all independent predictors in the best fitted model. A similar model for risk factors (excluding renal markers) showed triglycerides (p<0.0001) and WBC (p=0.002) to be the strongest independent predictors. The best fitting combined model of complications and risk factors was comprised of all of these predictors (ie. micro-or-greater-albuminuria, CAD, DSP, triglycerides and WBC).
Conclusion: These results suggest important roles for dyslipidemia and inflammation, in addition to the development of complications per se, for long term survival in T1D, while the role of HbA1c appears to be largely explained by development of these complications and risk factors.

Life expectancy in type 1 diabetes: a Scottish Registry Linkage study
S.J. Livingstone, on behalf of the Scottish Diabetes Research Network epidemiology group;
Diabetes Epidemiology Unit, University of Dundee, UK.

Background and aims: Historically those with type 1 diabetes mellitus (T1DM) have been reported to have a reduced life expectancy compared to the general population but estimates are seldom based on contemporary data. Given advances in medical care and the availability of nationwide data we sought to determine current life expectancy (LE) in people with T1DM in Scotland.
Materials and methods: The nationwide Scottish Care Information - Diabetes Collaboration database contains data for over 99% of individuals with diabetes in Scotland. Anonymised data extracted from this database was linked with death data from the General Register. Abridged period life tables for those with T1DM in Scotland aged 20 years and older were derived using Chiang's method with 5 year age intervals (plus an open-ended interval for 80 years and older), and a 3 year time interval from 2008-2010, corresponding to latest Scottish general population abridged life tables from the Office of National Statistics (ONS) . 95% Confidence Intervals (CI) for the expected future life time at each age group were derived using Monte-Carlo simulations on the estimated probability of death during each age interval. The period LE estimates for T1DM were compared with interim estimates from the ONS for the general population of Scotland calculated over the same period. These period rather than cohort LE estimates do not attempt to use trends in LE to project further improvements in survival in the future.
Results: 24,971 persons aged 20 years and older were identified as living with T1DM in Scotland at any point in the calendar year period 2008-2010 inclusive, contributing 68,392 person years of follow-up and 1,079 deaths. The population at the mid-point of the study period was 22,592 persons. In those with T1DM, the remaining LE for attained age group 20-24 years was 45.4 years (95% CI: 44.2, 46.5) and 46.6 years (95% CI: 45.2, 47.9) for men and women respectively compared to estimates of 56.5 and 60.9 years respectively for the male and female general populations. The remaining LE at attained age group 65-69 years was estimated at 11.7 years (95% CI: 11.0, 12.6) for men and 12.5 years (95% CI: 11.8, 13.2) for women with T1DM compared to 16.8 and 19.3 for the male and female general population. Overall the difference in life expectancy between those with T1DM versus the general population ranged from 11.1 to 14.3 in men and women respectively at attained age group 20-24 to 5.1 and 6.8 in men and women respectively at attained age group 65-69.
Conclusion: These period LE estimates show that there has been a marked improvement in LE for men and women with T1DM compared with earlier reports. These improvements should now be reflected in life insurance and other relevant policies for those with T1DM. Despite these improvements there remains a substantial gap in LE between the T1DM and general populations that needs to be addressed.

Excess mortality in early adulthood in a population-based cohort of childhood onset type 1 diabetes
M.N. Cooper[1,2], N.H. de Klerk[1], T.W. Jones[1,3], E.A. Davis[1,3];
[1]Telethon Institute for Child Health Research, West Perth, [2]Department of Endocrinology and Diabetes, Princess Margaret Hospital for Children, Perth, [3]Princess Margaret Hospital for Children, Perth, Australia.

Background and aims: Recent reports have suggested that mortality in young adults with Type 1 Diabetes (T1DM) has reduced and it is proposed that this is a result of improved glycaemic control and care during childhood. To date however, data have not been available to link population based phenotypic and clinical data during childhood with mortality in young adulthood. The primary aim of this study was to determine the standardised mortality rate for young adults in Western Australia (WA) who had childhood onset T1DM relative to the general population. A secondary aim was to examine the association between demographic and treatment factors during childhood with risk of mortality.
Materials and methods: All children in WA with T1DM aged ≤16 years attend 3-monthly clinics facilitated by Princess Margaret Hospital with clinical records stored in the WA Childhood Diabetes Database (WACDD - established 1987, case ascertainment ≥99%). Records for the full paediatric management period (from diagnosis until transition to adult clinics) for all patients with T1DM from the WACDD born prior to 1st Jan 1993 were extracted and linked to the death registry by the WA Data Linkage Branch. A non-T1DM comparison group matched for date of birth and sex (matched 5:1) were randomly selected from the general population birth registry. Cause of death was determined from the death registry and was based on the International Classification of Diseases coding system. Statistical analyses were completed in R using both univariate and multivariate Cox proportional hazards models (adjusted for birth year) to estimate Hazard Ratios (HR).
Results: Data were available for 1,337 T1DM patients and 6,663 non-T1DM population subjects. Mean age of T1DM diagnosis was 9.5 (SD 4.1) years, mean duration of T1DM was 16.7 (SD 6.4) years and median cohort age at end of follow-up was 26.2 (SD 5.1) years. The overall mortality ratio for the T1DM group (20 deaths observed) relative to the non-T1DM group was 3.32 (p<0.001). The mortality ratio was higher among females (6.53, p<0.001) than males (1.67, p=0.31). Deaths from accidental narcotic overdose, cardiovascular disease and suicide were observed at higher rates (20 times, 7.5 times and 2.5 times respectively) in the T1DM group. Within the T1DM group, factors associated with an increased risk of all cause mortality included a low or middle level socio-economic background, relative to those from a high level socio-economic background (7.6 times, p=0.008; HR 3.7, p=0.1 respectively), a higher mean A1c during paediatric management (HR 1.54, p=0.005 for each 1% increase in mean A1c %) and a history of > 3 severe hypoglycaemic events during childhood.
Conclusion: The mortality rate is 3.3 times higher during early adulthood for those with childhood onset T1DM relative to the general population. Poor glycaemic control, recurrent severe hypoglycaemia and lower socio-economic status are predictors associated with increased risk of mortality. Knowledge of the risk factors for death in young adults with childhood onset T1DM will allow targeted intervention aimed to reduce the mortality risk.

Associations of genetic variants in thioredoxin (TXN) and mitochondrial thioredoxin reductase (TXNRD2) genes with kidney disease in type 1 diabetes
T.A. Patente[1], M.B. Monteiro[1], M. Queiroz[1], M. Nery[1], M.J. Azevedo[2], L.H. Canani[2], E.J. Pavin[3], M.C. Parisi[3], U.F. Machado[4], M. Passarelli[5], D. Giannella-Neto[6], M.L.C. Côrrea-Giannella[1];
[1]Endocrinology, Medical School of University of São Paulo, [2]Endocrinology, Federal University of Rio Grande do Sul, Porto Alegre, [3]Endocrinology, Medical School from State University of Campinas, [4]Physiology and Biophysics, Biomedical Sciences Institute of University of São Paulo, [5]Medical School of University of São Paulo, [6]UNINOVE, São Paulo, Brazil.

Background and aims: Deregulated cellular redox balance is a key factor in the development of diabetic nephropathy and impairment of the thioredoxin (Trx) system has already been demonstrated. This thiol-reducing system comprises Trx (encoded by *TXN),* thioredoxin reductases (the mitochondrial isoform is encoded by *TXRD2*) and a natural Trx inhibitor (encoded by

TXNIP). In the present study we analyzed associations of single nucleotide polymorphisms (SNPs) in *TXN, TXNRD2* and TXNIP with kidney disease in type 1 diabetes patients.
Material and methods: Three SNPs, rs2301242 (promoter region of *TXN*), rs3788319 (promoter region of *TXNRD2*) and rs7211 (3'UTR of *TXNIP*) were genotyped in 448 patients with type 1 diabetes (44.6% with diabetic nephropathy) by real time PCR.
Results: The minor allele A of rs2301242 in *TXN* was associated with established/advanced nephropathy in the overall population (OR 2.30, CI95% 1.11 - 4.81, p=0.0260). The minor allele A of rs3788319 in *TXNRD2* gene was associated with a low estimated glomerular filtration rate (eGFR) in men (p=0.0413) and the genotype AA was associated with established/advanced nephropathy in the overall population (OR 1.50, CI95% 1.04 - 2.16, p=0.0284). No associations were found for rs7211 in *TXNIP*.
Conclusion: The SNPs rs2301242 in *TXN* and rs3788319 in *TXNRD2* modulate the risk for renal disease in the studied population of type 1 diabetes patients and require validation in independent cohorts.

Experimental gene therapy of type 1 diabetes mellitus: dose-dependent effects on glucose levels in blood plasma of mice and rats
M.D. Tronko[1], L.N. Kalynska[1], O.I. Kovzun[1], I.P. Paster[1], O.K. Toropova[2], T.P. Gulko[2], V.A. Kordium[2];
[1]Director, State Institution, [2]Institute of Molecular Biology and Genetics of Natl. Acad. Sci, Kyiv, Ukraine.

Background and aims: Type 1 diabetes mellitus is associated with a destruction of insulin-producing pancreatic beta cells. In spite of the fact that type 1 diabetes is a multifactor disorder,to date there is no other method of treatment of the disease except insulin therapy. However, treatment with exogenous insulin is not perfect, since it may not always provide glycemic control within the physiological range, because the dose is adjusted empirically, taking into account the hyperglycaemia and disease duration, which leads to serious complications and decompensation. A radical treatment may be provided only by gene therapy after administration of a insulin gene integrated in such a molecular construction that would provide its synthesis in non-specific normal cells which do not produce endogenous insulin.
Materials and methods: Delivery of vectors containing a target gene to the body is the main challenge of gene therapy. We have optimized the system of in vivo delivery of a constructed plasmid vector containing human proinsulin gene, to hepatocytes of animal models using polyplexes. A model of experimental diabetes induced by streptozotocin (STZ) (Sigma, U.S.A.)at a dose 50 mg/kg, has been obtained in C57BL/6j mice and Wistar rats. DNA preparations were injected to liver parenchyma surgically. Transfection efficacy was determined on a flow cytometer, using an Enhanced Green Fluorescent Protein (EGFP). The highest efficacy of transfection was 66%. Glucose content in blood plasma was tested using a test-system "Hemoglan" from ("Norma", Ukraine) and on an analyzer "SUPER GL" (Germany).
Results: Investigations have demonstrated that proinsulin gene transfection led to a decrease in blood glucose levels in C57BL/6j mice and Wistar rats with different duration of STZ diabetes: 16 days (group 1) and 36 days (group 2 of animals). After administration of a plasmid with preproinsulin gene to mice on day 16 and 36 of STZ diabetes development, a decrease was noted, in glycaemia level from 18.78±1.74 to 9.78±1.08 mmol/L, and from 23.63±2.10 to 10.97±2.22 mmol/L (respectively) two weeks after experiment started. Proinsulin target gene administration to rats on day 16 and 36 of STZ diabetes development led to a significant decrease in blood glucose levels from 24.77±1.49 to 8.0±1.79 mmol/L, and from 31.10±1.84 to 13.40±3.67 mmol/L (respectively) two weeks after experiment started. Administration to liver parenchyma of rats with STZ diabetes of different concentrations of DNA preparations(within the range 30 to 40 μg of DNA per 200g of body weight) allowed to determine optimum DNA doses that led to a significant decrease (normalization) of blood glucose levels. It should stressed that a decrease in glycaemia level in mice and rats after a single procedure of gene therapy lasted for 8-10 weeks at most, after which blood glucose levels were increasing.
Conclusion: These results show that regression of diabetes has been achieved after a single course of gene therapy for STZ diabetes in rats and mice. A more pronounced decrease in glucose levels and a higher survival rate in mice was noted when using DNA at a dose 15 μg/g of body weight, compared with the group of mice which were administered with a dose 10μg/20g of body weight.

PS 005 What predicts type 1 diabetes?

Foetal transfer of preproinsulin through the neonatal Fc receptor protects from type 1 diabetes
S. Culina[1], R. Boisgard[2], N. Gupta[3], S. Lacroix-Desmazes[3], R. Mallone[1,4];
[1]Institut Cochin, INSERM U1016-CNRS UMR8104-Université Paris Descartes, Paris, [2]CEA/DSV/I2BM/SHFJ/LIME, Orsay, [3]Centre de Recherche des Cordeliers, INSERM UMRS 872, Paris, [4]Service de Diabétologie, Assistance Publique Hôpitaux de Paris, France.

Background and aims: Autoimmune type 1 Diabetes (T1D) results from a failure of immune tolerance towards beta cells, in which preproinsulin (PPI) is the initial target antigen triggering the autoimmune cascade. Since the neonatal Fc receptor (nFcR) is highly expressed in the placenta, we hypothesized that 1) Fc-coupled PPI may be efficiently transferred from mothers to foetuses; and 2) this early PPI introduction may "teach" the immune system to develop tolerance towards PPI before autoimmune epitope spreading, thus preventing subsequent T1D development.
Materials and methods: A PPI-Fc fusion protein was injected i.v. to pregnant G9C8 Cα-/- NOD mice, which are transgenic for a T-cell receptor recognizing the PPI B15-23 epitope. PPI-Fc transfer was documented by in vivo imaging and ELISA assays; its cellular uptake and subsequent effects on pathogenic and regulatory T cells was followed by flow cytometry along with effects on T1D incidence at the adult age.
Results: PPI-Fc was efficiently and selectively transferred to foetuses through binding of the Fc portion to nFcR. One single 100 μg injection of PPI-Fc was sufficient to protect the offspring from subsequent T1D development. This protection was associated with PPI-Fc uptake by migratory dendritic cells, which ferried it to the thymus; with a later decrease in circulating pathogenic CD8+ T cells; and with an increase in regulatory T cells specifically found in pancreatic lymph nodes.
Conclusion: Coupling of PPI with an Fc fragment allows its transfer from mothers to offspring and protects from T1D following a single low-dose administration. PPI-Fc ferrying to the thymus and subsequent changes in pathogenic and regulatory T cells suggest that a central tolerance mechanism may be at play. Since the human nFcR is also expressed throughout life on the intestinal epithelium, the translation of this strategy into clinical trials could be envisaged.

Lower physical activity in children with persistent islet autoantibodies than in matched controls
M. Rewers[1], K. Waugh[1], K. Barriga[1], J. Norris[2], J. Snell-Bergeon[1];
[1]Barbara Davis Center, [2]Epidemiology, University of Colorado, Aurora, USA.

Background and aims: Progression from islet autoimmunity to type 1 diabetes may be slower in physically active persons due to their higher insulin sensitivity or other effects of exercise. Physical activity of high-risk children who have developed persistent islet autoantibodies but remain free of diabetes has not been previously assessed using direct methods, such as accelerometry. Here we compare directly assessed physical activity of islet antibody positive children and genetically comparable autoantibody negative controls.
Materials and methods: Diabetes Autoimmunity Study in the Young (DAISY) has been following since 1993 a cohort of 2547 children at genetically increased risk for type 1 diabetes. Of those, 198 children have developed persistent islet autoantibodies (to insulin, GAD65, IA-2 or ZnT8) and 70 have progressed to diabetes. Of the 97 children with persistent islet autoantibodies who are in active follow-up, but have not yet progressed to diabetes, parents of 62 agreed to participate in this study. Islet antibody-negative DAISY participants were frequency matched to the islet autoimmune group on age and gender and 50 of these were enrolled as controls. Children wore an Actigraph GT3X accelerometer (ActiGraph, Pensacola, FL) for 7 days to record physical activity. Physical activity was classified by counts per minute (cpm) as sedentary (≤400 cpm), light (401-1900 cpm), moderate (1901-3919 cpm) and vigorous (≥3920 cpm).
Results: Children with persistent islet autoantibodies and controls were similar in terms of age, sex, BMI, and waist circumference (TABLE). In mul-

tivariate linear regression models, adjusted for age, sex, BMI and total time recorded, children with islet autoimmunity spent a higher percentage of time sedentary and less time engaged in vigorous physical activity than controls and took fewer total steps and steps per minute.

TABLE. Characteristics and physical activity measures of study participants

Characteristic	IA+ cases n=62	IA- controls n=50	p-value
Age [y]	12.7 ± 3.6	13.0 ± 3.9	0.67
Sex [M]	55%	53%	0.83
BMI [kg/m2]	19.9	21.1	0.20
Waist circ. [cm]	72.4	74.7	0.40
Time sedentary*	85 ± 0.5%	83 ± 0.6%	**0.045**
Time of vigorous activity*	2.9 ± 0.2%	3.6 ± 0.2%	**0.01**
Total steps*	52,561 ± 2,126	59,882 ± 2,354	**0.02**
Steps per minute*	9.3 ± 0.4	10.6 ± 0.4	**0.03**

For the *adjusted models, TABLE presents least square means ± SE.

Conclusion: Children who are persistently positive for islet autoantibodies and at high risk for type 1 diabetes engage in slightly lower physical activity than antibody-negative children of similar age, sex, BMI and genetic susceptibility to diabetes. These differences translated into ~110 extra minutes spent sedentary and 70 fewer minutes spent doing vigorous activity per week. Whether lower levels of activity among some of the autoantibody positive children will accelerate the development of diabetes requires further follow-up of the study participants.
Clinical Trial Registration Number: NIH R01 DK032493

Prognostic and diagnostic relevance of ZnT8 antibodies in autoimmune diabetes

K. Wilhelm[1], K. Tornow[1], V. Lampasona[2], U. Walschus[1], I. Rjasanowski[3], W. Kerner[3], M. Schlosser[1];
[1]Department of Medical Biochemistry and Molecular Biology, Ernst Moritz Arndt University Greifswald, Karlsburg, Germany, [2]San Raffaele Scientific Institute, Milan, Italy, [3]Center of Diabetes and Metabolic Disorders, Karlsburg, Germany.

Background and aims: Autoantibodies (AAbs) are highly specific and sensitive markers of autoimmune diabetes. Beside GADA, IA-2A and IAA, AAbs against zinc transporter 8 (ZnT8A) are part of autoimmunity in human type 1 diabetes (T1D). A single nucleotide polymorphism in the SLC30A8 gene at aa 325 encoding Arg, Trp and Gln causes the induction of different ZnT8A variants ZnT8RA, ZnT8WA and ZnT8QA, respectively. The present study aimed at differentiating ZnT8A in patients at onset of T1D, LADA and AAb-positive subjects from the general population to examine their diagnostic value and their correlations with the other AAbs.
Materials and methods: Sera from 102 T1D patients at disease onset (median age 13 yr, interquartile range (IQR) 8-20 yr), 97 LADA patients (median age 59 yr, IQR 48-66 yr; median latency to insulin treatment 5 yr, IQR 2-9 yr), 139 AAb-positive schoolchildren from the Karlsburg type 1 diabetes risk study, of those 31 with multiple AAbs as identified by combined screening for GADA, IA-2A and IAA, were analyzed for different ZnT8A variants based on immunoprecipitation of the 35S-Methionine labeled antigens. Additionally, 113 sera from patients with Type 2 Diabetes (T2D; median age at disease onset 49 yr, IQR 35-92 yr) were included.
Results: In T1D patients the ZnT8A prevalence amounted to 51% (n=53), predominantly directed against all three ZnT8 isoforms in 24.5% (n=25). ZnT8WA only were found in 10.7% (n=11), ZnT8RA only in 7.8% (n=8) whereas ZnT8QA only did not appear. In contrast, none of the LADA patients with an overall ZnT8A prevalence of 25.8% (n=25) had reactivity against all three ZnT8 isoforms. Among the single reactivities, ZnT8WA was most frequent with 11.3% (n=11) whereas both ZnT8RA and ZnT8QA only were found in 2.1%. Only 3.5% (n=4) of the patients with T2D had ZnT8A, all directed against ZnT8R only. The prevalence of ZnT8A in high risk schoolchildren with multiple AAbs was 67.7% (n=21), predominantly directed against all ZnT8 isoforms in 32.2% (n=10), similar to T1D patients. In contrast, only 2.8% (n=3) of the schoolchildren at lower risk and with single AAbs were positive for ZnT8A, however two of them progressed to T1D. In T1D, LADA and AAb-positive children ZnT8WA were highly correlated with ZnT8QA (r_S= 0.61-0.94; p<0.0001). In T1D patients and AAb-positives all three ZnT8 isoforms were correlated with IA-2A (r_S= 0.29-0.53; p<0.0001). Additionally, in LADA patients and in AAb-positive children ZnT8WA and ZnT8QA were correlated to a lesser extent with GADA (r_S= 0.21-0.41; p=0.033-p<0.0001).
Conclusion: ZnT8A were detected in all investigated groups but especially in probands with beta cell directed autoimmunity. In patients with T1D and AAb-positive at-risk probands, ZnT8A are directed against multiple variants and AAbs against ZnT8Q only are rare, whereas in LADA patients AAbs against ZnT8W only are most frequent. The strong correlation between ZnT8A and the particular high risk marker IA-2A in patients with T1D and at-risk probands as well as the fact that ZnT8A were detected in schoolchildren previously classified as low risk probands but with later progression to T1D further underlines the importance of these AAb in autoimmune diabetes.

308

Levels of 12-HETE are elevated in patients with newly diagnosed but not with established type 1 diabetes

E. Hennessy[1], A. Rakovac Tisdall[2], N. Murphy[3], A. Carroll[3], C. Clarke[1], M. Clynes[1], P. Dowling[1], S. Sreenan[2];
[1]National Institute for Cellular Biotechnology, Dublin City University, [2]Connolly Hospital Blanchardstown, [3]Children's University Hospital Temple Street, Dublin, Ireland.

Background and aims: Global, non-targeted metabolomic screening identified 12-hydroxyeicosatetraenoic acid (12-HETE) as being elevated in serum from patients with newly diagnosed type 1 diabetes (T1DM) relative to controls. 12-HETE has been implicated in inflammatory processes and associated with oxidative stress. It has been extensively linked with pancreatic beta cell dysfunction in both human and mouse islets. This study aimed to determine if this result could be validated in a larger cohort of samples, in a range of disorders of glucose metabolism, using a more specific and quantitative ELISA test, to determine if 12-HETE may be of potential value as a biomarker for diabetes.
Materials and methods: 12-HETE levels were measured in serum from both adult and paediatric patients using a commercially available ELISA. The adult cohort studied included newly diagnosed T1DM (n=8), established T1DM (n=29), newly diagnosed type 2 diabetes (n=34), poorly controlled type 2 diabetes (n=21), impaired glucose tolerance (n=10), controls with BMI ≤ 30 (n=29) and controls with BMI ≥ 30 (n=15). The paediatric cohort included newly diagnosed T1DM (n=14), established T1DM (n=39) and control individuals (n=52).
Results: Significantly raised 12-HETE levels were identified in this study in both adult (2.31 fold, p=0.0022) and paediatric newly diagnosed T1DM specimens (2.60 fold, p=0.0016) compared to controls while levels in established T1DM specimens were similar to levels in control specimens. ROC curve analysis evaluates the power of 12-HETE to distinguish newly diagnosed T1DM patients from control individuals. AUC values of 0.867 for adults and 0.797 for children were calculated for 12-HETE in the T1DM new cohorts analysed here, placing 12-HETE in the average to good range of biomarker evaluation criteria. Sensitivity rates of 100% in adult and 91.7% in paediatric specimens indicate the power of 12-HETE to identify true positive T1DM new patients from control individuals.
Conclusion: We have demonstrated elevated levels of 12-HETE in newly diagnosed T1DM which suggests a potential role for 12-HETE in the inflammatory processes underscoring the condition. Further studies are required to determine possible utility of 12-HETE as a marker of risk of diabetes development in at-risk individuals.

Relationship of serum cytokines and proinflammatory markers to development of type 1 diabetes

K. Siewko, M. Szelachowska, A. Poplawska-Kita, D. Lipinska, A. Nikolajuk, M. Gorska;
Department of Endocrinology, Diabetology and Internal Medicine, Medical University, Bialystok, Bialystok, Poland.

Background and aims: Elevated tumor necrosis factor α (TNFα), C-reactive protein (CRP), chemerin, fetuin-A, have been reported in insulin resistance patients with type 2 diabetes. It is known that insulin resistance and distur-

bances of insulin secretion play a role in type 1 diabetes. However, it is not entirely clear whether these alterations in adipokine serum concentrations are already present in prediabetic states and in type 1 diabetes. The aim of the study was to investigate whether adipokine profiles (chemerin, fetuin-A, TNFα) and inflammatory markers (CRP) are associated with decreases in insulin sensitivity and beta cell function in first degree relatives of patients with type 1 diabetes (T1D) and their usefulness in the assessment of the risk of development of diabetes.

Materials and methods: The study was conducted in 90 first- degree relatives of the patients with T1D (mean age 27.1±15.48 years; mean BMI 24.6±4.95 kg/m^2) and 60 healthy individuals (mean age 29,9±13,7 years; mean BMI 22,8±2,3 kg/m^2). TNFα , chemerin and fetuin-A concentrations were determined using ELISA method, CRP by turbidimetric method. HOMAIR and HOMA%B indices were calculated using computer calculator from the Website Oxford Centre for Diabetes, Endocrinology and Metabolism.

Results: CRP and TNF-alpha concentrations were significantly higher in the relatives compared to the controls (3.27mg/L±2,48 vs 1.14±1.39; p<0,007; 8.58pg/ml±15.49 vs 0.63±0.79, p<0.005, respectively). We found significantly higher chemerin concentration (0.6848±28.67 vs 0.5112±32.41, p<0.006) and fetuin-A concentration (276.92±30.9 vs 214.66±34.2; p<0.001) in the study group as compared to the healthy controls. Significantly higher HOMAIR (1.16±0.63 vs 0.79±0.34, p<0.002) and significantly lower HOMA%B index (92.84±29.39 vs 114.0±47.06, p<0.015) were found in the relatives as compared to the controls. HOMAIR correlated positively with TNFα (r=0.430, p<0.001), and chemerin (0.732, p<0.0001) and fetuin-A (0.454, p<0.0001) and CRP (r=0.445, p<0.0001). HOMA%B negatively correlated with TNFα (r=-0,431, p<0.0001) and CRP (r=-0,460; p<0.0001).

Conclusion: Alterations in chemerin, fetuin-A, CRP and TNFα are already detectable in first degree relatives of T1D, and may reflect to identify insulin resistance as an early pathogenetic event before T1D development. Fasting levels of chemerin, fetuin-A, CRP and TNFα might be used as biomarkers to identify insulin resistance and decrease of beta cell function in healthy individuals with higher risk of T1D.

310

Targeting IL-15 for immunotherapy in autoimmune diabetes

S. Ramanathan, D. Bobbala, M. Mayhue, S. Ilangumaran;
University of Sherbrooke, Sherbrooke, Canada.

Background and aims: Inflammatory cytokines promote the development of autoimmune diseases by different mechanisms. Recently, we have also shown that NOD mice lacking IL-15 are protected from T1D due to inefficient activation of diabetogenic CD8+ T cells. Furthermore, inhibition of IL-15 signaling using a mAb to IL-15R beta chain, during the initiation phase of the disease, protected NOD mice from T1D. A greater understanding of the effect of inhibiting IL-15 signaling at different stages of T1D will lay the foundation to develop strategies to target IL-15 signaling in human T1D patients. The aim of this study is to determine whether IL-15 signaling blockade is effective in inhibiting autoreactive T cells after the development of clinical T1D.

Materials and methods: Female NOD mice were treated with anti-IL-15 receptor beta chain (TM-β1) or control antibody corresponding to specific stages of T1D: initation, progression or frank diabetes. The donor splenocytes were extensively phenotyped for T, B and NK cell markers before adoptive transfer to male NOD.Scid recipients. Recipients were monitored for T1D. At sacrifice, pancreata were fixed in formalin for histology and the phenotype of the recovered donor cells was assessed.

Results: We observed that adoptive transfer of splenocytes from diabetic female NOD mice that received anti-IL-15 receptor beta antibody, but not control antibody after the development of T1D did not induce diabetes in NOD.Scid recipients. Treatment with TM-β1 resulted in a decrease in the frequency of CD8+ T cells in the diabetic NOD mice. The reduction was more pronounced in the CD44hi CD62Llo population, which defines the memory CD8+ T cell subset.

Conclusion: Our results suggest that blocking IL-15 signaling in clinically diabetic mice results in the depletion of islet-reactive T cells. These observations are of potential significance in the clinics where islet-specific T cells that are present in circulation compromise the efficient long-term engraftment of transplanted islets.

Non-diabetic first degree relatives of type 1 diabetics vs recent-onset type 1 diabetics: insulin secretion and insulin sensitivity changes at onset of type 1 diabetes

T. Milicic[1], N. Lalic[1], A. Jotic[1], I. Markovic[2], K. Lalic[1], L. Lukic[1], N. Rajkovic[1], M. Macesic[1], J. Seferovic[1], J. Stanarcic[1];
[1]Clinical Center of Serbia, Clinic for Endocrinology, [2]Institute for Biochemistry, Belgrade, Serbia.

Background and aims: Previous studies have reported an important role of impairments in insulin secretion in prediabetes and in the initial phase of type 1 diabetes (T1D), while the data regarding insulin sensitivity levels in previous conditions are still controversial. In addition, the onset of T1D is associated with impairments in the ratio between pro vs anti-inflammatory (Th1 and Th2) T memory cell subsets (characterized with expression of chemokine receptors CXCR3 and CCR4, respectively). However, the relationship between the metabolic and immunological/pro-inflammatory changes at recent onset type 1 diabetes and their first-degree relatives (FDRs) has not yet been clarified. Therefore, the aim of this study was to analyse the changes in (a) insulin secretion, (b) insulin sensitivity levels and (c) percentage of CXCR3+ and CCR4+ T memory cell subsets in peripheral blood in the following groups of subjects: (1) high-risk nondiabetic FDRs of patients with T1D (glutamate decarboxylase antibody (GADA)+, IA2 antibody (IA2A)+) (group A, N=10); (2) low-risk nondiabetic first-degree relatives (FDRs) of patients with T1D (GADA-, IA2A-) (group B, N=34); (3) recent-onset T1D patients (group C, N=24) and (4) healthy, unrelated control subjects (group D,N=18).

Materials and methods: Insulin secretion was evaluated by first-phase insulin response (FPIR) as insulin levels 1+3 min after IVGTT. Insulin sensitivity was tested by using euglycemic hyperinsulinemic clamp method. Total glucose uptake (M value) was calculated on the basis of the amount of glucose infused during steady state period (80-120 min). Plasma insulin levels were determined by RIA. GADA and IA-2A levels were determined by ELISA. The percentages of CXCR3+ and CCR4+ T memory cell subsets were analyzed in peripheral blood by using four-color immunofluorescence staining and flowcytometry.

Results: The levels of FPIR were lower in group A vs B and D (A: 84.56±11.79, B: 121.54±23.39 μU/ml, D: 140.53±38.11, A vs B, D p<0.01, B vs D p=NS), while on all three groups they were significantly higher than in C (9±3.68μU/ml, p<0.001). However, the M value did not vary between groups A, B and D (A: 5.87±0.11, B: 6.58±0.27; D: 6.78±0.28 mg/min/kg, p=NS), but it was significantly lower in C (C: 4.7 ±0.22, C vs A, B,D p<0.05). Simultaneously, the percentage of CXCR3+ T memory cells was found to be higher in group A vs B, C and D (A: 64.27±6.53 vs B: 51.79±6.79; C: 40.19±11.52; D: 53.09±6.29%, p<0.05), while the percentage of CCR4+ T memory cells was significantly lower in groups A, C vs B and D (A: 30.04±3.26 vs B: 41.90±8.59; C: 31.53±9.67; D: 40.90±7.24 %, p<0.05).

Conclusion: Our results have demonstrated that high risk nondiabetic FDRs showed lower levels of FPIR, increases in CXCR3+ Th1 cells and lower levels of CCR4+ Th2 cells subsets without impairments in insulin sensitivity, and in recent-onset T1D similar changes are accompanied with decreased insulin sensitivity. The results imply that initial changes in the course of type 1 diabetes comprise early decline of insulin secretion associated with pro-inflammatory response which does not affect insulin sensitivity while later in the course of the disease insulin sensitivity impairments appear to be primarily due to the marked decrease in insulin secretion.

312

Validation of insulin dose-adjusted HbA_{1c} (IDAA1c) in 129 Danish children with new-onset type 1 diabetes

M.-L.M. Andersen[1], S. Pörksen[1], L.B. Nielsen[1], J. Svensson[1], J. Thomsen[2], N.T. Hertel[3], J. Vikre-Jørgensen[4], J.S. Petersen[5], L. Hansen[1], P. Hougaard[6], H.B. Mortensen[1];
[1]Pediatrics, Herlev Hospital, Herlev, [2]Pediatrics, Kolding Hospital, Kolding, [3]Pediatrics, Odense Hospital, Odense, [4]Pediatrics, Skejby Hospital, Aarhus, [5]Diabetes Pharmacology and Bioanalysis, Novo Nordisk A/S, Måløv, [6]Statistiscs, University of Southern Denmark, Odense, Denmark.

Background and aims: The aim of the present study is to validate the remission definition as assessed by insulin dose-adjusted HbA1c (IDAA1c) and to investigate the clinical value of IDAA1c (with and without age) as predictor

of stimulated C-peptide (SCP) 12 months after diagnosis in a Danish cohort of children and adolescent with new onset type 1 diabetes (T1D).
Materials and methods: The IDAA1c measure was developed using 251 children aged <16 years from the European Hvidoere Remission Phase Study (1999-2000 Cohort). To confirm the relations in the Hvidoere study 129 newly diagnosed T1D patients aged <17 years from the Danish Remission Phase Study (2004-2005) were followed from onset of T1D. After 1, 3, 6, and 12 months a MMTT (Boost High protein: 33 g carbohydrate, 15 g protein, 6 g fat in Hvidoere; Boost Original: 41 g carbohydrate, 10 g protein, 4g fat in the Danish cohort) was performed and SCP was used as a measure of the residual beta cell function. HbA1c and insulin dose per kg body weight were recorded. The definition of IDAA1c: HbA1c (%) + [4 x insulin dose (units/kg/24H]. IDAA1c ≤ 9 was used to define partial remission. ROC-curves (receiver operating characteristic curve) were calculated to evaluate the predictive value of IDAA1c and age (using the score function from the Hvidoere data) on partial SCP remission (defined as SCP > 300 pmol/l). Additionally, the SCP value after 6 and 12 months in the Danish cohort was regressed on IDAA1C and age.
Results: Partial remission in the Danish cohort occurred in 62,4% at 3 months, 47% at 6 months (45% Hvidoere), 26% at 9 months and 19% at 12 months (18% Hvidoere) after diagnosis with no statistical significant difference (P=0.29) to the proportion of patients in partial remission in the Hvidoere Cohort at the same time points. There was a negative correlation between SCP and IDAA1c at 6 and 12 months with no significant differential effect between the two cohorts (P=0.68). The regression coefficient to IDAA1c is similar in the two cohorts, (Hvidoere: -0.22 vs Danish: -0.21, 6 months; -0.23 vs -0.24 12 months) but the effect of age (0.087 vs 0.18, 6 months; 0.14 vs 0.23, 12 months) is much higher in the Danish cohort compared to the Hvidoere cohort (P<0.0001). Using IDAA1c=9 and age=10 years the predicted C-peptide level is 311 pmol/L in the Hvidoere cohort compared to 428 pmol/L in the Danish Cohort. The ROC curves (6 and 12 months after diagnosis) show a clear predictive power as age and IDAA1c in combination give a more precise prediction of partial remission defined by SCP>300pmol/L in the Danish cohort than age alone. Odds ratio (CI): 6 months: 2.5 (1.8- 3.6); 12 months: 2.4 (1.7-3.2).
Conclusion: We have confirmed the findings for remission defined by IDAA1c≤9 in an independent cohort of children with new onset T1D. A comparable proportion of patients are in remission in the two cohorts despite a higher level of SCP in the Danish Cohort particularly in the adolescent group. As age has a stronger effect on IDAA1c in the Danish cohort, which is most likely due to a different MMTT stimulation, age must be taken into account when using IDAA1c for prediction of SCP in this cohort.

Ethnic disparities in conversion from impaired fasting plasma glucose to type 2 diabetes
W. Admiraal, F. Holleman, M. Snijder, R. Peters, L. Brewster, J. Hoekstra, K. Stronks, I. Van Valkengoed;
Academic Medical Center, Amsterdam, Netherlands.

Background and aims: Despite the ethnic differences in prevalence and incidence of type 2 diabetes (DM), the evidence on ethnic disparities in conversion from prediabetes to DM is scarce. We aimed to compare the association of impaired fasting glucose (IFG) with the 10-year cumulative incidence of DM in individuals of South-Asian, African and Caucasian origin.
Materials and methods: We analysed data from a population based sample of 90 South Asians, 190 Africans and 176 Caucasians, who had participated in the population based SUNSET study between 2001 and 2003 and who had also participated in a follow up visit between 2011 and 2012. We excluded those with a missing fasting plasma glucose at baseline, a missing fasting plasma glucose at follow up, or with DM at baseline. Baseline IFG was defined as fasting plasma glucose of 5.7 mmol/L - 6.9 mmol/L. At follow up, DM was defined as fasting plasma glucose ≥ 7.0 mmol/L, HbA1c ≥ 48 mmol/mol (6.5%) or self reported DM.
Results: Of all participants, 41.0% were men and the mean age at baseline was 45.4 ± 6.5. The 10-year cumulative incidence of DM was 18.9% in South Asians, 13.7% in Africans and 4.5% in Caucasians (p<0.05). We found a much stronger association between baseline IFG and incident DM in South Asians than in Africans and Caucasians. This ethnic difference conversion from IFG to DM remained after adjustment for sex, age, baseline BMI and change in BMI over 10 years (odds ratio of 11.1 [3.0-40.8] in South Asians, 5.1 [2.0-13.3] in Africans, 2.2 [0.5-10.2] in Caucasians).
Conclusion: We found a higher 10-year cumulative incidence of DM and a stronger association of DM with baseline IFG in South Asians and Africans than in Caucasians. Our findings do not only emphasize the high risk of DM in South Asians and Africans when compared to Caucasians, but also suggest a more rapid conversion from IFG to DM in South Asians and, to a lesser extent, Africans than in Caucasians.

Impact of parental socio-economic resources on excess mortality in subjects with childhood onset type 1 diabetes
Y.T. Berhan[1], M. Eliasson[2], A. Mollsten[1], I. Waernbaum[3], G.G. Dahlquist[1], the Swedish Childhood Diabetes Study Group;
[1]Clinical Sciences, Pediatrics, [2]Medicine, Public Health and Clinical Medicine, [3]Statistics, Umeå School of Business and Economics, Umeå, Sweden.
Background and aims: Maternal education and other socio-economic factors are known to associate with general health care and child death. The aim of this study was to analyze the possible impact of parental socio-economic resources on mortality in a population based cohort of childhood onset type-1 diabetes (T1D).
Materials and methods: The Swedish Childhood Diabetes Registry (SCDR) has recorded cases of childhood onset T1D (0-14years) since 1 July 1977 with a high level of coverage. A total of 14 827 childhood onset T1D were recorded by 31st Dec 2008. The SCDR was linked to the Swedish Cause of Death Register and the Labor Market Research database. We retrieved data on parental educational level by 31st Dec 2010 and family's (parental) requirement of income support between the years 1990-2010. Mortality data were recorded as of 31st Dec 2010.The age and sex standardized mortality ratio (SMR) was based on national statistics. Cox proportional hazard functions were used for multivariate analyses. 95 % confidence intervals (CI) are given.
Results: A total of 250 deaths (male/female; 167/87) occurred in a total of 357 552 person-years at risk. Mean follow-up was 19.9 years, and maximum was 33.8 years. The overall SMR was 2.3 (CI 1.35 - 3.63). *Parental education*: Crude analyses on the effect of low maternal education (less than college) as compared to high (collage or above) showed an increased mortality for male cases (HR 1.48, CI 1.05-2.09, p=0.025) but not for female cases (HR

1.29, CI 0.78-2.13). Paternal education level had no effect on mortality in a crude analysis (HR 1.17, CI 0.89-1.55). In Cox-models, male sex and higher age at onset predicted increased mortality (p<0.001) together with maternal education (HR 1.35, CI 1.01-1.80, p=0.037). *Familial income support:* In crude analyses the family's requirement of income support (any/none) was associated with an increased risk of death for both men and women (HR 1.87, CI 1.35-2.59, p<0.001 and HR 1.99, CI 1.26-3.18, p=0.003, respectively). In a Cox model adjusting for age at onset and sex, ever having required income support was associated with doubled mortality (HR 1.99, CI 1.52-2.59, p<0.001). *Parental education versus income support*: In a final Cox model including maternal education level together with familial income support, age at onset and sex; ever having required income support was still an independent risk factor while maternal education was not (table 1). Further analyses will be performed stratifying for age at death.

Conclusion: Familial need for income support, in addition to male sex and higher age at onset, seems to be a strong predictor of all cause mortality among childhood onset T1D subjects in Sweden.

Table 1.

COX MODEL	HR (95% CI)	p-value
Male sex	1.83 (1.38-2.42)	0.001
High age at onset	1.47 (1.21-1.78)	0.001
Low maternal education	1.25 (0.93-1.68)	0.145
Family received income support	1.95 (1.49-2.55)	0.001

Factors associated with sustained poor glycaemic control in Chinese patients with type 2 diabetes in Hong Kong

J.M. Yin, R. Yeung, Y. Zhang, Y. Sui, N. Brown, A. Kong, R. Ozaki, A. Luk, R.C.W. Ma, W. Chan, P. Tong, W. So, J. Chan;
Department of Medicine and Therapeutics, The Chinese University of Hong Kong,Prince of Wales Hospital, Asia Diabetes Foundation, Qualigenics Diabetes Centre., Hong Kong SAR, China.

Background and aims: We hypothesised that specific clinical, psychological and behavioral factors all contribute to sustained poor glycaemic control in people with type 2 diabetes.

Materials and methods: Amongst 15,622 Hong Kong Chinese patients with type 2 diabetes enrolled in the Joint Asia Diabetes Evaluation (JADE) Program since 2007, 3,648 patients underwent repeat comprehensive assessments(CA) after a median (IQR) follow-up period of 1.36 (1.04-1.99) years. We defined subjects with sustained poor glycaemic control (SUS+ group) as those with A1c≥9% at baseline CA and repeat CA. Factors that were significant in the univariate analysis (p<0.15) were selected to enter multivariate logistic regression analyses to identify predictors for sustained poor glycaemic control.

Results: Amongst 516 patients with A1c≥9% at baseline, 164 (32.4%) remained in the SUS+ group (A1c:10.40±1.25% at baseline CA and 10.30±1.09% at repeat CA). The respective figures were 10.35±1.15% and 7.19±0.92% (p<0.001) in the SUS- group. Compared to the SUS- group, the SUS+ group had longer disease duration, higher body mass index, higher rates of insulin treatment, and lower perceived state of health. On logistic regression analysis, longer disease duration (β=0.052, p=0.017), and use of insulin (β=0.768, p=0.033) predicted sustained poor glycaemic control. On the other hand, higher adherence to balanced diet (β= -0.907, p=0.020), increased physical activity (β= -0.865, p=0.016), increased follow up (β= -1.200, p=0.024), increased use of oral anti-diabetic drugs (β= -1.822, p=0.110), and higher perceived state of health (β= -0.017, p=0.103) were associated with improved glycaemic control.

Conclusion: These results highlight the multidimensional aspects in determining glycaemic control, and emphasize the importance of empowering patients to improve self-management practices. Addressing psychological health may also be particularly important in patients with sustained poor glycaemic control.

Characteristics associated with sustained poor glycemic control

Variable	Parameter		Hazard ratio			P value	R2 %

316

Age, glycaemic control and social deprivation independently predict 10-year mortality in a UK type 1 diabetes cohort

S. Thomas[1], L. Yassa[2], D. Simpson[2], T. Evans[3], S. Amiel[4], A. Simonds[5], D. Hopkins[6];
[1]Dept of Diabetes and Endocrinology, Guy's and St Thomas' Hospitals NHS Foundation Trust, London, [2]Monitor Deloitte, London, [3]DENOVaRS Clinical Academic Group, King's Health Partners, London, [4]Diabetes Research Group, King's College London School of Medicine, [5]Novo Nordisk Ltd, Crawley, [6]Dept of Diabetic Medicine, King's College Hospital NHS Foundation Trust, London, UK.

Background and aims: Patients with type 1 diabetes continue to have increased mortality and morbidity despite advances in diabetes care. In order to optimise provision of specialist services with the aim of improving outcomes, this study set out to determine potentially modifiable factors that influence mortality in type 1 diabetes in a defined urban population.

Materials and methods: Retrospective analysis of combined biochemical (HbA1c), demographic (age, sex, ethnicity and socio-economic status) and health resource utilisation data collected over a 10 year period for a cohort of T1D patients (n=1038) attending two inner city London specialist diabetes outpatient clinics. The cohort was defined to include all patients attending the service in 2002 with sequential HbA1c data available for each year from 2002 to 2004 and with on-going follow-up within the clinics until 2010. Baseline glycaemic control was defined based on mean HbA1c for the period 2002-2004. Economic status was determined using the index of multiple deprivation (IMD) a weighted deprivation score derived from a national dataset based on postcode of residence.

Results: At baseline, mean (±SD) age was 41.6 + 12.3 years and duration of diabetes 17.7 ±13.7 years . Mean HbA1c was 8.1 ± 1.4. 37 deaths occurred in the cohort by December 2012 (3.6% total cumulative mortality). Patients who died were significantly older (50.9 + 9.1 years, p <0.001) and had higher mean baseline A1c (9.1+ 1.6%, p<0.001) but did not differ in duration of diabetes (14.7+15.6, p=0.8) For individuals with baseline HbA1c ≥ 9.0% cumulative 10-year morality was significantly increased at 9.0 % (p< 0.001). Patients who died were more likely to be socially deprived, 61% of deceased patients having scores in the upper quintile of the population range (mean IMD score 32.3 ± 11.2 deceased vs 23.6+12.3 alive, p=0.001). In a three step regression analysis, the effects of baseline HbA1c, age and IMD score on mortality were mutually independent.

Conclusion: Glycaemic control and social deprivation are independent risk factors for mortality in type 1 diabetes and identify characteristics of a population that may benefit from targeted interventions aimed at improving health outcomes.

Does birth weight affect insulin sensitivity and secretion and the prevalence of diabetes in a Japanese general population?

J. Oya[1], T. Nakagami[1], M. Kurita[1], Y. Yamamoto[1], Y. Hasegawa[1], Y. Tanaka[1], Y. Endo[2], Y. Uchigata[1];
[1]Diabetes center, Tokyo Women's Medical University, Tokyo, [2]Health and Community Medicine, Saitamaken Saiseikai Kurihashi Hospital, Saitama, Japan.

Background and aims: In Japan, babies with low birth weight (LBW) are increasing and average of birth weight (BW) is decreasing. Recently, LBW has been considered as an independent risk factor for diabetes mellitus (DM) in the studies from Europe and U.S, but there are few data from Asia. The unfavorable intrauterine environment may lead to future insulin resistance (IR) and beta cell dysfunction. Japanese are characterized by a lower BMI but higher percent body fat, than that in Whites, and have lower insulin secretary capacity than Whites, since the impact of birth weight on insulin sensitivity and secretion might be different from previous reports in Europe and U.S. Thus, the aim of this study was to assess the effect of BW on insulin sensitivity and secretion and the prevalence of DM in a Japanese population.
Materials and methods: Subjects were 847 (534 men, mean age 47±7 years) who participated in the health checkups at SSK hospital from February '06 to January'07 and answered the questionnaire about BW. Subjects with diabetic medication (n=20) were excluded when analyzing data for plasma glucose and insulin concentrations. DM was defined as self-reports of diabetes, or if they have fasting plasma glucose (FPG) ≥126mg/dl. BW was divided into three groups: G1; <2500g (LBW), G2; 2500-3000g, G3; 3001-3999g (Normal birth weight divided equally), G4; ≥4000g (high birth weight (HBW)). LBW was defined <2500 according to the summaries from American Academy of Pediatrics. Homeostasis model assessment of insulin resistance (HOMA-IR) and homeostasis model assessment of β-cell function (HOMA-B) were used to assess IR and insulin secretion. General liner model was used to analyze the association between BW and FPG, and log-transformed value of HOMA-IR or HOMA-B. Multivariate logistic regression model was used to calculate odds ratios (ORs) associated with DM, IR (highest quartile of HOMA-IR) and low insulin secretion (lowest quartile of HOMA-B) in subjects with LBW compared with those with G3 adjusted for age, sex, BMI and family history of DM.
Results: The average BW was 3070±430g, and the prevalence of LBW and HBW were 5.2% and 3.1%. The prevalence of DM was higher in subjects with LBW (9.1%) than those with normal BW(G2: 6.2%, G3: 2.6%), whereas there was no DM in subjects with G4 (HBW). Adjusted means for FPG and log HOMA-IR increased with decreasing BW ($p<0.05$ for both) while there was no significant association between adjusted means for log HOMA-B and BW. Multiple logistic regression analysis showed that the risk of having DM continuously decrease by 46% according to increase of 500g of BW. The adjusted OR of having DM, IR and low insulin secretion in subjects with LBW was 2.3 (95% confidence interval: 1.1-5.1), 3.9 (1.5-10.3) and 1.4 (0.5-3.4) compared with those with G3. In subjects with G4 (HBW), the adjusted ORs for having IR and low insulin secretion were 1.5 (0.9-2.5) and 2.1 (0.7-6.3), respectively, compared with those with G3.
Conclusion: BW was inversely associated with FPG and HOMA-IR, whereas there was no association with HOMA-B. LBW increase the risk of DM, and IR may be the key factor of the association in Japanese population.

318

Predictive ability of simple clinical information without blood tests for future incident diabetes: a meta-analysis

S. Yoshizawa[1], S. Kodama[1,2], K. Fujihara[1,3], C. Horikawa[1,3], A. Sugawara[1,3], Y. Heianza[1,3], Y. Yachi[1], S. Tanaka[4], S. Minakawa[1], T. Yamada[1], A. Suzuki[1], O. Hanyu[1], H. Sone[1];
[1]Department of Hematology, Endocrinology and Metabolism, Niigata University Faculty of Medicine, Niigata, [2]Department of Health Management Center, Mito Kyodo General Hospital, Mito, [3]Department of Internal Medicine, University of Tsukuba Institute of Clinical Medicine, Tsukuba, [4]Department of Clinical Trial Design & Management, Translational Research Center, Kyoto University Hospital, Japan.

Background and aims: Development of a simple method to predict diabetes mellitus is essential for early detection of persons at high risk of diabetes due to its worldwide growing epidemic and the seriousness of its many complications. This meta-analysis aimed to assess the predictive ability of clinical information without blood testing for future incident diabetes.
Materials and methods: Electronic literature search was conducted for cohort studies that prospectively followed up incident diabetes using MEDLINE (from 1950 to Dec. 3, 2012) and EMBASE (from 1974 to Dec. 3, 2012). Studies had to include at least age, an obesity indicator, and family history of diabetes as clinical information to predict future diabetes and allow calculations of the number of true-positive, false-negative, true-negative, and false-positive cases. Pooled sensitivity, specificity, positive likelihood ratio (LR+), and negative likelihood (LR-) were estimated with a hierarchical summary receiver-operating characteristic model.
Results: Of 15,908 citations retrieved from the two databases, 8 eligible studies (follow-up duration from 5 to 15 y) consisting of 98,191 participants and 9,358 cases were identified. Two studies had samples that included both a derivation and validation study. Finally, 10 datasets were included in this meta-analysis. Point estimates of sensitivity, specificity, LR+, and LR- with 95% confidence interval were 0.70 (0.62-0.75), 0.69 (0.62-0.75), 2.25 (2.00-2.53), and 0.44 (0.38-0.50), respectively (Figure). Definite heterogeneity in study results was not observed through several specified population characteristics such as gender, mean age, and ethnicity. Slightly low LR+ (<2) was observed in 4 studies that had an observation period of <6 years (LR+=1.94) and in 4 studies that used the oral glucose tolerance test for ascertaining diabetes (LR+=1.97). LR- was consistently <0.5 throughout these study characteristics.
Conclusion: Using simple clinical information could be a modest help in considering whether a person will develop diabetes. However, there was not strong evidence for effectiveness in detecting persons at high risk of future diabetes without results of blood tests.

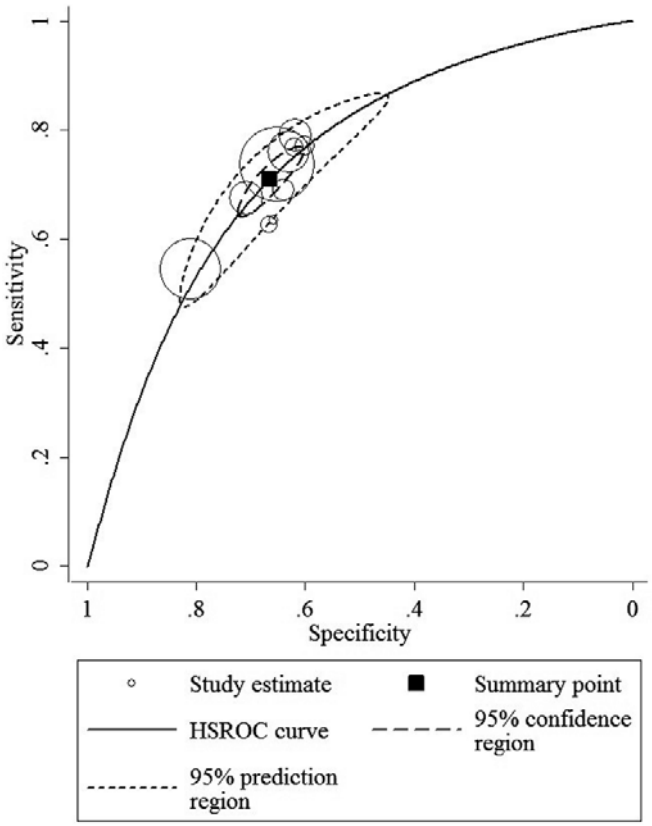

Figure Hierarchical summary receiver-operating characteristic curve with its accompanying 95% prediction region for predicting incident diabetes using simple clinical information without a blood test. Point estimate is indicated by a solid square. Each data point is indicated by a circle, the size of which depended on the study sample.

319

Increased incidence of disorders of carbohydrate metabolism and metabolic syndrome in persons exposed to ionising radiation

O.V. Kaminskyi[1], D.E. Afanasyev[1], O.V. Tepla[1], I.O. Kiselova[2];
[1]Endocrinology, State Enterprise "National Research Center for Radiation Medicine of AMS of Ukraine", [2]Kiev City Center of Clinical Endocrinology, Kiev, Ukraine.

Background and aims: The most wide-scale man-made accident at the Chernobyl NPP (ChNPP) on April 26, 1986 was followed by the massive release of radioactive elements being tropic to many endocrine tissues. Fallout of the mentioned substances resulted in both external and internal irradiation of population. The hormone-producing pancreatic cells were exposed at that among other tissues leading to an increased risk of diabetes mellitus DM) and associated disease.
Materials and methods: Retrospective analysis (i.e. 20-25 years upon radiation impact) was applied among the ChNPP accident survivors (n=606) and general population of Ukraine (n=589) (control group) to the indices of: 1) DM incidence, 2) basal serum levels of insulin, C-peptide, leptin, thyroid-stimulating hormone and free thyroxin, 3) coefficients of tissue resistance (HOMA, QUICKI), 4) incidence of thyroid disease.
Results: Incidence of type 2 DM (21,4%) was higher in all subgroups of the ChNPP accident survivors (χ2Yates=25,64; p=0) vs. control group (10,5%). The supreme probability of type 2 DM was found in Chernobyl emergency workers engaged in work within so-called "non-iodine" period in 1986-1987, namely in 60% of persons (χ2Yates=89,72; p=0) who for the most long time had stayed in the 30-kilometer exclusion zone. High probability was found also in the emergency workers of the "iodine" period (April-August of 1986), namely in 23,5% of persons (χ2Yates=25,21; p=0).
Conclusion: Metabolic syndrome (MS) was more often diagnosed in the ChNPP accident survivors i.e. in 49,8% (χ2Yates=207,14; p=0) vs. control group (9,5%). Type 2 DM and MS were diagnosed mainly in people having an excess of body adipose tissue (body mass index >25 kg/m2). Cases of type 2 DM and MS were associated with increased indices of insulin resistance and leptin resistance.

Social network and development of prediabetes and type 2 diabetes in middle-aged Swedish women and men

A. Hilding[1], C. Shen[2], C.-G. Östenson[1];
[1]Dept. of Molecular Medicine and Surgery, The Endocrine and Diabetes Unit, Karolinska Instititet, Stockholm, Sweden, [2]Dept. of Epidemiology and Biostatistics, School of Public Health, Nanjing Medical University, Nanjing, China.

Background and aims: In general, social ties are associated with health benefits. The aim of the present study was to explore if social network affects the development of prediabetes and type 2 diabetes (T2D).
Materials and methods: The study included 2924 women and 2039 men, aged 35-56 years and with normal glucose tolerance (NGT) at baseline. A follow-up was performed 8-10 years later and again the participants were investigated with an oral glucose tolerance test (OGTT). By then prediabetes (IFG and/or IGT) and type 2 diabetes (T2D, including also those who were diagnosed with T2D during the follow-up period) was detected in 168 and 50 women and in 236 and 93 men, respectively. We analyzed the associations of prediabetes and T2D with different measures of social network recorded by questionnaire at baseline; AVSI-index (availability of social integration i.e. quantity and quality of daily social contacts), marital status (married or living with partner) and social activity (being member and regularly taking part in meetings of association, club or congregation and/or taking part in study circles, sports or music playing together with other people). We calculated odds ratios (OR) and 95% confidence intervals (CI), age-adjusted and additionally adjusted for potential confounding variables (BMI, physical activity, smoking, socioeconomic status, psychological distress, decision latitude at work and sense of coherence), using multiple logistic regression analysis.
Results: Having AVSI scores in the highest tertile, i.e. better social integration, was associated with a decreased risk to develop T2D in women, age-adjusted OR=0.41 (95% CI: 0.19-0.88) although not significant after full adjustment, OR=0.51 (0.22-1.17). Contrary, in men AVSI was associated with an increased risk to develop T2D, especially in the middle tertile, OR=2.05 (1.20-3.49) and OR=2.48 (1.41-4.36) for age- and multi adjusted models, respectively. Taking part in social activities decreased the risk to develop prediabetes and T2D in women, age-adjusted OR=0.65 (0.46-0.91) and OR=0.43 (0.24-0.77) although less significant when adjusted for confounders, OR=0.77 (0.53-1.11) and 0.59 (0.31-1.13), respectively. Also in men a decreased risk was observed, but only for prediabetes, OR=0.60 (0.43-0.83) in the multi-adjusted model. Being married or living with partner was associated but only in men in whom a decreased risk for T2D was observed, OR=0.57 (0.33-0.97) and OR=0.60 (0.34-1.07) for age- and multi adjusted models, respectively.
Conclusion: Individuals having a social network in terms of family, friends, acquaintances and social activities seemed less likely to develop abnormal glucose regulation. When significance was decreased after multi-adjustments, this might be due to that the measures of social network and psychosocial confounders to some extent capture similar conditions. However, contradictory to an overall protective pattern of having a social network, AVSI showed in men an increased risk to develop T2D.

A chronic exposure to a mixture of low-dosed food contaminants predisposes to the risk of developing metabolic disorders

B. Le Magueresse-Battistoni[1], N. Vega[1], C. Pinteur[1], E. Labaronne[1], C. Luquain-Costaz[2], H. Vidal[1], D. Naville[1];
[1]Inserm U1060 CarMeN, Inra USC 1362, Université Lyon 1, Oullins, [2]Inserm U1060 CarMeN, INSA-Lyon IMBL, Université Lyon 1, Villeurbanne, France.

Background and aims: Apart from genetic alterations and behaviors associated with excessive food intake and low physical activity, environmental pollutants have emerged as a new cause of metabolic diseases. Based on biodegradation, pollutants are classified as short-lived or Persistent Organic Pollutants (POPs). POPs are chemicals created intentionally (polychlorinated biphenyls, PCBs) or by-products (dioxins). Being lipophilic, POPs accumulate through the food chain. Bisphenol A (BPA) and phthalates are short-lived chemicals but because of their massive production (plastic goods), they largely contaminate food and beverages by leaching from containers and packaging. Consequently, non-occupational exposure is characterized by lifetime exposure to a whole host of chemical agents of which resulting effects could not be predicted from the effect of each individual pollutant, and food ingestion is a primarily route of exposure (especially fatty foods). Yet, human health risk assessment studies have focused primarily on single chemicals, setting up Tolerable Daily Intake (TDI) doses based on the No Observed Adverse Effect Levels (NOAELs) from animal studies. These findings prompted us to directly explore the hypothesis that a chronic exposure to a mixture of low-dosed food contaminants may predispose to the risk of developing metabolic disorders.
Materials and methods: Briefly, mice were challenged from preconception throughout life with a high-fat high-sucrose diet containing food pollutants (2,3,7,8-tetrachlorodibenzo-p-dioxin, PCB153, diethylhexyl-phthalate and BPA) added at doses 500-1000 lower than their NOAEL. Therefore, it grossly corresponded to the TDI for each pollutant. We measured several blood parameters, glucose and insulin tolerance, hepatic lipid accumulation and gene expression by RT-qPCR and Western blotting analysis in adult mice.
Results: Pollutant-exposed mice exhibited significant sex-dependent metabolic disorders (all with $p<0.05$) in absence of toxicity and weight gain. In males, there was no modification of either glucose tolerance or insulin sensitivity. However, we observed that pollutants increased the expression of hepatic genes (from 36 to 88% at the mRNA level) encoding proteins related to cholesterol biosynthesis, and decreased (40%) hepatic total cholesterol levels. In females, exposure to pollutants resulted in a marked deterioration of glucose tolerance. Analysis of gene expression in liver indicated reduced expression of estrogen receptor alpha by 25% (observed at mRNA and protein level) and of estrogen-target genes by >34% (mRNA level). Interestingly, a parallel two-fold induction of estrogen-sulfotransferase (EST) expression was observed indicative of enhanced estrogen metabolism and hence of reduced estrogen bioavaibility in liver. Estrogens protecting from metabolic disorders, it may well contribute to hepatic insulin resistance in exposed females.
Conclusion: Because of the very low doses of pollutants used in mixture, these findings may have strong implications in terms of understanding the potential role of environmental food contaminants in the development of metabolic diseases.

Foodborne cereulide causes beta cell dysfunction and apoptosis

R. Vangoitsenhoven[1], D. Rondas[1], I. Crèvecoeur[1], W. D'Hertog[1], G. Bomfim Ferreira[1], C. Matthys[1], M. Maris[1], M. Andjelkovic[2], J. Van Loco[2], L. Overbergh[1], C. Mathieu[1], B. Van der Schueren[1];
[1]Clinical and Experimental Medicine and Endocrinology, KU Leuven, [2]Food, Medicines, and Consumer Safety, Scientific Institute of Public Health, Brussels, Belgium.

Background and aims: The prevalence of both type 1 and type 2 diabetes mellitus is rising and the increase is believed to be related to environmental factors. Foodborne toxins that can directly induce beta cell dysfunction and apoptosis might partly explain the diabetes epidemic in this era of prepared and prepackaged meals. In our study, we investigate the beta cell toxicity of cereulide, a mitochondriotoxic peptide produced by certain strains of Bacillus cereus that is frequently found at low concentrations (approximately 4 ng/g of food) in rice, pasta and potatoes meals.
Materials and methods: Mouse and rat insulin producing beta cell lines, MIN6 and INS-1E respectively, as well as human hepatocellular HepG2 and monkey fibroblast-like COS cells were exposed to cereulide concentrations ranging from 0.05ng/ml to 5ng/ml for 24, 48 and 72h. Cell death was evaluated by a Hoechst/Propidium Iodide assay by two investigators blinded for exposure. Whole mouse islets, isolated from 2 week old C57Bl/6J mice, were exposed to similar cereulide concentrations for 1, 3 and 5 days and cell death was determined similarly. To evaluate the exact mechanisms leading to cell death, MIN6 cells were exposed to low concentrations of cereulide (0.15 - 0.5 ng/ml) for 24h and mechanisms of toxicity were evaluated by mRNA profiling and caspase 3/7 activation bioluminescence assay. Finally, beta cell function was assessed by analyzing glucose-stimulated insulin secretion of MIN6 cells, treated for 24 h with low concentrations (0.15 - 0.5 ng/ml) of cereulide.
Results: Cereulide exposure caused cell death in MIN6, INS-1E and pancreatic islets, but not in HepG2 or COS cells (see table 1). Caspase 3/7 activation confirmed the apoptotic cell death process (1.54 ± 0.07 fold induction by 0.25 ng/ml cereulide compared to control; $p < 0.01$). Interestingly, exposure to 0.25ng/ml cereulide induced markers of mitochondrial stress, including PUMA (p53 upregulated modulator of apoptosis; 180 ± 57 % of control; $p < 0.05$) but also markers of ER stress, such as CHOP (CCAAT/-enhancer-binding protein homologous protein; 294 ± 69 % of control; $p < 0.01$). Glucose-stimulated insulin secretion decreased from 10.48 ± 3.33 fold to 2.012 ± 0.51 ($p < 0.05$) after 24h exposure with 0.25 ng/ml cereulide.
Conclusion: Cereulide, a toxin frequently found in prepackaged or prepared starchy meals, increases levels of mitochondrial and ER stress markers in beta cells of rats and mice, even at low doses. In a dose dependent way, it also leads to impaired beta cell function and apoptosis. Cereulide might thus be involved in the current diabetes epidemic and in particular be responsible for observed clusters of sudden onset diabetes in Asia.

Table 1. Apoptosis induced after 24h exposure to cereulide (mean percentage ± SEM).

Pancreatic islet expression of enteroviral receptors and dsRNA sensors in human type 1 diabetes

I. Spagnuolo[1], S.J. Richardson[2], G. Sebastiani[1], F. Mancarella[1], A. Patti[1], N.G. Morgan[2], F. Dotta[1];
[1]University of Siena and Umberto Di Mario Foundation, Siena, Italy, [2]Institute of Biomedical & Clinical Science, University of Exeter Medical School, Plymouth, UK.

Background and aims: Type 1 diabetes mellitus (T1D) is a chronic autoimmune disease in which pancreatic beta cells are selectively destroyed by an autoimmune process. Among the environmental factors potentially involved in T1D etiology, viral infections have been suggested as key players, with several studies reporting evidence of enteroviral infection in pancreatic islets. Intriguingly, such infections are restricted to beta cells in recent-onset T1D patients. Susceptibility to viral infections is determined both by viral variants and by the nature of infection, while the specific tropism of viruses is modulated by local expression of cellular receptors, such as Coxsackie and Adenovirus receptor (hCAR). In addition, intracellular viral RNA sensors (e.g. RNA helicases RIG-I and MDA5) and other molecules (e.g. interferon -induced protein ISG-15) can trigger and/or modulate antiviral response. The aim of the present study was to characterize islet expression of molecules (hCAR, RIG-I, MDA5 and ISG-15) involved in virus-target cell interaction, in T1D and in non-diabetic pancreatic samples from multi-organ donors
Materials and methods: We analyzed pancreatic specimens obtained from 4 recent onset T1D, from 2 long standing T1D (disease duration 7 and 14 years respectively) and from 10 non-diabetic organ donors. Expression of

hCAR, RIG-I, MDA5 and ISG-15 was analyzed by immunohistochemistry. In order to establish which islet cell subset(s) express the molecules of interest (i.e. alpha-, beta- and delta cells) double immunofluorescence with confocal microscopy analysis was used. The extent of colocalization of hCAR, RIG-I, MDA5 and ISG-15 with insulin, glucagon or somatostatin was quantified by Leica Application Advance Fluorescence (LasAF) software.
Results: Viral receptor hCAR was expressed in islets from both T1D and non-diabetic donors almost exclusively within beta cells (average colocalization rate with insulin was 82.0±12.0% in T1D and 75.2±9.1% in non-diabetic donors; colocalization with glucagon was <15.0%), suggesting the existence of a differential distribution of enterovirus receptors among islet cell subsets. Of note, the few alpha cells expressing hCAR were single cells located outside the islets but scattered throughout the exocrine tissue. Expression of viral sensor RIG-I was observed mainly in delta cells both in T1D and in non-diabetic donors (colocalization rate with somatostatin 47.8±21.6% and 51.6±21.2% respectively; colocalization with insulin and with glucagon <5%). A similar delta-cell specific expression was observed for ISG-15 (colocalization rate with somatostatin 48.3±11.5% in T1D and 45.77±7.33% in non-diabetic donors). MDA5 was detected mainly within alpha cells (colocalization rate with glucagon 40.1±7.1%; colocalization with insulin <5%).
Conclusion: We show that the enteroviral receptor hCAR is expressed almost exclusively in beta cells, thereby providing a potential explanation for the beta cell specific tropism of certain enteroviruses. In addition, our discovery that expression of the viral sensors MDA-5, RIG-I and ISG-15 occurs mainly in non-beta cells, suggests that these cells are equipped with anti-viral response mechanisms that may limit their susceptibility to enterovirus infection.

Therapies which lower advanced glycation end products influence experimental autoimmune diabetes in a time dependent manner
D.J. Borg[1], F.Y.T. Yap[2], A.K. Fotheringham[1], B.E. Harcourt[1], D. McCarthy[1], M. Ward[1], R. Slattery[3], M.T. Coughlan[2], P. Kantharidis[2], J.M. Forbes[1,4];
[1]Glycation and Diabetes, Mater Research, Woolloongabba, [2]Division of Diabetes Complications, Baker IDI Heart and Diabetes Institute, Melbourne, [3]Department of Immunology, Monash University, AMREP, Melbourne, [4]Mater Clinical School, University of Queensland, St Lucia, Australia.

Background and aims: The incidence of type 1 diabetes is increasing worldwide within lower risk genotypes most likely as a result of environmental risk factors. Increasing exposure to advanced glycation end products (AGE), attributable to altered food processing and dietary patterns, has been shown to influence islet secretory function. Thus we aimed to examine the effects of various interventions to reduce AGE exposure administered either as short term interventions prediabetes as compared with intervention for the remainder of life.
Materials and methods: Fifty day old female NODShiLt mice (n=10/group) were randomised to receive (i) no intervention (ii) a diet with 4-fold lower AGE content or (iii) the AGE lowering therapy, alagebrium chloride (ALT; 1mg/kg/day) from day 50 to day 100 or day 50 to day 200 of life. Two additional groups were infected at day 50 with an adeno-associated virus (AAV) encoding either the human endogenous soluble receptor for AGEs (esRAGE) or a GFP-labelled scrambled protein.
Results: Prediabetic NODShiLt mice treated with ALT from day 50 to day 100 of life, had a substantial reduction in autoimmune diabetes by day 200 as compared to control mice (80% vs 20%, p=0.005). Conversely, mice fed with a low AGE diet prediabetes from day 50 to day 100 of life or overexpressing esRAGE were not protected from autoimmune diabetes as compared to control (40% vs 20%, p=0.33) or control AAV mice (30% vs 60%, p=0.19), at day 200 of life. Specifically, glucose and insulin tolerance were each improved by ALT therapy while a low AGE diet only improved glucose tolerance prediabetes (day 80) despite a decline in insulin sensitivity compared to control mice. Both cohorts of mice treated with AAV exhibited an increase in insulin secretion as compared to control mice at day 80 of life, which only reached significance in the control AAV group (control AAV: p=0.01, esRAGE: p=0.06). However, long term administration of either a low AGE diet or ALT (day 50 to day 200) decreased circulating AGE concentrations and prevented the development of autoimmune diabetes compared to control mice (90% and 95% respectively vs 50%, p<0.05) as well as improving glucose tolerance and islet secretory function, although again the low AGE group had a demonstrable decline in insulin sensitivity prediabetes when compared to control mice (p<0.05).
Conclusion: Our results demonstrate that protection afforded by targeting advanced glycation in experimental autoimmune diabetes can vary depending on the type and length of therapy. A better understanding of the mechanisms responsible for the variability of this protection would be highly desirable in order to better assess the applicability of this type of approach in the prevention of type 1 diabetes in humans.

Increased degradation of insulin granule proteins, caspase-like activity and MHC class I in Coxsackievirus infected insulin producing cells
A. Petzold[1], K.-P. Knoch[1], E. Töpfer[1], A. Sönmez[1], C. Wegbrod[1], C. Münster[1], M. Roivainen[2], M. Solimena[1];
[1]Molecular Diabetology, Paul Langerhans Institute Dresden, Dresden University of Technology, Germany, [2]National Institue for Health and Welfare, Helsinki, Finland.

Background and aims: Type 1 Diabetes (T1D) is characterized by the progressive autoimmune destruction of pancreatic beta cells. Proteins of the insulin secretory granules (SGs) are among the dominant autoantigens of T1D. Human Enteroviruses (HEVs) such as Coxsackievirus B (CVB) are among the environmental factors thought to trigger and/or accelerate the development of the disease. However, the mechanistic relationship between viral infection and loss of tolerance toward beta cell antigens remains unclear. Here we investigated whether infection of HEVs alters the expression of SG autoantigens and induce changes that may favor their presentation to the immune system.
Materials and methods: Mouse MIN6, rat INS-1, and human 1.1E7 insulinoma cells were infected with CVB5 serotypes Faulkner (F) and MIN6 cell adapted (MCA). Infected cultures were compared to non-infected cultures 96h post-infection. Mouse, rat and human islets were harvested 72h post-infection with CVB5 strains. Proteasome activities were measured by luminescence assay and protein expression by immunoblotting.
Results: CVB5 infection of MIN6 cells inhibited the biosynthesis of total protein, but not the glucose-stimulated translation of SG proteins. In CVB5-infected cells, however, the expression of mature SG proteins and insulin release were dramatically reduced. CVB5 infection increased the caspase-like proteolytic activity associated with the proteasome, while trypsin-like and chymotrypsin-like proteolytic activities were not altered. Evidence for cleavage of caspase 3 and poly (ADP-ribose) polymerase (PARP) was also negative. The increased caspase-like activity was not associated with increased apoptosis, while necrosis was increased. Finally, the levels of Major Histocompatibility Complex class I molecules (MHC class I) did not change in CVB5 infected mouse MIN6, rat INS-1 and human 1.1E7 insulinoma cells, but were increased in CVB5 infected rodent and human pancreatic islets relative to control islets.
Conclusion: By reducing total protein biosynthesis while increasing i) the degradation of SG proteins, ii) the caspase-like activity of the proteasome, and iii) the expression of MHC class I, CVB infection may poise beta cells for preferential presentation of SG protein-derived peptides to the immune system, and thus directs autoimmunity towards them.

Effect of nanopowder (TiO_2 and CO_3O_4) on circulating angiogenic cell viability, function and inflammatory response
M. Cito[1], V. Spigoni[2], M. Pinna[1], S. Pinelli[1], R. Alinovi[1], M. Goldoni[1], I. Zavaroni[1], A. Mutti[1], A. Dei Cas[1];
[1]University of Parma, [2]University of Brescia, Italy.

Background and aims: Recent evidences showed that nanoparticle (NP) exposure is associated to an increased cardiovascular (CV) disease risk. NPs size allows the passage through the pulmonary capillary barrier inducing systemic inflammation, accelerated atherosclerosis and altered cardiac autonomic function that have been claimed to account for NP-induced CV mortality. Among NPs, TiO_2 and Co_3O_4 are currently attracting enormous industrial interest due to their peculiar size- and shape-dependent properties and applications as pigments, catalysts, sensors for electrochemistry, magnetism, energy storage. NPs may contaminate living and working environments, thus representing a health hazard. The increased oxidative stress and inflammation associated to NP exposure, could exacerbate CV damage, especially in subjects at increased CV risk, such as diabetic patients. Studies on subjects exposed to NPs are not feasible, due to the difficulty to evaluate exposure. Thus,

hazard characterization and risk assessment ought to be based on NP toxicity to cell models derived from CV system, such as circulating angiogenic cells (CACs), considered key regulators of vascular homeostasis and repair. Aim of the study is the evaluation of possible effects of commercially available nanopowders on CAC viability, function and production of pro-inflammatory/oxidative stress species.

Materials and methods: CACs have been isolated from healthy donors' buffy coats after culturing lymphomonocytes on fibronectin-coated dishes in endothelial medium for 7 days. Different concentration of TiO_2 and Co_3O_4 (1-10-20-50-100 μg/ml) were added to the culture media to test nanopowder effects on EPC viability/proliferation, apoptosis, and function (adhesion assay). The effects of TiO_2 and Co_3O_4 on pro-inflammatory (IL1β, TNFα and monocyte chemoattractant protein-1 (MCP-1)) cytokine gene expression and oxidative stress (TBARS) were also tested.

Results: CAC viability was significantly reduced in the presence of 10, 20, 50 and 100 μg/ml Co_3O_4 following 24h and 48h exposure. Apoptosis assay (Caspase 3 activation) confirmed Co_3O_4 cytotoxic effect ($p<0.001$). The capacity of CACs to adhere to fibronectin resulted impaired when 50 and 100 μg/ml of Co_3O_4 were added to the culture media. On the contrary, no significant effect on CAC viability and function was observed in the presence of TiO_2. Oxidative stress induction was increased by 20% ($p<0.05$) in the presence of Co_3O_4 (20 μg/ml; 24h) and inflammatory cytokine (IL1β and TNFα) gene expression was significantly higher ($p<0.05$) following 6h exposure to Co_3O_4 and TiO_2 compared to controls.

Conclusion: Our results show that Co_3O_4 nanopowder induce cytotoxicity and an altered function in CACs accompanied by an increased inflammation and ROS production, suggesting potential adverse CV effects after occupational and/or accidental exposure to metal-containing nanopowder or NPs (Co_3O_4 in particular).

DNA methylation analysis in adipose tissue after long term high-fat diet-induced obesity in mice

L. Parrillo[1], V. Costa[2], R. Esposito[2], G.A. Raciti[1], C. Legault[1], C. Nigro[1], V. Vastolo[1], A. Ciccodicola[2], C. Miele[1], F. Beguinot[1];
[1]Dismet & Ieos-Cnr, Federico II University of Naples, [2]Igb-Cnr, Naples, Italy.

Background and aims: Emerging evidence suggests that epigenetic factors, including DNA methylation, are involved in the development of obesity. Because of the importance of lifestyle factors in obesity development, DNA methylation can provide a putative mechanism by which specific environmental exposures convey risk for obesity. However, current understanding of the regulation and maintenance of the methylome, as well as its relationship with this disease, remains poorly characterised. In this study, we examined genome-wide DNA methylation status of white adipose tissue (WAT) of obese mice fed a high fat diet in order to identify epigenetic changes secondary to obesity.

Materials and methods: Five weeks old male C57BL/6J were fed either a standard (STD) or a high fat diet (HFD) for 5 months. Methylated DNA immunoprecipitation combined with high-throughput sequencing (MeDIP-Seq) on Illumina platform was performed on pooled DNA isolated from epididymal fat pads of STD fed mice and HFD fed mice (n=6/group). RT qPCR was performed in WAT and in skeletal muscle (SM) of these mice.

Results: The metabolic characteristics of the HFD fed mice are reported in Table 1. MeDIP-Seq analysis generated non-biased DNA methylation maps by covering - with sufficient depth and resolution - the entire mouse genome. Globally, methylated DNA regions showed a different distribution across the genome between the two mice groups. The analysis at gene level revealed a distinctive DNA methylation pattern in CpG islands and gene promoters of genes involved in inflammatory processes, gonadotropin releasing hormone receptor, Wnt and integrin signaling pathways, and in the regulation of transcription. Among the differentially methylated genes in the obese mice, Ankrd26 gene was identified, as well. We have recently demonstrated that Ankrd26 gene plays an important role in the development of both obesity and diabetes in vivo. Interestingly, Ankrd26 mRNA expression is decreased both in WAT (STD: 0.518 ± 0.005 vs. HFD: 0.478 ± 0.002; $p< 0.001$) and in SM (STD: 0.589 ± 0.009 vs. HFD: 0.548 ± 0.009; $p< 0.001$) from diet induced obese mice, indicating that Ankrd26 mRNA expression levels were consistent with its DNA methylation profile.

Conclusion: We used high-throughput sequencing for studying genome-wide DNA methylation in a well-characterised mouse model of diet-induced obesity. These studies indicate that, at least in this animal model, obesity is associated with DNA methylation changes in WAT on a genome-wide scale. Moreover, the differentially methylated regions are enriched in genes regulating transcription and in genes involved in the pathogenesis of obesity, such as Ankrd26, indicating the impact of nutrition on gene expression changes.

Table 1. Metabolic characteristics of the HFD fed mice.

	SD(n=6)	HFD(n=6)	p values

PS 008 Genetics: functional studies

328

Functional analyses of the type 2 diabetes associated 12-bp deletion in repin1

J. Krüger[1], K. Weidle[1], M. Kern[1], B. Enigk[1], I. Müller[1], M. Prellberg[1], D. Schleinitz[1], J. Breitfeld[1], A. Tönjes[1], M. Stumvoll[1], M. Blüher[1], P. Kovacs[1], N. Klöting[1,2];
[1]University Leipzig, [2]IFB Adiposity Diseases, Leipzig, Germany.

Background and aims: *Repin1* maps within a quantitative trait locus for total cholesterol, body weight, serum triglycerides and serum insulin in the rat. Sequencing of human *repin1* revealed a 12-bp deletion within the coding region (rs3832490). We investigated the functional consequences of this variant.
Materials and methods: 1) *Population genetic studies:* The deletion in *repin1* was genotyped for subsequent association studies in two independent cohorts: the Leipzig cohort (N=1830) and the Sorbs (N=1046). In addition *repin1* mRNA levels were determined in paired human samples of visceral and subcutaneous adipose tissue (N=86). 2) *Functional studies:* 3T3-L1 preadipocytes were transfected with plasmids carrying either the *repin1-wildtype* or the *repin1-deletion*. We tested two different methods for transfection, lipofection (GeneJammer) and electroporation (NeonTransfectionSystem). The transfection efficiency was examined by using FACS and the overexpression of both variants was checked by Western Blot. After the differentiation we stained the cells with oil red O.
Results: 1) Compared with the non-carriers, subjects homozygous for the deletion variant seemed to be protected against type 2 diabetes (T2D) (P=0.011, after adjusting for age, sex and BMI). This variant was also associated with body fat mass and fasting plasma glucose. Compared with non-carriers, subjects with the deletion had a lower maximum adipocyte size in visceral and subcutaneous fat (P=0.065 and 0.014, respectively) and tended to have a lower mRNA *repin1* expression in the subcutaneous fat. 2) Substantially higher transfection efficiency was achieved by electroporation when compared with lipofection (84.2% vs. 15.2%). Using microscopy, there was no visual difference between the *repin1-deletion* and *repin1-wildtype* transfected cells. Compared with the untransfected 3T3-L1 adipocytes the *repin1*-transfected cells showed less and smaller lipid droplets.
Conclusion: The variant in *repin1* might reduce the risk for T2D most likely by influencing the adipocyte function and morphology. Furthermore, the study encourages further *in vitro* experiments in 3T3-L1 cells to pinpoint the role of the identified deletion in *repin1´s* biology.

Regulation of alternative splicing in human obesity loci

D. Kaminska[1], S. Venesmaa[2], P. Käkelä[2], H. Gylling[1], M. Laakso[3], J. Pihlajamäki[1,4];
[1]Institute of Public Health and Clinical Nutrition, University of Eastern Finland, [2]Department of Surgery, University of Eastern Finland and Kuopio University Hospital, [3]Department of Medicine, University of Eastern Finland, [4]Clinical Nutrition and Obesity Center, Kuopio University Hospital, Kuopio, Finland.

Background and aims: Genome wide association (GWA) analyses have significantly increased the number of confirmed candidate loci for obesity. We hypothesized that non-coding SNPs in these candidate loci could alter splicing of candidate genes. Aim of our study was to investigate alternative splicing events in known obesity loci.
Materials and methods: Genes in obesity loci (n=138) were selected based on recent GWA analyses. Alternative splicing in adipose tissue was investigated using PCR-capillary electrophoresis on subcutaneous adipose tissue samples extracted from 51 men (23 with type 2 diabetes, 28 with normal glucose tolerance) from the population-based Metabolic Syndrome in Men (METSIM) study. Furthermore, splicing pattern was determined in subcutaneous and visceral adipose tissue of 110 participants of Kuopio Obesity Surgery study (KOBS).
Results: Out of the 138 genes in known obesity loci 48 genes had known alternatively spliced isoforms based on UniProt and Alternative Splicing and Transcript Diversity (ASTD) databases. We found alternative splicing in adipose tissue for 11 of these genes. Altered splicing pattern between individuals with type 2 diabetes and non-diabetic was observed in 4 out of 11 genes: *BAT3* ($p= 2\times10^{-5}$), *SFRS10* ($p= 3\times10^{-5}$), *MSH5* (p= 0.002), and *LPIN1* (p= 0.003). Moreover, we found different distribution of *BAT3* ($p= 6\times10^{-12}$), *SFRS10* (p= 0.009) and *LPIN1* ($p= 5\times10^{-15}$) splice variants between visceral and subcutaneous fat. Finally, distribution of *MSH5* splice variants changed in response to weight loss (p= 0.002).
Conclusion: Alternative splicing was observed in genes located in the known obesity loci. The function of these splice isoforms needs to be investigated in experimental studies and their significance needs to be determined in larger population studies.

Defective glucose homeostasis in mice inactivated selectively for *Tcf7l2* in the adult beta cell with an Ins1-controlled Cre

G. da Silva Xavier[1], A. Mondragon[1], R. Mitchell[1], D.J. Hodson[1], J. Ferre[2], B. Thorens[3], J.A. McGinty[4], P.M.W. French[4], G.A. Rutter[1];
[1]Cell Biology, Imperial College, London, UK, [2]Imperial College, London, UK, [3]Department of Physiology and Center for Integrative Genomics, Lausanne, Switzerland, [4]Physics, Imperial College, London, UK.

Background and aims: Single nucleotide polymorphisms in the transcription factor T-cell factor 7 like-2 (TCF7L2) gene, including rs7903146, are associated with an elevated risk of type 2 diabetes in man. *TCF7L2* encodes a member of the TCF family of transcription factors involved in the control of cell growth and signalling downstream of wingless-type MMTV integration site family (Wnt) receptors. Mice inactivated for *Tcf7l2* throughout the pancreas using Pdx1.Cre-mediated recombination (Pdx1.Cre::Tcf7l2$^{fl/fl}$) display impaired glucose tolerance, beta cell expansion and insulin secretion, particularly in response to GLP-1. In this study we assess the impact of *Tcf7l2* deletion specifically in the adult pancreatic beta cell.
Materials and methods: To achieve deletion more specifically in the adult pancreatic beta cell, *Tcf7l2*-flox mice were crossed with mice in which Cre recombinase was knocked-in at the Ins1 locus to generate beta cell specific *Tcf7l2* knockout mice (Ins1.Cre::Tcf7L2$^{fl/fl}$). Intraperitoneal and oral glucose tolerance on mice maintained on a normal chow diet was monitored between 8-20 weeks.
Results: Compared to littermate controls Ins1.Cre::Tcf7L2$^{fl/fl}$ mice bred on a C57BL/6 background displayed impaired intraperitoneal glucose tolerance by 16 weeks (increase in AUC of 13.6 ± 2.8 %, n=6 mice per genotype), and impaired oral glucose tolerance from 8 weeks (increase in AUC of 10.6 ± 1.3 %, n=6), values similar to those previously observed in Pdx1.Cre::Tcf7L2$^{fl/fl}$ mice (where glucose intolerance was observed at 20 and 12 weeks when glucose was administered by the intraperitoneal or oral route, respectively).
Conclusion: These findings provide further evidence for a cell-autonomous role for *Tcf7L2* in the beta cell and suggest that lowered levels of active TCF7L2 in these cells may contribute to the effects of the risk allele. The impact of *Tcf7l2* deletion on isolated islet function, pancreatic beta cell mass, and the effect of maintenance on a high (60 %) fat diet are currently under investigation.

Functional characterisation of the transcriptional machinery bound across the type 2 diabetes associated TCF7L2 intronic variant, rs7903146

S.F.A. Grant, S. Deliard, C.-X. Yuan, M.E. Johnson, Q. Xia;
Genetics, Children's Hospital of Philadelphia, Philadelphia, USA.

Background and aims: Resolving the underlying functional mechanism to a given genetic association has proven extremely challenging. However the key type 2 diabetes (T2D) associated locus, TCF7L2, presents an opportunity for translational analyses, as studies in multiple ethnicities and with Baysian modeling strongly suggest that SNP, rs7903146, is the causal variant within this gene.
Materials and methods: We hypothesized that protein factors bind to this intronic region to modulate TCF7L2 function. We carried out oligo pull-down combined with mass spectrophotometry (MS) to elucidate the transcriptional machinery across the SNP. Nuclear lysates from HCT116 cells, where TCF7L2 is abundantly expressed, were incubated with biotin-labeled, double-stranded 60bp oligonucleotides spanning rs7903146. The DNA-protein complexes were precipitated with streptavidin-agarose beads, and the bound proteins were isolated by denaturing SDS-PAGE. Following digestion with trypsin, the samples were analyzed by MS.

Results: We observed that poly (ADP-ribose) polymerase 1 (PARP1) is by far the most abundant binding factor. We also used stable isotope labeling to quantify binding affinity changes following insulin treatment. Although PARP1 binding was modestly increased by 20%, among the next most abundant binding proteins, ATP-dependent RNA helicase A and thyroid hormone receptor-associated protein 3 (THRAP3) showed markedly increased binding of 12 and 7 fold, respectively. Interestingly, all three proteins dimerize with TCF7L2 itself, supporting the notion of an expression feedback loop. In addition, we found evidence for an allelic difference for proteins with less abundant binding, namely X-ray repair cross-complementing 5 (XRCC5) and RPA/p70.
Conclusion: Our results point to a protein complex binding across rs7903146 within TCF7L2, that is both sensitive to insulin and allelic status, and reveal a possible mechanism by which this locus confers T2D risk.

The type 2 diabetes-associated gene *ADCY5* modulates glucose-stimulated network connectivity and insulin secretion from human islets
R.K. Mitchell[1], M. Bugliani[2], P. Marchetti[2], D. Bosco[3], P. Johnson[4], S. Hughes[4], W.-H. Li[5], D. Li[5], D.J. Hodson[1], G.A. Rutter[1];
[1]Section of Cell Biology, Imperial College London, UK, [2]Department of Endocrinology & Metabolism, University of Pisa, Italy, [3]Cell Isolation and Transplantation Center, University of Geneva, Switzerland, [4]Nuffield Department of Surgical Sciences, University of Oxford, UK, [5]UT Southwestern Medical Center, Dallas, USA.

Background and aims: The coordinated behaviour of individual beta cells within the islet syncytium is thought to be important for the stimulation of insulin secretion. Whether, and how, this may be affected by known genetic risk factors for type 2 diabetes is unknown. Genome-wide association studies (GWAS) have recently identified a single nucleotide polymorphism (SNP), rs2877716, which increases the risk of elevated fasting blood glucose and type 2 diabetes. This SNP is located in the *ADCY5* gene, encoding the cAMP-generating enzyme adenylate cyclase 5. We sought here to determine how forced changes in *ADCY5* expression affect beta cell network coordination and insulin secretion from isolated human islets.
Materials and methods: Human islets were isolated from normoglycemic donors ($n \geq 3$) with appropriate local ethical permissions. Intracellular free Ca^{2+} ($[Ca^{2+}]_i$) was imaged in intact islets using confocal microscopy and cell-cell interactivity mapped by correlation analyses. Real-time insulin secretory dynamics were measured using the Zn^{2+}-probe ZIMIR. Gene-silencing was achieved by treatment for 72 h with lentiviral particles (MOI=100) harbouring shRNA against *ADCY5,* or scrambled RNA.
Results: Lentivirus treatment decreased *ADCY5* mRNA expression by ~90% in dissociated islets and ~30% in intact islets. *ADCY5* silencing dramatically (53.0±3.5%; P<0.01; n=11 islets) suppressed glucose- (11 *vs* 3 mM) stimulated rises in $[Ca^{2+}]_i$ and mildly (20.8±2.5%) reduced coordinated cell activity (P<0.01, n=11 islets). Apparent insulin release in the continued presence of 11 mM glucose was also lowered by *ADCY5* silencing (57.6±2.2%; P<0.01; n=7 recordings). These actions were not due to cAMP-independent effects on ATP-sensitive K^+- or voltage-gated Ca^{2+} channels, as silencing did not alter Ca^{2+} rises induced by the depolarising stimulus KCl. Paradoxically, *ADCY5* knockdown subtly but significantly enhanced the amplitude of GLP-1-evoked increases in $[Ca^{2+}]_i$ (P<0.01).
Conclusion: ADCY5 activity is required for normal glucose- but not GLP-1-stimulated insulin secretion from human islets. These data, which are consistent with clinical findings in carriers of rs2877716 risk alleles, suggest that distinct ADCY isoforms modulate cAMP increases in beta cells in response to nutrient *versus* incretin stimulation and exert differing effects on intercellular connectivity and insulin output.

Effects of functional polymorphisms in GLIS3 and a putative target gene on insulin secretion
S. Calderari[1], C. Gérard[1], M. Ria[2], P.J. Kaisaki[2], D. Gauguier[1];
[1]Centre de Recherche des Cordeliers - UMRS 872, Paris, France, [2]Wellcome Trust Centre for Human Genetics, Oxford, UK.

Background and aims: Altered beta cell mass and/or dysfunction are central pathophysiological features in type 2 diabetes (T2D). Recent genetic findings have highlighted the transcription factor GLIS3 as a susceptibility gene for T2D, neonatal diabetes and congenital hyperthyroidism. GLIS3 maps to a locus associated with diabetes phenotypes in a genetic cross derived from the Goto-Kakizaki (GK) rat model of spontaneous T2D and Brown Norway (BN) controls. We identified DNA variants in Glis3 in the GK, including two non synonymous variants leading to potentially functionally important amino acid substitutions. We developed a congenic strain (CS1.a) which carries a short (1.7MB) GK genomic region containing Glis3 and surrounding genes (including Slc1a1), isolated on a BN resistant background, to test the relevance of these variants to diabetes, and carried out functional studies to identify GLIS3 targets
Materials and methods: We determined the genomic sequence across the entire GK haplotype in the CS1.a congenics. Glucose tolerance and insulin secretion tests were performed in CS1.a and BN rats. For transfection experiments, the promoter region of Slc1a1 was cloned into pGL3 basic vector upstream of the luciferase reporter gene, and co-transfected into INS-1 cells, together with the expression vector pcDNA3 containing the full cDNA for Glis3. A GLIS3 antibody (Abcam) was used for chromatin immunoprecipitation.
Results: Rats of the CS1-a strain exhibited hyperglycaemia and increased glucose-induced insulin secretion in vivo and in vitro. In INS1 cells, glucose induced insulin secretion was significantly altered when cells were transfected with a plasmid containing the GK allele of GLIS3. Sequence analysis of the GK congenic region identified polymorphisms in the promoter region of Slc1a1, close to a common binding motif for GLIS3. Luciferase assay of the cloned Slc1a1 promoter region showed that the GK variants are functional and are associated with decreased promoter activity. Results from chromatin immunoprecipitation experiments in INS1 cells showed an enrichment of SLC1A1 when GLIS3 was immunoprecipitated. Cotransfection experiments in INS1 cells demonstrated the interaction of GLIS3 with the promoter of Slc1a1, which could be further confirmed by ChIP-seq experiments.
Conclusion: We showed the impact of GK polymorphisms in GLIS3 on insulin secretion, which may at least partly account for the diabetes locus identified in the GKxBN cross. Our results demonstrate the functional impact of GK polymorphisms identified in Slc1a1 promoter and suggest that the gene encoding the glutamate transporter Slc1a1 is a direct target of GLIS3. These results provide advances in the characterization of the role of GLIS3 on insulin secretion and the molecular mechanisms involved.

Functional analysis of MODY2 mutations in the nuclear export signal of glucokinase
M.-A. Navas[1,2], A. Gutierrez-Nogués[1], C.M. Garcia-Herrero[1,2], J. Oriola[3,2], R. Casamitjana[3,2], O. Vincent[4];
[1]Biochemistry and molecular biology III. Faculty of Medicine, Complutense University of Madrid, [2]CIBERDEM, Madrid, [3]Hospital Clinic, IDIBAPS, Barcelona, [4]Instituto de investigaciones Biomédicas Alberto Sols. CSIC-UAM, Madrid, Spain.

Background and aims: Glucokinase (GK) is a key enzyme in glucose homeostasis. GK acts as a glucose sensor in the pancreatic beta cell regulating insulin secretion and also plays a key role in glucose metabolism in the liver. Mutations in the GCK gene cause different monogenic glycaemic disorders, being the most common the familial, mild fasting hyperglycaemia or MODY2, caused by heterozygous inactivating mutations. The specific function of GK is based on the particular kinetic characteristics of this enzyme in addition to other regulatory mechanisms including covalent modifications, protein-protein interactions and subcellular localization of the enzyme. The aim of this work is to study the nuclear export mechanism of GK from the analysis of MODY2 mutations located in the nuclear export signal (NES) of the enzyme.
Materials and methods: MODY2 mutations located in the NES sequence of GK (residues 300-310) have been introduced by directed mutagenesis into

the human beta cell isoform of GCK. The biochemical effects of these mutations on the catalytic activity and thermostability of the enzyme were measured with bacterially expressed GST-GK fusion proteins. Physical interaction of GK with its regulatory protein GKRP was analyzed by enzymatic assays and/or the yeast two hybrid system. Glucokinase NES function was analyzed with a GFP fusion to rat GK residues 299-359 (pEGFP-N2-GK(299-359)). Confocal microscopy was used to study the nucleo-cytoplasmic localization of GFP constructs in transiently transfected Cos7 and Hek293T cells.
Results: Mutations V302E, L304P and L306R impaired GK enzymatic activity, reducing the activity index up to 3% of wild type level in the case of L306R. In addition, mutations V302E and L304P caused protein instability and mutations V302E, L306R and L309P altered the interaction of GK with GKRP. When transfected into Cos7 or Hek293T cells, the wild type GK(residues 299-359)-GFP fusion protein was homogenously localized in the nucleus and cytoplasm in more than 80% of transfected cells. This percentage decreased up to 65% in cells expressing GFP fusion proteins containing mutations L309P or L309H and up to 20% in cells expressing mutations V302E, R303W, L304P and R308W, where the fluorescence distribution is nuclear-enriched in more than 50% of transfected cells. Treatment with leptomycin b resulted in nuclear enrichment of fluorescence in more than 80% of cells transfected with the wild type fusion protein and did not affect the predominant nuclear distribution of mutants V302E, R303W, L304P and R308W. Moreover, overexpression of exportin-1 by cotransfection of cells with pCMV-HA-CRM1 and wild type GFP-fusion constructs resulted in an increase of cells with cytoplasmic enrichment of fluorescence, whilst cotransfection with the R308W mutant still resulted in a relative high percentage of cells with nuclear enrichment of fluorescence.
Conclusion: Our results indicate that GK nuclear export directed by the NES (residues 300-310) is mediated by the exportin-1 complex and MODY2 mutations in the NES sequence can affect this process, thus identifying an additional mechanism contributing to the disease.

Usefulness of genetic risk score constructed from 49 loci for type 2 diabetes in Japanese individuals
M. Imamura[1], M. Iwata[2], H. Maegawa[3], H. Watada[4], H. Hirose[5], Y. Tanaka[6], K. Tobe[2], K. Kaku[7], A. Kashiwagi[3], R. Kawamori[4], S. Maeda[1];
[1]Laboratory for Endocrinology and Metabolism, RIKEN, Center for Genomic Medicine, Yokohama, [2]Toyama University, [3]Shiga University of Medical Science, Otsu, [4]Juntendo University, Tokyo, [5]Keio University, Tokyo, [6]St. Marianna University School of Medicine, Kawasaki, [7]Kawasaki Medical School, Kurashiki, Japan.

Background and aims: Genome wide association studies (GWAS) have identified over 60 susceptibility loci for type 2 diabetes (T2D). Although it has been shown that the ability of previous genetic information (~40 loci) to discriminate between susceptible and non-susceptible individuals is limited, effect of the updated genetic information for T2D has not been evaluated. Therefore, we intended to assess the clinical utility of GWAS-derived T2D susceptibility variants in a Japanese population.
Materials and methods: First, we examined up to 11,532 Japanese individuals for 55 GWAS-derived T2D susceptible single nucleotide polymorphisms (SNPs), and selected 49 SNPs, which showed consistent effect direction with the original reports [Odds Ratio (OR) > 1]. GRS was constructed in 2,613 T2D cases and 1,786 controls, whose genotype information for the 49 SNPs was complete, by counting the number of risk alleles of the 49 SNPs in each individual. We also constructed a GRS for β cell function (β-GRS) with 24 SNPs and a GRS for insulin resistant (R-GRS) with 7 SNPs based on the function of the genes encoded in these 49 loci. The association of the GRS with the disease or T2D-related traits was analyzed using a logistic regression model or linear regression analysis respectively.
Results: The GRS was significantly associated with T2D [OR/per risk allele = 1.12, 95% confidence interval (CI); 1.10 - 1.13, $p = 2.92 \times 10^{-44}$]. The association was similar even after adjustment for age, sex and log-transformed BMI (OR/per risk allele = 1.13, 95% CI; 1.11 - 1.15, $p = 8.75 \times 10^{-45}$) In receiver operating characteristic (ROC) analyses, area under the curve (AUC) for the GRS alone (model-1) and for age, sex, and BMI (model-2) were 0.624 and 0.743, respectively. Addition of the GRS to model-2 (model-3) resulted in a small, but significant increase in the AUC [AUC for model-3 = 0.773, p-value for model-2 vs. model-3 = 7.99×10^{-15}, ΔAUC (model 3- model 2) = 0.03]. The effect of the GRS was more conspicuous in non-obese individuals (BMI < 25, AUC = 0.640, ΔAUC = 0.029, $p = 2.31 \times 10^{-11}$) than in obese individuals (BMI ≥ 25, AUC = 0.601, ΔAUC = 0.021, p = 0.006). The GRS was associated with age at onset (β = -0.199, se = 0.073, p = 0.0069) in T2D patients (n = 1,591) and with fasting plasma glucose (β = 0.009, se = 0.004, p = 0.021) in non-diabetic controls (n = 804). The GRS was not associated with either Homeostasis Model of Assessment β-cell function (HOMA-β) or HOMA of insulin resistance (IR) in 574 control participants ($p \geq 0.05$), whereas β-GRS and R-GRS were significantly associated with HOMA-β (β-GRS: β = -0.017, se = 0.007, p = 0.011) and HOMA-IR (R-GRS: β = 0.031, se = 0.014, p = 0.028) respectively.
Conclusion: Currently available genetic information is still not sufficient for translation into clinical practice, but may have a greater impact on T2D susceptibility in non-obese individuals.

A genetic risk score comprising common variants associated with fasting insulin is associated with OGTT- and clamp-based indices of whole body insulin sensitivity
R.A. Scott[1], D. Pasko[2], T. Fall[3], H. Yaghootkar[2], A. Barker[1], S.J. Sharp[1], M. Walker[4], N.J. Wareham[1], E. Ingelsson[3], T. Frayling[2], C. Langenberg[1];
[1]MRC Epidemiology Unit, Cambridge, UK, [2]Genetics of Complex traits, University of Exeter Medical School, Exeter, UK, [3]Department of Medical Sciences, Molecular Epidemiology and Science for Life Laboratory, Uppsala University, Sweden, [4]Institute of Cellular Medicine (Diabetes), Newcastle University, Newcastle upon Tyne, UK.

Background and aims: Recently, a genome-wide association study of glycaemic traits identified 19 variants associated with fasting insulin at genome-

wide levels of significance. These variants showed an association with the dyslipidaemic profile of higher triglycerides and lower HDL, consistent with an effect on insulin resistance. We sought to investigate the association of these variants with euglycaemic-hyperinsulinaemic clamp- and OGTT-based indices of whole body insulin sensitivity.
Materials and methods: We investigated the association of a genetic risk score comprising 18 variants associated with fasting insulin (after excluding *FTO*, which had an association with fasting insulin driven entirely by BMI) with clamp- and OGTT-based measures of insulin sensitivity in up to 3,409 non-diabetic individuals from the Ely (N=1,371), RISC (N=1,031) and ULSAM (N=907) studies using linear regression models adjusted for age and sex (and other covariates where specified). Per-fasting insulin-raising allele effects on log-transformed and standardised outcomes (including glucose and insulin at 0, 30, 60 and 120 min during the OGTT, anthropometric and lipid traits as well as clamp- and OGTT-based indices) were combined across studies using fixed effects meta-analysis.
Results: The genetic score was associated with clamp-based whole body insulin sensitivity (β-coefficient for M/I (95% CI): -0.02 (-0.04, -0.01); p=0.003) and with the OGTT-based Matsuda index (-0.03 (-0.04, -0.01); p<0.001); these associations remained significant after adjustment for triglyceride levels (p<0.01). Associations of the score with HDL and triglycerides were abolished after adjustment for M/I (both p>0.2). The score was not associated with BMI, waist circumference, or body fat percentage (all p>0.5), nor with glucose levels at 0, 30, 60, or 120 minutes during the OGTT (all p>0.15), although we did observe associations with higher insulin levels at all time points (all p<0.001), as well as with the insulinogenic index (0.03 (0.01, 0.04); p<0.001).
Conclusion: A genetic risk score comprising variants associated with fasting insulin is associated with clamp- and OGTT-based measures of insulin sensitivity independently of BMI or triglyceride levels. Confirmation that this score is associated with whole-body insulin sensitivity offers opportunities for understanding the role of insulin resistance in the aetiology of a range of disease processes.

337

Type 2 diabetes genetic risk score is more strongly associated with basal insulin secretion and insulin requirement than family history in Japanese type 2 diabetic patients

M. Iwata[1,2], S. Maeda[3], Y. Kamura[1], A. Takano[4], H. Kato[5], S. Murakami[6], K. Higuchi[7], R. Temaru[8], H. Oda[9], S. Asamizu[10], Y. Fukushima[11], K. Fukuda[1], K. Yamazaki[12], I. Usui[1], K. Tobe[1];
[1]First internal of medicine, Toyama University, [2]Community Medical Support Unit, Faculty of Medicine, Toyama University, [3]Laboratory for Endocrinology and Metabolism, RIKEN Center for Genomic Medicine, Yokohama, [4]Division of Endocrinology and Metabolism, Department of Internal Medicine, Saiseikai Takaoka Hospital, Takaoka, [5]Division of Endocrinology and Metabolism, Department of Internal Medicine, Shakaihoken Takaoka Hospital, [6]Division of Endocrinology and Metabolism, Department of Internal Medicine, Toyama Rosai Hospital, Uozu, [7]Department of Internal Medicine, Itoigawa General Hospital, Itoigawa, [8]Department of Internal Medicine, Nanto City hospital, [9]Department of Internal Medicine, Jonan hospital, Toyama, [10]Department of Internal Medicine, Sakurai hospital, Kurobe, [11]Department of Internal Medicine, Asahi General Gospital, Asahimachi, [12]Internal of medicine, Kawai Clinic, Tsukuba, Japan.

Background and aims: We have previously demonstrated that type 2 diabetes (T2DM) genetic risk score (GRS) was associated with the early age at diagnosis of diabetes (AOD), basal insulin secretion, and the future requirement of insulin injections. On the other hand, a family history of diabetes was well known to be a strong risk factor for the development of T2DM. However, no reports examined which genetic information was stronger associated with clinical information about T2DM. Therefore, in this study, we compared the clinical usefulness between GRS and family history.
Materials and methods: We analyzed 14 SNPs at HHEX, CDKAL1, CDKN2B, SLC30A8, KCNJ11, IGF2BP2, PPARG, TCF7L2, FTO, KCNQ1, IRS-1, GCKR, UBE2E2, and C2CD4A/B in 831 Japanese type 2 diabetic patients by using TaqMan PCR assay and the GRS was calculated according to the number of risk alleles by counting all 14 SNPs (T-GRS) as well as 11 SNPs related to β-cell function (β-GRS). We also examined self-reported family history of T2DM in first- and second-degree relatives and defined the number of parental history of T2DM as family history score (FHS). Furthermore, we obtained clinical information about T2DM and defined the subjects who were required to inject more than 10 units of insulin a day continuously as insulin requiring subjects.
Results: The FHS had stronger effects on AOD than both GRS (β for FHS=-4.448; $P = 3.7 \times 10^{-9}$, β for T-GRS=-0.663; $P = 8.0 \times 10^{-4}$, β for β-GRS=-0.608; $P = 2.9 \times 10^{-3}$) after adjustments for sex and the maximum BMI. However, both GRS had slightly stronger effects on F-CPR than the FHS (β for T-GRS=-0.032; $P = 0.025$, β for β-GRS=-0.036; $P = 0.014$, β for FHS=-0.115; $P = 0.035$) after adjustments for related co-variables. Moreover, both GRS were also significantly associated with insulin requirement, whereas FHS were not associated with insulin requirement (β for T-GRS=0.014; $P = 0.030$, β for β-GRS=0.014; $P = 0.041$, β for FHS=0.019; $P = 0.474$) after adjustments for related co-variables.
Conclusion: In this study, we have demonstrated that whereas family history of diabetes was stronger associated with onset of T2DM than GRS, GRS for T2DM was stronger associated with the basal insulin secretion and future insulin requirement than family history of diabetes.

Loss of function mutation carriers (long QT type 1 patients) of the type 2 diabetes gene *KCNQ1* have reactive hyperinsulinaemia and postprandial hypoglycaemia

S.S. Torekov[1,2], J.K. Kanters[1], E.P.W. Iepsen[1,2], M. Christiansen[3], A. Linneberg[4], O. Pedersen[2], J.J. Holst[1,2], T. Hansen[2];
[1]Department of Biomedical Sciences, [2]Novo Nordisk Foundation of Basic Metabolic Research, [3]Department of Clinical Biochemistry, [4]Research Centre for Prevention and Health, Copenhagen, Denmark.

Background and aims: Carriers of common intronic single nucleotide polymorphisms in *KCNQ1* have increased susceptibility of type 2 diabetes, presumably through a reduced beta cell function. *KCNQ1* expresses the voltage-gated K^+ channel in cardiomyocytes and pancreatic beta cells. Patients with type-1 long QT syndrome have loss of function mutations in *KCNQ1*. These mutations reduce the function of the potassium channel resulting in prolonged cardiac ventricular repolarization and thus lengthened QT-interval. The patients are thereby in increased risk of syncope, arrhythmia and cardiac arrest. Over-expression of *KCNQ1* in beta cells decreases insulin secretion due to premature repolarization of the action potential in beta cells, whereas inhibition of KCNQ1 in beta cells increases insulin secretion due to prolonged depolarization. The aim of this study was to investigate if carriers of loss of function mutations of *KCNQ1* have altered islet insulin secretion and glucose regulation compared to matched control subjects.
Materials and methods: 14 (5 men / 9 women) patients (age 44.4 ±2,5 years, BMI 28.5±1,7 kg/m2, QTcB 479 ± 9 ms) from six unrelated families, diagnosed with type 1 long QT syndrome were recruited. Each patient was BMI-, age- and gender-matched with two randomly chosen control subjects with normal electrocardiogram (28 (10 men /18 women), age 47.1±1,6 years, BMI 29.0±1,1 kg/m2, QTcB 425 ± 4 ms).
Results: KCNQ1 mutation carriers had significantly increased insulin secretion upon glucose stimulation compared to matched control participants, $p_{anova} < 10^{-6}$ (45,560 ± 6,300 vs. 26,040 ± 2,777 pmol /l insulin, $p_{AUCinsulin} < 10^{-5}$). Correspondingly, the patients had significantly increased C-peptide and proinsulin levels, $p_{anova} < 10^{-5}$. The glucose levels were lower for mutation carriers compared to controls with significant lower levels 3 hours after glucose ingestion (4.4 ± 0.3 vs. 5.4 ± 0.5 mmol/l glucose, $p_{180} = 0.03$). Furthermore, KCNQ1 mutation carriers had significantly increased insulinogenic index compared to matched control participants (41.5 ± 6.6 vs. 24.3 ± 3.7, $p < 10^{-3}$). The potassium levels were significantly lower in mutation carriers compared to control participants, $p_{anova} < 10^{-4}$. Follow-up studies on prolonged oral glucose tolerance test for 6 hours were made in four available patients and matching control subjects and showed that the patients developed hypoglycaemia in the time period 3.5 -5 hours after glucose ingestion in contrast to the matched control subjects that remained normoglycemic (plasma glucose range 1.4 - 3.6 vs. 4.1 -5.4 mmol/l glucose, $p < 10^{-2}$).
Conclusion: In this study we show that long QT type 1 patients, with known loss of function mutations in *KCNQ1,* have reactive hyperinsulinemia and postprandial hypoglycaemia. These findings confirm that the voltage-gated K^+ channel encoded by *KCNQ1* is a key player in insulin secretion and suggest that this mutation underlies some cases of "essential" postprandial reactive hypoglycaemia.

PROX1 type 2 diabetes predisposing genetic variant is associated with visceral fat accumulation and lower carbohydrate oxidation

K. Maliszewska[1], A. Kretowski[1,2], A. Citko[1], N. Wawrusiewicz-Kurylonek[1], E. Adamska[2], J. Goscik[3], D. Lipinska[1], M. Waszczeniuk[4], M. Gorska[1];
[1]Department of Endocrinology, Diabetology and Internal Medicine, [2]Centre for Clinical Research, [3]Centre for Experimental Medicine, [4]Department of Dietetics and Clinical Nutrition, Medical University of Bialystok, Poland, Poland.

Background and aims: Genome-wide association studies have shown that PROX1 gene, which encodes a co-repressor of hepatocyte nuclear factor 4α64 playing a crucial role in β-cell development - is associated with type 2 diabetes susceptibility. It has been recently suggested that reduced expression of PROX1 gene results in altered β-cell insulin secretion. We conducted genetic and phenotypic studies to better understand the role of PROX1 in type 2 diabetes.
Materials and methods: We genotyped rs340874 PROX1 SNP previously identified by GWAS as type 2 diabetes risk gene in 944 subjects (463 women,481 men). In all subjects body composition analysis: percent of body fat, visceral and subcutaneous abdominal adipose tissue by multi-frequency bioimpedance method have been performed. Total energy intake, energy density and content of total carbohydrates, fat, protein were estimated using 3 days nutritional report. Non-diabetic subjects underwent an oral glucose tolerance test (OGTT). Moreover, in a subgroup of 48 subjects carbohydrate and lipid oxidation was evaluated with indirect calorimetry during two consecutive: normal- carb and high-carb meal tests.
Results: In the studied group the PROX1 genotypes were significantly associated with visceral fat tissue accumulation (respectively for CC vs. CT vs.TT: 114.4 vs. 96.1 vs. 94.0 cm3, $p < 0.019$), but with lower calories ($p< 0.01$), and carbohydrates ($p< 0.001$) intake. Additionally, carriers of risk allel C showed higher glucose level during oral glucose tolerance test ($p<0.004$). Moreover, subjects with CC genotype presented lower carbohydrate oxidation rate after high-carb meal ($p = 0.033$) and had statistically higher glucose ($p =0.004$) and insulin levels ($p= 0.049$) after normal carb meal.
Conclusion: Our results suggest that analyzed PROX1 gene affects insulin secretion and is associated with accumulation of visceral fat tissue. We believe that our study may help to understand the mechanisms of type 2 diabetes risk development.

The BDNF, NEGR1 and TMEM18 genetic variants are associated with body fat content and components of metabolic syndrome in humans

A. Citko[1], A. Kretowski[1,2], N. Wawrusiewicz-Kurylonek[1], M. Waszczeniuk[3], E. Adamska[2], J. Goscik[4], K. Maliszewska[1], J. Wilk[1], D. Lipinska[1], J. Pliszka[1], M. Ciborowski[2], M. Gorska[1];
[1]Department of Endocrinology, Diabetology and Internal Medicine, [2]Centre for Clinical Research, [3]Department of Dietetics and Clinical Nutrition, [4]Centre for Experimental Medicine, Medical University of Bialystok, Poland.

Background and aims: It has been recently reported that genes encoding proteins involved in the regulation of brain function, including: BDNF (brain-derived neurotrophic factor), NEGR1 (neuronal growth regulator 1) and TMEM18 (transmembrane protein 18) are associated with BMI and risk of obesity. It is also generally accepted that risk of metabolic syndrome development depends on the amount of visceral fat rather than on total body weight or BMI. The aim of the study was to evaluate the association of common variants of NEGR1, BDNF and TMEM18 genes with the body fat distribution and occurrence of selected components of metabolic syndrome (including type 2 diabetes, dyslipidemia, hypertension).
Materials and methods: We genotyped BDNF (rs925946), NEGR1 (rs2568958, rs2815752, rs3101336) and TMEM18 (rs7561317) SNPs in 619 overweight/obese and 332 normal weight healthy subjects (484 men and 467 women), who underwent anthropometric (BMI, WHR) and body composition analysis: total body fat, visceral (VAT) and subcutaneous abdominal adipose tissue (SAT) content by multi-frequency bio-impedance method. Measured genotype analysis (MGA) was used to test association between SNPs and phenotypes.
Results: We have found a significant association of the studied SNPs with total fat mass: respectively for BDNF rs925946 ($p<0.05$) and for NEGR1: rs2568958 ($p=0.013$), rs2815752 ($p=0.008$), rs3101336 ($p=0.010$). On the other hand there was a preferential accumulation of visceral fat related to TMEM18 rs7561317 AA genotype ($p=0.022$). Moreover, different studied gene variants were related to different components of metabolic syndrome: NEGR1 SNPs were significantly associated with waist circumference ($p=0.0003$); BDNF variants with higher risk of type 2 diabetes ($p=0.002$) and hypertension development ($p=0.01$), while TMEM18 genotypes were associated with dyslipidemia ($p=0.001$).
Conclusion: Our results confirmed the association of genes encoding proteins involved in the regulation of brain function with obesity and fat accumulation, however we demonstrated that studied SNPs can have different effect on components of metabolic syndrome. We believe that our study may help to understand the mechanisms that control body fat mass deposition and development of metabolic syndrome.

Association of mitochondrial respiratory chain polymorphisms with type 2 diabetes in the Spanish population

G.O. De Marco Solar[1], M.L. Mansego[1], G. Rojo-Martínez[2,3], R. Carmena[3,4], F.J. Chaves[1], S. Morcillo[5,3], M. Pineda-Alonso[6], G.M. Martín-Núñez[5], J.C. Martín Escudero[6], J. Redon[7,8], F. Soriguer[2,3], M. Serrano-Rios[9,3];
[1]Genotyping and genetic diagnosis unit, Research Foundation of the clinic Hospital of Valencia-INCLIVA, Valencia, [2]Endocrinology and nutrition service, Carlos Haya Universitary Hospital, Malaga, [3]CIBER of Diabetes and Associated Metabolic Diseases (CIBERDEM), Barcelona, [4]Research Foundation of University Clinic Hospital-INCLIVA, Valencia, [5]Endocrinology and nutrition service, Carlos Haya Universitary Hospital, Málaga, [6]Internal Medicine Service, Rio Hortega University Hospital, Valladolid, [7]Department of Internal Medicine, Clinic Hospital of Valencia, [8]CIBER 03/06 Physiopathology of Obesity and Nutrition, Institute of Health Carlos III, Ministery of Health, Valencia, [9]Diabetes Research Laboratory, Biomedical Research Foundationof the University Clinic Hospital San Carlos, Madrid, Spain.

Background and aims: Study the association between genes codifying for mitochondrial respiratory chain (MRC) subunits and type 2 diabetes mellitus (T2DM) in general population of Spain.
Materials and methods: Three thousand seven hundred and thirty-one subjects (age range 21 to 89) from three different population-based studies of Spain, were studied. Forty-eight single nucleotide polymorphisms (SNPs) of chromosomal genes which codify MRC proteins were selected and genotyped by the SNPlex method. Association between presence of T2DM and glycaemia levels and these SNPs were assessed.
Results: Significant associations were observed between polymorphisms rs1053517 (NDUFS1 gene), rs683943 (COX7A2 gene) and rs4806187 (COX6B1 gene) and glycaemia (p-value= 0.0054, 0.0096, 0.0059 and 0.0077, respectively). Moreover, rs4656993 and rs1136224 SNPs (NDUFS2 gene) were associated to T2DM (OR=0.74, with a p-value of 0.0098 and OR=2,2 with p-value=0.0038, respectively). Finally, polymorphisms rs2410718 (COX7C gene) and rs11205591 (NDUFS5 gene) were associated with both glycaemia (p-value of 0.04 and 0.029 respectively) and T2DM risk (OR=4.34 and p-value 0.0013 for the first SNP and OR=0.37 and p-value 0.0008 for the second SNP).
Conclusion: Polymorphisms of genes codifying MRC can be involved in glycaemia variation and might contribute to the risk of developing T2DM in the general population of Spain.

Association of mitochondrial respiratory chain polymorphisms with the presence of obesity and their impact in type 2 diabetes mellitus development in the Spanish population

F.J. Chaves[1], G.O. De Marco Solar[1], M. Pineda-Alonso[2], G. Rojo-Martínez[3,4], S. Morcillo[3,4], G.M. Martín-Núñez[3], J.C. Martín Escudero[5], J. Redon[6,7], F. Soriguer[3,8], R. Carmena[4,9], M. Serrano-Rios[4,10], M.L. Mansego[1];
[1]Genotyping and Genetic Diagnosis Unit, Research Foundation of the University Clinic Hospital-INCLIVA, Valencia, [2]2 Internal Medicine Service, Rio Hortega University Hospital, Valladolid, [3]Endocrinology and nutrition service, Carlos Haya Universitary Hospital, Málaga, [4]CIBER of Diabetes and Associated Metabolic Diseases (CIBERDEM), Barcelona, [5]Internal Medicine Service, Rio Hortega University Hospital., Valladolid, [6]Department of Internal Medicine, Clinic Hospital of Valencia, [7]CIBER 03/06 Physiopathology of Obesity and Nutrition, Institute of Health Carlos III, Minister of Health, Valencia, [8]CIBER of Diabetes and Associated Metabolic Diseases (CIBERDEM),, Barcelona, [9]Research Foundation of University Clinic Hospital-INCLIVA, Valencia, Spain, [10]Diabetes Research Laboratory, Biomedical Research Foundation. University Hospital Clínico San Carlos, Madrid, Spain.

Background and aims: Analyze a group of genes codifying for some important mitochondrial respiratory chain (MRC) subunits and their association with BMI and obesity in the general population of Spain, regarding the impact of these associations in the development of type 2 diabetes mellitus.
Materials and methods: Three thousand seven hundred and thirty one subjects from three different population based studies from different regions of Spain, with an age range 21 to 89 were studied. Forty eight single nucleotide polymorphisms (SNPs) of chromosomal genes which codify MRC proteins were selected and processed by SNPlex method.
Results: Significant associations were observed between rs4600063 (SDHC), rs11205591 (NDUFS5), rs10891319 (SDHD) SNPs and BMI (p-value= 0.04, 0.0011 and 0.0004, respectively) and obesity risk (p-value=0.0072, 0.039 and 0.0038, respectively). In addition, two of them, the rs11205591 and the rs10891319 polymorphisms, showed a significant epistatic interaction for BMI levels and obesity risk. Finally, the GG genotype of rs11205591 polymorphism significantly reduced the risk of being diabetic after including age and sex (OR= 0.32, 0.17-0.62; p-value =0.0001), and BMI (OR=0.37, 0.19-0.72; p-value =0.0008) as covariables.
Conclusion: Several polymorphisms of genes codifying MRC can be involved in BMI variation and can be related to the risk of being obese in Spanish general population. Furthermore, the rs11205591 (NDUFS5 gene) polymorphism might contribute to the risk to develop type 2 diabetes.

Role of microRNAs in pancreatic beta cell dysfunction associated with ageing

K. Tugay, R. Regazzi;
DNF, University of Lausanne, Switzerland.

Background and aims: With age many different factors including increased insulin resistance and oxidative stress and decreased insulin secretion can result in the development of type 2 diabetes. MicroRNAs are short non-coding RNAs that are involved in a variety of metabolic diseases, including type 2 diabetes. In this study, we investigated the role of microRNAs in pancreatic beta cell dysfunction associated with aging.
Materials and methods: In order to identify changes in the global microRNA expression profile, associated with aging, RNA was isolated from pancreatic islets of 3 and 12 month old Wistar rats and analyzed by microarray. The results of the microarray for microRNAs of interest were confirmed by qPCR. To mimic changes observed in the aged rats, microRNA expression levels were specifically overexpressed or down-regulated by oligonucleotides or anti-miRs, respectively in MIN6 cells and dispersed human and rat islet cells. Apoptosis was triggered by exposure of MIN6 cells or primary islet cells to cytokine mix. Apoptotic cells displaying picnotic nuclei were counted using Hoechst staining Proliferation study was assessed by treating dissociated islet cells with Exendine-4 for 5 days. After that cells were stained for Ki-67 and analyzed in fluorescent microscope. Statistical differences were determined using a Student's t test or, for multiple comparisons, with one-way analysis of variance (ANOVA) of the means, followed by a post hoc Dunnett test.
Results: In order to validate our aging model we have measured GLUT-2 and pro-insulin expression in the pancreatic islets of aged rats and investigated their proliferative capacity. We observed that pancreatic beta cells of 12 month old rats display a significant decrease in pro-insulin and GLUT-2 mRNA levels and fail to proliferate after exposure to Exendin-4 ex vivo. From 312 micro-RNAs, detected by microarray 70 microRNAs were showing significant changes in their expression level in aged animals. We focused our investigations on miR-34a, miR-383 and miR-130b for which we confirmed by qPCR an up-regulation of 2 and 4 folds and down-regulation of 3 folds, respectively, in aged animals. We then investigated the impact on beta cell survival. We have previously shown that miR-34a overexpression in MIN6 cells increases apoptosis. Here we observed that miR-34a overexpression increases apoptosis also in dispersed rat and human islet cells. In contrast, miR-383 overexpression as well as down-regulation of miR-130b in MIN6 cells and dispersed rat and human islet cells was found to protect from cytokine-mediated apoptosis.
Conclusion: Pancreatic islets of 12 month old rats have a decrease of expression if pro-insulin and GLUT-2 and fail to proliferate after exposure to Exendine-4. These results correlate with aging phenotype. We have identified several changes in pancreatic islets in microRNA expression which are associated with aging. Among them miR-34a upregulation induces beta cell apoptosis, whereas miR-383 upregulation and miR-130b down-regulation promote beta cell survival. Ongoing experiments will determine the impact of these microRNAs on insulin secretion and beta cell proliferation.

Genome-wide DNA methylation analysis identifies epigenetic alterations in pancreatic islets from patients with type 2 diabetes

T. Dayeh[1], P. Volkov[1], S. Salo[1], E. Hall[1], E. Nilsson[1], A.H. Olsson[1], L. Eliasson[2], K. Bacos[1], T. Ronn[1], C. Ling[1];
[1]Epigenetics and Diabetes, Lund University, [2]Islet cell exocytosis, Lund University, Malmö, Sweden.

Background and aims: Impaired insulin secretion from pancreatic islets is a key characteristic of type 2 diabetes (T2D). Studying gene regulation in pancreatic islets from patients with T2D will help understanding the pathogenesis of the disease. Epigenetic modifications, including DNA methylation and histone modifications, control cell specific gene expression and may play a role in disease development. We have previously identified al-

tered DNA methylation of *PDX-1*, *INS* and *PPARGC1A* in parallel with decreased mRNA expression of respective gene and reduced insulin secretion in pancreatic islets from patients with T2D. To further examine if epigenetics play a role in the pathogenesis of T2D, we performed a genome-wide DNA methylation analysis in human pancreatic islets from donors with or without T2D.

Materials and methods: DNA methylation of ~480,000 sites in 21,231 RefSeq genes was analysed in human pancreatic islets from 15 patients with T2D and 34 non-diabetic donors using the Infinium HumanMethylation450 BeadChip from Illumina. The DNA methylation pattern was related to T2D status and the transcriptome in the human islets. Identified candidate genes were overexpressed in clonal beta cells and insulin secretion was analysed.

Results: Pancreatic islets from human donors with T2D cultured in vitro show decreased glucose-stimulated insulin secretion compared with islets from non-diabetic donors ($P < 0.05$). We identified 3,116 CpG sites with altered DNA methylation in T2D compared with non-diabetic pancreatic islets after correction for multiple testing using a false discovery rate analysis ($q < 0.05$). These include 1,649 sites in 853 unique genes with an absolute difference in DNA methylation ≥ 5%. The majority of these sites (97%) show decreased methylation in diabetic versus non-diabetic islets and several of the differentially methylated sites are located in genes with previously known functions in pancreatic beta cells e.g. calcium channels. We also identified 102 genes exhibiting both differential expression and DNA methylation in the diabetic versus the non-diabetic islets. Furthermore, reporter gene constructs were used to functionally test if DNA methylation affects gene expression and increased DNA methylation of gene promoters resulted in a decreased transcriptional activity in clonal beta cells in vitro. Finally, overexpression of some of the identified candidate genes in clonal beta cells resulted in decreased insulin secretion

Conclusion: Epigenetic modifications in human pancreatic islets seem to contribute to impaired insulin secretion in the pathogenesis of T2D.

Identification of SNPs associated with DNA methylation in human pancreatic islets and its role in the pathogenesis of type 2 diabetes

A.H. Olsson[1], P. Volkov[1], T. Dayeh[1], E. Hall[1], E.A. Nilsson[1], C. Ladenvall[2], T. Rönn[1], C. Ling[1];
[1]Department of Clinical Sciences, Epigenetics and Diabetes, Lund University Diabetes Centre, Lund University, [2]Department of Clinical Sciences, Diabetes and Endocrinology, Lund University Diabetes Centre, Lund University, Malmö, Sweden.

Background and aims: DNA methylation of cytosines in CpG dinucleotides has a regulatory role in multiple biological processes and altered DNA methylation patterns may contribute to the development of human diseases, e.g. type 2 diabetes (T2D). We have previously shown that ~50% of today known T2D associated single nucleotide polymorphisms (SNPs) introduce or remove a CpG site (CpG-SNPs). These loci are associated with differential DNA methylation of the CpG-SNP site in human pancreatic islets, representing the candidate genes TCF7L2, KCNQ1, PPARG, HHEX, CDKN2A, SLC30A8, DUSP9, CDKAL1, ADCY5, SRR, WFS1, IRS1, DUSP8, HMGA2, TSPAN8 and CHCHD9. Some of the T2D CpG-SNP sites that exhibit differential DNA methylation were further associated with gene expression, alternative splicing events and hormonal secretion in the human islets. The aim of this study was to further explore how genetic variation controls DNA methylation in human pancreatic islets by performing a global methylation quantitative trait locus (mQTL) analysis.

Materials and methods: Human pancreatic islets from 89 donors not diagnosed with diabetes mellitus were included in the study. SNP genotyping was performed using the HumanOmniExpress BeadChip (Illumina) and DNA methylation profiling in the islets was performed using the Infinium HumanMethylation 450K BeadChip (Illumina). Gene expression was quantified in the islets using the microarray GeneChip HumanGene 1.0 ST (Affymetrix).

Results: In total, 574,553 SNPs were analysed and related to DNA methylation levels of 468,787 CpG sites by using a linear regression model. Here 67,438 SNP-CpG pairs showed significant association in cis (≤ 500 kb between SNP and CpG site) and 2,562 in trans, with significance threshold < 0.05 after Bonferroni correction. Several of the identified SNPs in the mQTL analysis were further associated with differential gene expression in the human islets, including genes involved in diabetes related pathways.

Conclusion: Our results demonstrate how genetic and epigenetic factors can interact in human pancreatic islets and provide a molecular mechanism that may contribute to the pathogenesis of diabetes.

Genome-wide analysis of DNA methylation variations caused by chronic glucolipotoxicity in beta cells

Y. Hu, X.H. Xu, T.T. Feng, X.M. Mao;
Department of Endocrinology, Nanjing First Hospital Affiliated to Nanjing Medical University, China.

Background and aims: There is a growing body of literature suggesting the role of interactions between genes and the environment in development of type 2 diabetes mellitus (T2DM). However, the interplay between environment and gene in developing and progressing T2MD are not fully understood. To determine the mechanism of glucolipotoxicity affecting beta cells, this study profiled the DNA methylation of Genome-wide genes in beta cells cultured with high-glucose-lipid medium.

Materials and methods: A high throughput NimbleGen RN34 CpG Island & Promoter Microarray was used to investigate the DNA methylation profile in RINm5f beta cell line cultured with high-glucose-lipid medium, and identified the genes which experienced aberrant DNA methylation with differential enrichment peaks (DEP) analysis. Methylated DNA immunoprecipitation(MeDIP) PCR was used for further validation of the microarray results. Growth viability of beta cells was evaluated with MTT, and RT-PCR and western blot were used for analysis of insulin expression to show glucolipotoxicity affecting beta cells.

Results: In MTT assay, the growth viability of beta cells was inhibited with one-month Glu+PA treatment compared with control cells (P<0.05), and insulin mRNA and protein expression in beta cells decreased (P<0.05). Compared to control, there were 6.44% genes abnormal hypermethylated and 8.14% genes abnormal demethylated in promoter region, 11.50% genes abnormal hypermethylated and 14.07% genes demethylated at CpG loci in beta cells cultured with high-glucose-lipid medium. Some of the genes have been confirmed to play important roles in regulating the function of beta cells, such as TCF7L2, ADCY5, HNF1B, DUSP9, WFS1, PRC1, and variants in these genes have been associated with T2DM in Genome-Wide Association Study (GWAS).The MeDIP PCR results were consistency to microarray,and the mRNA expression of these genes were consistent with the methylation status apart from TCF7L2 gene. TCF7L2 promoter region was hypermethylated after Glu+PA treatment while the mRNA expression increased (P<0.05) and protein expression decreased (P<0.05), which is similar to previous studies.

Conclusion: We conclude that chronic glucolipotoxicity could induce some genes to experience an aberrant DNA methylation and affect these genes expression in beta cells, which might contribute to beta cell function failure in T2DM and be helpful to explain, at least partially, the mechanism of glucolipotoxicity on beta cells deterioration.

347

Implication of insulin-like growth factor binding protein 1 DNA methylation and protein variation for type 2 diabetes

T. Gu[1], H.F. Gu[1], A. Hilding[1], L.K. Sjöholm[2], L. Kärvestedt[3], C.-G. Östenson[1], T.J. Ekström[2], K. Brismar[1];
[1]Molecular Medicine and Surgery, Karolinska Institutet, [2]Center for Molecular Medicine, Department of Clinical Neuroscience, Karolinska Institutet, [3]Stockholm Sjukhem, Stockholm, Sweden.

Background and aims: Low levels of circulating insulin-like growth factor binding protein-1 (IGFBP-1) are associated with type 2 diabetes (T2D). To evaluate whether epigenetic changes provide a link for translating environmental exposures into IGFBP-1 variation in T2D, we have investigated DNA methylation levels in the 5'-UTR of the IGFBP1 gene.

Materials and methods: IGFBP1 DNA methylation analyses were performed in 506 Swedish men, including normal glucose tolerance (NGT) subjects, newly diagnosed and anti-diabetic treated T2D patients with bisulfite pyrosequencing. Serum IGFBP-1 levels were measured with radio-immunoassay.

Results: DNA methylation levels of the IGFBP1 gene in T2D patients (newly diagnosed and anti-diabetic treated patients) were higher compared to NGT

subjects (19.8% and 18.9% vs. 16.9%, p<0.001). The IGFBP1 hyper-methylation in T2D was independent of body mass index (BMI). Furthermore, newly diagnosed T2D patients with a family history of diabetes (FHD) had higher IGFBP1 methylation levels than those without FHD (20.3% vs. 18.6%, p=0.014). Serum levels of IGFBP-1 in T2D were significantly lower compared to NGT (18 μg/l in newly diagnosed T2D and 17 μg/l in anti-diabetic treated T2D vs. 24 μg/l in NGT subjects, p=0.028, p=0.002). Unlike DNA methylation, serum IGFBP-1 protein variation was dependent of BMI.
Conclusion: Data from the present study provide the first evidence that DNA hyper-methylation in the IGFBP1 gene is associated with T2D in Swedish men, and suggest that increased IGFBP1 DNA methylation and decreased IGFBP-1 serum levels may implicate the risk for T2D.

DNA methylation, cardio metabolic risk and type 2 diabetes in south Asians and Europeans
H.R. Elliott[1], T. Tillin[2], N. Chaturvedi[2], A.D. Hughes[2], W. McArdle[1], G. Davey Smith[1], T.M. Frayling[3], S. Ebrahim[4,5], C.L. Relton[1,6];
[1]School of Social and Community Medicine, University of Bristol, UK, [2]International Centre for Circulatory Health, Imperial College London, UK, [3]Peninsula School of Medicine and Dentistry, University of Exeter, UK, [4]South Asia Network for Chronic Disease, New Delhi, India, [5]Department of Epidemiology and Population Health, London School of Hygiene and Tropical Medicine, London, UK, [6]Institute of Genetic Medicine, Newcastle University, Newcastle-upon-Tyne, UK.

Background and aims: People of South Asian origin have one of the highest rates of diabetes in the world. Genetic studies have not explained this excess risk. Epigenetic processes may play a role. This study aims to identify the association between DNA methylation, type 2 diabetes and related traits and to identify ethnic differences between individuals of South Asian and European origin living in the UK.
Materials and methods: Baseline samples (n = 192) from the extensively characterised population based SABRE (Southall And Brent Revisited) cohort were utilised. Men aged between 40-69 years at baseline were included, matched for ethnicity, age, smoking status and subsequent development of diabetes and/or CHD over 20 years of follow up. Genome-wide DNA methylation analysis was performed using the Illumina HumanMethylation450 array.
Results: Numbers of CpG sites associated with traits of interest were calculated with a family wise error rate (FWER) of 0.05. Effect sizes and standard errors are shown as the % change in methylation per unit change in metabolic measure described (mmol/L). Marked ethnic differences were observed in methylation sites throughout the genome (n = 2284). Methylation was also associated with metabolic traits including fasting insulin (n = 69 methylation sites including sites in ASXL2 (effect size = 0.20%, std error = 0.02%, t statistic = 8.72, p = 1.63E-15) and TET3 (effect size = -0.69%, std error = 0.08%, t statistic = -8.26, p = 3.65E-14)) and triglycerides(n = 585 sites in >45 loci including 14q32.31 (effect size = 3.10, std error = 0.33, t statistic = 9.35, p = 2.87e-17) and TXNDC12 (effect size = 0.42, std error = 0.05, t statistic = 8.95, p = 4.04E-16)). Association between fasting glucose and methylation was less marked (no methylation sites attained FWER cut-off, the strongest association observed was in RBM28 (effect size = -0. 92, std error = 0.18, t statistic = -5.14, p = 6.99E-07).
Conclusion: Wide-spread differences in methylation by ethnic group were observed. Associations between methylation and fasting insulin and triglycerides but not fasting glucose were also identified. Ongoing investigation of ethnic differences in these methylation sites and predictive power for subsequent cardio metabolic disease may provide valuable novel insights into the determinants of excess cardio metabolic disease risk in South Asians.

Maternal transmission of variants in the THADA gene to offspring with type 2 diabetes
R.B. Prasad[1], A. Lessmark[1], P. Almgren[1], W. Poon[1], M. Sterner[1], G. Gremsperger[1], T. Tuomi[2], L. Groop[1];
[1]Department of Clinical Sciences, Diabetes and endocrinology, Lund University Diabetes Centre, Malmö, Sweden, [2]Department of Medicine, University of Helsinki, Finland.

Background and aims: Type 2 diabetes (T2D) is a complex heterogeneous disease resulting from a complex interplay between genetic and environmental factors. Several GWAS have established a genetic basis for T2D in the form of >65 genetic variants accounting for ~15% of the heritability. However, transmissions of risk alleles in families have been mostly unexplored and the function of most of these variants unknown. Our goal was to assess the transmission and parent-of-origin effects (POE) of SNPs in risk of T2D and related traits, including glucose metabolism and insulin secretion in families.
Materials and methods: The Botnia study comprising of 4189 individuals (1083 families) from Western Finland & Southern Sweden were genotyped on a custom-designed SNP panel containing 88 variants in risk of T2D and related traits, including glucose metabolism and insulin secretion using a Sequenom MassArray platform. Distorted transmission of T2D risk alleles to (1) T2D and (2) hyperglycemic (T2D+IFG+IGT) offspring were assessed in 180-280 independent trios using TDT (PLINK) and combined with parental discordant tests to increase power (parenTDT, PLINK). Transmissions within nuclear families with multiple offspring were assessed using FBAT. Parent-of-origin (POE) tests were performed using PLINK. 11 quantitative traits related to glucose metabolism and insulin secretion were assessed in non-diabetic individuals using qTDT and POE tests. OGTT values were adjusted for BMI.
Results: Distorted transmission was seen for 19 T2D risk SNPs to diabetic offspring, and for 20 to hyperglycemic offspring. The most significant results include excess-transmission of the risk T allele in rs7903146 in the *TCF7L2* gene applying the TDT (p=0.009), parenTDT (p= 1.432e-006) and FBAT (0.006) tests and rs163184 in the *KCNQ1* gene in the TDT (p=0.03) and FBAT (0.0028) tests to diabetic offspring. In support of previous findings, SNP rs163184 (KCNQ1) showed a trend towards maternal transmission (p= 0.035). The rs7578597 SNP in the THADA gene showed a consistent over-transmission of the maternal risk allele T to diabetic (p= 0.019) and hyperglycemic (p=0.006) offspring. Among 88 SNPs tested for distorted transmission to quantitative traits like glucose and insulin in offspring, the strongest effect was observed for rs10830963 (MNTR1B) for 30 and 60 min glucose, (p<0.01 and CIR (p=4,40e-03). SNP rs8042680 (PRC1) showed preferential maternal transmission for 30 min glucose (p=0,0002), rs7593730 (RBMS1/ITGB6 locus) (p=0,0038) for fasting insulin, rs7961581 (TSPAN8/LGR5) for ISI (p=0,0086) whereas rs6467136 (PAX4) (p=0,018) showed preferential paternal transmission for CIR.
Conclusion: Distorted parental transmission is not an uncommon feature of T2D risk SNPs with a very strong maternal transmission shown for rs7578597 in THADA. This is interesting in light of the view that variation in the *THADA* gene also has shown evolutionary selection from Neanderthals to modern humans.

DOLCE: new cohort to study the effects of famine on the risk of diabetes and its complications
W. Poon[1], S. Alkayyali[1], L. Cherviakova[2], N. Khalimon[2], T. Svietleisha[3], T. Buldenko[3], H. Vasylkova[3], V. Lyssenko[1,4];
[1]Diabetes & Endocrinology, Lund University, Malmö, Sweden, [2]Chernihiv Regional Hospital, Ukraine, [3]Public Health Authority of Chernihiv regional public administration, Ukraine, [4]Steno Diabetes Centre, Gentofte, Denmark.

Background and aims: We hypothesized that studies on long-term consequences of prolonged starvation during famine periods in Ukraine might shed light on key mechanisms associated with risk of or freedom from early-onset diabetes and its complications.
Materials and methods: DOLCE (Diagnostic Optimization and Treatment of diabetes and its complications in the Chernihiv region) is a population-based study of diabetic individuals and their healthy relatives in northern Ukraine. All participants underwent anthropometric and clinical measurements, blood samples were drawn for biochemical measurements and for DNA and RNA analyses, and all participants completed a questionnaire on family history, smoking, medication, and complication status for cardiovas-

cular diseases (CVD), nephropathy, retinopathy, angiopathy and amputation. We are currently investigating temporal effects on genetic risk associated with diabetes and its complications.
Results: Our current study population includes 3,670 individuals; 570 (54.9% male, age-at-onset/duration 25/11 years) were clinically diagnosed with type 1 diabetes (T1D) and 2,360 (32.7%, 54/5) with type 2 diabetes (T2D). 39.3% of T1D patients were GAD antibody positive (≥10 kE/l), possibly due to admixture with other diabetes types. Despite the differences in diabetes duration and age, prevalence of CVD was equally high in people born during the famine in the 1930's, World War II and the 5-year post-war period. Notably, while famine had a profound effect on risk of macrovascular complications of diabetes, this pattern was absent for prevalence of microvascular complications, which were similar across all birth year groups. Similarly to previous reports, the *TCF7L2* rs7903146 risk genotypes were significantly more frequent among T2D compared to T1D patients (p=0.03), as well as less frequent in T2D patients born before the 1950's (p<0.05), potentially due to survival selection. Additionally, preliminary genetic data suggest involvement of pleiotropic loci at *FADS1*, *HNF1A* and *DGKB* known to affect lipid metabolism in survival during starvation.
Conclusion: Famine is an important risk factor for development of macrovascular complications of diabetes, while other mechanisms seem to be operative for the progression of microvascular complications. Genetic markers could possibly help to pave the way to these pathways.

PS 011 Genetics: monogenic forms

351

Clinical widened diagnostic criteria and prediction models identify "MODY-X" patients who should benefit from new specific genetic screening
C. Leroy[1], I. Fajardy[2], DIAMENORD Study Group, M. Vaxillaire[3], P. Froguel[3], P. Fontaine[1], A. Vambergue[1];
[1]Endocrinology - Diabetology - Metabolism, CHRU Lille, [2]Biology and Pathology, CHRU Lille, [3]CNRS UMR-8199, Lille University - North of France, France.

Background and aims: Maturity Onset Diabetes of the Young (MODY) is underestimated because prevalence of obesity and type 2 diabetes in young patients are actually really increasing. Monogenic diabetes can be misdiagnosed as type2 diabetes. However, the correct molecular diagnosis has implication in patient treatment, prognosis and is important for patient's family.
Materials and methods: Direct sequencing of *GCK* and *HNF1A* genes were performed for 155 patients with a clinical suspicion of MODY. We compared the phenotype of all patients according to genetic results. We compared the probability to be MODY according to classical diagnostic criteria of MODY and according to the clinical prediction models proposed by Shields and all (2012) and by Béllanné-Chantelot and all (2011).
Results: A molecular abnormality of *GCK* was found in 15 patients ("MODY 2") and of *HNF1A* in 20 patients ("MODY 3"). 119 patients did not present any mutation of *GCK* or *HNF1A* ("No mutation "). Phenotype of the "MODY 2" and "MODY 3" patients help us to define "widened criteria " who are: age in the diagnosis < 40 years, BMI < 30 kg/m^2, ≥ 3 affected generations, among which at least 2 before age of 40ans. "No Mutation " are significantly older and have a higher BMI. MODY 2 and MODY 3 patients have more often ≥ 3 affected generations and a lower age at diagnosis. Algorithms find stronger probability of MODY for "MODY2" and "MODY3" than for "No Mutation". However, among "No Mutation" patients, 21 present the "widened criteria" of the MODY and 17 others have a probability of MODY X according to Shields > 25 %. 6 other patients present morphological renal anomalies suggestive of a genetic development abnormality.
Conclusion: In the "No mutation" group phenotype is variable. This group is probably constituted with MODY-X and with type 2 diabetes. Use of "widened diagnostic criteria" and on-line predictive probability calculators identifies, in this group, 44 patients who are likely to benefit from specific genetic explorations. This will be possible with the development of new methods for genetic screening.

Reclassification of diabetes aetiology in a family with multiple diabetes phenotypes
F.K. Kavvoura[1,2], A. Raimondo[1], G. Thanabalasingham[1,2], A. Barrett[1], A.L. Webster[1], N. Mann[3], S. Ellard[4], A.L. Gloyn[1,2], K.R. Owen[1,2];
[1]Churchill Hospital, Oxford Centre for Diabetes, Endocrinology & Metabolism (OCDEM), [2]Oxford NIHR Biomedical Centre, Churchill Hospital, [3]Department of Paediatrics, Royal Berkshire Hospital NHS Foundation Trust, Reading, [4]Royal Devon and Exeter NHS Trust, UK.

Background and aims: MODY is rare (1% of all diabetes) but the diagnosis has significant implications for probands and relatives by allowing personalised management and informing prognosis. The aim of this study was to show that appropriate use of genetic and non-genetic investigations leads to correct classification of diabetes aetiology.
Materials and methods: A Caucasian family had six members (D1-D6) with diabetes, with diverse phenotypes. Clinical history, HbA1c, C-peptide, pancreatic β-cell antibodies and sequencing for monogenic causes of diabetes were obtained.
Results: D1 had insulin-treated gestational diabetes (GDM), with normal delivery at 38 weeks. Insulin was discontinued post-delivery, but fasting hyperglycaemia persisted. She was β-cell antibody negative, with HbA1c 43 mmol/mol and C-peptide 0.79 nmol/l. Her sister (D2) also had a history of GDM. D1 and D2 were found to have the previously reported heterozygous GCK missense mutation T206M, confirming the diagnosis of GCK-MODY, consistent with the clinical scenarios.
Results: D3 (D2's daughter) had low birth weight, failed to thrive and presented with diabetic ketoacidosis (DKA) at 16 weeks. She was negative for

mutations in KCNJ11, ABCC8 and INS and was on insulin since diagnosis. Genetic screening showed that she carried the T206M and also the R43P missense mutation in GCK. Therefore, she has GCK- permanent neonatal diabetes (PNDM) due to compound heterozygous mutations. Both mutations have been functionally characterised in GCK-MODY and shown to be kinetically inactivating due to decreased affinities for glucose and decreased maximal specific activities compared to wild type GCK. The other three family members (D4: D1's mother, D5: D1's other sister and D6: D1's daughter) had a clinical diagnosis of type 1 diabetes (T1D). Both D4 and D5 had history of DKA, microvascular complications and investigations showed HbA1c >86 mmol/mol and undetectable C-peptide <0.02 nmol/l. D4 had positive GAD antibodies. D6 was diagnosed aged 3, had positive GAD and ICA at diagnosis and undetectable urinary C-peptide. These features were inconsistent with GCK-MODY and confirmed T1D in these three cases. We later showed D4 and D5 were negative for GCK mutations. We also deduced that the fathers of D1 and D3 carry undiagnosed GCK mutations.

Conclusion: Two family members, previously misclassified, were found to have GCK-MODY with important management consequences. Three family members were confirmed with T1D and along with the child with GCK-PNDM, should continue insulin therapy. This family demonstrated three different diabetes phenotypes and exemplifies the importance of careful phenotyping and investigation of relatives after discovering a genetic aetiology of diabetes.

Detection of PAX4 mutations in Japanese patients with maturity-onset diabetes of the young

M. Takizawa[1], N. Iwasaki[1,2], M. Ogata[1], R. Ide[1], Y. Uchigata[1];
[1]Diabetes center, [2]Institute of Medical Genetics, Tokyo Women's Medical University, Japan.

Background and aims: Maturity-onset diabetes of the young (MODY) is the most common form of monogenic diabetes mellitus (DM), and mutations in twelve different disease-causing genes have been identified till date. However, in Japan, approximately 80% patients with a clinical diagnosis of MODY did not have pathogenic mutations in the screening with MODY1, 2, 3, and 5 genes. PAX4 is a transcription factor that plays an important role in the differentiation of islet β-cells. *PAX4* mutations were recently reported to be associated with MODY (also known as MODY9) in the Thailanders. Because there is no report regarding the association between *PAX4* and MODY in the Japanese, the aim of this study was to investigate the contribution of *PAX4* mutations to MODY in a subset of Japanese patients.

Materials and methods: Forty-three probands with MODY were studied. The inclusion criteria were as follows: (a) DM diagnosis before 25 years of age; (b) absence of obesity; (c) history of familial DM spanning either three or two generations, with one family member being diagnosed with DM before 25 years of age in the latter case; and (d) absence of disease-causing mutations in MODY1, 2, 3, and 5 genes. *PAX4* coding regions were examined in each subject by direct nucleotide sequencing. The frequency of each *PAX4* mutation was compared with that previously reported for Japanese patients with type 2 diabetes mellitus (T2DM) and non-DM. The χ^2 test was used for statistical analysis; $p < 0.05$ was considered significant.

Results: The mean age at DM diagnosis was 16.2 ± 4.6 years, and the mean maximum body mass index was 22.2 ± 2.2 kg/m^2. We identified five missense and one silent mutations: R31Q (minor allele frequency = 0.036, genotype frequency: homo/hetero/wild = 0/3/40), R121W (0.081, 0/7/36), Q173Q (0.012, 0/1/42), R192S (0.047, 0/4/39), R192H (0.151, 0/13/30), P321 (0.465, 14/12/17). These mutations were previously described in Japanese patients with T2DM and non-DM, indicating that these substitutions were not the genetic cause of MODY. However, we found the frequency of R192H mutation to be significantly higher in patients with MODY than in those with T2DM or non-DM ($\chi^2 = 11.45$, $p = 0.001$ and $\chi^2 = 7.939$, $p = 0.005$). Moreover, the prevalence of R121W mutation, which was previously reported to be associated with T2DM, was four times higher in our subset of patients ($\chi^2 = 12.49$, $p = 0.002$)

Conclusion: We identified five missense and one silent substitutions in *PAX4* in Japanese patients with MODY. The frequencies of two of these were significantly higher in patients with MODY than in those with T2DM, suggesting that R121W and R192H mutations may contribute to the early onset of DM.

Phenotypic heterogeneity in Japanese patients with hepatocyte nuclear factor-1b mutations

N. Iwasaki[1,2], M. Takizawa[1], T. Yamamoto[2], M. Ogata[1], R. Ide[1], Y. Uchigata[1];
[1]Diabetes Center, [2]Institute for Integrated Medical Science, Tokyo Women's Medical University, Japan.

Background and aims: The aim of this study was to investigate clinical spectrum of hepatocyte nuclear factor-1b(*HNF1B*) mutation in Japanese patients with urogenital and /or pancreatic abnormality.

Materials and methods: Among 292 patients who were diagnosed with diabetes at age of 30 or younger, and gave consent for the study from 1992 to end of 2012, 185 patients were evaluated by abdominal ultrasonography. Kidney cysts and/or hydronephrosis, or pancreatic abnormality were detected in unrelated 46 patients among them, who were recruited in this study. *HNF1B* mutation was screened by direct sequencing. If the sample did not show any substitution, we next performed MLPA for screen genomic rearrangements. To confirm complete deletion in *HNF1B*, the array CGH experiment using the human genome CGH microarray (Agilent technologies, Santa Clara, CA, USA) was performed. Paired t-test and chi2 test were used.

Results: The age at diagnosis of diabetes and BMI in 46 patients (M/F=29/17) were 20.0±6.4 years old, and 25.8±6.6. Five heterozygous mutations (het) including R177X, W238R, Q275X, R276Q, and IVS 2nt+1G>A were identified. Seven patients were found to have hemizygous deletion mutation (del) spanning 1.4 Mb on 17q12 including whole *HNF1B*, and one case with aberration in exon 3 was identified. Detection rate of mutations in *HNF1B* was 13/46 (28.3%), and genomic rearrangements were found in 8/13 (61%). Since pathogenicity of exon aberration in this patient was unclear, we analyzed 12 patients for the further study. All patients with (het) had a family history; however, six patients were de novo in patients with (del) ($p < 0.05$). The age at diagnosis of diabetes and BMI were smaller in subjects with mutations compared to those without (Age 16.9±5.5 vs. 21.3±6.3, $p < 0.05$), (BMI 19.3±1.7 vs. 28.3±6.1, $p < 0.05$). Agenesis of pancreatic body and tail was observed in two with (del) and one with (het), hydronephrosis and/or ureterectasis were found in four with (del) and one with (het), kidney cysts were found in five with (del) and four with (het), though none of them were statistically significant. Three cases with (del) developed diabetes suddenly with DKA/ketosis, but none with (het).

Conclusion: Detection rate of mutation in *HNF1B* among patients with early onset and with malformations in kidney or pancreas was 28.3%, and genomic rearrangements was observed with 61%. Patients carrying mutations in *HNF1B* were characterized by lower BMI and younger onset. Deletion mutation was occurred with de novo except one. Those information will be useful for clinical diagnosis of MODY5.

No attenuation of CRP response to acute inflammation is seen in HNF1A-MODY

K.R. Owen[1,2], S.A. Mughal[1,2], S. Beatty[1,2], T.J. James[3], M.I. McCarthy[1,2];
[1]OCDEM, University of Oxford, [2]Oxford NIHR Biomedical Research Centre, [3]Department of Biochemistry, Oxford University Hospital Trust, UK.

Background and aims: HNF1A is known to regulate hepatic C-reactive protein (CRP) production. We have shown that European subjects with *HNF1A* mutations (causing HNF1A-MODY) have low baseline levels of CRP. HNF1A

is part of the transcriptional complex involved in interleukin-6 stimulated CRP production during acute inflammation, so we hypothesised that they would also have an attenuated CRP rise during an acute inflammatory stimulus. This could lead to impaired complement activation and macrophage function in HNF1A-MODY. We used a standardised model of acute inflammation (endotoxin infusion) to investigate this.
Materials and methods: HNF1A-MODY subjects with diabetes (n=7) and normoglycaemic controls, matched for BMI and gender (n=9), were given intravenous endotoxin (E. coli lipopolysaccharide: 2ng/kg). Serum CRP, white cell count (WCC) and erythrocyte sedimentation rate (ESR) were measured at baseline and 2, 4, 6, 24 hours and 8 days after endotoxin administration.
Results: Apart from fasting glucose, baseline characteristics were well-matched between cases and controls.CRP and WCC rose as expected in response to endotoxin in both groups (Figure 1) while no consistent response was seen with ESR. There was no difference in either the CRP levels or the WCC at any time point during the acute inflammatory response in subjects with HNF1A-MODY compared to controls (p=0.42 and 0.15 respectively by repeated measure analysis of variance). Peak mean CRP (HNF1A-MODY vs. controls) was 28.1 vs. 31.7 mg/L at 24hrs (p=0.45) and peak mean WCC was 11.2 vs. 9.5 at 6 hours (p=0.31).
Conclusion: In this study we demonstrate that *HNF1A* haploinsufficiency does not appear to impair CRP production during the response to a moderate acute inflammatory stimulus. Whether HNF1A is present in adequate amounts or transcription occurs via an HNF1A-independant mechanism remains to be elucidated.

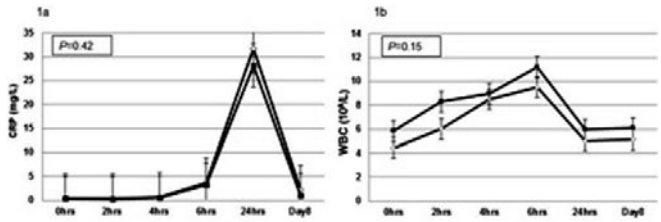

Figure 1 shows mean (±SEM) CRP (panel a) and WCC (panel b) for HNF1A-MODY (filled squares) and controls (open diamonds) for each time point. P values refer to differences between groups calculated by repeated measure analysis of variance.

Cellular re-uptake of secreted carboxyl-ester lipase protein in CEL-MODY, a syndrome of diabetes and pancreatic exocrine dysfunction
A. Molven[1], J. Torsvik[2], B.B. Johansson[2], M. Marie[3], K. Fjeld[2], S. Johansson[2], J. Saraste[3], P.R. Njølstad[2];
[1]Dept. of Clinical Medicine, [2]Dept. of Clinical Science, [3]Dept. of Biomedicine, University of Bergen, Norway.

Background and aims: Single-base mutations in the carboxyl-ester lipase (CEL) gene have previously been identified in families with an autosomal dominantly inherited syndrome of diabetes and pancreatic exocrine dysfunction (CEL-MODY). The mutation c.1686delT is located in the last exon of the CEL gene and leads to a secreted protein with an altered C-terminus and a tendency to self-associate and aggregate. The aim of this study was to characterize the effect of the mutation in cellular model systems.
Materials and methods: Wild type (WT) and mutant (MUT) CEL proteins were expressed in stably transfected HEK293 cells and HeLa cells. We employed cell fractionation, immunoperoxidase electron microscopy and immunofluorescense confocal microscopy, and performed a comparison of the intracellular distribution of CEL-WT and CEL-MUT.
Results: In stably transfected HEK293 cells, we found that CEL-WT was predominantly detected in the endoplasmatic reticulum and Golgi compartments (left image), whereas CEL-MUT was present in a cytoplasmatic punctate pattern (right image). Electron microscopy demonstrated the presence of CEL-MUT aggregates at the plasma membrane and in the lumen of single-membrane vacuoles, which by immunofluorescense confocal microscopy was shown to express Lamp-1. Evidence for involvement of autophagy in CEL-MUT degradation was not found. However, when untransfected HEK293 or HeLa cells were grown in conditioned media from CEL-expressing HEK293 cells, we observed uptake and accumulation of the CEL-MUT protein variant in Lamp-1-positive organelles.
Conclusion: Our results suggest that the altered physicochemical properties of the C-terminal end of CEL-MUT causes this protein to be reabsorbed by endocytosis after its secretion, followed by degradation in the lysosomes. This finding may have implications for the understanding of how the acinar-specific CEL-MUT protein induces both exocrine and endocrine pancreatic disease.

Preserved postprandial GLP-1 and GIP responses in patients with maturity onset diabetes of the young
J.I. Bagger[1,2], S.H. Østoft[1,2], T. Hansen[2], O. Pedersen[2], J.J. Holst[2,3], F.K. Knop[1], T. Vilsbøll[1];
[1]Diabetes Research Division, Department of Medicine, Copenhagen University Hospital Gentofte, Hellerup, [2]Novo Nordisk Foundation Center for Basic Metabolic Research, Copenhagen, [3]University of Copenhagen, Denmark.

Background and aim: Maturity onset diabetes of the young (MODY) is a clinically and genetically heterogeneous subgroup of non-autoimmune diabetes, which constitutes 1-2% of all diabetes. We aimed to evaluate postprandial glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP) responses in patients with MODY2 (glucokinase gene mutations) and MODY3 (hepatocyte nuclear factor (HNF) 1α gene mutations), respectively, and in healthy control subjects (CTRLs) matched for body mass index (BMI).
Material and methods: Ten MODY3 patients (age: 31±3 years (mean±SEM); BMI: 24±1 kg/m^2; fasting plasma glucose (FPG): 8.4±0.8 mmol/l; HbA_{1c}: 52±4 mmol/mol), 9 MODY2 patients (age: 43±5 years; BMI: 24±2 kg/m^2; FPG: 7.3±0.3 mmol/l: 49±2 mmol/mol) and 10 CTRLs (age: 40±5 years; BMI: 24±1 kg/m^2; FPG: 5.1±0.1 mmol/l; 34±1 mmol/mol) were examined with and 4h liquid test meal (525 kcal: 65 g carbohydrate, 20 g fat, 21 g protein).
Results: The 3 groups exhibited similar peak meal-stimulated plasma GLP-1 (27±5 (MODY3), 25±3 (MODY2), 27±2 pmol/l (CTRLs), p=0.89) and similar AUCs for plasma GLP-1 (3.7±0.4 (MODY3), 3.9±0.4 (MODY2), 4.3±0.3 nmol/l×min (CTRLs), p=0.50). Similar peak GIP (88±9 (MODY3), 114±16 (MODY2), 109±9 pmol/l (CTRLs), p=0.18) was also observed, but a higher AUC for GIP was observed for MODY2 patients (17.9±1.7 nmol/l×min) compared to MODY3 patients (13.9±1.3 nmol/l×min, p=0.022) but not compared to CTRLs (12.7±0.7 nmol/l×min, p=0.097). No difference in AUC between MODY3 patients and CTRLs was observed, p=0.76.
Conclusion: MODY3 and MODY2 patients exhibit preserved postprandial responses of the two incretin hormones GLP-1 and GIP.

Differential glucagon responses to glucose in maturity onset diabetes of the young type 2 and 3
S.H. Østoft[1,2], J.I. Bagger[1,2], T. Hansen[3], O. Pedersen[3], J.J. Holst[2,3], F.K. Knop[1,3], T. Vilsbøll[1,3];
[1]Diabetes Research Division, Department of Medicine, Copenhagen University Hospital Gentofte, Hellerup, [2]Department of Biomedical Sciences, Panum Institute, University of Copenhagen, [3]Novo Nordisk Foundation Center for Basic Metabolic Research, University of Copenhagen, Denmark.

Background and aim: Maturity onset diabetes of the young (MODY) is a clinically and genetically heterogeneous subgroup of non-autoimmune diabetes, which constitutes 1-2% of all diabetes. Impaired suppression of gluca-

gon following oral ingestion of glucose is a characteristic feature of type 1 and type 2 diabetes. We aimed to study glucagon responses to oral and intravenous (iv) glucose, respectively, in patients with MODY2 (glucokinase gene mutations) and MODY3 (hepatocyte nuclear factor (HNF) 1α gene mutations) and in healthy control subjects (CTRLs) matched for body mass index (BMI).

Material and methods: Ten MODY3 patients (age: 31±3 years (mean±SEM); BMI: 24±1 kg/m^2; fasting plasma glucose (FPG): 8.4±0.8 mmol/l; HbA_{1c}: 52±4 mmol/mol), 9 MODY2 patients (age: 43±5 years; BMI: 24±2 kg/m^2; FPG: 7.3±0.3 mmol/l: HbA_{1c}: 49±2 mmol/mol) and 9 CTRLs (age: 41±5 years; BMI: 24±1 kg/m^2; FPG: 5.1±0.2 mmol/l; HbA_{1c}: 34±1 mmol/mol) were examined on 2 separate occasions: 4h 50g-oral glucose tolerance test (OGTT) and isoglycaemic iv glucose infusion (IIGI).

Results: A hyperglucagonaemic response was seen in MODY3 patients compared to MODY2 patients and CTRLs during OGTT, but not during IIGI ($\Delta AUC_{0\text{-}60min}$ (OGTT): 46±33 vs. −121±46 pmol/l×min, p=0.013, −142±36 pmol/l×min, p=0.006, respectively; $\Delta AUC_{0\text{-}60min}$ (IIGI): −83±20 pmol/l×min (MODY3) vs. −190±55 pmol/l×min (CTRLs) vs. −132±34 pmol/l×min (MODY2), p=0.15). No difference in glucagon response between OGTT and IIGI was seen in MODY2 patients, p=0.86 and CTRLs, p=0.34, but MODY3 patients showed a significantly (p=0.005) higher response during OGTT compared to IIGI.

Conclusion: MODY3 patients exhibit hyperglucagonaemia in responses to oral glucose, but are able to suppress glucagon normally following iv glucose. In contrast, MODY2 patients respond with normal glucagon suppression to both oral and iv glucose.

A case of Transient Neonatal Diabetes (TND) in a young woman with Beckwith-Wiedemann Syndrome (BWS) and a molecular diagnosis of Hypomethylation of Multiple Loci (HIL)

N.I. Wreglesworth[1], D. Mackay[2], K. Chokkalingam[1];
[1]City Campus Dundee House, Nottingham University Hospitals, [2]Life Sciences Building, University of Southampton, UK.

Background and aims: BWS is an overgrowth disorder associated with tumour predisposition. TND is a rare form of diabetes with neonatal presentation, remission in infancy, but subsequent relapse in ~50% of cases. TND and BWS have heterogeneous, partially-overlapping clinical features, and multiple genetic aetiologies causing deregulation of imprinting. Genomic imprinting is restriction of gene expression dependent on parent of origin, effected by changes not in DNA sequence but DNA expression. Notably, 50% of TND patients and 20% of BWS patients with imprinting errors have additional epigenetic mutations at multiple loci. We present a case with clear, separate, clinical features of both disorders.

Results: A 25 y old woman with BMI 25 and a background of BWS presented with recurrent genitourinary infections. She had glycosuria and an HbA_1C of 104mmol/mol (20-40mmol/mol). Fasting serum insulin was 8.3 mU/L (6-25) and C-peptide 506 pmol/L (364-1655) but islet antibodies were absent. Endocrine investigations for secondary diabetes were normal. She was born at 36 weeks gestation with birth weight 3.18kg (75th centile) and length 58cm (99th centile). Neonatal hyperglycaemia was treated with insulin for about 8 weeks. She also had a history of juvenile osteoporosis and fractures. After dietary advice and Metformin, she lost 6kg and her HbA_1C improved to 62mmol/mol after 4 months. Further molecular testing was carried out due to the history of neonatal diabetes and BWS. No mutations were discovered in the *KCNJ11*, *ABCC8* and *INS* genes. Imprinting analysis identified imprinting mutations at both the BWS and TND loci, as well as at other loci. These findings are consistent with her dual diagnosis of TND and BWS.

Conclusion: This is the first report where an individual has fully presented clinically and molecularly with TND and BWS in addition to epigenetic mutation of other imprinted loci. There is very little published literature on this subset of imprinting disorders. The cause may have been purely environmental or stochastic, or mutation of a regulatory factor involved in imprinting of all the affected loci; further genetic studies are ongoing.

Diabetes mellitus and intestinal ulcers: it's a Wolfram Syndrome 2?

E. Mozzillo[1], M. Delvecchio[2], R. Genesio[3], R. Nugnes[1], V. Fattorusso[1], E. De Nitto[1], A. Franzese[1];
[1]Pediatric Diabetology, University Federico II, Naples, [2]Paediatrics Unit IRCCS, Casa Sollievo della Sofferenza Hospital, San Giovanni Rotondo, [3]University Federico II, Naples, Italy.

Background and aims: Wolfram syndrome (WS) is an autosomal recessive disease with incomplete penetrance. WS is also known as DIDMOAD syndrome defined by the association of childhood-onset non-autoimmune diabetes mellitus (DM), optic atrophy (OA), diabetes insipidus (DI), and deafness (D). The majority of patients shows mutations in the WFS1 gene on chromosome 4p16.1, but a second WS gene on chromosome 4q22-24, named CISD2, is responsible of WS2. The mutation of CISD2 gene was identified only in few familial Jordanian consanguineous members. Patients affected by WS2 had additional features to those previously described in WS, such as defective platelets aggregation with collagen and upper intestinal peptic ulcers (UIU). We describe the first European girl affected by WS2.

Materials and methods: A 17 year old girl, first child of unrelated healthy parents, was referred to our hospital because of weight loss, polyuria and polydipsia. Laboratory investigations showed hyperglycaemia (glucose value 26.7mmol/L), HbA1c 13%, absence of chetonemia and acidosis, iron deficiency anemia (Hb: 10.7g/dl, MCV: 68.2fl, serum iron: 16μg/dl), presence of glycosuria, absence of chetonuria. Auto-antibodies for type 1DM were not detected. Diagnosis of both non-autoimmune diabetes and anemia were made, treated with insulin and martial therapy respectively. Her history was characterized by presence of UIU, from age of 5 years to 14 years, all diagnosed with esophagogastroduodenoscopy, and treated with pump proton inhibitors (PPI) therapy that has never been suspended during her entire life. On the age of 14 years, an abdominal laparoscopy, performed in the suspicion of annular pancreas, showed intussusception of the duodenum, that was treated with resection of a part of the duodenal and with a duodenal-jejunal anastomosis. At the age of 16 years an opthalmological evaluation, performed for visual impairment, revealed optic atrophy; the visual-evoked potentials executed, showed a pathological speed conduction, while both multifocal electroretinogram and Brain Magnetic Resonance were normal. The suspicion of Optic neuropathy Leber was placed without genetic testing. On the basis of clinical history and the presence of DM we suspected a WS. An audiologic evaluation was executed, showing sensorineural hearing loss at high frequencies. The presence of diabetes, optic atrophy, deafness and UIU, suggested the diagnosis of WS2. The platelets aggregation defect was explored, showing a defective platelet aggregation with collagen, while DI was absent. Genetic testing for WS2 was requested.

Results: The genetic testing showed a homozygous deletion of exon 2 and exon 3 of CISD2 gene in the patient, while her parents and brother were heterozygous for the same mutation.

Conclusion: The patient currently is 20 years old and presents: diabetes mellitus, treated with insulin therapy; visual impairment, because of optic atrophy, treated with lenses; tinnitus, due to sensorineural hearing loss at high frequencies; platelet aggregation defect; tendency to UIU treated with PPI therapy. This is the first case of a European girl with WS2 and reminds us that, although rare, the WS2 is a diagnosis to be suspected in presence of DM, OA, D and UIU.

PS 012 Genetics: gene-lifestyle interactions and pharmacogenetics

Dietary polyunsaturated fatty acids and the Pro12Ala polymorphisms of PPARG regulate serum lipids through divergent pathways: a randomised crossover clinical trial

J.A. Pihlajamäki[1], U. Schwab[1], D. Kaminska[1], M. Kolehmainen[1], J. Paananen[1], M. Laakso[2], M. Uusitupa[1];
[1]Public Health and Clinical Nutrition, [2]Department of Medicine, University of Eastern Finland, Kuopio, Finland.

Background and aims: Human and animal studies suggest an interaction between the Pro12Ala polymorphism of PPARG and dietary fat. To investigate if subjects with the Pro12Pro and Ala12Ala genotypes of PPARG respond differently to a diet supplemented with high saturated (SAFA) or polyunsaturated fat (PUFA).
Materials and methods: We recruited nondiabetic subjects from a population based METSIM study to obtain individuals with the Ala12Ala and the Pro12Pro genotypes. Seventeen men with the Pro12Pro genotype and 14 with the Ala12Ala genotype were randomized to both a PUFA diet and a SAFA diet for 8 weeks in a crossover setting. Adipose tissue biopsies for mRNA expression of PPARG2 variant were obtained during the diet intervention.
Results: At baseline subjects with the Ala12Ala genotype had higher levels of HDL cholesterol and lower levels of LDL cholesterol, total triglycerides and apolipoprotein B compared to those subjects with the Pro12Pro genotype ($p<0.05$, FDR <0.1). PPARG2 mRNA expression was higher in participants with the Ala12Ala genotype than in participants with the Pro12Pro genotype throughout the study (FDR <0.001), and PPARG2 mRNA expression correlated negatively with total triglycerides ($p<0.05$). PUFA diet resulted in lower levels of fasting glucose, total cholesterol, total triglycerides and apolipoprotein B ($p<0.05$, FDR <0.1) independent of the genotype and without affecting PPARG2 mRNA expression in adipose tissue. No effect of the genotype on serum glucose and insulin levels was observed.
Conclusion: Beneficial effects of dietary PUFA and the Ala12Ala genotype of PPARG on serum lipids are mediated through divergent mechanisms.
Clinical Trial Registration Number: NCT01274091

High heritability and genetic correlation of intravenous glucose- and tolbutamide-induced insulin secretion

A. Jonsson[1], M. Hornbak[1,2], A.P. Gjesing[1], K.H. Allin[1], C.T. Ekstrøm[3], H. Eiberg[4], O. Pedersen[1,5], T. Hansen[1,6];
[1]The Novo Nordisk Foundation Center for Basic Metabolic Research, Section of Metabolic Genetics, University of Copenhagen, [2]Department of Drug Design and Pharmacology, University of Copenhagen, [3]Department of Biostatistics, University of Southern Denmark, Odense, [4]Department of Biochemistry and Medical Genetics, University of Copenhagen, [5]Faculty of Health Science, University of Aarhus, [6]Faculty of Health Sciences, University of Southern Denmark, Odense, Denmark.

Background and aims: It has been established that the etiology of type 2 diabetes has a significant genetic contribution and that an altered beta cell function is central in the development of the disease. The aim of this study was to estimate the genetic influence on the beta cell response to a physiological (glucose) and a none-physiological (tolbutamide) stimulation.
Material and methods: 284 non-diabetic family-members of type 2 diabetic patients underwent a tolbutamide-modified frequently sampled IVGTT (t-FSIGT) during which glucose was injected at 0 min and tolbutamide at 20 min. Measurements of plasma glucose, serum insulin and serum C-peptide were taken at 33 time points from fasting to 180 min and insulin secretion rate (ISR), and acute insulin response (AIR) were calculated. Heritability estimates were performed using a polygenic variance component model calculating the additive effect and the unique environmental effect. The genetic correlations are presented as Pearsons genetic correlation coefficients (RhoG).
Results: We found high levels of heritability for measures of insulin secretion, especially after glucose stimulation, while plasma glucose was equally influenced by genes and environment. The highest level of heritability was found in the immediately stimulated state, with peak heritability for serum insulin and ISR within the first 7 min after glucose injection (90±14% and 69±14%, respectively) and within 4 min after tolbutamide injection (72±14% and 76±15%, respectively). A strong genetic correlation (correlations coefficients of 0.85-0.93) was found between measures of beta cell responsiveness after glucose and tolbutamide injections.
Conclusion: Our data suggest that the insulin secretion in response to both glucose and tolbutamide is under high genetic influence and that the response to both substances may be under control of the same genes.

363

The CTRB1/CTRB2/BCAR1 locus is associated with GLP-1 stimulated insulin secretion and DPP-4 inhibitor treatment response

L.M. 't Hart[1,2], A. Fritsche[3], N. van Leeuwen[2], G. Nijpels[4], L.A. Donnelly[5], J.M. Dekker[4], J. Fadista[6], L. Groop[6], F. Carlotti[7], E.J.P. de Koning[7], D.I. Boomsma[8], E.J.C. de Geus[8], E.M.W. Eekhoff[9], E.R. Pearson[5], M. Diamant[9];
[1]Molecular Epidemiology, Leiden University Medical Center, Netherlands, [2]Molecular Cell Biology, Leiden University Medical Center, Netherlands, [3]Eberhard Karls University Tübingen, Germany, [4]EMGO Institute, VU University Medical Center, Amsterdam, Netherlands, [5]University of Dundee, UK, [6]Lund University Diabetes Center, Malmö, Sweden, [7]Nephrology, Leiden University Medical Center, Netherlands, [8]VU University, Amsterdam, Netherlands, [9]Diabetes Center, VU University Medical Center, Amsterdam, Netherlands.

Background and aims: The incretin hormone glucagon-like-peptide 1 (GLP-1) promotes glucose homeostasis and enhances beta cell function after a meal. GLP-1 receptor agonists (GLP-1 RA) and dipeptidyl peptidase-4 (DPP-4) inhibitors, which inhibit the physiological inactivation of endogenous GLP-1, are used for the treatment of type 2 diabetes. The goal of this study was to identify genetic loci influencing insulin secretion in response to stimulation with GLP-1. We also evaluated the effect of these loci on response to treatment with GLP-1 RA and DPP-4 inhibitors in type 2 diabetes patients.
Materials and methods: In the present study the Metabochip (200k SNPs) was used to identify genetic variants affecting GLP-1 stimulated insulin secretion (SIS) during hyperglycemic clamps in non-diabetic participants from the Netherlands and Germany. Subsequently their effect on response to GLP-1 RA and DPP-4 inhibitor treatment was analyzed in 527 type 2 diabetes patients from the Netherlands and UK. Data were analyzed using linear regression with adjustment for potential confounders. In addition we examined the effect of the genetic variants on mRNA expression and enzyme activity.
Results: We identified three novel genetic loci with large effects (32-46%) on GLP-1 stimulated insulin secretion during hyperglycemic clamps (*TMEM114; CHST3/SPOCK2/ASCC1* and *CTRB1/CTRB2/BCAR1*; n=232, all $p \leq 8.8*10^{-7}$). Furthermore the G allele of rs7202877 (MAF=0.11, +43% GLP-1 SIS) near *CTRB1/2* and *BCAR1* was associated with a lower decrease in HbA1c during DDP-4 inhibitor (0.51±0.16% (5.6±1.7 mmol/mol); $p=0.0015$) but not GLP-1 RA treatment ($p>0.5$). In addition we found that in human pancreas and islets rs7202877 enhances the expression of *CTRB1/2* but did not change the expression of *BCAR1*. *CTRB1/2* encode the enzyme chymotrypsin which cleaves proteins in food into smaller peptides suitable for further digestion and as expected we found that rs7202877 also enhanced enzyme activity in stool samples. Interestingly this locus is a known diabetes risk locus for both type 1 (G allele) and type 2 diabetes (T allele). Our data showing increased insulin secretion in G allele carriers thus provide a plausible mechanistic explanation for the protective effect of the G allele on type 2 diabetes susceptibility. We hypothesize that in the absence of a functional beta cell mass (i.e. in type 1 diabetics) this protective effect is lost thereby enhancing type 1 diabetes susceptibility via a yet unknown mechanism but possibly involving the gut which may also account for the observed difference in treatment response in DPP-4 inhibitor users.
Conclusion: In this study we have identified chymotrypsin in the regulation of the incretin pathway, type 1 and type 2 diabetes susceptibility and GLP-1 based treatment response in type 2 diabetes.

Polymorphisms associated with serum 25-hydroxyvitamin D concentration and their impact on subclinical atherosclerosis in patients with type 2 diabetes

A. Deleskog[1,2], R. Strawbridge[2], O. Piksasova[2], J. Öhrvik[2], K. Gertow[2], C.-G. Östenson[1], A. Hamsten[2], the IMPROVE Study Group;
[1]Molecular medicine and surgery, [2]Department of Medicine, Atherosclerosis Research Unit, Stockholm, Sweden.

Background and aims: Vitamin D deficiency has been associated with type 2 diabetes (T2D) and myocardial infarction as well as multiple cardiovascular risk factors. Several single nucleotide polymorphisms (SNPs) associated with serum 25-hydroxyvitamin D (vitamin D) concentrations have been identified. The aim of this study was to investigate causality of vitamin D in cardiovascular disease using vitamin D-associated genetic variants and subclinical atherosclerosis in the IMPROVE study.
Materials and methods: IMPROVE is a European, multicentre, longitudinal cohort study, which enrolled individuals aged 54 to 80 years with at least three cardiovascular risk factors and no history or symptoms of cardiovascular disease from 7 centers in Finland, Sweden, the Netherlands, France, and Italy. Participants underwent carotid ultrasound examination at baseline, month 15 and month 30. Based on genome-wide association studies, 8 SNPs associated with serum vitamin D were identified for investigation here. Genotyping of SNPs was carried out using the Illumina Immunochip (6 SNPs) or Taqman (2 SNPs) platforms. In total 3430 subjects were included, of which 900 were T2D subjects.
Results: Genetic variants in the vitamin D binding protein *(GC or DBP*, rs2282679 and rs7041) and the 7-dehydrocholsterol reductase/NAD synthetase 1 gene (*NADSYN1*, rs12785878 and rs3829251) were negatively associated (bonferroni-corrected significance) with vitamin D levels after adjustment for established risk factors. Effect size and significance of associations between SNPs and vitamin D levels differed between subjects with and without T2D. SNPs in *GC* and *NADSYN1* were found to interact with T2D to influence vitamin D levels. In the multiple linear regression analyses including the interaction term, there were significant (bonferroni-corrected) positive associations between SNPs and segment-specific or composite carotid intima-media thickness (cIMT) measures (at baseline and after progression) independent of vitamin D levels and established risk factors.
Conclusion: SNPs in *DBP* and *NADSYN1* were associated with levels of vitamin D. Significant interactions between T2D and SNPs in *GC* and *NADSYN1* were independently related to cIMT and cIMT progression after adjustment of established risk factors and vitamin D levels. This suggests a role of vitamin D-related SNPs in early subclinical atherosclerosis, independent of vitamin D levels, but in a manner that depends on T2D status.

TCF7L2 gene polymorphisms may influence decreased postprandial glucose oxidation - looking for personalised nutrition for obesity/type 2 diabetes mellitus prevention

E. Adamska[1], A. Kretowski[1,2], J. Goscik[3], M. Waszczeniuk[4], J. Wilk[2], A. Golonko[4], N. Wawrusiewicz-Kurylonek[2], A. Citko[2], M. Ciborowski[1], D. Lipinska[2], J. Pliszka[2], K. Maliszewska[2], M. Gorska[2];
[1]Centre for Clinical Research, [2]Department of Endocrinology, Diabetology and Internal Medicine, [3]Centre for Experimental Medicine, [4]Department of Dietetics and Clinical Nutrition, Medical University of Bialystok, Poland.

Background and aims: Genome-wide association studies have identified the number of genetic susceptibility loci for type 2 diabetes (T2DM). Single nucleotide polymorphisms (SNPs) in the transcription factor 7-like 2 gene (TCF7L2) seem to be one of the most predictive factors promoting T2DM development. Genetic variants of TCF7L2 have been implicated in the pathogenesis of T2DM primarily due to the influence pancreatic β-cell function, but the biological basis of these associations remains to be precisely determined. The aim of our study was to analyze whether SNPs of TCF7L2 gene influence postprandial insulin secretion and glucose utilization in nondiabetic men.
Materials and methods: We genotyped previously identified TCF7L2 SNPs: rs7901695 and rs7903146 in 943 subjects (330 normal-weight, 337 overweight, 276 obese; 463 women/480 men) who underwent anthropometric measurements, body composition analysis and OGTT. In randomly selected 48 subjects high-carb (HC), norm-carb (NC) and high-fat (HF) standardized meal tests were performed and postprandial carbohydrate utilization were evaluated with indirect calorimetry. Kruskal-Wallis non-parametric analysis of variance was used to evaluate difference between the studied parameters in subjects with the TCF7L2 genotypes.
Results: Subjects with CC genotype (rs7901695) presented 3 fold lower area under the curve (AUC) for glucose utilization (p=0.003) after high- carbohydrate meal intake in comparison to those with other genotypes. Similar results were found for TT homozygotes (rs7903146) for glucose utilization ($p<0.05$) and lower AUC for glucose oxidation (p=0.02) in the postprandial state. In non-diabetic subjects with the risk TCF7L2 genotypes glucose levels were significantly higher at 30, 60 and 120 min with 2.5 fold higher AUC for postprandial insulin levels (p=0.04) after standardized HC meals.
Conclusion: We believe that our study may help to understand the mechanisms that TCF7L2 gene influences the risk of T2DM. If our results are confirmed TCF7L2 gene-related personalized nutrition for obesity/type 2 diabetes mellitus prevention could be considered.

Interaction between vitamin D receptor gene variants and dairy intake: effects on incident metabolic syndrome and incident IFG/type 2 diabetes in the D.E.S.I.R. study

F. Fumeron[1,2], A. Lamri[1,2], L. Rozenblum[2], A. Nicolas[2], N. Bellili[1,2], O. Lantieri[3], B. Balkau[4], G. Velho[1], M. Marre[1,2];
[1]INSERM U695, Paris, [2]UFR de Médecine, Univ Paris Diderot, Sorbonne Paris Cité, Paris, [3]IRSA, La Riche, [4]CESP, INSERM U1018, Villejuif, France.

Background and aims: Epidemiological studies have suggested that vitamin D deficiency is associated with coronary heart disease. The vitamin D endocrine system is involved in the regulation of calcium metabolism. Actions of vitamin D are mediated by the specific cytosolic/nuclear vitamin D receptor (VDR). Several polymorphisms in the VDR gene have been reported to be associated with a variety of phenotypes, including insulin sensitivity and susceptibility to type 2 diabetes. In the D.E.S.I.R. cohort, we have shown that the consumption of dairy products is associated with the incidence of the metabolic syndrome and impaired fasting glycaemia/type 2 diabetes (IFG/T2D). Our aim is to study now the associations of VDR polymorphisms with the 9-year incidence of the metabolic syndrome and of IFG/T2D, testing for interactions with dairy product intake.
Materials and methods: Among 5212 subjects from the D.E.S.I.R. cohort, 4619 individuals born in mainland France were genotyped for three VDR gene polymorphisms (Fok1 G>A, Taq1 T>C, Bsm1 G>A) by the Kaspar method. Study participants completed a food frequency questionnaire. The metabolic syndrome was defined according to the International Diabetes Federation as waist circumference ≥ 94/80 cm for men/women plus two of the following factors: 1) elevated triglycerides: ≥ 1.70 mmol/l or specific treatment for this lipid abnormality; 2) reduced HDL cholesterol (HDL-C): ≤ 1.03 mmol/l for men and 1.29 mmol/l for women or specific treatment for this lipid abnormality; 3) elevated blood pressure: ≥ 130/85mmHg or treatment of previously diagnosed hypertension; 4) elevated fasting glycaemia ≥ 5.6 mmol/l or previously diagnosed type 2 diabetes (treated by glucose lowering drugs and/or fasting glycaemia ≥ 7.0 mmol/l). Associations were tested by logistic regression analysis with multiple adjustment (sex, age, alcohol, physical activity, smoking, BMI).
Results: No overall association was found between the VDR polymorphisms and the metabolic diseases; however the polymorphisms modulated associations with dairy product intake. A higher consumption of dairy products other than cheese was negatively associated with 9-year incident IFG/T2D in Bsm1 GG homozygotes (Odds Ratio [95%CI]: 0.67[0.47-0.95], P=0.025) but not in the other genotypes. A higher consumption of cheese was negatively associated with the incidence of the metabolic syndrome in Bsm1 G carriers (Odds Ratio [95%CI]: 0.72[0.59-0.87], P=0.001) and in Taq1 T carriers (Odds ratio [95%CI]: 0.73[0.60-0.88], P=0.001), but not in the other genotypes.
Conclusion: In conclusion, the associations between dairy product consumption and the risk of the metabolic syndrome and hyperglycaemia are modulated by genetic variation at the VDR locus.

Several type 2 diabetes associated variants in genes involved in WNT-signalling interact with dietary fibre intake on type 2 diabetes incidence

G. Hindy, I.G. Mollet, G. Rukh, U. Ericson, M. Orho-Melander;
Department of Clinical Sciences, Diabetes and Cardiovascular Disease, Genetic Epidemiology, Lund University, Malmö, Sweden.

Background and aims: TCF7L2 is a principal transcription factor in the canonical WNT-signaling pathway. Short chain fatty acids, fermentation products of dietary fibers, are potent histone deacetylase inhibitors that can up-regulate WNT activity and *TCF7L2* rs7903146 was earlier reported by us to interact with dietary fiber intake on type 2 diabetes (T2D) incidence. Here we study whether other GWAS identified T2D associated single nucleotide polymorphisms (SNPs) in genes involved in the WNT pathway interact with dietary fiber on T2D incidence.
Materials and methods: We included 26,930 individuals without diabetes from the Malmö Diet and Cancer (MDC) population based cohort. Diet data was collected at baseline (1991-1996) using a modified diet history method (an extensive food frequency questionnaire, a 7-day food diary, and an interview). Altogether 51 gene loci (58 SNPs) were analyzed for links to WNT-signalling using annotations from Gene Ontology, Kioto Encyclopedia of Genes and Genomes, Biocarta, Panther pathways and Literature integrated within the DAVID-ABR. Over a mean follow up period of 14 years 2,860 cases of T2D were recorded. COX proportional hazards was used to analyze association with T2D (adjusted for age and sex) and interaction between genotypes and quintiles of fiber intake (adjusting for age, sex, BMI, total energy intake, season, diet method version, physical activity, smoking, alcohol intake, and education).
Results: Seven genes (9 SNPs) were annotated as involved in WNT-signalling (upstream of TCF/LEF) including *TCF7L2* (rs7903146 and rs12255372), *HHEX* (rs1111875), *HNF1A* (rs7957197), *NOTCH2* (rs10923931), *TLE4* (rs13292136), *ZBED3* (rs4457053) and *PPARG* (rs1801282 and rs13081389). SNPs in *TCF7L2*, *HHEX* and *HNF1A* loci predicted future T2D [HR 95% CI: 1.32 (1.24-1.39), 1.23 (1.16-1.30), 1.07 (1.01-1.12), and 1.14 (1.07-1.22) per risk allele]. SNPs in *TCF7L2*, *NOTCH2* and *ZBED3* loci interacted significantly with fiber intake on T2D incidence ($P_{interaction}$ = 0.04, 0.006, 0.01, and 0.003, respectively). Higher fiber intake associated with lower T2D risk only among homozygotes for the non-risk alleles of *TCF7L2* SNPs [N=13482 and 13522: HR 95% CI 0.95 (0.91-0.99) and 0.94 (0.90-0.98) per fiber intake quintile]. Higher fiber intake associated with lower T2D risk only among risk allele carriers of *NOTCH2* rs10923931 [N=4375 (GT) and 228 (TT): HR 95% CI: 0.90 (0.84-0.97) and 0.70 (0.50-0.99) per fiber intake quintile]. Higher fiber intake associated with lower T2D risk only among homozygotes for the risk allele of *ZBED3* rs4457053 [N=1643: HR 95% CI: 0.84 (0.75-0.94)]. *HHEX* rs1111875 had a tendency for interaction with fiber intake ($P_{interaction}$ = 0.11), but no interaction was observed for *HNF1A*, *TLE4*, and *PPARG* SNPs. Of the 44 loci not annotated to WNT signaling, none indicated interaction with fiber intake.
Conclusion: Our results indicate that several T2D susceptibility genes involved in WNT-signalling interact with dietary fiber intake on T2D incidence. The putative mechanisms by which fiber intake could modify the WNT signalling by the susceptibility variants in T2D pathogenesis include effects on beta cell survival, adipogenesis and adipocyte proliferation, and/or GLP-1 production in intestinal L-cells.

Genetic variants within *AKR1B10* may influence human eating behaviour

K. Rohde[1], M. Federbusch[2], A. Horstmann[1,2], A. Tönjes[3], A. Villringer[2,4], M. Stumvoll[1,3], P. Kovacs[3], Y. Böttcher[1];
[1]Integrated Research and Treatment Center IFB Adiposity Diseases, University of Leipzig, [2]Department of Neurology, Max-Planck-Institute for human Cognitive and Brain Sciences, Leipzig, [3]Department of Medicine, University of Leipzig, [4]Clinic of Cognitive Neurology, University of Leipzig, Germany.

Background and aims: Preliminary data from a genome wide association study (GWAS; data unpublished) showed significant associations between Single Nucleotide Polymorphisms (SNPs) in the 5'UTR Region of the *Aldoketoreductase 1B10 gene* (*AKR1B10*) and human eating behavior. AKR1B10 is a monomeric enzyme that may play a role in detoxification processes and regulatory mechanisms like differentiation, proliferation and apoptosis. The aim of the present study was to investigate the effects of intragenic variants of *AKR1B10* on the eating behavior factors restraint, hunger and disinhibition.
Material and methods: The initial analysis included 548 Sorbs from Germany. This cohort is clinically well characterized for a variety of metabolic parameters including data on eating behavior (FEV). 4 tagging-SNPs (r^2=0.8, MAF<0.05) within the *AKR1B10* locus were genotyped in all subjects using the TaqMan SNP Genotyping assay (Applied Biosystems, Inc., Foster City, CA). Subsequently, genetic association analyses were calculated for restraint, hunger and disinhibition using linear regression models adjusted for age, sex and BMI. Replication analyses included another independent cohort from Leipzig (N=334).
Results: Among the Sorbs population the minor T-allele and the minor G-allele of the variants rs1834150 and rs782881 were significantly associated with increased disinhibition (additive mode of inheritance, *P*=0.006 and *P*=0.032). Further, we identified significant associations between the minor alleles and decreased waist circumference (rs1834150 and rs782881), increased alcohol consumption (rs782881) and higher coffee consumption (rs1834150) (all *P*<0.05). In our replication cohort we detected the same effect direction for the association with disinhibition (ß=0.152 for rs1834150 and ß=0.007 for rs782881). The meta-analysis for rs1834150 resulted in a combined *P* =0.0096 (Z-score=2.589). Moreover, in the replication cohort we further identified the variants rs1834150 and rs782881 significantly associated with increased restraint (respectively, *P*=0.008 and *P*=0.028). Albeit non-significant in the initial Sorbs population both SNP markers presented same effect directions for restraint (ß=0.439 for rs1834150 and ß=0.357 for rs782881). A meta-analysis for restraint resulted in combined *P*=0.0078 for rs1834150 (Z-score 2.659) and *P*=0.0178 for rs782881 (Z-score 2.371).
Conclusion: Our data suggest that genetic variants within the *AKR1B10* gene may play a role in the regulation of human eating behavior.

The search for the variant explaining type 2 diabetes linkage on chromosome 9

E. Ottosson Laakso[1], P. Vikman[1], A. Kvist[2], H. Mattisson[1], L. Sarelin[3], P. Almgren[1], B. Isomaa[3], L. Groop[1];
[1]Diabetes and Endocrinology, Department of Clinical Science, Malmö, Sweden, [2]Onkologi, Department of Clinical Science, Lund, Sweden, [3]Folkhälsan Research Center, Helsinki, Finland.

Background and aims: Previous studies have shown a suggestive linkage between type 2 diabetes (T2D) and a region on chromosome 9 in families from the Botnia region in Finland. One family with many affected individuals had a non-parametric LOD (NPL) score >15 to chromosome 9 p21-p23. Our aim in this study is to identify the variant(s) explaining the linkage using next generation sequencing and to explore the effect of these variants in T2D.
Materials and methods: The initial study was performed in 10 T2D and 3 non-diabetic family members using targeted sequencing of 3 Mb of chromosome 9 on the Illumina Genome Analyzer platform. Variants were selected for further genotyping in the extended family (10 T2D and 10 non-diabetics) based on four criteria; 1) novel, 2) segregation with diabetes, 3) location in or in the vicinity of a gene and 4) expression differences in peripheral blood leukocytes from the family members. Additional whole exome sequencing was performed in 20 members of the family (10 T2D and 10 non-diabetics). Replication genotyping was performed in 31 families from the same region traced back to the 17th century with 130 T2D patients and 213 non-diabetic subjects.
Results: After filtering of the variants identified in the targeted sequencing 52 variants remained. Fourteen of these have been additionally genotyped in the extended family, where a haplotype of three variants segregated with T2D (p=0.02) with an odds ratio of 21 (95% CI 1.78- 248.12). This haplotype was also seen in the replication cohort (p=0.02) although the frequency of the haplotype decreased from 20% in the family to 0.5% in the 31 families. The variants are located in the MPDZ gene encoding a G-protein interacting protein which is part of the signaling of both melatonin and serotonin. This gene seems to be differentially expressed in the peripheral blood leukocytes in risk genotype carriers (p=0.049) and has a nominally significant differential expression in the lymphocytes from diabetic patients compared to non-diabetic subjects in the family (p=0.07). In addition, exome sequencing also identified a novel, missense mutation in the ADAMTSL1 gene, segregating with T2D in the family (p=0.01).
Conclusion: Reported linkage of T2D to a region on chromosome 9 p21-p23 in this family may be caused by variants in the MPDZ and ADAMTSL1 genes.

Novel gene-bases and pathway analysis GWAS methods for the identification of new candidate genes and pathways for type 2 diabetes

J.M. Mercader[1], C. Voichita[2], M. Donato[2], F. Sánchez[1], S. Bonàs[1], A.L. Tarca[2,3], S. Draghici[2,4], D. Torrents[1,5];
[1]Joint IRB-BSC program on Computational Biology, Barcelona Supercomputing Center, Barcelona, Spain, [2]Department of Computer Science, Wayne State University, Detroit, USA, [3]Perinatology Research Branch, NICHD/NIH/DHHS, Bethesda, Maryland, and Detroit, USA, [4]Department of Clinical and Translational Science, Wayne State University, Detroit, USA, [5]Institució Catalana de Recerca i Estudis Avançats (ICREA), Barcelona, Spain.

Background and aims: Genome wide association studies (GWAS) have represented a promising tool to identify new genes involved in complex diseases, such as type 2 diabetes (T2D). However, despite large GWA meta-analyses efforts, less than 10% of the heritability can be explained by the to-date identified loci. A possible explanation for this limited success may be that several independent variants in a given gene or pathway, each of them with a small effect, contribute cooperatively to increase the susceptibility to the disease. To overcome this limitation, and to further exploit the available GWAS data, we have developed a gene-centred test able to take into account several SNPs in each gene and its pre-specified boundaries. We then applied the scores generated by this method to perform pathway analysis in T2D GWAS data.
Materials and methods: This test is based on a first step of SNP selection, followed by a multiple logistic regression fitting allowing correction for linkage disequilibrium. An empirical p-value for each gene is provided using adaptive permutation approaches. This method provides a single score for each gene, which can be applied to several pathway analysis techniques, including gene set enrichment analysis (GSEA) and Signalling Pathway Impact Analysis (SPIA), which also takes into account the network topology of the pathways.
Results: The application of this method to T2D GWAS data from the WTCCC, besides replicating previous loci, allowed the identification of several novel candidate genes for type 2 diabetes, including, one gene of the same family of the widely replicated KCNJ11 gene. Furthermore, pathway analyses based on the previously obtained gene scores ranked as the most associated pathway, the KEGG adipocytokine signalling pathway, which has been confirmed by other T2D meta-analyses, which suggest that reliable results can be obtained from applying this approach in modest GWAS datasets. The results applying this method on several extended replication datasets from the database of genotypes and phenotypes (dbGaP) and European Genome-phenome Archive (EGA) datasets involving six multi-ethnic cohorts involving 17.000 additional individuals will be presented.
Conclusion: We provide a novel gene-centred statistical method that allows the identification of novel T2D candidate genes, and provides a useful input for downstream systems biology analyses, such as pathway analyses methods. This study also proves the value of sharing individual-level GWAS data in public repositories, such as dbGaP or EGA, to apply novel statistical and systems biology methodologies to better understand the aetiology of complex diseases.

Identification of new genetic associations to type 2 diabetes through accurate genotype imputation with *1000 Genomes* reference panel

S. Bonàs[1], F. Sánchez[1], J.M. Mercader[1], D. Torrents[1,2];
[1]Joint IRB-BSC program on Computational Biology, Barcelona Supercomputing Center, [2]Institució Catalana de Recerca i Estudis Avançats (ICREA), Barcelona, Spain.

Background and aims: Despite the clear contribution of Genome-Wide Association Studies (GWAS) in the understanding of the genetics of Type 2 Diabetes (T2D), known associated loci published to date only explain a small fraction of the estimated heritability associated to T2D. Genotype imputation consists in predicting unobserved genotypes using a reference panel of haplotypes densely genotyped to increase the statistical power of the GWAS data. The *1000 Genomes Project* reference panel (1KG), based on low whole genome and exome sequencing data, constitutes a unique opportunity to perform a more accurate fine-mapping of known and replicated associated regions and to identify new genetic variants associated to T2D re-analysing published GWAS datasets stored in public repositories. The 1KG catalogue, including more than 37M SNPs, small insertions and deletions (INDELs) and structural variants, needs a thoroughly evaluation of the current post genotype imputation strategies in order to minimize false positive associations arising from inaccurate genotype imputation without compromising statistical power. The main goal of this study was applying this methodology to identify new candidate genes involved in the aetiology of T2D.
Materials and methods: Previous work of our group consisted in stating novel quality standards for genotype imputation adapted to the requirements of novel reference panels such as 1KG. For this purpose, we used the set of 1958 British Birth controls (~3.000 subjects) from the Wellcome Trust Case Control Consortium (WTCCC) genotyped by two independent platforms allowing us to select the appropriate quality filters to avoid inaccurate imputed variants that could result in false positive associations. We applied this strategy to the genotyped T2D data from the original WTCCC study involving ~2.000 individuals and ~3000 controls from the WTCCC2 study.
Results: Accurate imputed variants with minor allele frequency as low as 0.01 allowed the identification of 272 associated regions (p-value ≤ 5x10-8). The three loci found in the original WTCCC study have been identified and characterized with higher genomic resolution, enhancing functional annotation. Moreover, we detected 2 associated loci close to the ARAP1 and HNF1A genes identified in large meta-analysis (involving 34.412 cases and 59.925 controls) posterior to the WTCCC study from which we obtained the data of this study. These findings prove that imputation with 1KG allows the identification of new T2D loci without such large sample sizes and thus, less investment. In addition, 15 genes involved in the crosstalk between the insulin signalling pathway and the mitochondria function, recently reported by our group, are located in these novel T2D identified loci. The replication of these results in independent T2D case-control publicly available cohorts, encompassing more than 17.000 T2D individuals will be presented.

Conclusion: Genotype imputation using dense reference panels such as the 1KG allowed the identification of novel candidate genes as well as fine-mapping of already known associated regions using less sample sizes. These results, which we will confirm in independent populations, will lead to a better description of the genetic basis of T2D, allowing a better exploitation from the previously spent resources in large GWAS datasets.

Large-scale genome-wide association meta-analysis of the 1000 genomes project imputed data identifies 19 novel lipid loci and new variants in previously known loci

I. Prokopenko[1,2], I. Surakka[3,4], A.-P. Sarin[3,4], R. Mägi[5], M. Horikoshi[2,6], T. Ferreira[2], L. Marullo[7], G. Thorleifsson[8], A. Mahajan[2], M.I. McCarthy[2,6], A.P. Morris[2], S. Ripatti[3,4], for the ENGAGE Consortium;
[1]Department of Genomics of Common Disease, Imperial College London, UK, [2]Wellcome Trust Centre for Human Genetics, University of Oxford, UK, [3]Institute for Molecular Medicine Finland FIMM, University of Helsinki, Finland, [4]National Institute for Health and Welfare, Helsinki, Finland, [5]Estonian Genome Center, University of Tartu, Estonia, [6]Oxford Centre for Diabetes, Endocrinology and Metabolism, Radcliffe Department of Medicine, University of Oxford, UK, [7]Department of Life Sciences and Biotechnology, University of Ferrara, Italy, [8]Thorleifsson, Reykjavik, Iceland.

Background and aims: Hyperlipidemia is a frequent companion to T2D, reflecting shared insulin resistance, and contributes to diabetes-related complications. Genome-wide association (GWA) studies have been successful in detecting numerous associations with blood lipids (high and low density lipoprotein cholesterols (LDL/HDL), total cholesterol and triglycerides), through a substantial proportion of the genetic contribution to trait variances remains unexplained.
Materials and methods: In order to find more loci and to approach potential causal variants by fine-mapping in already known loci, we performed GWA meta-analysis of studies imputed from high density reference panel provided by the June 2011 release of 1000 Genomes project. This reference allows us to analyze markers with minor allele frequency as low as 0.5%. 17 population-based studies of European origin were used with total sample size up to 51,204 individuals.
Results: In a fixed-effects meta-analysis following imputation, we found 79 loci associated with at least one of the lipid measures with $P<5\times10^{-8}$, 19 of these were previously unreported (>2Mb from known loci) and lead variant at 7 of them had minor allele frequency less than 5%. We could replicate previously-reported associations at 3 missense SNPs (*APOE, ANGPTL4* and *PCSK9*, with MAFs 16.5%, 3.0% and 1.9% respectively) identified from candidate-gene resequencing efforts, and 3 others (*APOB, GCKR* and *HNF4A*, with MAFs 23.8%, 35.9% and 4.1%) found in GWA studies as the new lead SNPs. Initial fine-mapping analyses have identified at least two coding variants (*ABCA6/8* and *MOSC1,* with MAFs 1.9% and 28.0%) being lead SNPs at those loci and several other examples of low frequency lead SNPs.
Conclusion: Our results highlight the potential for the identification of novel associations using existing GWAS genotyping data, supplemented with imputation from high-density reference panel of 1000 Genomes Project without the need for costly re-sequencing experiments.

Pleiotropic effects of obesity-susceptibility loci on metabolic traits: a meta-analysis of up to 37,874 individuals

J.V. van Vliet-Ostaptchouk[1], M. den Hoed[2,3], J. Luan[2], J. Zhao[2], K. Ong[2], A. Wong[4], R. Hardy[4], D. Kuh[4], M. Van der Klauw[1], M. Bruinenberg[1], K.-T. Khaw[5], B. Wolffenbuttel[1], N. Wareham[2], H. Snieder[1], R. Loos[2,6];
[1]University of Groningen, University Medical Center Groningen, Netherlands, [2]Institute of Metabolic Science, Addenbrooke's Hospital, Cambridge, UK, [3]Uppsala University, Sweden, [4]Institute of Epidemiology and Health Care, University College London, UK, [5]University of Cambridge, UK, [6]Icahn School of Medicine at Mount Sinai,, New York, USA.

Background and aims: Obesity is a key risk factor for a number of metabolic diseases, including type 2 diabetes, dyslipedimia and cardiovascular disease. Although the exact biological mechanisms linking obesity to these co-morbidities are not fully understood, a set of common genetic factors with pleiotropic effects (i.e. affecting multiple traits) might in part explain the observed associations. We aimed to investigate whether the currently established obesity-susceptibility loci that were identified through genome-wide associations studies for body mass index (BMI) and waist-to-hip-ratio (WHR) are also associated with metabolic traits, independently of obesity-related traits.
Materials and methods: We systematically assessed associations of the 32 BMI and 14 WHR loci, individually and combined in two genetic predisposition scores (GPS-BMI, GPS-WHR), with glycaemic traits, blood lipids, and blood pressure (BP) by meta-analyzing data of up to 37,874 individuals of European ancestry from six population-based studies. We also examined whether these associations were influenced by (central) adiposity.
Results: The meta-analyses showed associations of both the individual obesity-susceptibility loci and the genetic predisposition scores with metabolic traits that were not driven by the obesity-related phenotypes. We observed significant associations of BMI-increasing alleles at five BMI-loci with lower levels of 2-hr glucose (RBJ, QPTCL: effect sizes -0.068 and -0.107 SD, respectively), HDL-cholesterol (SLC39A8: -0.065 SD, MTCH2: -0.039 SD), and diastolic BP (SLC39A8: -0.069 SD), and higher and lower levels of LDL- and total-cholesterol (QPTCL: 0.041 and 0.042 SD, respectively, FLJ35779: -0.042 and -0.041 SD, respectively) (all Ps<2.4x10-4), independently of BMI. The WHR-increasing alleles at two WHR-loci were significantly associated with higher proinsulin (GRB14: 0.069 SD) and lower fasting glucose levels (CPEB4: -0.049 SD), independently of BMI and WHR. A higher GPS-BMI was associated with lower systolic BP (-0.005 SD), diastolic BP (-0.006 SD) and 2-hr glucose (-0.013 SD), while a higher GPS-WHR was associated with lower HDL-cholesterol (-0.015 SD) and higher triglyceride levels (0.014 SD) (Ps<2.9x10-3), independently of BMI and/or WHR.
Conclusion: Our results provide evidence that obesity susceptibility loci have pleiotropic effects on metabolic traits, independently of adiposity. These findings bring a novel insight into mechanisms that link obesity with metabolic abnormalities and highlight that the genetic variants predisposing to obesity might also predispose to, or protect from, other metabolic disorders.

Dissecting the pleiotropic effects of established type 2 diabetes and other cardiometabolic trait loci to define pathways and gene networks involved in type 2 diabetes pathogenesis

L. Marullo[1,2], B. Voight[3], C. Fuchsberger[4], C. Scapoli[1], J. Dupuis[5], J.B. Meigs[6], A.P. Morris[2], I. Prokopenko[7];
[1]Department of Life Sciences and Biotechnology, Genetic Section, University of Ferrara, Ferrara, Italy, [2]Wellcome Trust Centre for Human Genetics, University of Oxford, UK, [3]Departments of Pharmacology and Genetics, University of Pennsylvania, Philadelphia, USA, [4]Center for Statistical Genetics, University of Michigan, Ann Arbor, USA, [5]Department of Biostatistics, Boston University School of Public Health, USA, [6]General Medicine Division, Massachusetts General Hospital, Boston, USA, [7]Department of Genomics of Common Disease, Imperial College London, UK.

Background and aims: Recent genome-wide association studies (GWAS) for human complex phenotypes have identified hundreds of genetic variants for cardio-metabolic traits and risk of disease. At many loci or specific variants associations are observed with multiple epidemiologically correlated traits. We formed the Cross-Consortia Pleiotropy Group to investigate the patterns of multi-cardio-metabolic trait associations across the genome. We aimed (a) to examine the associations of cardio-metabolic trait loci with epidemiologically correlated traits by grouping shared patterns of individual trait effects; (b) to define pathway and gene networks involved in the trait variability within the association pattern groups.
Materials and methods: We evaluated the genetic effects of 544 independent variants ($r^2<0.8$) from a total of 687 SNPs from published GWAS meta-analyses (thru Sep 2012) of 20 quantitative cardio-metabolic traits, including systolic/diastolic blood pressure, 8 glycaemic, 6 obesity/anthropometric, 4 lipid traits, and 2 diseases (Type 2 Diabetes (T2D), hypertension). We applied a complete hierarchical cluster analysis, which grouped variants according to their impact on the cardio-metabolic traits. We combined these data with annotated pathways, protein-protein interactions and semantic relationships from the published literature using GRAIL and DAPPLE software tools, which estimated the significance of connections between putative genes.
Results: We identified 33 groups of variants with shared patterns of associations with cardio-metabolic traits. Of these, 22 clusters contained groups of variants showing association with one or a group of highly correlated phe-

notypes. In the other 11 clusters, genetic variants were grouped according to their patterns of phenotypic effects. A group of 17 BMI/WC loci, such as *MC4R, TMEM18, BDNF, TFAB2B, NEGR1*, were related to BMI, lower HDL, higher triglycerides (TG), T2D risk, insulin resistance and obesity traits, the latter two being insignificant after BMI adjustment. 19 loci from another cluster were related to "healthy obesity/unhealthy leanness" by association with higher BMI and HDL, lower TG, glycaemic traits and risk of T2D, where three growth factors, *GRB14, PDGFC, VEGFA* showed significant connectivity ($p<0.001$). A cluster of 23 loci primarily associated with lower height or higher total cholesterol were also related to lower skeletal growth and higher HDL, accompanied by significant direct ($p=0.05$) and indirect ($p=0.001$) physical gene interactions. A cluster containing *CDKAL1, THADA, IGF2BP2, RREB1, DGKB, PROX1* and 6 other loci were related to beta cell function and glucose homeostasis traits and higher T2D risk.
Conclusion: This approach shows great promise for dissecting genetic effects on cardio-metabolic traits.

PS 014 Nutrition and mechanisms in diabetes: observational studies

375

Anti-obesity and anti-diabetic effect of chronic coffee consumption in mice

I. Rustenbeck[1], V. Lier-Glaubitz[1], M. Willenborg[1], U. Engelhardt[2], A. Jörns[3];
[1]Institute of Pharmacology and Toxicology, Technical University of Braunschweig, [2]Institute of Food Chemistry, Technical University of Braunschweig, [3]Institute of Anatomy, Hannover Medical School, Germany.

Background and aims: Chronic coffee consumption is correlated with a substantially lower incidence of type 2 diabetes. Apparently the association does not depend on race, gender or geographic distribution of the study populations. For the experimental exploration of the underlying mechanisms the demonstration of this effect in a mouse model of type 2 diabetes is needed.
Materials and methods: From week 10 on, male C57BL/6NCrl mice consumed regular coffee (i.e. coffee containing a natural content of caffeine) as filtered brew of 20 g ground coffee per litre (mean caffeine concentration 327 ± 30 mg/l, n = 29) or 40 g/ litre *ad libitum* or continued to drink tap water. The development of obesity and diabetes caused by a high fat diet (55% lipids, HFD) was observed for 35 weeks in comparison with mice feeding on normal chow (9% lipids, ND). In addition to parameters of metabolism, the morphology of the endocrine pancreas was quantified.
Results: The massive weight gain in HFD mice was dose-dependently delayed, the moderate weight gain in aging ND mice was abolished by coffee consumption. In both cases this was due to a lower feeding efficiency. Water or coffee consumption depended on the type of diet but not on the type of fluid. HFD mice had a 50% lower intake. At week 21 intraperitoneal glucose tolerance tests (IPGTT) showed a dose-dependent significantly faster decline of elevated glucose levels in coffee-consuming HFD mice, but not in ND mice. At week 39 the IPGTT showed diminished peak levels in coffee-consuming HFD mice, but also an improved glucose tolerance in all treatment groups vs. week 21. This spontaneous improvement was also visible as a decrease of the non-fasting glycaemia between week 21 and week 30, both in HFD and ND mice. Coffee-consuming ND mice and control ND mice had closely similar values for total cholesterol, triglycerides, HDL cholesterol and also blood glucose. The coffee-consuming HFD mice, in contrast, differed significantly from the corresponding ND mice in each single parameter. Irrespective of coffee consumption HFD mice were hyperinsulinaemic at week 21, grossly hyperinsulinaemic at week 39 and had significantly enlarged islets at week 45. Coffee consumption did not affect islet size or parameters of beta cell apoptosis, proliferation and insulin granule content.
Conclusion: The chronic consumption of regular coffee diminishes weight gain both in HFD and ND mice and favourably affects glucose tolerance in HFD mice. Thus, this model seems appropriate to explore which of the coffee constituents is responsible for the diabetes-preventive effect of coffee consumption in humans.

Dietary intake of carbohydrates and risk of type 2 diabetes: European Prospective Investigation into Cancer in Norfolk study

S. Ahmadi Abhari[1], R.N. Luben[1], N. Powell[1], A. Bhaniani[1], N.J. Wareham[2], N.G. Forouhi[2], K.-T. Khaw[1];
[1]Department of Public Health, University of Cambridge, [2]MRC Epidemiology Unit, Cambridge, UK.

Background and aims: To better understand the role of dietary patterns in development of type 2 diabetes we investigated the association of dietary intake of carbohydrates and risk of type-2 diabetes in a large prospective study.
Materials and methods: A total of 25,639 men and women aged 40-79 were recruited in the European Prospective investigation into Cancer in Norfolk study. Incident cases of diabetes (N=749) were identified and compared with a randomly selected sub-cohort of 3496 participants. Seven-day food diary administered at baseline was used for dietary assessment. We performed modified Cox-proportional hazards regression analyses and compared results from the different methods of adjustment for total energy intake.
Results: Dietary intakes of sucrose, starch, lactose, maltose, or total carbohydrates were not significantly related to diabetes risk after adjustment for con-

founders. However, in the standard method for energy adjustment, intakes of fructose and glucose were inversely related to diabetes risk. The multivariable adjusted hazard ratio (95% CI) of diabetes comparing extreme quintiles of intake was 0.66 (0.48-0.91, P-trend 0.003) for glucose and 0.70 (0.52-0.95; P-trend 0.01) for fructose. In the nutrient density method, only fructose was inversely related with diabetes (HR 0.65, 95%CI 0.48-0.88). Exchanging 5% energy intake from fructose for saturated fatty acids was associated with 30% lower diabetes risk (HR 0.69, 95%CI 0.50-0.96). Results of the residual and energy partition method were similar to the standard method.
Conclusion: These prospective findings suggest that starch and sucrose are not associated, but that intakes of fructose and glucose are inversely associated with diabetes risk. Whether the inverse associations with fructose and glucose reflect the effect of substitution of these carbohydrate sub-types for other nutrients (i.e., saturated fatty acids), their net higher intake, or other nutrients associated with their intake, remains to be established through further investigation.

The association between dietary flavonoid and lignan intakes and incident type 2 diabetes in European populations: the EPIC-InterAct study
R. Zamora-Ros[1,2], InterAct Consortium;
[1]MRC Epidemiology Unit, Cambridge, UK, [2]Unit of Nutrition, Environment and Cancer, Catalan Institute of Oncology (ICO-IDIBELL), Barcelona, Spain.

Background and aims: Epidemiological evidence on the relationship between flavonoid and lignan intake and type 2 diabetes risk is limited and inconclusive. Therefore, we aimed to study these associations prospectively.
Material and methods: The European Prospective Investigation into Cancer and Nutrition (EPIC)-InterAct case-cohort study included 12,403 incident type 2 diabetes cases and a stratified subcohort of 16,154 participants from among 340,234 participants with 3.99 million person-years of follow-up in 8 European countries. At baseline, country-specific validated dietary questionnaires were used. A flavonoid and lignan food composition database was developed from the Phenol-Explorer, the UK Food Standards Agency, and the US Department of Agriculture databases. Hazard ratios (HRs) from country-specific Prentice-weighted Cox regression models were pooled using random-effects meta-analysis.
Results: In multivariable models, a trend for an inverse association between total flavonoid intake and type 2 diabetes was observed (HR for the highest versus the lowest quintile 0.90; 95% confidence interval (CI): 0.77-1.04; *P*-trend 0.040), but not with lignans (HR 0.88; 95% CI: 0.72-1.07; *P*-trend 0.119). Among flavonoid subclasses, flavonols (HR 0.81; 95% CI: 0.69-0.95; *P*-trend 0.020), and flavanols (HR 0.82; 95% CI: 0.68-0.99; *P*-trend 0.012), including flavan-3-ol monomers (HR 0.73; 95% CI: 0.57-0.93; *P*-trend 0.029), were associated with a significantly reduced hazard of diabetes.
Conclusion: Prospective findings in this large and heterogeneous European cohort demonstrate inverse associations between flavonoids, particularly flavanols and flavonols, and incident type 2 diabetes. This suggests a potential protective role of eating a diet rich in flavonoids, a dietary pattern based on plant-based foods, on the prevention of type 2 diabetes.

Glucosinolates for the prevention of type 2 diabetes? Reduction of glucose production and induction of protective principles
V. Guzman[1], C. Bumke-Vogt[1], A. Borchert[1], M. Schreiner[2], I. Mewis[2], A.F.H. Pfeiffer[1];
[1]German Institute of Human Nutrition, Potsdam-Rehbrücke, [2]Leibniz-Institute of vegetable and ornamental crops, Großbeeren/Erfurt, Germany.

Background and aims: Nasturtium (Tropaeolum majus) contain bioactive phytochemicals such as glucosinolates and isothiocyanates. We found that aglycons of glucosinolates modulate the intracellular localization of FOXO1. FoxO transcription factors can antagonize insulin effects and trigger a variety of cellular processes involved in tumor suppression, longevity, development and metabolism. Most of the glucosinolates have been evaluated in the cancer pathogenesis prevention, but only few have been evaluated in metabolic pathways. The current study evaluated the ability of Brassicales species to modulate the insulin-signaling pathway, the intracellular localization of FOXO1 and the expression of proteins involved in glucose metabolism, ROS detoxification, cell cycle arrest and DNA repair and their relation with the prevention of type 2 diabetes.
Materials and methods: FOXO1 translocation: Stably transfected cells expressing FOXO1-GFP (U-2OS human Osteosarcoma cells) were treated for 1h with benzyl-glucosinolate pretrated with myrosinase (formation of BITC) 1μM-100μM. Cells were stained with DAPI for the calculation of ratios of GFP-intensities in nuclear and cytoplasmic areas. Protein modification and gene expression: HepG2 cells (human hepatoma cells) were incubated with BITC for 30' followed by insulin 100nM for 15'. Proteins were analysed by Western immuno-blots using antibodies against AKT (pan AKT), p-AKT (phospho AKT), FOXO1, p-FOXO1/3a (Phospho FOXO1/3a), and GAPDH (housekeeping protein). For gene expression analyses HepG2 cells were incubated with 0.1μM-100μM of BITC for 24 hours followed by RNA-extraction. Semi quantitative real-time polymerase chain reaction assays were performed for: FOXO1, AKT, NRF2, SIRT1, and PEPCK (Phosphoenolpyruvate-carboxykinase), G6Pase (Glucose-6-Phosphatase) for gluconeogenesis; CAT (Catalase), MnSOD2 (Superoxid Dismutase) for antioxidative defense; CCNG2 (Cyclin G2), CDKN1A/1B (Cyclin Dependent kinase Inhibitor 1A p21 Cip1 /1B p27 Kip), GADD45 (Growth Arrest and DNA Damage induced Protein) for cell cycle arrest and DNA repair; SRXN1 (Sulfiredoxin 1), NQO1 (NAD(P)H dehydrogenase (quinone1)), and GPX2 (Glutathione peroxidase 2) for detoxification. RPL32 (Ribosomal Protein L32) was used as housekeeping gene. For analyses of involvement of specific factors HepG2 cells were transfected with siRNAs for FOXO1, AKT, NRF2, and SIRT1. Following 48h for knock down of these proteins, the gene expression for each factor and all targets was analyzed.
Results: BITC induced a dose-dependent nuclear translocation of FOXO1-GFP in U-2OS cells. In HepG2 cells an inhibition of AKT-phosphorylation and a reduction of FOXO1-phosphorylation were observed. BITC up regulated MnSOD2, CDKN1A, GADD45, SRXN1, NQO1, and GPX2 gene expression and induced a significant reduction of G6Pase and PEPCK-expression. The effect of BITC on the gene expression was not influenced by FOXO1, AKT, SIRT1, and NRF2 knock down except a less pronounced up regulation of SRXN1 under NRF2 knock down.
Conclusion: BITC potentially down regulates the hepatic glucose production, enhances the antioxidant response and promotes longevity. Despite knocking down the described factors the response to BITC was not altered indicating the involvement of additional molecular pathways.

Effects of 12 weeks of trichosanthis kirilowii and manitolatodimolybdate in the treatment of Hispanic prediabetic patients
J.A. Rojas Jiménez[1], G.C. Levin Pick[2], S. Albarrán Echeverría[2], E.R. Romero Gutiérrez[2];
[1]Internal Medicine, [2]Clinical Nutrition, Centro Especializado en Diabetes (CED), Mexico City, Mexico.

Background and aims: Diabetes evolves through prediabetes, defined as having an impaired fasting plasma glucose (FPG) and HbA1c 5.7-6.4%. People with prediabetes and increased visceral fat (Vf) have higher risk of developing diabetes and cardiovascular disease compared to normoglycemic individuals. The prevalence of prediabetes in Hispanic population has increased appreciably. The aim of this study was to examine the effects of 12 weeks of treatment with trichosanthis kirilowii (Tk) and manitolatodimolybdate (Mm) as a novel combination insulin sensitizer on HbA1c, FPG, and Vf in adult Hispanic obese prediabetic patients.
Materials and methods: This prospective study enrolled subjects aged 18 or older, with HbA1c 5.7-6.4%, FPG 100-125 mg/dl, BMI ≥25 kg/m2, Vf ≥2.1 kg, without any medication, and with normal hepatic or renal function. The patients were instructed to take 2.0mg of Tk and 1.6mg of Mm in one tablet, twice a day during 12 weeks. HbA1c, FPG, and AST/ALT were measured initially and at week 12. Bioelectrical impedance analysis (BIA) was used to estimate visceral fat accumulation and total body water (Zeus 9.9 plus, Jawon medical). All data was obtained using data from labs and BIA. Registered Dietitians (RD) certified in diabetes management provided medial nutrition therapy (MNT) and exercise guidelines based on the American Diabetes Association´s clinical practice recommendations.
Results: 93 patients participated; 53.7% were female. The mean age was 42.1 (±9.4). After 12 weeks of treatment, significant reductions were observed in HbA1c from 6.2±0.26 to 5.6±0.2%, FPG (mean 114±8.60 to 102.9; p>0.05),

BMI (32.3±5.9 to 30.4±5.1; p<0.05), and Vf (4.64±1.2 to 3.8±1.0; p<0.05). 81% of the study sample reached HbA1c within normal ranges (<5.7%) after 12 weeks. No significant changes were seen in neither AST/ALT nor total body water levels.

Conclusion: The combined therapy with Tk and Mm significantly improved HbA1c and reduced both Vf and BMI in prediabetic patients. These findings highlight the potential to treat prediabetic state effectively while ensuring hepatic safety without edema. Further study is needed using a larger sample size but these results suggest significant comparisons useful for primary treatment.

A short-term high-cholesterol diet deteriorates glucose tolerance to a different extent and through different mechanisms in controls and type 2 diabetes offspring

S. Trifiro'[1], C. Morgantini[1,2], S. Baldi[1], D. Trico'[1,2], E. Barsotti[1], E. Ferrannini[1], A. Natali[1];
[1]Department of Clinical and Experimental Medicine, University of Pisa, [2]Scuola Superiore Sant'Anna, Pisa, Italy.

Background and aims: In vitro and in experimental animals, extreme and prolonged exposure to lipid substrates induces insulin resistance and impairs insulin secretion. In addition, offspring of individuals with type 2 diabetes display a higher sensitivity to the detrimental effects of hyperlipidaemia. Whether and how changes in serum cholesterol concentrations affect glucose tolerance is still debated. While short-term LDL lowering with statins has no relevant effect, recent experimental and clinical studies have suggested that cholesterol rich lipoproteins can acutely influence both insulin secretion and insulin sensitivity. Whether more physiologic (diet-induced) short-term manipulations of serum cholesterol affect glucose metabolism and whether the genetic background influences this response is unknown.

Materials and methods: Twenty-one healthy young subjects (age: 26±1 yrs; BMI: 23±1 kg/m^2,12 males) of whom 10 with at least one parent with type 2 DM (T2Doff) were studied twice: after 14 days of an eucaloric low-cholesterol (100-150 mg/day) diet (LCD) and after a further 14 days of an eucaloric high-cholesterol (250-300 mg/day) diet (HCD). A 180-min OGTT was performed at the end of each dietary intervention. Insulin secretion was evaluated by C-peptide deconvolution and beta cell function modelling according to Mari et al (Best Pract Res Clin Endocrinol Metab 2003); insulin sensitivity was estimated by the OGIS method.

Results: In the whole study group, the HCD diet raised serum total- and HDL-cholesterol by 12% (p<0.04), while serum triacylglycerols and body weight were unaffected. On the OGTT, the glucose incremental area-under-curve (AUC) was 20% higher following the HCD (+68±33 mmol/L, p≤0.02) and beta cell glucose sensitivity was reduced by 20% (from 129±12 to 104±9 pmol min^{-1}m^{-2}nM^{-1}, p<0.04). When analysed separately, T2Doff showed a similar diet-induced change in serum lipids, but developed a more marked deterioration of glucose tolerance in response to HCD (AUC change: +104±34 *vs* +15±35 mmol/L, p<0.03). In this group, the HCD diet produced also a small decline in peripheral insulin sensitivity (from 442±18 to 414±20 ml min^{-1}m^{-2}, p<0.03), which was not observed in the 11 subjects without familial T2D.

Conclusion: A short-term increment of dietary cholesterol content, not affecting body weight or serum triacylglycerols, induces a worsening of glucose tolerance due to a decline in beta cell function; in T2D off, this change is associated with a reduction in peripheral insulin sensitivity.

381

Lipopolysaccharide is negatively correlated with beta cell function

S. Liang[1], S. Liu[2], Y. Li[3], X. Gan[4], Y. Liang[3], F. Li[3];
[1]Special Medical Treatment Center, The Third Affiliated Hospital of Sun Yat-sen University, [2]Research Center of Medicine, [3]Endocrinology Department, [4]Medical Examination Center, Sun Yat-sen Memorial Hospital, Guangzhou, China.

Background and aims: Studies suggested that lipopolysaccharide (LPS) may induce insulin resistance via stimulating non-specific inflammatory response, which may lead to impaired glucose regulation. However, whether LPS is correlated with β-cell function, the crucial pathophysiology of type 2 diabetes, is still unclear. This study was designed to investigate the relationship of LPS and β-cell function in people with different glucose tolerances.

Materials and methods: Sixty-seven subjects were divided into normal glucose tolerance (NGT) group (n=23), impaired glucose tolerance (IGT) group (n=21), and type 2 diabetes (T2DM) group (n=23) based on OGTT, with sex, weight, BMI, blood pressure, lipid profiles matched. After 10h overnight fast, subjects were provided with a high-fat diet(486.6kcal, 47.7%fat). Blood samples were collected for measurement of glucose, insulin, C-peptide, LPS levels at 0-h, 0.5-h and 2-h after a high-fat diet and fasting expression of toll-like receptor 4(TLR4) on surfaces of plasma monocytes. β-cell function was evaluated by HOMA-β/HOMA-IR, $_{\Delta}$Ins30/$_{\Delta}$G30÷IR ($_{\Delta}$Insulin30/$_{\Delta}$Glucose30÷HOMA-IR), $AUC_{Ins120min}$/IR ($AUC_{Insulin120min}$/HOMA-IR), and $AUC_{Cp120min}$/ IR($AUC_{C\text{-}peptide120min}$/ HOMA- IR).

Results: LPS levels at all time points during a high fat diet and TLR4 expression increased from NGT to IGT and T2DM (Table 1). But LPS levels and TLR4 expression were not statistically different between T2DM and IGT (P>0.05). Fasting LPS, 0.5-hLPS, 2-hLPS were negatively correlated with β-cell function indices (HOMA-β/HOMA-IR: r= -0.304,r= -0.291, r= -0.297; $_{\Delta}$Ins30/$_{\Delta}$G30 ÷ IR: r = -0.467, r= -0.446, r= -0.451; $AUC_{Ins120min}$/IR: r= -0.445, r= -0.439, r= -0.447; $AUC_{Cp120min}$/IR: r= -0.519, r= -0.500, r= -0.506; P<0.05), respectively. TLR4 was negatively correlated with $_{\Delta}$Ins30/$_{\Delta}$G30÷IR, $AUC_{Ins120min}$/IR and $AUC_{Cp120min}$/IR(r= -0.274, r= -0.263, r= -0.344, P<0.05). Further multiple linear regression analysis showed that 0.5-h LPS was independently correlated with $_{\Delta}$Ins30/$_{\Delta}$G30÷IR, $AUC_{Ins120min}$ /IR, and $AUC_{Cp\text{-}120min}$, respectively.

Conclusion: Compared with NGT people, patients with IGT and T2DM have higher LPS levels and TLR4 expression. LPS may affect β-cell function.

LPS levels before and after a high-fat diet and fasting TLR4

		NGT (n=23)	IGT (n=21)	T2DM (n=23)
LPS (EU/ml)	0-h	0.62 (0.22, 0.64)	0.71 (0.39, 0.82) *	0.86 (0.45, 0.94) *
	0.5-h	0.73 (0.31, 0.76)	0.84 (0.50, 1.07) *	1.10 (0.55, 1.18) *
	2-h	0.96 (0.33, 0.99) #	1.08 (0.53, 1.22) *#	1.23 (0.62, 1.43) *#
TLR4 (MIF/10^5 cells)	0-h	15.66 (6.09, 9.76)	30.34 (15.00,45.18) *	36.96 (17.22, 55.19) *

* P<0.01 vs. NGT group, # P<0.01 vs. 0-h LPS

PS 015 Lifestyle factors as risk factors

Smoking and risk of type 2 diabetes: the EPIC-InterAct study

A.M.W. Spijkerman[1], D.L. van der A[1], P.M. Nilsson[2], E. Ardanaz[3], D. Gavrila[4], on behalf of the InterAct Consortium;
[1]National Institute for Public Health and the Environment, Bilthoven, Netherlands, [2]Lund University, Malmö, Sweden, [3]Navarre Public Health Institute (ISPN), Pamplona, Spain, [4]Department of Epidemiology, Murcia Regional Health Council, Spain.

Background and aims: The aim is to investigate the association between smoking and incidence of type 2 diabetes (T2D) accounting for a large number of potential confounding factors and to explore potential effect modifiers and intermediate factors.
Materials and methods: The European Prospective Investigation into Cancer and Nutrition EPIC-InterAct case cohort study was conducted in 26 centres of the EPIC study in eight European countries and consists of 12,403 incident T2D cases and a centre-stratified subcohort of 16,154 individuals (including 778 T2D cases). Smoking was modelled by smoking status (never, former, current), with never smokers as the reference category. Prentice-weighted Cox-regression was used for the case-cohort analyses and random effects meta-analysis to estimate hazard ratios (HRs) for T2D.
Results: In men, the HRs (95% confidence interval (CI) of T2D were: 1.40 (1.26-1.55) for former smokers and 1.43 (1.27-1.61) for current smokers independent of age, education, centre, physical activity and consumption of alcohol, coffee and meat. In women, the associations were weaker (HRs (95%CI): 1.18 (1.07-1.30) and 1.13 (1.03-1.25) for former and current smokers, respectively. There was some evidence of effect-modification by BMI. The association tended to be slightly stronger in normal weight participants compared to those with overall or regional adiposity.
Conclusion: Former and current smoking was associated with a higher risk of incident T2D compared to never smoking in men and women, independent of educational level, physical activity, alcohol and diet. Smoking may be regarded as one of the modifiable risk factors for T2D and smoking cessation should be encouraged for diabetes prevention.

Low birth weight is associated with alterations in dietary intake in later life independent of genetic factors

S. Doornweerd[1], R.G. IJzerman[1], P.J.M. Weijs[2], M. Diamant[1], E.J.C. De Geus[3], D.I. Boomsma[3];
[1]Diabetes Centre/Internal Medicine, VU University Medical Centre, [2]Nutrition & Dietetics, Internal Medicine, VU University Medical Centre, [3]Biological Psychology, VU University, Amsterdam, Netherlands.

Background and aims: Low birth weight is associated with an increased risk of type 2 diabetes and cardiovascular disease. These associations may, in part, be explained by alterations in dietary intake in later life. We examined whether low birth weight is associated with alterations in food intake, and whether this association is due to intrauterine environmental or genetic factors.
Materials and methods: Studies in dizygotic and monozygotic twin pairs offer a unique opportunity to investigate the influence of intrauterine environmental and genetic factors. Specifically, differences within dizygotic twin pairs are a function of both genetic and nongenetic factors, whereas differences within monozygotic (genetically identical) pairs can only be caused by nongenetic factors. We investigated data on birth weight and food intake in 42 dizygotic and 46 monozygotic adolescent same sex twin pairs. Birth weight was obtained from the mothers. Food intake was assessed by two-day food diaries and macronutrient content was calculated as proportions of total energy intake (E%). Fiber intake was calculated in grams/1000 kcal.
Results: In the overall sample of twins, birth weight was negatively associated with intake of saturated fat after adjustment for current weight (regression coefficient β: -0.9 E%/kg, p=0.02). Within pair analysis in dizygotic and monozygotic twin pairs combined demonstrated that twins with the lowest birth weight from each pair had a dietary intake of saturated fat that was 0.7% higher compared with their cotwins with the highest birth weight (14.8 ± 2.7 E% vs. 14.1 ± 3.0 E% p<0.05). This difference was similar in dizygotic and monozygotic twins (0.6% vs. 0.8% respectively). In a further within pair analysis, after adjustment for differences in current weight, intrapair differences in birth weight were negatively and significantly associated with differences in intake of saturated fat in dizygotic and monozygotic twins combined (β: -1.7 E%/kg, p<0.05). This intrapair association was also similar in dizygotic and monozygotic twins (β: -1.7 E%/kg and -2.0 E%/kg respectively). In the overall sample of twins, birth weight was not associated with intake of fibers after adjustment for current weight (β: + 0.1 g/1000kcal, p=0.8). However, in the intrapair analysis, a positive association was found between differences in birth weight and differences in intake of dietary fibers (β: 1.8 g/1000 kcal, p=0.04). Again, this association was similar in dizygotic and monozygotic twins.
Conclusion: In line with findings in singletons, we demonstrated that low birth weight is associated with higher intake of saturated fat and lower intake of dietary fibers within twin pairs. Our findings, indicating that these associations were similar in dizygotic and monozygotic twin pairs, suggest that intrauterine environmental rather than genetic factors explain the association between birth weight and alterations in dietary intake in later life. These data support the concept that improvement of the intrauterine environment may be beneficial for dietary habits in later life.

Adherence to predefined dietary patterns and incident type 2 diabetes in European populations: EPIC-InterAct study

J. Kröger, InterAct Consortium;
Molecular Epidemiology, German Institute of Human Nutrition, Nuthetal, Germany.

Background and aims: Few studies investigated the relationship between predefined dietary patterns and incidence of type 2 diabetes; little is known about the generalizability of these associations. We aimed to assess the association between predefined dietary patterns and risk of type 2 diabetes in European populations.
Materials and methods: From among a case-cohort of 12,403 incident diabetes cases and 16,154 subcohort members nested within the European Prospective Investigation into Cancer and Nutrition study, we used data on 9,682 cases and 12,595 subcohort participants from seven countries. Habitual dietary intake was assessed at baseline with country-specific dietary questionnaires. Two widely-known diet-quality scores (Alternative Healthy Eating Index (aHEI), Dietary Approaches to Stop Hypertension (DASH) score) and three reduced rank regression (RRR)-derived dietary pattern scores were constructed. Country-specific HRs were calculated and combined using a random-effects meta-analysis.
Results: After multivariable adjustment including BMI and waist circumference, the aHEI and DASH dietary patterns were not significantly associated with diabetes, although there was a tendency towards an inverse association in countries with higher mean age. We observed inverse associations of the three RRR-derived dietary pattern scores with diabetes: HRs (95% CIs) for a 1-SD difference were 0.91 (0.86-0.96), 0.92 (0.84-1.01), and 0.87 (0.82-0.92), respectively. Random-effects meta-analyses revealed heterogeneity between countries that was explainable by differences in the age of participants or the distribution of dietary intake.
Conclusion: Adherence to specific RRR-derived dietary patterns, commonly characterized by high intake of fruits or vegetables and low intake of processed meat, sugar-sweetened beverages, and refined grains, may lower risk of type 2 diabetes.

385

Fatty fish is associated with a reduced risk of latent autoimmune diabetes in adults (LADA) and type 2 diabetes

J. Edwall Löfvenborg[1], M. Dorkhan[2], L. Groop[2], T. Tuomi[3], A. Wolk[4], S. Carlsson[1];
[1]Div. of Epidemiology, Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden, [2]Diabetes and Endocrinology, Dept. of Clinical Sciences, Lund University, Malmö, Sweden, [3]Department of Medicine, Helsinki University, Finland, [4]Div. of Nutritional Epidemiology, Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden.

Background and aims: It has been suggested that fish consumption, especially of fatty fish, may protect against type 2 diabetes (T2DM), possibly through

improvements in insulin sensitivity. Despite its autoimmune nature, latent autoimmune diabetes in adults (LADA) shares the T2DM characteristic of insulin resistance. Our aim was to investigate, for the first time, whether fish consumption is associated with the risk of LADA.
Materials and methods: The results were based on data from the ESTRID Study, an ongoing population-based case-control study including incident cases of LADA (n=143) and T2DM (n=295), and population-based controls (n=646). Information on diet was obtained by a validated 127-item questionnaire which also included questions on potential confounders including education, smoking, physical activity, and family history of diabetes. Cases of LADA had onset age ≥35 years and were distinguished from cases of T2DM by measures of GAD autoantibodies. Mean age was 60.5 years (LADA), 64.0 years (T2DM), and 58.8 years (controls). Odds ratios adjusted for age, sex, and other potential confounders were calculated using logistic regression.
Results: Weekly consumption of fatty fish (≥ 1 serving/week) was associated with a tendency for a reduced risk of LADA (OR=0.47, 95% CI=0.21-1.05). Similar results were seen for T2DM (OR=0.45, 95% CI=0.23-0.88), and there were no considerable differences between men and women. These associations remained after adjustments for BMI, physical activity, education, smoking, and family history of diabetes (OR=0.50, 95% CI=0.21-1.18 for LADA, and OR=0.37, 95% CI=0.16-0.87 for T2DM). Consumption exceeding two servings per week did not further reduce the risk (OR=0.44, 95% CI=0.15-1.25 for LADA, and OR=0.48, 95% CI=0.21-1.10 for T2DM). No reduced risk was observed for weekly consumption of lean fish neither for LADA (OR=1.12, 95% CI=0.49-2.57) nor T2DM (OR=1.24, 95% CI=0.64-2.43).
Conclusion: Our findings suggest that weekly consumption of fatty fish, but not lean fish, may be beneficial in the prevention of both LADA and T2DM, indicating a protective effect related to a shared disease characteristics. The lack of association for lean fish supports posed hypotheses that nutrients specifically prevalent in fatty fish, such as marine polyunsaturated n-3 fatty acids and/or vitamin D, may be mechanistically involved in a protective effect.

The influence of the duration of exposure to westernised lifestyle and childhood environment on development of lifestyle-related diseases in Japanese-Americans
M. Shiwa, S. Nakanishi, M. Yoneda;
Department of Molecular and Internal Medicine, Graduate School of Biomedical and Health Sciences, Hiroshima University, Japan.

Background and aims: Japanese-Americans, who are genetically identical to their Japanese progenitors, but have undergone rapid and intense westernization of their lifestyle. We reported that body mass index (BMI) was significantly higher and the prevalence of diabetes mellitus (DM) and metabolic syndrome (MS) were significantly higher, and atherosclerosis progressed more rapidly in Japanese-Americans by comparing with Japanese living in Hiroshima. The Japanese-Americans born of 2 Japanese parents were divided into 2 groups: first generation migrants (JA-1) who were born in Japan; and second or later generation migrants (JA-2) who were born and raised in the United States (USA). Therefore JA-1 and JA-2 have different backgrounds concerning the beginning and duration of their exposure to a westernized lifestyle. It is anticipated that the risk of obesity and DM differ between different generations of Japanese immigrants. On the other hand, it is well known that childhood lifestyle has a strong effect on the incidence of obesity and DM in the future. The second or later generation from the JA-2 group who are educated chiefly in Japan and return later to the USA are separated further into group Kibei. Due to this custom of returning to the USA later in life, Kibei often avoid exposure to westernized lifestyle in their childhood, and we speculated that Kibei would have a lower incidence of obesity and DM after maturity. The aim of this study was to determine whether the period of exposure to the westernized environment and a custom practiced by Kibei are associated with the incidence of lifestyle-related diseases.
Materials and methods: We investigated the prevalence of obesity, MS and DM among Japanese in Hiroshima in 2009 and Japanese-Americans in Hawaii in 2007 and Los-Angeles in 2010 (515 Japanese, 442 JA-1, and 375 JA-2). BMI cutoff for obesity was 25kg/m2. The diagnosis of MS was based on the International Diabetes Federation criteria. DM was diagnosed as a fasting glucose concentration >/= 126 mg/dl and/or at 2 hours post-load >/= 200 mg/dl or receiving medication for DM.
Results: The prevalence of obesity was 25.2, 28.5 and 42.1% for Japanese, JA-1 and JA-2, respectively. The prevalence of MS was 21.7, 20.8 and 32.8%, respectively. These two prevalence rates in JA-2 were significantly higher than in Japanese and in JA-1. The prevalence of DM was 8.7, 18.1 and 18.9%, respectively. This prevalence rate in JA-1 and in JA-2 was significantly higher than in Japanese. When accounting for Kibei status within the JA-2 group, we found the prevalence of obesity was 32.6 and 45.2%, the prevalence of MS was 21.7 and 36.4%, and the prevalence of DM was 16.3 and 19.8% for Kibei and Non-Kibei, respectively. The prevalence of obesity and MS in Non-Kibei were significantly higher than in Kibei, but the prevalence of DM was not significantly different.
Conclusion: We have demonstrated that the prevalence of obesity and MS in JA-2 were higher than in JA-1. It was also observed that the incidence rates for obesity and MS in Non-Kibei were higher than in Kibei within JA-2 subgroups. It was suggested that duration of exposure to westernized lifestyle and childhood environment were associated with an increase in lifestyle-related diseases.

Chewing betel-quid and its association with metabolic disease, cardiovascular disease, and all-cause mortality: a meta-analysis of observational studies
T. Yamada, K. Hara, T. Kadowaki;
Department of Diabetes and Metabolic Diseases, University of Tokyo, Japan.

Background and aims: Asia already has 60% of the world's diabetic population and diabetes is increasing more rapidly in Asia than anywhere else. Metabolic diseases have a major influence on public health, since a modest increase in the risk of morbidity and mortality translates into a substantial social burden, so prevention of these diseases is extremely important. Betel nut (Areca nut) is the fruit of the Areca catechu tree, which grows in Asia. Approximately 600 million individuals regularly chew betel nut (or betel quid) worldwide, and betel quid chewing is common in South-East Asia and Western Pacific. Chewing betel quid is a known risk factor for oral cancer and esophageal cancer. It was recently proposed that an association may exist between inflammatory oral condition and systemic disorders. Numerous studies have shown that chewing betel quid is associated with the risk of systemic diseases as well as oral diseases. Thus, clarifying the relationship between chewing betel quid and metabolic disease may be important for the development of preventive strategies. Accordingly, we performed a meta-analysis to assess the influence of chewing betel quid on metabolic disease, cardiovascular disease, and all-cause mortality.
Materials and methods: We searched Medline, Cochrane Library, Web of Science, and Science Direct for pertinent articles (including the references) published between 1951 and 2013. The adjusted relative risk (RR) and 95% confidence interval were calculated using the random effect model. We employed the sex and the ethic group as an independent category for comparison within each study. The Newcastle-Ottawa Scale for assessing the quality of nonrandomized studies in meta-analysis was used to quantify the validity of each study.
Results: Of 580 potentially relevant studies, 17 studies from Asia (6 cohort studies and 11 case-control studies) covering 393,077 subjects (range: 1,049 to 97,244) were selected. Eight studies (N=126,622) showed significant dose-response relationships between betel quid consumption and the risk of events. According to pooled analysis, the adjusted RR of betel quid chewers vs. non-chewers was 1.47 (p<0.001) for obesity (N=30,623), 1.56 (p=0.001) for metabolic syndrome (N=28,328), 1.47 (p<0.001) for diabetes (N=51,412), 1.45 (p=0.06) for hypertension (N=89,051), 1.2 (p=0.02) for cardiovascular disease (N=201,488), and 1.21 (p=0.02) for all-cause mortality (N=179.582).
Conclusion: Betel quid chewing is associated with an increased risk of metabolic disease, cardiovascular disease, and all-cause mortality. Addition to reason preventing oral cancer, stopping betel quid use could be valuable for preventing metabolic diseases that are showing a rapid increase in South-East Asia and the Western Pacific.

Association between urinary phthalate metabolites and diabetes mellitus: a pilot study

M. Medić-Stojanoska[1,2], B. Vuković[3,2], J. Novaković-Paro[1,2], I. Bajkin[1,2], T. Ičin[1,2], N. Ćurić[2,4], N. Miljić[5], A. Milankov[1,2], B. Kovačev-Zavišić[1];
[1]Clinic of endocrinology, diabetes and metabolic diseases, Clinical centre of Vojvodina, [2]Medical faculty, University of Novi Sad, [3]Emergency centre, Clinical centre of Vojvodina, [4]Clinical centre of Vojvodina, [5]Department of farmacology, Medical faculty, University of Novi Sad, Serbia.

Background and aims: Phtalates present widespread endocrine disrupting chemicals in many personal care and consumer products. A limited number of studies suggest that exposure to phtalates may be associated with metabolic disturbances of diabetes mellitus. The aim of this study was to examine the presence of urine phtalate metabolites in diabetic patients and their association with diabetes mellitus.
Materials and methods: We included 100 newly diagnosed patients with non insulin dependent diabetes mellitus who are without medical treatment, 50 males and 50 females, mean age 47,19±9,75 years. Body mass index (BMI), fasting glycaemia, fasting insulinemia and urinary phtalate metabolites (MEP - monoethyl phtalate, MEHP - mono -(2-ethylhexyl)-phtalate, MBP - monobuthyl phtatale) were mesured. Insulin resistance was calculated by HOMA IR. The same examinations were performed in 100 healthy persons as a control group.
Results: Patients with diabetes mellitus had significantly higher levels of BMI (29,75±7,22 vs 22,95±2,12 kg/m^2; p<0,0001), fasting blood glucose (9,06±4,06 vs 5,09±0,49 mmol/l; p<0,0001) and fasting blood insulin levels (13,64 +/- 13,29 mIU/l vs 7,74+/- 3,75 mIU/l, p<0,0001). HOMA IR was significantly higher in these patients than controls (3,41 +/- 2,05 vs 1,76+/- 0,95, p<0,0001). Urinary phtalate metabolites were non significantly lower in diabetic patients than controls (MEP 16,16 +/- 79,25 vs 35,57 +/- 133,91 ng/ml, p=0,22 ; MBP 9,59 +/- 59,53 vs 11,58+/- 82,63 ng/ml; p=0,33; MEHP 19,52+/- 59,28 vs 21,98+/-61,69 ng/ml; p=0,78). We found only positive correlation between MEHP and fasting glycaemia (r=0,23) in diabetic patients.
Conclusion: According to our data only exposure to diethylphtalate may have impact on glucose levels. Futher studies with more participants are needed to elucidate this association.

389

Alcohol consumption is associated with a reduced risk of latent autoimmune diabetes in adults (LADA) and type 2 diabetes: the ESTRID case-control study

B. Rasouli[1], V. Grill[2,3], L. Groop[4], T. Tuomi[5], T. Andersson[1], M. Dorkhan[4], S. Carlsson[1];
[1]The Institute of Environmental Medicine (IMM), Karolinska institutet, Stockholm, Sweden, [2]NTNU Institute of Cancer Research and Molecular Medicine, Norwegian University of Science and Technology, Trøndheim, Norway, [3]Department of Endocrinology, Trøndheim University Hospital, Trøndheim, Norway, [4]Diabetes and Endocrinology, Dept. of Clinical Sciences, Lund University, Lund, Sweden, [5]Department of Medicine, Helsinki University Hospital, Finland.

Background and aims: Moderate alcohol consumption is associated with a reduced risk of type 2 diabetes. The protective effect is attributed primarily to improvement in insulin sensitivity. Our aim was to investigate whether alcohol consumption is associated with risk of LADA, an autoimmune form of diabetes with possible features of type 2 diabetes.
Materials and methods: We used data from an ongoing Swedish case-control study of LADA and type 2 diabetes-ESTRID (epidemiological study of risk factors for LADA and type 2 diabetes); where information on alcohol intake is collected by validated questionnaires. Logistic regression was used for carrying out analyses on data including 242 incident LADA and 445 incident type 2 diabetes cases and 689 controls; odds ratios (OR) were adjusted for age, sex, body mass index, family history of diabetes, smoking, and education.
Results: Moderate alcohol consumption (5-15g/day) was associated with a 37% reduced risk of LADA (OR; 0.63, 95% CI; 0.43-0.92) which persisted after adjustment for confounders; OR; 0.64, 95% CI; 0.44-0.94 (all); OR; 0.58, 95% CI; 0.33-1.02 (women), and OR; 0.67, 95% CI; 0.39-1.14 (men). The results were similar for type 2 diabetes; OR; 0.66, 95% CI; 0.47-0.93 (all); OR; 0.60, 95% CI; 0.35-1.03 (women); and OR; 0.72, 95% CI; 0.46-1.14 (men). A reduced risk was also suggested at higher levels of consumption (>25 g/day); OR; 0.55, 95% CI; 0.31-0.95 (LADA); and 0.71, 95% CI; 0.45-1.11 (type 2 diabetes). Beverage specific analysis suggest that consumption of liquor confers no protective effect; OR for per 5g/day; 1.04, 95% CI; 0.92-1.18 (Type 2 diabetes); and 1.08, 95% CI; 0.95-1.22 (Type 2 diabetes). The results suggest a protective effect of wine for LADA (OR for per 5g/day; 0.97, 95% CI; 0.91-1.04); and for type 2 diabetes the protective effect seemed linked to consumption of beer; OR for per 5g/day=0.88, 95% CI; 0.75-1.03.
Conclusion: Moderate alcohol consumption was associated with reduced risk of both LADA and type 2 diabetes, emphasizing that the risk of LADA alike type 2 diabetes can be reduced through lifestyle factors which improve insulin sensitivity.

PS 016 Lifestyle interventions

Barriers to participation in a community-based lifestyle intervention programme to prevent type 2 diabetes following gestational diabetes mellitus

A. O'Dea[1], J.J. Infanti[1], I. Gibson[2], E. Noctor[1], B.E. McGuire[3], L.G. Glynn[4], F.P. Dunne[1], Galway Diabetes Research Centre (GDRC) - NUIG;
[1]School of Medicine, National University of Ireland Galway, [2]Croí The West of Ireland Cardiac Foundation, [3]School of Psychology, National University of Ireland Galway, [4]Discipline of General Practice, National University of Ireland Galway, Ireland.

Background and aims: Gestational diabetes mellitus (GDM) is growing and progression to type 2 diabetes is increased seven-fold following GDM.
Materials and methods: We have designed and recruited into a community-based randomised controlled trial (RCT) of an intensive lifestyle intervention compared to standard care for delaying diabetes onset following GDM. This paper compares the clinical, anthropometric and demographic characteristics of 89 consenters versus 156 non-consenters to the RCT using data available from post-partum clinic visits following GDM. It also examines the barriers to participation in women eligible for recruitment but who declined to participate.
Results: 410 women with prior GDM were invited to participate in the study; 89 consented, 156 refused, and the remainder were not contactable. Stated barriers to participation are available from the 156 non-consenters. The barriers cited by women can be grouped as follows: access/transport (distance, location, expense or lack of transportation) [n=75]; lifestyle (too busy, work schedule, caring for parents) [n=49]; parental commitments [n=48]; health-related (poor health, not concerned about health or diabetes risks, already taking action to improve health) [n=29]; research and intervention programme deterrents (research fatigue, test procedures, programme times/content) [n=26]; lack of social support [n=9].
Conclusion: To improve recruitment into similar programmes, researchers should consider offering home-based assessments; providing on-site child care; ensuring a variety of programme times; providing regular feedback, follow-up, and pragmatic advice for the target population. It is also important for health care providers to focus on updating and reinforcing knowledge about the future health implications of GDM. Finally, it would be valuable to integrate the use of cognitive behavioural strategies into such interventions in order to: (i) address underlying psychological barriers mitigating success in regard to behaviour change, and (ii) progress women who are still 'pre-contemplators' in regard to lifestyle modification to the stages of contemplation and action.

Prevention of type 2 diabetes; a systematic review and meta-analysis of different intervention strategies

C. Merlotti, A. Morabito, A.E. Pontiroli;
Cattedra di medicina interna, Università Degli Studi di Milano, Milano, Italy.

Different intervention strategies can prevent new cases of type 2 diabetes (T2DM). Aim of the present systematic review and meta-analysis was to evaluate the effectiveness of different strategies. Studies were grouped into 15 different strategies: 1: diet plus physical activity; 2: physical activity; 3-6: anti-diabetic drugs [glitazones, metformin, beta cell stimulating drugs (sulphanylureas, glinides), alfa-glucosidase inhibitors]; 7-8: cardiovascular drugs (ACE-inhibitors, ARB, calcium-antagonists); 9-14 [diets, lipid-affecting drugs (orlistat, bezafibrate), vitamins, micronutrients, estrogens, alcohol, coffee]; 15: bariatric surgery. Only controlled studies were included in the analysis, whether randomized or non-randomized studies. Appropriate methodology (PRISMA statement) was used. Seventy-one studies (490,813 subjects), published in english language as full papers, were analysed to identify predictors of new cases of T2DM, and were included in a meta-analysis (random-effects model) to study the effect of different strategies. Intervention effect (new cases of diabetes) was expressed as odds ratio (OR), with 95% confidence intervals (CIs). Body mass index was in the overweight range for 13 groups, obese or morbidly obese in lipid-affecting drugs and in bariatric surgery. Non-surgical strategies, except for beta cell stimulating drugs, estrogens, and vitamins, were able to prevent T2DM, with different effectiveness, from 0.37 (0.26,0.52) to 0.85 (0.77,0.93); the most effective strategy was bariatric surgery in morbidly obese subjects [0.16 (0.11,0.24)]. These data indicate that several, but not all strategies, prevent T2DM, making it possible to make a choice for the individual subject; for morbidly obese subjects bariatric surgery appears an adequate strategy.

392

Effectiveness of an intervention in primary care to prevent type 2 diabetes in people with impaired fasting glucose, a cluster-randomised controlled trial

A.E. Hesselink[1], H.J.G. Bilo[2,3], G.E.H. Rutten[4], S.M. Slootmaker[5], I. de Weert[5], M. Martens[6], R. Jonkers[1];
[1]Research and consultancy, ResCon, Amsterdam, [2]Center of Excellence Diabetes, Isala clinic, Zwolle, [3]Department of Internal Health, University of Medical Centre, Groningen, [4]Julius Center for Health Sciences and Primary Care, University Medical Center MC Utrecht, [5]Netherlands Diabetes Federation, Amersfoort, [6]Research and consultation, ResCon, Amsterdam, Netherlands.

Background and aims: Effective diabetes prevention strategies are needed. The Netherlands Diabetes Federation developed a protocol for coaching people with impaired fasting glucose (IFG) to a sustainable healthy lifestyle change: the 'Route planner diabetes prevention' (RP) within a primary health care setting. The protocol focuses on promotion of a healthy lifestyle among people with IFG within one year by providing 6 consultations and, if applicable, referrals to other health professionals (dieticians, physiotherapists or locally organised lifestyle activities). We evaluated the feasibility and effectiveness of care provided according to the RP.
Materials and methods: A cluster randomised clinical trial, including 22 general practices was performed. Patients with a newly diagnosed IFG were included in the trial. Participants in the intervention group received care according to the RP protocol (n=197). The control group received usual care (n=169). The outcome measure anthropometrics and biochemical parameters were assessed in the practices. Physical activity, food intake and their determinants were assessed by a validated questionnaire. All measurements were performed at baseline, and after one (post-intervention) and two years. A process evaluation among health professionals was performed by personal interviews.
Results: Multilevel analyses showed that after two years the number of participants adhering to the physical activity guideline increased more in the intervention (OR=1.97 95%CI 1.22, 3.20) than in the control group. Additionally risk perception (β=0.15; 95%CI 0.02,1.28) and the perceived knowledge about healthy lifestyle (β=0.17; 95%CI 0.10,0.33) were higher in the intervention group. Per protocol analyses showed an intervention effect on nutrition (β=-1.36; 95%CI -2.69.-0.03). Process evaluation revealed that participants in the intervention group received less consultations than described in the RP protocol while those in the control group received more consultations than expected. Post-hoc analyses showed that the number of consultations was associated with greater decrease in body mass index (β =-0.39; 95%CI -0.78;-0.01). Health professionals experienced the RP as time consuming; they found it hard to motivate unmotivated patients to participate in the RP.
Conclusion: Despite the small difference in consultations between the intervention and control group, the findings on physical activity suggest that promotion of a healthy lifestyle among people with IFG by providing the RP protocol are promising. Additionally, the study results showed that the intervention effect is bigger among motivated patients and those receiving care as prescribed by the RP. Adjustments must be made to make the RP protocol more applicable and (time-)efficient.

Sustained weight loss and risk reduction following lifestyle intervention in the community: results of the Rethinking Eating and ACTivity study (REACT)

G.A. Piatt[1], M. Seidel[2], J.C. Zgibor[3];
[1]Medical Education, University of Michigan, Ann Arbor, [2]School of Sustainability and the Environment, Chatham University, Pittsburgh, [3]Epidemiology, University of Pittsburgh, USA.

Background and aims: Understanding the long-term comparative effectiveness of multiple lifestyle intervention modalities in community settings is critical to assist consumers, clinicians, purchasers, and policy makers to make informed decisions. Evidence supports the effectiveness of lifestyle change, including weight loss and diabetes risk reduction, in the short-term; however mixed results are reported with follow-up greater than one year, particularly in underserved community settings. We therefore aimed to determined whether three Group Lifestyle Balance (GLB) intervention modalities that resulted in weight loss and diabetes and CVD risk reduction at 3 month follow-up were effective at achieving sustained improvements at 18 month follow-up.
Materials and methods: 555 individuals (86.1% female, 95.1% white, 55.8% obese) from 8 underserved, rural communities, in Pennsylvania were screened for BMI ≥ 25 kg/m2 and waist circumference ≥ 102 cm in men and 88 cm in women. Communities, along with their eligible participants (n=493; mean age: 51 yrs, 87.6% female, 94.1% Caucasian, 86.8% BMI ≥ 30 kg/m2) were assigned to 4 GLB intervention groups: Face to Face (FF) (n=119), DVD (n=113), internet (INT) (n=101), and self-selection (SS) (n=101). Participants in SS were empowered to select the modality of their choosing (60% chose FF, 40% INT, 0% DVD). Outcomes for these analyses included sustained improvement in the proportion of participants who met the 5% weight loss goal and the proportion of participants who decreased ≥ one diabetes and CVD risk factor at 18 months following the intervention. Diabetes and CVD risk factors included fasting glucose ≥100 mg/dL, waist circumference ≥ 102 cm in men and 88 cm in women, blood pressure ≥ 130/85 mmHg, triglycerides ≥ 150 mg/dL, and HDLc < 40 mg/dL in men and 50 mg/dL in women.
Results: Following the GLB intervention, 60.1% of participants lost at least 5% of their total body weight at the 3 month assessment (FF: 57.9%, DVD: 56.1%, INT: 62%, SS: 66.7%). All groups achieved maintenance of 5% weight loss in at least 50% of their participants at 18 months with the SS group having the largest number of participants who maintained weight loss (FF: 67.3%, DVD: 67.6%, INT: 67.7%, SS: 89.5%). A similar trend was observed in participants who reduced ≥ one diabetes and CVD risk factor at the 3 months. Nearly 75% of these participants maintained the reduction at 18 months. After adjustment for age, gender, baseline values, intervention group, and the clustering of communities within each intervention group, participants in SS were 2.3 times more likely to maintain 5% weight loss at 18 months compared to the other three groups (p=0.0007), but were not more likely to maintain reduction of diabetes and CVD risk factors (p=0.89).
Conclusion: These results demonstrate that despite the modality, the GLB intervention was effective at sustaining improvements in weight loss and risk reduction. Moreover, SS participants, who were empowered to choose their GLB modality, were twice as likely to sustain improvements compared to other groups. Indeed, the importance of patient-centered decision-making in healthcare is paramount.

Feasibility of a controlled intervention with physical activity in individuals with impaired glucose tolerance, recruited by FINDRISC

M.I. Hellgren[1], M. Petzold[2], H. Bertéus Forslund[3], P.-A. Jansson[4], U. Lindblad[1];
[1]Department of Primary Health Care, Institution of Medicine, [2]Center for Applied Biostatistics, Institution of Medicine, [3]Department of Internal Medicine and Clinical Nutrition, Institute of Medicine, [4]Wallenberg Laboratory, Department of Molecular and Clinical Medicine, Institution of Medicine, University of Gothenburg, Sweden.

Background and aims: Landmark studies have given proof of the positive effect of a life-style intervention with physical activity and diet in individuals with impaired glucose tolerance. The aim of this study was to explore the feasibility and effect of an intervention with isolated physical activity in individuals with impaired glucose tolerance (IGT) recruited by the FINDRISC questionnaire.
Materials and methods: The questionnaire was sent to a population of 9734 individuals, 35-75 years old, in a selected area in a middle-sized town in Sweden. Those with a risk-score >11 were encouraged to perform an oral glucose tolerance test and all with IGT were invited to participate in a randomized controlled trial with focus on physical activity. The participants were allocated to one of three arms; basic intervention with a recipe for physical activity, a step-counter and a personal nurse for support, an intensive care group with additional group sessions or to care as usual. A total of 52 individuals were examined for common risk factors for diabetes and CVD including anthropometric measurements, blood pressure, serum lipids and questionnaires about diet and lifestyle. A new examination was performed after one year.
Results: There was a high prevalence of co-morbidity in individuals recruited with the questionnaire. In these with IGT 17% were diagnosed with ischemic heart disease, 4% with chronic obstructive pulmonary disease and 6% had had a stroke. At base-line mean age was 64 (8.9) years, BMI 30 (4.2) kg/m^2, fasting P-glucose 6.0 (0.5) mmol/L, systolic blood pressure 150 (18) mmHg, diastolic blood pressure 83 (10.9) mmHg and mean cholesterol was 5.3 (1.2) mmol/L. During this first year six individuals developed diabetes, one died and another five dropped off because of disease or for social reasons (n=40). Differences between groups were assessed with general linear models adjusted for differences in age, sex and energy intake and in spite of the high co-morbidity the intervention was efficient. Body weight decreased significantly more Δ3.5kg, p=0.045 (CI, 0.076-6.881) in the intensive care group compared to the other groups, as did diastolic blood pressure Δ9.4 mmHg, p=0.013 (2.2-17.0), while the difference in decreased waist-circumference (p=0.091), and increased high density lipoproteins (HDL) p=0.071 both were non-significant. Furthermore, participants in the intensive care group had significant decreases in systolic blood pressure 12 mmHg (p=0.007), and waist-circumference 3cm (p=0.049) when assessed with paired samples T-test.
Conclusion: It is generally feasible to implement a life-style intervention with physical activity in screen-detected individuals with IGT, but high prevalence of co-morbidities needs to be considered. Though - despite these individual's burden of chronic diseases the intervention had effect on essential risk factors and may indicate a future prevention of type 2 diabetes.

395

Characteristics of smoking behaviour in patients with diabetes attending a tertiary referral centre

R.J. Smyth, A. Mohamed, M. Bell;
Endocrinology&Diabetes, University College Hospital, Galway, Ireland.

Background and aims: Cigarette smoking is a known cardiovascular risk factor. Smoking has been shown to have adverse effects on insulin resistance and body fat distribution. Studies have consistently highlighted an increased risk of morbidity and mortality in patients with diabetes who smoke, primarily from excess cardiovascular disease. There is little evidence that smoking is addressed consistently by healthcare providers, and smoking cessation trials rarely report separate results for diabetes patients.
Materials and methods: As a tertiary referral diabetes centre with 4000 active patients, we sought to better understand the burden of smoking within our patient cohort and its potential effects on glycemic control. 400 patients were surveyed regarding their smoking habits, their understanding of smoking with diabetes and potential barriers to quitting. We then matched for markers of glycemic control and other markers of cardiovascular risk.
Results: Of the 400 patients surveyed, mean age was 55.1 years (17-93.9 years), with 58% male. Current smokers accounted for 19.25%, 34.5% were ex smokers and 44% were never smokers. Mean age of current smokers was 49.2 years. Mean pack years in current smokers was 24.8 years, and 15.9% of never smokers were exposed to passive smoking at home. 87% of current smokers wanted to quit, and 70% thought having diabetes gave them an incentive to do so. The most significant concern about stopping smoking in 48% of patients was weight gain followed by increasing stress levels in 42.9%. Nicotine replacement had been used in the vast majority of smokers 97.4%. 49% typically relapsed within 1 month of a quit attempt. Patients typically attempted to quit smoking on 3 previous occasions. 56.7% of those current smokers who wanted to quit were accepting of help from a smoking cessation officer when offered this service. Current smokers had worse glycemic control (as measured by most recent HbA1c) compared to never smokers. Mean HbA1c of current smokers was 65.8 mmol/mol vs. 61.7 mmol/mol in the never smoking group (p= 0.043). Current smokers vs. ex smokers revealed

mean HbA1c of 65.8mmol/mol vs. 60.9 mmol/mol, but failed to reach statistical significance. (p=0.052). The number of anti-hypertensive medications prescribed for the patient was taken as a surrogate marker of blood pressure control. Significantly, current smokers were prescribed less antihypertensive medications (n=0.93) than ex smokers (n=1.65) (p=0.0001) or never smokers (n=1.29) (p=0.04). There was no statiscally significant difference in albumin creatinine ratio (ACR) or estimated glomerular filtration rate (eGFR) between the groups.
Conclusion: Smoking prevalence in patients with diabetes is less than that of the general population. Diabetes patients who smoke want to quit, yet they face similar barriers to smoking cessation as other smokers. Smokers with diabetes are keen to try pharmacological therapy and are accepting of smoking cessation support, have inferior glycemic control but are less troubled by systemic hypertension.

396

Six month follow-up results from a registry observing Duodenal-Jejunal Bypass Liner treatment outcomes in subjects with type 2 diabetes and/or obesity

P. Koehestanie[1], B. Betzel[1], I. Janssen[1], F. Berends[1], H. de Boer[2], A. Escalona[3], D.T. Araya[3], H. Frydenburg[4], K. Fogarty[4];
[1]Department of Surgery, Rijnstate Hospital, Arnhem, Netherlands,
[2]Department of Endocrinology, Rijnstate Hospital, Arnhem, Netherlands,
[3]Department of Surgery, Catolica University Hospital, Santiago, Chile,
[4]Department of Bariatric Surgery, Epworth Centre for Bariatrics, Melbourne, Australia.

Background and aims: The Duodenal-Jejunal Bypass Liner (DJBL) is an endoscopically placed and removed device to create a bypass of the proximal intestines mimicking the Roux-en-Y and Duodenal-Jejunal Bypass without the risks associated with surgery. The DJBL is indicated for the treatment of type 2 diabetes and/or obesity and remains implanted for up to 12 months. The aim of this registry is to report on the effectiveness and safety of the DJBL in the commercial setting.
Materials and methods: To date, 30 patients implanted with the DJBL in the commercial setting have been included in the registry study. Baseline mean BMI was 37.9 kg/m2 (29.7-48.1 kg/m2), weight 108.1kg (77-143.3kg) and 11 (36.7%) patients were reported to have had type 2 diabetes for a mean duration of 8.1 years (1-18 years), with HbA1c of 7.2% (5.0-10.2%). Data are collected at Baseline, Implant, 6 months post implant, 12 months post implant/removal, and 3, 6, 9 and 12 months post removal. Six month post implant weight, blood pressure, HbA1c, fasting plasma glucose, total cholesterol, LDL, and TG are presented here.
Results: At 6 months post implantation the mean BMI (34.9, - 3.0kg/m2,), weight (99.3, -8.8kg), HbA1c (6.7, -0.5%), fasting plasma glucose(6.8, -0.6 mmol/L), SBP (127.3, -5.8mmHg), DBP (82.1, -6.5mmHg), total cholesterol (4.84, -0.46mmol/L), LDL (2.76, -0.30 mmol/L) and TG (2.52, -0.30 mmol/L) were reduced from baseline/implant.
Conclusion: Use of the DJBL leads to improved glycaemic control, body weight, and associated biomarkers at 6 months compared to baseline in patients with type 2 diabetes and/or obesity in the real world setting.

Duodenal-Jejunal Bypass Sleeve for obesity and type 2 diabetes: systematic review with meta-analysis of clinical studies

N. Hedbäck[1,2], U. Rohde[1], L.L. Gluud[1], T. Vilsbøll[1], F.K. Knop[1,2];
[1]Diabetes Research Division, Gentofte University Hospital, Copenhagen,
[2]Department of Biomedical Sciences, University of Copenhagen, Denmark.

Background and aims: The duodenal-jejunal bypass sleeve (DJBS) is designed to treat obesity and type 2 diabetes by mimicking the bypass effect obtained after gastric bypass surgery. DJBS is inserted and removed endoscopically, and thus, a fully reversible procedure. We aimed to evaluate clinical evidence of DJBS for the treatment of obesity and type 2 diabetes.
Materials and methods: We did a protocol-based systematic review with meta-analysis of clinical studies on the effects of DJBS vs. no intervention, sham-endoscopy and/or low-calorie diet in patients with obesity and/or type 2 diabetes. Randomized controlled trials were included in meta-analyses. Observational studies were included in sensitivity analyses to evaluate the risk of adverse events. The primary endpoint was change in body weight. Secondary endpoints included changes in glycated haemoglobin (HbA_{1c}). Meta-analyses were performed and results presented as mean differences (MD) with 95% confidence intervals (CI).
Results: Thirteen studies with a total of 273 patients were included. Meta-analysis showed that DJBS lead to a greater weight loss compared with controls (MD [95% CI]: -7.2 [-8.4,-5.9] kg; three trials). Furthermore, treatment with DJBS reduced HbA_{1c} compared with controls (-0.5 [-0.9,-0.2]%). Adverse events included transient abdominal pain, nausea and vomiting. Few cases of gastrointestinal bleeding and device obstruction were reported. No deaths occurred.
Conclusion: This systematic review found promising evidence to support additional trials on treatment with DJBS for obesity and/or type 2 diabetes.

398

Bariatric surgery in France in 2011 and temporal trends since 2006

A. Fagot-Campagna, M. Paita, S. Czernichow, A. Weill, S. Rican, D. Nocca, J.C. Thalabard, E. Fery-Lemonnier, M. Marty, M.H. Rodde-Dunet, A. Basdevant, B. Millat;
CnamTS, Paris, France.

Background and aims: To monitor practices and trends in bariatric surgery at a national level, including for people with diabetes.
Materials and methods: Hospital stays for bariatric surgery were extracted from the hospital discharge national database, and were linked with the national medical insurance data system (SNIIRAM) to collect patient characteristics from 2010 to 2011.
Results: In 2011, 30,529 patients underwent bariatric surgery (30,684 procedures), a rate of 47/100,000 inhabitants (men 16/100,000; women 75/100,000). Mean age was 39 years (n=114<age 18). The proportion of women (80%) and beneficiaries of the medical insurance for low income people (17%) were high. BMI was between 30 and 39 kg/m^2 for 29% of all patients, 40-49 for 60% and ≥50 kg/m^2 for 11%. Women underwent surgery at a younger age and a lower BMI compared to men. Treatments for obstructive sleep apnoea (23%), hypertension (24%), asthma/COPD (12%) and depression (17%) were more frequent compared to the general population after adjustment for age and sex. 3461 patients (11%) had diabetes. Sleeve gastrectomy was practiced in 44% of all cases, gastric by-pass in 31% and adjustable banding in 25%. Teenagers underwent more often adjustable banding (50%) than adults, and people with diabetes gastric bypass (39%) and sleeve gastrectomy (47%) than those without diabetes. A total of 426 different hospitals/clinics practiced bariatric surgery, with wide variation in numbers and types of procedure between hospitals/clinics. Major geographical variations in rates and types of procedures were also observed across France. The mean annual increase in all procedures was +16% from 2006 through 2011, with a major increase being recently observed for sleeve gastrectomy.
Conclusion: Our national administrative database provides a unique opportunity to contribute to monitoring medical practices at a national level as part of the national plan against obesity. This large national cohort of patients with and without diabetes will enable the analysis of consequences of bariatric surgery, with almost complete follow-up and a cost-effectiveness analysis.

PS 017 Body composition and diabetes aetiology in epidemiology

399

Association between changes in body composition and risk of developing type 2 diabetes in Koreans

C.-H. Kim[1], E.-H. Kim[2], S.-J. Bae[2], H.-K. Kim[2];
[1]Internal Medicine, Soonchunhyang University Bucheon Hospital, Bucheon, Kyeonggi-do, [2]Health Screening & Promotion Center, Asan Medical Center, Seoul, Korea, Republic of.

Background and aims: Changes in body composition with aging are characterized by loss of muscle mass and increase of fat mass. Cross-sectional studies have shown that decreased muscle mass and increased fat mass are associated with insulin resistance and type 2 diabetes. However, there is a paucity of data that examined the effects of longitudinal changes in muscle or fat mass on the risk of type 2 diabetes. We assessed the association between changes in body composition and risk of developing type 2 diabetes in non-diabetic Korean individuals.
Materials and methods: We analyzed the clinical and laboratory data of 18,687 Korean adults (age 20-79 years, 11,510 men and 7,177 women) who underwent routine medical check-ups in 2007-08 (baseline) and again in 2011-12 (follow up) with a mean 4.3-year (range 3.0-5.7 years) interval. All non-pregnant adults who did not have diabetes at baseline examination were included for the analysis. Total fat mass, lean body mass, and soft lean mass were assessed using bioelectrical impedance. Odds ratios (ORs) for incident type 2 diabetes were estimated using multiple logistic regression analysis.
Results: Among the 18,687 participants who did not have diabetes at baseline, a total of 692 subjects (3.7%, 524 men and 168 women) developed type 2 diabetes during the 4.3-year follow-up period. Those who developed type 2 diabetes had significantly higher percentage of total body fat (23.5±5.5% vs. 21.6±5.4%, P <0.001) and lower percentage of lean body mass (76.6±5.6% vs. 78.5±5.5%, P <0.001) and soft lean mass (72.5±5.3% vs. 74.2±5.2%, P <0.001) at baseline compared with those who did not develop diabetes. After 4.3 years, those who developed diabetes showed greater increase of percent body fat (2.9±3.0 vs. 2.6±3.2 percentage points, P=0.043), decrease of percent lean body mass (-3.0±3.3 vs. -2.7±3.3 percentage points, P=0.008) and percent soft lean mass (-2.8±3.1 vs. -2.4± 3.1 percentage points, P=0.003) compared with those who did not develop diabetes. There was no significant difference in change of total body weight and BMI between the two groups. In multiple logistic regression analysis, increase of fat mass more than 10% was associated with increased OR for diabetes (1.32; 95% CI, 1.05-1.64), and decrease of fat mass was associated with lower OR (0.61; 0.47-0.81) after adjustments for age, sex, and baseline BMI, waist circumference, glucose level. Loss of lean body mass more than -5% was associated with increased OR for diabetes in age and sex-adjusted models (OR 1.32; 1.11-1.56), but this association became insignificant after further adjustments for baseline BMI, waist circumference, and glucose level (OR 1.09; 0.90-1.32). Increase of lean body mass was not significantly associated with lower OR for diabetes (0.84; 0.64-1.11).
Conclusion: These results showed that changes in total body fat mass are associated with development of type 2 diabetes independent of changes in BMI, while changes in lean body mass are not.

400

Ethnicity-specific obesity cut-points in the development of incident diabetes: a prospective study including three ethnic groups in the United Kingdom

T. Tillin[1], N. Sattar[2], I.F. Godsland[3], E. Coady[1], D. Key[1], C. Tuson[1], A.D. Hughes[1], N. Chaturvedi[1], N.G. Forouhi[4];
[1]National Heart and Lung Institute, Imperial College, London, [2]Institute of Cardiovascular and Medical Sciences, University of Glasgow, [3]Endocrinology and Medicine, Imperial College London, [4]MRC Epidemiology Unit, Institute of Metabolic Science, University of Cambridge, UK.

Background and aims: Conventional definitions of obesity, e.g. body mass index (BMI)> 30 kg/m^2 or waist circumference cut-points of 102cm (men) and 88cm (women), may underestimate metabolic risk in non-European populations. We compared incidence of diabetes in British Europeans, South Asians and African Caribbeans and identified equivalent sex- and ethnicity-specific BMI and waist circumference cut-points for estimation of diabetes risk.
Materials and methods: Population based cohort of 4202 non-diabetic Europeans, South Asians and African Caribbeans from London. Participants were aged 40-69 at baseline (1988-91), when they underwent anthropometry and fasting and post-load blood tests. Follow-up data to 19 years (median) were available for 2533 (60%). Incident diabetes was identified from primary care records, participant recall and/or follow-up biochemistry.
Results: Incidence rates of diabetes in men were greater in South Asians and African Caribbeans (respectively 20.8 (95%CI:18.4, 23.6) and 16.5 (12.7, 21.4)/1000 person years) compared with 7.4 (6.3, 8.7)/1000 person years in Europeans. Likewise, incidence rates in women were highest in South Asians (12.0 (8.3,17.2) and African Caribbeans 17.5 (13.0,23.7) compared with 7.2(5.3,9.8)/1000 person years in Europeans. For the equivalent incidence of diabetes at a BMI of 30 kg/m^2 in Europeans, age and sex adjusted BMI cut-points were: South Asian men and women: 26.0(24.6, 26.5) kg/m^2; African Caribbean men and women: 27.0 (26.7, 29.3) kg/m^2. For men of both ethnic minorities,age adjusted waist cut-points of 91.0 (87.4, 92.4) cm were equivalent in risk to 102cm in European men, and in women cut-points of 84.3 (76.5, 89.8) cm in South Asians and 81.6 (73.4, 85.5)cm in African Caribbeans were equivalent to 88cm in Europeans.
Conclusion: Middle-aged British South Asians and African Caribbeans had equivalent risk of developing diabetes at substantially lower cut-points of BMI or waist circumference than Europeans. Our findings suggest the potential benefit of public health measures for the prevention of metabolic risk in South Asian and African Caribbean populations long before the current conventional obesity cut-points are reached.

Body fat distribution, glucose tolerance and metabolic profile in young adult twins: an exploration of sex differences

S.M. Kaye[1], L.H. Bogl[2], A. Rissanen[3], A.J. Kangas[4], P. Soininen[5], A. Ortega-Alonso[6], M. Ala-Korpela[5], J. Kaprio[7], K.H. Pietiläinen[8];
[1]Department of Medicine, Division of Endocrinology, Helsinki University Central Hospital, Diabetes and obesity research program, Finland, [2]Department of Public Health, The Finnish Twin Cohort Study, Helsinki, Finland, [3]Department of Medicine, Helsinki, Finland, [4]Computational Medicine, Institute of Health Sciences, Oulu, Finland, [5]Computational Medicine, Institute of Health Sciences, University of Oulu, Finland, [6]Institute for Molecular Medicine Finland, Helsinki, Finland, [7]Department of Public Health, University of Helsinki, The Finnish Twin Cohort Study, Helsinki, Finland, [8]Department of Medicine, Division of Endocrinology, Helsinki University Central Hospital, Diabetes and obesity research program, University of Helsinki, Finland.

Background and aims: We aimed to study a) whether gender differences in body composition account for differences in the metabolic profile among young adults; b) whether metabolic profile associates with body fat distribution and glucose tolerance independent of genetic factors; c) the extent to which genetic factors contribute to the covariance of central adiposity and metabolic profile.
Materials and methods: Metabolic profile of 46 metabolites (mainly lipids, lipid fractions and amino acids) was measured by nuclear magnetic resonance (NMR) in 1368 healthy young adult twins (age range: 22-36y, 531 monozygotic (MZ), 497 same sex dizygotic (SSDZ), 340 opposite sex dizygotic

(OSDZ) with BMI and waist measures. Oral glucose tolerance test (OGTT) was performed and body composition (android and gynoid fat by DEXA) was measured in a subsample of 128 MZ and SSDZ twin pairs. Metabolic profile was examined in men and women matched individually for BMI and android-to-gynoid (A/G) fat ratio and in OSDZ pairs partially matched for genes. Quantitative genetic modeling of twin similarity was used to assess genetic and environmental contributions to the covariation of metabolites and waist circumference (WC).
Results: Men had significantly higher ApoB, LDL-C, VLDL particle, and phenylalanine concentrations and lower levels of ApoA1, HDL-C and glutamine, tyrosine and branched chain amino acids (BCAA) than women. Sex-differences in ApoA1, HDL-C and amino acids remained significant even in males and females matched for BMI, A/G fat ratio and the genetic background (OSDZ). In individual twins, android fat and AUC insulin during the OGTT associated significantly with an unfavourable metabolic profile, and adiponectin and Matsuda index with a favourable profile in both males and females. Within MZ twin pairs, associations between AUC insulin and adiponectin and metabolic profile remained strong, but those with android fat were substantially weaker or non-significant indicating that genes may be important in explaining their association. Bivariate sex-limitation models utilizing the whole twin cohort confirmed that genes for abdominal obesity and metabolites partially overlap. For example, the genetic effects between BCAA's and WC correlated by r_g=0.37 (men) and 0.40 (women) and genes explained 66% and 94% of the covariance between BCAA and WC in men and women respectively.
Conclusion: Women have a more beneficial metabolic profile than men and this difference cannot be explained by differences in BMI or body fat distribution. Obesity and abdominal obesity in particular is associated with an adverse metabolic profile in young adults, which is largely explained by shared genes.

Waist circumference and blood pressure are associated with microvascular vasomotion in a healthy population: the Maastricht study
D. Muris, M. Schram, A. Houben, C. Stehouwer;
Internal Medicine, Maastricht University Medical Centre, Netherlands.

Background and aims: Microvascular vasomotion, i.e. rhythmic changes in vascular diameter, is thought to play an important role in ensuring optimal delivery of nutrients and oxygen to tissue. Impaired microvascular vasomotion has been demonstrated in states of obesity and type 2 diabetes mellitus (T2DM) (i.e. decreased vasomotion), and hypertension (i.e. enhanced vasomotion). It is unclear however, which factors influence microvascular vasomotion. Therefore, we investigated associations between traditional risk factors and microvascular vasomotion in a healthy population.
Materials and methods: We measured skin microvascular vasomotion in 241 healthy individuals (mean age 56 ± 8 years, 42% men, mean body mass index (BMI) 25.4 ± 3.6 kg/m^2) enrolled in the Maastricht Study. We selected a healthy population without T2DM, hypertension, prior cardiovascular disease, or use of cardiovascular medication. Skin blood flow was measured with a laser Doppler probe at the dorsal side of the left wrist. Fast-Fourier transform analysis was performed to determine the five frequency components to the variability of the laser Doppler signal (i.e., endothelial, 0.01-0.02 Hz; neurogenic, 0.02-0.06 Hz; myogenic, 0.06-0.15 Hz; respiratory, 0.15-0.40 Hz; and heart beat, 0.40-1.60 Hz). The associations of age, sex, waist circumference, total-to-HDL cholesterol, 24-h mean arterial pressure (MAP), fasting plasma glucose, and cigarette smoking with microvascular vasomotion was analyzed by use of multiple linear regression analysis.
Results: Higher waist circumference and 24-h MAP were associated with a lower and higher total microvascular vasomotion, respectively. Per one standard deviation (SD) higher waist circumference total microvascular vasomotion was -0.17 SD (95%CI: -0.32; -0.03) lower. One SD higher 24-h MAP was independently associated with a 0.18 SD (0.04; 0.32) higher total microvascular vasomotion. We found no associations of microvascular vasomotion with age, sex, total-to-HDL cholesterol, fasting plasma glucose, or smoking. Analysis of the five frequency bands revealed that these results were largely attributable to the contributions of the endothelial, neurogenic, and myogenic components. Sub-analysis with exclusion of the obese subjects (BMI>30 kg/m^2; n = 23) gave similar results.
Conclusion: In conclusion, in a healthy population waist circumference is inversely associated with microvascular vasomotion. In addition, blood pressure is directly associated with microvascular vasomotion. These data suggest that both elevations in waist circumference and blood pressure may affect microvascular vasomotion, and subsequently optimal nutrients delivery and tissue perfusion.

The differences between serum fingerprints of healthy and pre-diabetic humans are dependent on BMI
M. Ciborowski[1], A. Kretowski[1,2], E. Adamska[1], A. Citko[2], M. Waszczeniuk[3], J. Wilk[2], A. Golonko[3], J. Pliszka[2], D. Lipinska[2], J. Goscik[2], J. Teul[4], J. Godzien[5], S. Angulo[5], C. Barbas[5], M. Gorska[2];
[1]Centre for Clinical Research, Medical University of Bialystok, Poland, [2]Department of Endocrinology, Diabetology and Internal Medicine, Medical University of Bialystok, Poland, [3]Department of Dietetics and Clinical Nutrition, Medical University of Bialystok, Poland, [4]Department of Pharmaceutical Analysis, Medical University of Bialystok, Poland, [5]Center for Metabolomics and Bioanalysis (CEMBIO), Universidad CEU San Pablo, Madrid, Spain.

Background and aims: Development of type 2 diabetes mellitus (T2DM) is preceded by insulin resistance (IR). The IR may evolve to impaired fasting glucose (IFG) and/or impaired glucose tolerance (IGT), which are considered as pre-diabetic states. The transition from pre-diabetic states to diabetes may take many years. However, it is estimated, that up to 70% of pre-diabates subjects eventually develop T2DM. The risk of T2DM development is increased in overweight (OW) and obese (OB) people; however lean (L) individuals also suffer from T2DM. The purpose of this study was to evaluate whether metabolic differences between healthy and pre-diabetes humans are dependent on BMI. Metabolomic approach by use of LC-QTOF-MS was used to fingerprint serum samples obtained from L, OW or OB humans whom were healthy (controls), IR or had IFG and/or IGT (pre-diabetes).
Materials and methods: 78 people (40 female, 38 male, mean age 45 years) took part in this study. Participants were classified according to health status (controls, IR or pre-diabetes) based on fasting glucose level, HOMA-IR, and 2-h 75-g OGTT. And as L, OW or OB based on BMI. Age and sex were matched between the groups. Fasting serum samples were fingerprinted by LC-QTOF-MS. Data were collected in ESI(+) mode (50-1,000 m/z). Chromatograms were aligned and quality assurance of obtained data was performed. LOESS function was used for signal correction. Statistical analysis was performed to compare controls with pre-diabetes in each BMI group. Significant metabolites were selected by univariate (t-test) and multivariate (s-plot) analyses. S-plot was obtained for OPLS-DA model. The same model was used to predict IR individuals in each BMI group. Identification of significant features was performed based on custom library with accurate mass and retention time of more than 100 metabolites.
Results: 21 metabolites discriminating controls from pre-diabetes were identified. In the L group fatty acid amides (FAA), lysophospholipids (LPL), cortisol, and sphingosine-1-phoshate were significantly higher in pre-diabetes as compared to controls. These metabolites were also increased in OW/OB controls in comparison to L controls. In the OW/OB groups LPL were main metabolites responsible for samples classification. Valine discriminated controls from pre-diabetes independently on BMI. Majority of the samples obtained from IR individuals, when predicted by OPLS-DA model, were classified between samples obtained from controls and pre-diabetes.
Conclusion: Metabolites discriminating controls from pre-diabetes are changing with BMI. As compared to L controls, serum fingerprint of pre-diabetes is characterized by increased amount of FAA, cortisol, and lipids. In OW/OB people elevation in mentioned metabolites is probably related to increased BMI. Mechanisms responsible for rising of these metabolites in L pre-diabetic humans require further investigations.

A propensity-matched comparison of insulin secretion and resistance between subjects from 1990's and 2000's in a Korean population

H. Yang[1], J.-H. Lee[2], H. Kwan[1], J. Cho[1], K. Yoon[1];
[1]Endocrinology and Metabolism, [2]Graduate School of Healthcare Management and Policy, The Catholic University of Korea, School of Medicine, Seoul, Korea, Republic of.

Background and aims: We aimed to evaluate the differences in insulin secretion and insulin sensitivity between individuals from 1990's and 2000's in Korean population.
Materials and methods: A total of 769 subjects during 1990's and 720 subjects during 2000's who underwent 75g-oral glucose tolerance test (OGTT) were recruited from Seoul St. Mary's Hospital in Korea. Insulinogenic index, Matsuda index and total-are-under-the-curve (insulin/glucose) (total AUC(I/G) were calculated. Individuals were categorized into 3 groups according to their glucose tolerance status; normal glucose tolerance (NGT), prediabetes (preDM) and diabetes (DM) group. Further subgroup analysis was performed according to body mass index (BMI) level. Propensity score model was constructed to adjust significant differences in the baseline characteristics of enrolled subjects in 1990's and 2000's.
Results: In NGT group, there was no significant differences in Matsuda index, Total AUC (I/G) and insulinogenic index between subjects from 1990's and 2000's. In preDM group, Matsuda index was lower in the subjects from 2000' scompared to those from 1990's, but total AUC(I/G) and insulinogenic index showed little differences. In DM group, Matsuda index was lower, and total AUC(I/G) and insulinogenic index was higher in subjects from 2000's compared to those from 1990's. There were no significant differences according to BMI levels across the glucose tolerance status. Hyperbolic relationship was observed between Matsuda index and total AUC(I/G) in subjects with NGT(ß=-0.67(-0.77, -0.57), preDM(ß=-0.80 (-0.91, -0.68) and DM (ß=-0.98 (-1.10, -0.88) in 1990's. Hyperbolic relationship was also confirmed in 2000's, in subjects with NGT (ß=-0.80 (-0.86, -0.73), preDM (ß=-0.90, (-1.01, -0.77) and DM (ß=-0.96, (-1.08, -0.84).
Conclusion: In conclusion, compared to subjects from 1990's, clinical phenotype of prediabetes and diabetes patients from 2000's showed increased insulin resistance regardless of their BMI levels, and the early-phase compensatory insulin secretion was only minimal in the prediabetes group. It is well known that type 2 diabetes in Asian population differ from those in Western countries. However, our study suggest that the clinical characteristics of prediabetes and diabetes have been westernised compared to those in the past decades.

Baseline Characteristics

		1990's (n=769)	2000's (n=720)	p-value†

Association of body fat mass and liver fat content with insulin resistance in euglycaemic Chinese middle-aged and elderly adults

M. Xia, H. Lin, X. Li, H. Yan, H. Bian, X. Chang, L. Zhang, X. Gao;
Endocrinology, Zhongshan Hospital, Shanghai, China.

Background and aims: The risk of type 2 diabetes mellitus is heterogeneous among obese individuals. Recent studies indicated that a dysfunctional adiposity phenotype, characterized by the alteration of body fat distribution to visceral site, may contribute to the diabetes development and explain the heterogeneity. The aim of the current study is to investigate association of insulin resistance with whole body fat mass and ectopic liver fat content (LFC) in euglycemic Chinese middle-aged and elderly adults, and further determine the cutoff value for LFC to indicate insulin resistance in euglycemic Chinese people.
Materials and methods: The whole body fat mass were measured using dual-energy x-ray absorptiometry (Lunar iDXA, GE Healthcare) in 1445 euglycemic participants aged over 45 yr from Shanghai Changfeng community. Liver fat content was quantified via a newly-established computer-aided ultrasound quantitative method. Multivariate stepwise regression and general linear models were carried out to determine the independent association of insulin resistance with whole body fat mass as well as liver fat content.
Results: ① The body insulin resistance estimated by HOMA-IR is significantly correlated with fat mass (r=0.544, P<0.001) and LFC (r=0.316, P<0.001). ② Multivariate stepwise linear regression analysis shows that both body fat mass and LFC have positive independent associations with insulin resistance (Standardized β=0.376,P<0.001 and Standardized β=0.087, P<0.001, respectively). Besides, FBG, TG, HDL-c, SBP and gender are also independently associated with insulin resistance. ③ The subjects are divided into five groups according to LFC at 5%-increments and an increasing trend in HOMA-IR is found to accompany the increase in LFC when liver fat content exceeds 10% after adjustment for all potential confounders (P for trend<0.001) (Figure 1).
Conclusion: Both body fat mass and ectopic fat accumulation in liver are independently associated with insulin resistance level and liver fat content over 10% may indicate early insulin resistance state in euglycemic Chinese middle-aged and elderly adults.

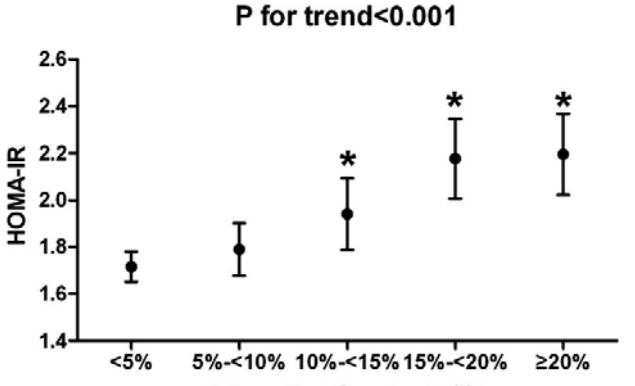

Figure 1 Comparison of HOMA-IR according to 5% increments of liver fat content after adjustment for age, BMI, gender, fat mass, components of metabolic syndrome, cigarette smoking, and alcohol drinking. P for trend<0.001.
*p<0.05, compared with subjects with liver fat content<5%.

The impact of reproductive factors on glucose metabolism in postmenopausal women: Korean National Health and Nutrition Examination Survey 2008-2010

K. Jin Hwa, J. So, S. Kim, H. Bae;
Department of Endocrinology and Metabolism, Chosun University Hospital, Gwangju, Republic of Korea.

Background and aims: Recent studies suggest that reproductive factors are related to metabolic syndrome in women. An earlier age at menarche has

been associated with an increased risk of cardiovascular disease. However, the impacts of reproductive factors on glucose metabolism has not been evaluated. The objective was to determine whether there is an association between the reproductive factors and glucose tolerance status in Korean postmenopausal women.
Materials and methods: The Korean National Health and Nutrition Survey (KNHANES) was a nationally representative survey with a stratified multistage sampling design. Datas were obtained from the KNHANES of 2008-2010. A total of 2,674 postmenopausal women were included in the analysis.
Results: The prevalences of impaired fasting glucose (IFG) and new diagnosed diabetes were 9.8% and 11.2%, respectively. Multivariate logistic regression analysis indicated that adolescent pregnancy was significantly associated with a decreased risk of IFG (odds ratio (OR), 0.87; 95% CI, 0.76-0.98) and diabetes (OR, 0.78; 95% CI, 0.65-0.85) after adjusting for risk factors associated with increasing glucose level. Other reproductive factors including age at menarche, age at menopause, parity, history of lactation, years since menopause, and oral contraceptives were not associated with a risk of IFG and diabetes.
Conclusion: Adolescent pregnancy is independently associated with a decreased risk of IFG and diabetes in Korean postmenopausal women.

407

Sarcopenic obesity was associated with decreased renal function in elderly, diabetic Koreans: from KNHANES 2008-2010
S. Lee[1], H. Kwon[1,2], O. Hong[1], J. son[1], M. Kim[2,3], K. Han[3], S. Kim[1], S. Yoo[1];
[1]Endicrinology and metasbolism, Catholic University, Bucheon-City Gyunggi province, [2]Physiology, Catholic University, Seoul, [3]Catholic University, Seoul, Republic of Korea.

Background and aims: Sarcopenia, low skeletal muscle mass is an important age-related health implication for older people. Because muscle is the major organ contributing to insulin-mediated glucose disposal and glycogen storage, the loss of muscle mass may promote insulin resistance and risk of metabolic syndrome development. Important changes in body composition with aging are a progressive loss of muscle mass and increase of fat mass. This study aimed to examine the relationship of body composition with decrement of GFR among 2767 subjects (1176 men and 1591 women) aged 60 years or older from Korean National Health Examination and Nutrition Survey (KNHANES) 2008-2010.
Materials and methods: Cross-sectional analysis based on the data acquired in the second and third year (2008-2009) of KNHANES IV and first year (2010) of KNHANES V.1176 men and 1591 women aged 60 years and older had complete data on body composition. Data were collected by household interviews and direct standardized physical examinations. Sarcopenia was defined as an appendicular skeletal muscle mass (ASM) divided by weight (%) of <2 SD below the sex-specific mean for young adults. The ASM(kg) was defined as the sum of the lean tissue masses of the arms and legs. Obesity was defined as a body mass index (BMI) ≥ 25 kg/m^2. The renal function was measured by glomerular filtration rate(GFR) and chronic renal failure was defined as GFR <60 ml/min/1.73m^2.
Results: After adjusted age, BMI, smoking, alcohol, and exercise, we divided subjects into 4 groups ; normal, obesity, sarcopenia, and sarcopenic obesity group. In male (n=1176), odds ratio (OR) of chronic renal failure risk was 1.815 for obesity group(95% CI : 0.556-5.924), 2.353 for sarcopenia group (95% CI : 1.402-3.948), and 3.107 for sarcopenic obesity group (95% CI : 1.48-6.524) compared with normal male reference group aged 60 years and older In female (n=1591), odds ratio (OR) of chronic renal failure risk was 1.832 for obesity group (95% CI : 0.955-3.513), 1.119 for sarcopenia group (95% CI : 0.678-1.848), and 2.255 for sarcopenic obesity group (95% CI : 1.182-4.302) compared with normal male reference group aged 60 years and older.
Conclusion: In this study, Sarcopenic obesity was associated with decreased renal function in the elderly Korean diabetes. We consider that differentiation of body composition is closed related with the decreased renal function in the elderly diabetes.

PS 018 Obesity and diabetes

408

In the grey zone of type 2 diabetes prediction: Can we separate poorly discriminated incident cases and non-cases?
B. Kowall[1], W. Rathmann[1], B. Bongaerts[1], C. Meisinger[2], A. Peters[2], C. Huth[2], A. Zierer[2], K.-H. Ladwig[2], R. Holle[3];
[1]German Diabetes Center, Düsseldorf, [2]Institute of Epidemiology II, Helmholtz Zentrum München, Neuherberg, [3]Institute of Health Economics and Health Care Management, Helmholtz Zentrum München, Neuherberg, Germany.

Background and aims: Addition of many novel biomarkers to conventional diabetes risk scores has so far yielded only little incremental value in diabetes prediction. We aim to clarify possible reasons: (1) Measures of discrimination, particularly areas under the receiver operating curve (AROC), might be inappropriate to reflect potential gain in risk prediction, (2) (lifestyle) changes after baseline lead to changes in risk profiles not reflected by risk scores, (3) information from novel biomarkers is already captured by conventional risk factors.
Materials and methods: Analyses are based on the population-based KORA S4/F4 cohort study (873 participants without diabetes and aged 55-74 years at baseline). During 7-year follow-up, 91 incident cases of diabetes occurred. Using three different conventional risk scores, cases and non-cases were seen as well discriminated if the estimated risk was at least 10% larger in cases than in non-cases. Levels of biomarkers (e.g. adiponectin, insulin, hematocrit, white cell blood count) and changes in anthropometry were calculated separately for well and poorly discriminated cases and non-cases.
Results: Only under condition of good, but not of poor discrimination by conventional risk scores, are levels of biomarkers significantly more adverse in cases than in non-cases. Weight change after baseline was significantly larger in cases under condition of poor, but not of good discrimination. To give some examples (all analyses adjusted for age and sex): Under condition of good discrimination (with 58 cases and 458 non-cases), the median of the level of adiponectin was 5.7 μg/ml in cases and 10.2 μg/ml in non-cases (p<0.001); the median of insulin was 15.8 mikroU/ml in cases, and 8.3 mikroU/ml in non-cases (p<0.001); mean change in BMI was 0.48 kg/m2 in cases, and 0.39 kg/m2 in non-cases (p=0.49). Under condition of poor discrimination (with 33 cases and 324 non-cases), the median of the level of adiponectin was 8.3μg/ml in cases and 8.1μg/ml in non-cases (p=0.87); the median of insulin was 10.4 mikroU/ml in cases, and 11.7 mikroU/ml in non-cases (p=0.51); mean change in BMI was 0.97 kg/m2 in cases, and 0.15 kg/m2 in non-cases (p=0.01).
Conclusion: Separate analyses for good and poor discrimination by conventional risk factors give better insight into the discriminatory potential of novel markers than AROCs. Weight change after baseline, but not the selected biomarkers differ significantly between cases and non-cases which are poorly discriminated by conventional risk scores. In a more general view, there are various factors (changes in risk factors after baseline, correlations between novel markers and conventional risk factors, limited reproducibility of diabetes ascertainment) which make it questionable that discrimination between incident cases of diabetes and non-cases can steadily be improved once a level of good diabetes prediction (in terms of AROCs of about 0.85 to 0.90) has been obtained.

Obesity paradox in diabetes mellitus: mortality and cardiovascular morbidity over 15 years of 12,025 patients
P. Costanzo[1], P. Pellicori[2], D. Hepburn[3], E. Kilpatrick[3], J.F.G. Cleland[2], S.L. Atkin[3];
[1]Department of Diabetes/Academic Cardiology Unit, UK, [2]Academic Cardiology Unit, of Diabetes, University of Hull, UK.

Background and aims: Obesity is a key factor for the development of insulin resistance and Type-2 diabetes mellitus (T2DM). However, recent evidence suggests that obese patients with T2DM may have lower morbidity and mortality compared to patients of normal weight. These reports are limited by statistical power and confounders. In this analysis, the relationship between Body Mass Index (BMI), mortality and cardiovascular (CV) morbidity is investigated in a prospective cohort, with a long-term follow up and a large number of events.

Materials and methods: Between 1995 and 2011, the following data were collected in patients attending the diabetes service at Hull & East Yorkshire Hospitals NHS Trust; age, sex, height and weight (and therefore body mass index), blood pressure, biochemical and information on co-morbidities (cardiovascular (CV) disease, chronic renal failure (CRF), chronic obstructive lung disease (CPD) and cancer). Total mortality and hospital admissions for acute coronary syndrome (ACS), cerebrovascular accidents (CVA) and heart failure (HF) were gathered. Subjects were divided according to BMI quartiles and in age tertiles. ANOVA and Chi square were used to compare covariates among the BMI groups. Cox-Regression analysis was used to assess the prognostic impact of BMI and confounders on the above-defined events. Sensitivity analysis was performed accounting for T1DM and BMI<18.5.
Results: In total, 12025 patients with diabetes (54% men, mean age 60±15 years, 1761 (15%) T1DM) were enrolled and followed for a mean of 10±4 years during which ACS occurred in 1098 (9%), a CVA in 893 (7%) and a HF hospitalization occurred in 731 (6%) subjects and 4125 (34%) died. The risk of ACS was lowest in the normal BMI group and increased progressively with increasing quartiles of BMI, being greatest in obese subjects (BMI >30 HR 1.49; 95%CI 1.24-1.79; p30 HR 1.53 95% CI 1.53; 95% CI 1.24-1.88; p30) (HR 0.75 95% CI 0.69-0.82). Adjusting the analysis for comorbidity did not significantly affect the results but adjusting for age did. Therefore, we divided the results according to age tertiles. CV events showed a similar pattern in each age tertile as in the overall population. However, for all-cause mortality higher BMI was associated with a survival benefit in the eldest age tertile, whilst in the youngest age tertile, the relationship assumed a U shape, with the highest and lowest quartiles being associated with and increased risk of death. Sensitivity analysis was applied by excluding T1DM or underweight patients. However, this did not significantly affect the results.
Conclusion: In this study, in patients with T2DM, although being overweight was associated with an increased risk of CV events, higher BMIs were associated with a survival benefit, especially amongst older patients. DM induced by the metabolic stress of obesity may be a fundamentally different problem from DM that develops in the absence of the stress of obesity. Alternatively, obesity may provide a protective metabolic reserve in older diabetic patients.

Evidence of reverse epidemiology between obesity and all-cause mortality in whites with type 2 diabetes from Italy

R. Di Paola[1], A. Marucci[1], A. Fontana[2], C. Menzaghi[1], L. Salvemini[1], M. Copetti[2], F. Pellegrini[2], S. De Cosmo[3], V. Trischitta[1,4];
[1]Research Unit of Diabetes and Endocrine Diseases, IRCCS "Casa Sollievo Della Sofferenza", San Giovanni Rotondo, [2]Unit of Biostatistics, IRCCS "Casa Sollievo Della Sofferenza", San Giovanni Rotondo, [3]Unit of Endocrinology, IRCCS "Casa Sollievo Della Sofferenza", San Giovanni Rotondo, [4]Department of Experimental Medicine, "Sapienza" University, Rome, Italy.

Background and aims: While obesity is an established major risk factor for all-cause mortality in otherwise healthy individuals, its role in patients with type 2 diabetes (T2D) is controversial. Our aim was to address the relationship between obesity and all-cause mortality in a real-life set of White patients with T2D from central-southern Italy. We also used genetic data from GWAs-derived SNPs firmly associated with BMI, in order to address the biology underlying the association between obesity and reduced mortality rate we did observe (i.e. Mendelian randomization approach).
Materials and methods: Patients with T2D (n=764) are part of the Gargano Mortality Study, aimed at unraveling predictors of incident all-cause mortality. Time-to-death analyses were performed by Cox regression models. Of the 38 SNPs established associated to BMI in GWAs, we investigated those with a BMI β value ≥0.10 Kg/m2 and an allele frequency ≥10% (n=20). Genotyping of established BMI SNPs from GWAs, was performed by KBioscience (http://www.lgcgenomics.com/). Association between genotype risk score (GRS; number of risk allele carried by each individual) and obesity was tested by logistic regression analysis.
Results: During the 7.46±2.13 year follow-up 149 (19.5%) patients died. Annual incidence rates were 2.6% in the whole sample, 3.4% in non-obese and 1.9%, in obese individuals. As compared to non obese, obese patients had 45% decreased risk of all-cause mortality (HR=0.55, 95% CI=0.40-0.76; p=0.0004; age, sex, smoking habit, hypertension and dyslipidemia adjusted HR=0.64, 95% CI=0.45-0.90, p=0.010). Individuals with high "obesity genetic load" (i.e. 10 SNP-derived GRS being ≥ 9, the median value of whole sample) were more likely to be obese (OR=1.61, 95% CI = 1.21-2.12, p=0.001) as compared to individuals with low "obesity genetic load" (i.e. 10 SNP-derived GRS being <9). Annual incidence rates of all-cause mortality were 2.65% and 2.58% in individuals with high and low "obesity genetic load", respectively. As compared to individuals with low "obesity genetic load", the HR for all-cause mortality in those with high load was 0.97 (95%CI=0.70-1.33, p=0.877). Although the observed HR was not different from the expected one (HR=0.75, p=0.17), its approaching 1, strongly suggest that no causality underlies the association between obesity and reduced mortality risk.
Conclusion: Obesity is associated with reduced mortality risk in White patients from central-southern Italy. Based upon genetic studies, this association seems not to be causal. Further studies are needed to get deeper insights on the biological link between obesity and all-cause mortality in diabetic patients.

Overweight is associated with LADA among women but not in men: results from ESTRID, a Swedish case-control study

R. Hjort[1], L. Groop[2], T. Tuomi[3], M. Dorkhan[2], S. Carlsson[1];
[1]IMM Institute of Environmental Medicine, Karolinska Institutet, Stockholm, Sweden, [2]Diabetes and Endocrinology, Dept. of Clinical Sciences, Lund University, Sweden, [3]Department of Medicine, Helsinki University Hospital, Finland.

Background and aims: LADA (Latent Autoimmune Diabetes in Adults) may be the second most common form of diabetes. Data from the Nordic countries suggests that it accounts for ~10% of the total diabetes burden among adults. Still, risk factors are largely unknown - LADA is an autoimmune form of diabetes, but similarities with type 2 diabetes has also been shown, including insulin resistance. Our aim was to investigate the risk of LADA in relation to overweight and obesity, the strongest known risk factors for type 2 diabetes and an important source of insulin resistance.
Materials and methods: ESTRID (epidemiological study of risk factors for LADA and type 2 diabetes) is an ongoing population based case-control study - the largest of its kind. Incident cases of LADA and type 2, onset ≥ age 35, were recruited from the ANDIS registry (All New Diabetics in Skåne) together with a random sample of disease free individuals, matched over time (to date; LADA n=205, type 2 n=402, and controls n=670). Cases were classified as LADA if they had autoantibodies against the insulin producing beta cells (anti-GAD) at diagnosis or else, as type 2 diabetes. Mean age was 59 in LADA, 63 in type 2 and 59 in controls and the proportion of women was 44, 40 and 52%, respectively. Information on BMI (kg/m^2) was based on self-report. By means of logistic regression we calculated Odds Ratios (OR) with 95% Confidence Intervals (CI) adjusted for age, sex, family history, physical activity, education, alcohol and smoking. Population Attributable Risk (PAR) was used to estimate proportion of cases attributed to overweight/obesity.
Results: Excessive weight was associated with an increased risk of LADA, OR was estimated at 1.60 (CI 1.07-2.36) for overweight (BMI 25-29.9) and 3.03 (CI 1.90-4.84) for obesity (BMI ≥30). Stratified analysis revealed that this augmented risk primarily was seen in women, OR 4.32, CI 1.96-9.50 (obesity), while OR for obese men was 1.75, CI 0.89-3.43. We also found that women reporting being overweight at both age 20 and at onset, had a 5-fold increased risk of LADA, OR 5.48 (CI 1.27-23.74) with no corresponding increase in men, OR 1.26 (CI 0.55-2.90). The risk of type 2 diabetes increased dramatically with BMI; OR 31.66 (CI 17.10-58.61) for obesity and the excess risk was seen in men (OR 19.70, CI 8.45-45.94) as well as women (OR 47.97, CI 18.73-122.88). Estimation of PAR indicates that overweight accounts for 58% (32-76%) of all cases of LADA in women. Corresponding estimates for type 2 was 89% (77-95%) in men and 94% (87-98%) in women.
Conclusion: Our results indicate that at least for women, overweight and obesity are risk factors for LADA. Estimation of PAR suggests that a large proportion of LADA among women could be prevented through weight modification. The association was weaker than for type 2 which would fit with previous reports of LADA being characterized by insulin resistance, but to a much lesser extent than type 2. The sex inequality requires further investigation, but it is possible that the results might have been different with another indicator of excess weight such as WHR. These findings also suggest that early onset of overweight further augments the risk of LADA. Hence, it seems important to acknowledge excessive weight already during adolescence in order to prevent LADA.

Comparison of abdominal obesity indicators and body mass index as a predictor of mortality among Europeans

X. Song[1], S. Söderberg[2], P. Jousilahti[3], C.D.A. Stehouwer[4], J.S. Yudkin[5], A. Onat[6], T. Laatikainen[3], R. Dankner[7], R. Morris[8], J. Tuomilehto[1], Q. Qiao[1]; [1]Hjelt Institute, University of Helsinki, Finland, [2]Department of Public Health and Clinical Medicine, Cardiology, Umeå University Hospital, Sweden, [3]National Institute for Health and Welfare, Helsinki, Finland, [4]Department of Internal Medicine, Maastricht University, Netherlands, [5]University College London, UK, [6]Department of Cardiology, Istanbul Medical Faculty, Istanbul University, Turkey, [7]Department of Epidemiology and Preventive Medicine, Sackler Faculty of Medicine, Tel Aviv University, Israel, [8]Primary Care & Population Health, Imperial College London, UK.

Background and aims: The body mass index (BMI) is the most commonly used surrogate marker for evaluating risk of cardiovascular (CVD) mortality in relation to general obesity, while abdominal obesity indicators have been proposed to be more informative in risk prediction. We aimed to compare obesity predictors including BMI, Waist circumference (WC), waist-hip ratio (WHR), waist-stature ratio (WSR), and A Body Shape Index (ABSI) in relation to mortality from CVD and all causes among four European populations enrolled in the Diabetes Epidemiology: Collaborative analysis Of Diagnostic criteria in Europe (DECODE) Study.
Materials and methods: Mortality from CVD and all causes in relation to baseline BMI, WC, WHR, WSR, and ABSI were investigated in a prospective cohort of 46651 Europeans aged 24-99. Hazard ratios were estimated by Cox proportional hazard models using age as time-scale.
Results: During a median follow-up of 7.9 years, 3435 participants died, 1409 from CVD. All obesity measures predicted CVD mortality but the prediction was mostly stronger with abdominal obesity indicators than with BMI ($P<0.05$ for all paired homogeneity tests except for ABSI in women), and independent of the BMI levels. The WSR appeared to be the strongest predictor among all the indicators, with a linear relationship with CVD and a quadratic relationship with all-cause mortality in both men and women.
Conclusion: Abdominal obesity indicators especially for WC, WHR and WSR, are stronger predictors for CVD mortality than BMI.

Are we failing to capture the relationship between body mass index and cardiovascular disease and mortality in subjects with type 2 diabetes?

D.M. Grant[1], P. McEwan[2], V. Foos[3], J. Palmer[3], A. Lloyd[4]; [1]Health Economics and Outcomes Research, IMS Health, London, UK, [2]Centre for Health Economics, Swansea University, Cardiff, UK, [3]Health Economics and Outcomes Research, IMS Health, Basel, Switzerland, [4]Health Economics and Outcomes Research, IMS Consulting Group, London, UK.

Background and aims: There is considerable epidemiological evidence relating increasing body mass index (BMI) to an elevated risk of cardiovascular disease and mortality in subjects with type-2 diabetes mellitus (T2DM). Coronary heart disease (CHD) and mortality risk equations typically incorporate the effects of elevated BMI via the inter-relationship between modifiable cardiovascular risk factors (cholesterol and systolic blood pressure) and BMI; this approach may underestimate risk. Therefore, the objective of this study was to assess if the risk equations used in a well validated diabetes model accurately capture the relationship between BMI and the risk of CHD and total mortality.
Materials and methods: Using published observational data from the Swedish National Diabetes Register we compared the predicted incidence of fatal/nonfatal CHD (fatal/non-fatal myocardial infarction, ischaemic heart disease, unstable angina) and total mortality over a mean follow-up period of 5.6 years using the IMS CORE Diabetes Model (CDM). Hazard ratios (HR) from the model were compared with study HRs stratified by BMI after adjusting for baseline age, sex, duration of diabetes, BMI, smoking, HbA1c, blood pressure, use of antihypertensive and lipid-reducing drugs, and microalbuminuria.
Results: Comparing subjects with BMI<25 kg/m2 (mean age 60.4 years, 53.8% male; 20.7% current smokers; duration of diabetes 9.8 years; HbA1c 7.56%; SBP 141.4mmHg and BMI 23.0 kg/m^2) to those with BMI >30 kg/m2 (mean age 59.7 years, 49.0 % male; 14.7% current smokers; duration of diabetes 7.7 years; HbA1c 7.7.4%; SBP 148.0mmHg and BMI 34.1 kg/m^2) produced study HRs of 1.25 (1.09 - 1.44) and 1.47 (1.16-1.85) for CHD and total mortality respectively. HRs derived from the CDM were 1.062 (1.051-1.072) and 0.966 (0.956-0.977) for CHD and total mortality respectively.
Conclusion: This study demonstrates that despite using a diabetes model that has been shown to have good predictive validity to cardiovascular and mortality events reported across a large number of major T2DM outcomes studies the model significantly underestimates the relationship between increasing BMI and CHD and total mortality risk. There is a need for improved risk equations for use in diabetes models that adequately capture the deleterious effects of increasing body weight, particularly, if the true value of avoiding weight gain or weight loss is to be characterised.

Trajectory of body mass index before the development of type 2 diabetes in Japanese men: Toranomon hospital health management centre study (TOPICS)

Y. Heianza[1,2], Y. Arase[3,4], S. Hara[3,4], K. Fujihara[1], S. Hsieh[3,4], A. Sugawara[1], A. Suzuki[2], O. Hanyu[2], K. Saito[2,5], S. Kodama[2,6], H. Shimano[1], H. Sone[2,3]; [1]Department of Endocrinology and Metabolism, University of Tsukuba Institute of Clinical Medicine, Ibaraki, [2]Department of Internal Medicine, Niigata University Faculty of Medicine, [3]Health Management Center, Toranomon Hospital, Tokyo, [4]Okinaka Memorial Institute for Medical Research, Tokyo, [5]Center for Medical Sciences, Ibaraki Prefectural University of Health Sciences, Ibaraki, [6]Mito Kyodo General Hospital, Japan.

Background and aims: To date longitudinal data on the trajectory of general adiposity with repeated clinical measurements before the actual onset of type 2 diabetes are sparse, especially in Asian individuals who are not predominantly overweight or obese. Evidence has shown rapidly increasing levels of glycemic concentrations could be observed before the diagnosis of diabetes. However, it remains unknown in which period of the natural history of diabetes an elevated BMI, increasing BMI or stable overweight/obesity could be observed among individuals who eventually develop type 2 diabetes. We aimed to investigate the trajectory of BMI and BMI histories before the development of type 2 diabetes in apparently healthy Japanese men.
Materials and methods: We reviewed data on 2068 non-diabetic Japanese men who underwent annual health examinations. Mean BMI and incident cases of diabetes (diabetes indicated by fasting plasma glucose level ≥7.0 mmol/L, self-reported clinician-diagnosed diabetes, or HbA1c ≥6.5%) were assessed on an annual basis over 8- to 10 years after the baseline examination. BMI trajectories before the development of diabetes were retrospectively evaluated from the baseline examination until the time of diagnosis of diabetes or to the end of the follow-up.
Results: Mean (SD) BMI at the time of diagnosis was 24.4 (3.2) kg/m^2 among diabetic individuals (n=241). An increasingly high BMI was associated with the 8- to 10-y pre-diagnosis period and diabetic individuals experienced a prolonged and stable elevated BMI of ≥24 kg/m^2 (range 24.1-24.4) over the 8 y prior to the diagnosis of diabetes. The mean BMI among the non-diabetic individuals did not exceed 23.2 kg/m^2 throughout the period. When we assessed the maximum BMI and the history of excessive obesity (BMI ≥27.5 kg/m^2), the mean maximum BMI was higher among diabetic individuals than non-diabetic individuals ($p<0.001$). The prevalence of individuals with a history of excessive obesity was also significantly higher among diabetic individuals (16.2% vs. 10.4%; $p=0.007$). Results of our assessment of the duration of overweight/obesity showed that diabetic individuals were more likely to have a history of stable overweight/obesity.
Conclusion: Japanese men who eventually developed diabetes during the 10-year observation period were not characterized as obese but had stable high-normal BMIs during the 8 y prior to onset of diabetes. Previous evidence indicated that values for glycemic markers rapidly increased before the development of diabetes; however, the present study showed a slight gain in BMI in the earlier stage of the natural history of diabetes followed by a prolonged period of overweight. Our findings would contribute to efforts to prevent the further deterioration of the glycemic state through a better understanding of the trajectory of general adiposity before the onset of diabetes.

Thinness in childhood, weight gain over adolescence and risk of type 2 diabetes: a generational perspective

M. Jacota[1], A. Forhan[1], E. Eschwège[1], A. Basdevant[2], M.-A. Charles[1];
[1]Centre for Research in Epidemiology and Population Health, INSERM U1018, Villejuif, France, [2]Institute of Cardiology metabolism and nutrition, ICAN, Paris, France.

Background and aims: Several growth trajectories in childhood have been associated with the risk of type 2 diabetes (T2D). We evaluated the link between adulthood T2D and the corpulence history between 8 and 18 years in a gender and generational perspective.
Materials and methods: Among the national sample of adult respondents to the ObEpi 2009 French survey, we included the subjects with available self-reported silhouettes at 8 and 18 years, diabetic status and maximum BMI in adulthood. We analyzed the relationship between T2D and silhouettes (thinnest: A to largest: G, regrouped in 4 main categories), as well as growth trajectories by logistic regression. We tested interactions with current age in three strata: 40-59 years, 60-79 years and 80 years or older.
Results: The inclusion criteria selected 23763 subjects (50.1±17.3 years, 52.8% women, 5.6% T2D). At age 8, leaner silhouettes (AB and C) were positively associated to T2D before and after adjustment on maximal adult BMI: adjusted ORs 1.54 (95%CI 1.30-1.82) and 1.35 (1.14-1.60) versus middle silhouette (D). The largest silhouettes at 18 years were significantly associated with T2D but the adjustment for maximum BMI reversed the association. The positive association T2D-large corpulence at 18 years persisted after adjustment only in the younger generation of men (40 to 59 years): adjusted OR 1.70 (1.04-2.79). For a similar maximum BMI in adulthood, subjects with the leanest silhouettes at 18 years had a higher risk of diabetes than the reference (D): OR 1.29 (1.09-1.52). In adjusted models, subjects of a D figure at age 8 had significantly protective ORs if growing thinner in adolescence, especially women: OR 0.54 (0.36-0.82), but change for a larger silhouette between 8 and 18 years increased the risk, especially in men: OR 1.51 (1.01-2.24).
Conclusion: Our results confirm, in a French context and for all age strata, previous data that childhood leanness is a risk factor for diabetes. They also show the detrimental effect of adolescent weight gain, independently of the obesity level reached in adulthood.

Adiposity and all-cause mortality in individuals with type 1 diabetes

E. Fagerholm[1,2], C. Forsblom[1,2], V. Harjutsalo[1,2], L. Thorn[1,2], N. Tolonen[1,2], S. Hägg[1,2], M. Saraheimo[1,2], D. Gordin[1,2], J. Wadén[1,2], P.-H. Groop[1,2], FinnDiane Study Group;
[1]Folkhälsan Institute of Genetics, Helsinki, [2]Department of Medicine, Division of Nephrology, Helsinki University Central Hospital, Finland.

Background and aims: The relationship of BMI with mortality in type 1 diabetes (T1D) has been suggested to start to resemble that of the general population, although with an exacerbated risk for mortality among the underweight. However, BMI may not capture the whole picture. We thus examined the relationship of mortality with different measures of adiposity: WHR, which specifically measures body fat distribution unrelated to BMI, Body Adiposity Index (BAI), which estimates the percent adiposity directly, as well as BMI in a large cohort of patients with T1D
Materials and methods: 4,426 patients with T1D (2322 M/2104 F, age 38.8±12.4 years, BMI 25.1±3.6 kg/m2) were followed until death (n=596 deaths) or for a mean of 11.2±3.4 years. HRs were calculated using Cox regression analysis for predefined WHO obesity categories (BMI) and for quartiles (BMI, BAI and WHR). Quartiles were created separately for men and women and thereafter combined for analysis. All analyses were adjusted for age, sex and duration of diabetes. Analyses were further stratified according to renal status into patients with and without end-stage renal disease (ESRD).
Results: Prevalence of overweight and obesity was 37.1% and 9.0%, respectively. The HRs for mortality are shown in Table. Underweight increased the risk for mortality even after stratification for ESRD (HR= 2.27 [1.21-4.25] with ESRD and HR=2.84 [1.26-6.43] without ESRD). Obesity was associated with mortality, without reaching statistical significance when all patients were included. However, obesity was a significant predictor of mortality among patients without ESRD (1.55 [1.15-2.09]). All quartiles of WHR increased the risk of mortality gradually with increasing quartile, even after stratification among patients without ESRD, but not in patients with ESRD. Quartiles of BAI did not predict mortality in this cohort.
Conclusion: The risk of mortality increased in parallel with higher quartile of WHR while there was a reversed J-shaped relationship between BMI and mortality, where the highest mortality risk was observed among underweight patients. BAI was not related to increased risk of mortality.

Risk of mortality in adiposity class (WHO) or quartile.

BMI WHO class	Underweight <18.5	Normal weight 18.5-24.9	Overweight 25.0-29.9	Obesity >30

The development of age-related time-to-event epidemiological models: the importance of age of type 2 diabetes diagnosis by gender and BMI

E.L. Badrick, I. Buchan, M. Sperrin, M. Carr, A. Renehan;
Institute of Population Health, University of Manchester, UK.

Background and aims: We have previously demonstrated the improved predictive ability of using age-related residual time-to-event modelling in the evaluation of disease risk, such as cancer-related outcomes. As an introduction to modelling body mass index (BMI) and cancer-related mortality in patients with type 2 diabetes, we explored the hypothesis that men develop type 2 diabetes at an earlier age compared with women across the range of body mass index (BMI) and waist circumference (WC) values.
Materials and methods: Data were analysed on 248,917 persons from the Salford Integrated Records healthcare electronic system, a stable predominantly Caucasian population, North West of England (1995 to 2010). Type 2 diabetes was defined based on age criteria (> 35 years), conservative text terms, and medication usage (n=14172). Data were available on BMI, WC, smoking and HbA1c (any measures recorded as a percentage using the DCCT method were converted into nmol/mol to conform to the IFCC standard) in 86%, 21%, 85%, and 63%, respectively. We modelled relationships between anthropometric measures and age, by gender, using linear regression.
Results: The mean ages at diagnosis per BMI category are shown in the Table - these decreased in men and women with increasing BMI category; mean ages were younger in men compared with women per BMI category. In regression models for age versus BMI sex is significant (in men compared to women the beta coefficient is -1.71 (-1.93- -1.49). In models separated by gender: the beta coefficient was -0.11 (95% CIs: -0.10 to - 0.12, p<0.001) in men; and -0.15 (-0.14 to -0.17, p<0.001) in women. The influence of smoking status on the model was significant for men and women (p<0.05). The mean ages at diagnosis per WC tertile are also shown in the Table - again, these decreased in men and women with increasing WC tertiles; mean ages were younger in men compared with women per WC tertile (significant difference between men and women p<0.001). For age versus WC, the beta coefficient was -0.16 (-0.09 to -0.23), p<0.001) in men; and significantly greater for women; -0.36 (-0.28 to -0.44, p< 0.001). There were no material effects on these relationships with the addition of HbA1c to the models.
Conclusion: A limitation of this study is high proportion of missing data for some of the variables examined. Nonetheless, with a population-based setting, the findings uphold the hypothesis that men develop type 2 diabetes at an earlier age compared with women across the range of body mass index (BMI) and waist circumference (WC) values. The baseline characterisations will inform more advanced modelling of BMI trajectory with cancer-related

outcomes in patients with type 2 diabetes, which in turn, will better inform clinical and health policy.

Age at menarche and type 2 diabetes risk: the EPIC-InterAct study

C. Elks, The InterAct Consortium;
MRC Epidemiology Unit, Cambridge, UK.

Background and aims: Earlier age at menarche, a marker of pubertal timing in girls, is associated with higher risk of later type 2 diabetes. We aimed to confirm this association in a multi-centre European study and to examine whether it is explained by adiposity.
Materials and methods: The prospective EPIC-InterAct case-cohort study consists of 12403 incident type 2 diabetes cases and a stratified sub-cohort of 16154 individuals from 26 research centres across eight European countries. We tested the association between age at menarche and incident type 2 diabetes using Prentice-weighted Cox regression in 15168 women (including 5995 diabetes cases). Models were adjusted in a sequential manner for potential confounding and mediating factors, including adult body mass index (BMI).
Results: Mean menarcheal age ranged from 12.6 to 13.6 years across InterAct countries. Each year later of menarche was associated with 0.32 kg/m2 lower adult BMI. Women in the earliest menarche quintile (8-11 years, n=2418) had 70% higher incidence of type 2 diabetes compared with those in the middle quintile (13 years, n=3634), adjusting for age at recruitment, research centre and a range of lifestyle and reproductive factors (Hazard Ratio=1.70; 95% CI 1.49-1.94, P<0.001). Adjustment for BMI partially attenuated this association (HR=1.42; 95% CI 1.18-1.71, P<0.001). Later menarche beyond the median age was not protective against type 2 diabetes.
Conclusion: Women with history of early menarche have higher risk of type 2 diabetes in adulthood. Less than half of this association appears to be mediated by higher adult BMI, suggesting that early pubertal development may also directly increase type 2 diabetes risk.

Type 2 diabetes and cardiovascular risks are present in adolescent girls with polycystic ovaries morphology

M.I. Bak[1], M. Walewska-Wolf[2], J. Szufladowicz-Wozniak[2];
[1]Dept. of Gastroenterology and Metabolic Diseases, Medical University of Warsaw, [2]The Children's Memorial Health Institute, Warsaw, Poland.

Background and aims: The association between obesity, insulin sensitivity and metabolic risks is already evident in adolescence. Insulin has a central role in the regulation of pubertal development; furthermore insulin resistance and corresponding hyperinsulinemia are important factors reflecting early signs of PCOS. Menstrual disorders in adolescence are a marker of the development of PCOS in adulthood. Therefore identifying the subset of girls with polycystic ovary morphology may provide data regarding the mechanisms for the development of PCOS and also could explore the role of insulin resistance as an early factor for diabetes and cardiovascular diseases in later life.
Materials and methods: Consecutive 91 girls with menstrual irregularity and polycystic ovary morphology on ovarian USG (age 11-18 years) were divided into 2 groups: obese (OBS, n=38) and with normal BMI (NOR, n=53). In all girls we took a medical history, complete physical examination and detailed biochemical and endocrine profile. Then, we measured glycemic and insulinemic response (INS, mUI/ml) to 75g OGTT.
Results: Fasting plasma glucose was normal in all girls, in both study groups. However, 27% of the OBS participants met the criteria for impaired glucose tolerance diagnosis. All tested girls had various degree of hyperandrogenemia. Fasting and post challenge insulinemia, insulin resistance (IR-HOMA) were significantly higher in the obese PCO girls. (TABLE - All results are means ± SEM,*, NOR vs. OBS P<0.01)
Conclusion: Although the metabolic interrelationship between obesity and PCOS development have not yet to be fully understood, the co-occurrence of significant differences in adipokines, namely dramatically low levels of adiponectin and high levels of leptin, and severe peripheral insulin resistance in adolescent girls could have a significant impact on the development of diabetes and emerges as a risk factors for developing cardiovascular complications in later life.

Results in both study groups		
Group	NOR	OBS
BMI	22 ± 0.3	30 ± 0.5*
SBP (mm Hg)	106.5 ± 2.4	126.5 ± 1.5*
IGTolerance (%)	11%	27%*
Fasting INS	13 ± 0.7	22 ± 1.0*
OGTT-120 min INS	88 ± 4	194 ±14*
IR-HOMA	2.9 ± 0.2	4.9 ± 0.3*
Adiponectin (mg/ml)	11.4 ± 1.6	5.8 ± 1.3*
Leptin (ng/ml)	8.5 ± 2.3	24.1 ± 4.2*

Cluster of insulin resistance and other metabolic risk factors predicts AMI morbidity in a Swedish population

C.A. Larsson[1,2], B. Daka[2], M. Hellgren[3], J. Eckner[3], L. Råstam[4], U. Lindblad[3];
[1]Department of Clinical Sciences, Malmö, Division of Social Medicine and Global Health, Lund University, Malmö, [2]Department of Primary Health Care, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, [3]Department of Primary Health Care, Institution of Medicine, Sahlgrenska Academy, University of Gothenburg, [4]Department of Clinical Sciences, Malmö, Division of Community Medicine, Lund University, Malmö, Sweden.

Backgrounds and aims: Risk factors for acute myocardial infarction (AMI) are known to cluster and insulin resistance is often included in such clusters; e.g. in the metabolic syndrome. The aim of the present study was to sex-specifically explore clusters of acknowledged risk factors for AMI, including metabolic factors such as insulin resistance, and to study whether such clusters are associated with AMI morbidity.
Materials and methods: In 2002-2005, 2816 subjects (30-74 years) were randomly selected from two municipalities in south-western Sweden (participation-rate 76%), and assessed with regard to cardiovascular risk factors. For the present study, 2328 subjects without known diabetes or hypertension were included.
Results: Factor analysis identified three identical factors in men and women. Homeostasis model assessment of insulin resistance (HOMA-ir), WHR, systolic blood pressure, and apolipoprotein B-to-A1 ratio loaded significantly on the principal "metabolic factor", leisure-time physical activity and self-rated health loaded significantly on the "vitality factor", and smoking and alcohol consumption loaded significantly on the "addiction factor". After a mean follow-up of 8 years, there were 29 first events of AMI in men and 7 in women. In a cox proportional hazard regression, adjusted for all factors, age, and educational level, only the metabolic factor was significantly associated with AMI morbidity in men, with a hazard ratio (HR) of 2.4 (95% CI: 1.6-3.5). There was a similar risk increase in women; however, due to the lower power in women the adjusted HR was only borderline-significant (HR: 1.9; CI: 0.96-3.9). When adding men and women together and instead adjusting the analysis also for sex, the HR was 2.3 (1.6-3.2).
Conclusion: Metabolic risk factors commonly known to constitute the metabolic syndrome clustered together in the present study and predicted AMI morbidity. As insulin resistance is believed to be one of the main factors that drive the metabolic syndrome and as it is also one of the main precursors to type 2 diabetes, these findings highlight the need of early preventive actions in insulin resistant men and women to decrease their risk of AMI.

Predictors of normalisation of prediabetes and of persistence of normal glucose tolerance

T.G. Dzebisashvili;
Endocrinology, Moscow Regional Research Clinical Institute named by M.F.Vladimirskiy, Moscow, Russian Federation.

Background and aims: Reversion from prediabetes to normal glucose tolerance (NGT) without specific interventions has been rarely studied. We investigated in a population - based study which factors beyond blood glucose (lifestyle variable, clinical parameters) are associated with normalization of glucose tolerance. In addition, we investigated which factors contribute to long-term persistence of NGT.
Materials and methods: Population-based screening for glucose metabolism impairments (GMI) among 2508 adults in Moscow County was conducted in 2006. 661 subjects participated in the 3 - year follow - up, among which 110 had prediabetes and 464 had NGT at baseline. Subjects who were prediabetic at baseline and normoglycaemic at follow up were only classified as "return to NGT". GMI at baseline and at follow -up was diagnosed using standard OGTT according to WHO 1996/2006 criteria. OR and regression coefficient (B) was calculated using logistic regression analysis.
Results: 29 of 110 (26%) subjects who had been prediabetic at baseline returned to NGT after 3 year. In a logistic regression model with age, sex, BMI, change of BMI, glucose values, hypertension, diabetes family history and smoking as independent variables, age(p=0.002), fasting plasma glucose (FPG) (p=0.044), hypertension (p=0.005) and smoking (p=0.005) were significant predictors of normalization of prediabetes. After adjustment for all possible confounders, higher levels of FPG (B= - 1.608, p=0.011) and 2h glucose (B= - 0.340, p=0.023), higher levels of systolic hypertension (B= - 0.031, p=0.032) and less smoking (B= 0.706, p=0.006) significantly decreased the chance of returning to NGT. Among 464 subjects with NGT (baseline) 336 (72%) remained normoglycaemic in the 3 - year follow - up. In adjusted logistic regression model with age, sex, BMI, change of BMI, glucose values, hypertension, diabetes family history and smoking as independent variables, higher levels of FPG (B= - 1.041, p<0.001) and 2h glucose (B= - 0.214, p=0.011), higher BMI at baseline (B= - 0.069, p=0.001) decreased the likelihood of NGT persistence. For BMI change, decrease in BMI improves the likelihood of NGT persistence (OR, 95%CI: 2.8, 1.4 - 5.7 for BMI change <= - 1kg/m², compared to BMI change > 1kg/m²).
Conclusion: Reversion to NGT without specific interventions is not a rare event in prediabetic subjects. Systolic hypertension and smoking influence on normalization of prediabetes in 3 years. BMI and change of BMI are both related to persistence of NGT.

Comparison between indexes of insulin sensitivity for risk prediction of cardiovascular diseases or development of type 2 diabetes

B. Zethelius[1], J. Cederholm[2];
[1]Dept. of Public Health and Caring Sciences/Geriatrics and Medical Products Agency, [2]Dept. of Public Health and Caring Sciences/Family Medicine and Preventive Medicine, Uppsala, Sweden.

Background and aims: The predictive effect of various insulin sensitivity indexes for risk of cardiovascular diseases (CVD) or type 2 diabetes (T2DM) is still unclear. We assessed two recent indexes, estimated at oral glucose tolerance test (OGTT), ISI-Ceder and ISI-Matsuda, with ISI-HOMA estimated using fasting glucose and insulin, and with M/I at the euglycemic insulin clamp as reference, in a large sample of subjects performing these tests.
Materials and methods: 71-years-old male participants (n=1049) from the Swedish ULSAM study, mean follow-up 9 years. All subjects performed the euglycemic insulin clamp with estimation of M/I [glucose disposal/mean plasma insulin], and a 75-g OGTT including insulin determinations with estimation of ISI-Ceder: metabolic clearance rate/mean plasma glucose/ log mean plasma insulin; ISI-Matsuda: 10,000/square root of [glucose0 (min) x insulin0 x glucose 120 x insulin120] and ISI-HOMA: 22.5 x 18 / [glucose0 x insulin0], respectively.
Results: Bland-Altman plots showed best agreement between M/I and ISI-Ceder with mean difference near zero, -0.07 (95% confidence intervalls: -1.52-1.66), while deviating from zero for M/I versus ISI-Matsuda-, -0.73 (-2.38-0.91) and M/I versus ISI-HOMA -0.85 (-2.89-1.19). Further, ISI-Ceder was a stronger predictor with best model fit at Cox regression for risk of non-fatal/fatal ischemic heart disease, CVD, and total mortality, when adjusted for BMI, systolic BP, smoking status, blood lipids, cystatin-C, microalbuminuria, Charlson-index and also the metabolic syndrome. Results for nonfatal or fatal CVDs combined are presented in table 1. Comparing highest versus lowest quartiles of each index, hazard ratios for these outcomes were strongly significant only using ISI-Ceder. Furthermore, ISI-Ceder was a stronger predictor for risk of development of T2DM in 1024 subjects free from T2DM at baseline, with best model fit at logistic regression, and also highest c-statistic, 0.84, when adjusting for BMI, systolic BP, HDL cholesterol, smoking, Charlson index as presented in table 1.
Conclusion: ISI-Ceder performed better as a predictor of risk for CVD/mortality and T2DM than ISI-Matsuda, ISI-HOMA and M/I, respectively.

Table 1. Type 2 diabetes and CVD prediction by indexes

Outcome		All patients						Q4 versus Q1	
T2DM (n=56)		OR [a]	Wald				C	OR [b]	P
CVDs (n=181)		(95% CI)	X^2	P	LR	AIC	stat	(95% CI)	value
T2DM	ISI-Ceder	0.12 (0.06-0.22)	43	<0.001	93	355	0.84	0.08 (0.02-0.26)	<0.001
	ISI-Matsuda	0.17 (0.08-0.38)	19	<0.001	57	391	0.78	0.11 (0.03-0.33)	<0.001
	M/I	0.59 (0.39-0.89)	6.3	0.01	34	414	0.71	0.48 (0.18-1.26)	0.1
	ISI-HOMA	0.35 (0.17-0.72)	8.1	0.004	38	410	0.72	0.37 (0.16-0.84)	0.02

	ISI-Matsuda	0.73 (0.59-0.92)	7.4	0.006	51	2402	0.65	0.53 (0.31-0.93)	0.03
	M/I	0.80 (0.65-0.97)	5.2	0.02	47	2405	0.65	0.62 (0.34-1.13)	0.1
	ISI-HOMA	0.81 (0.65-1.02)	3.2	0.07	46	2409	0.65	0.86 (0.50-1.48)	0.6

Table 1. The ability of various indexes of insulin sensitivity to predict T2DM and CVDs during a follow-up for a mean of 9 years.

-

Results from logistic regression in 1024 male participants free from T2DM at baseline and from cox regression in the total sample of 1049 male participants.

-

T2DM - Adjustments for BMI, systolic BP, HDL-chdesterol, smoking and Charlson index.

-

CVDs - Adjustments for BMI, systolic BP, smoker, LDL and HDL cholesterol, triglycerides, cystatin C, microalbuminuria, Charlson index, a history of CVD and of the metabolic syndrome.

-

[a] Indexes with increase per 1 SD to allow direct comparison between odds ratios (OR) and between Hazard Ratios (HR), respectively.

[b] ORs and HRs, respectively, with patients within the highest quartile (Q4) compared to lowest (Q1) as reference.

-

Wald X^2 statistic: a higher value indicates stronger association between a predictor and the outcome. Likelihood ratio (LR) X^2 statistics: a higher value indicates a better global model fit. AIC (Akaike Information Criteria): a lower value indicates a better model fit. C statistic: a higher value indicates a better discrimination. Q denotes quartile.

Plasma fibrinogen level as a predictor of incident metabolic syndrome in a community-based prospective study in Hong Kong Chinese

C.Y. Yeung[1], E.Y.L. Hui[1,2], T.H. Lam[3], W.S. Chow[1], Y.C. Woo[1], C.H.Y. Fong[1], A. Xu[1,2], B.M.Y. Cheung[1,2], K.S.L. Lam[1,2];
[1]Department of Medicine, The University of Hong Kong, Hong Kong, [2]Research Centre of Heart, Brain, Hormone and Healthy Aging, [3]School of Public Health, Li Ka Shing Faculty of Medicine, The University of Hong Kong, Hong Kong SAR

Background and aims: Metabolic syndrome (MS) comprises a constellation of metabolic abnormalities associated with a high risk of developing diabetes and cardiovascular diseases. Central obesity, with related insulin resistance and inflammation are considered the core of the underlying pathogenesis of MS. Fibrinogen, an acute-phase reactant in the coagulation cascade, has been shown to play pivotal role in determining the extent of local or systemic inflammation. In this study, we examined whether plasma fibrinogen was predictive of incident MS in a community-based Chinese cohort.
Materials and methods: Subjects were recruited from the Hong Kong Cardiovascular Risk Factors Prevalence Study (CRISPS) cohort. 2780 subjects were recruited in 1995-6 with baseline assessment performed. 1416 subjects without MS at baseline returned in 2005-8 for reassessment. MS was defined by ATP III criteria with waist circumference modified according to Asian cut-offs.
Results: Of the 2780 subjects at baseline, 560(20.1%) had MS. Fibrinogen level correlated positively with age, fasting glucose, waist circumference, systolic and diastolic BP, and triglycerides and inversely with HDL (all p<0.001). Fibrinogen level increased with the number of components (0 to 5) of MS (p<0.01) and was significantly higher in subjects with MS (p<0.001). Of the 1416 patients without MS at baseline, 286(20.2%) developed MS in 2005-8 reassessment. Subjects who had incident MS, when compared with those without, were older (45.7±11.2 vs 42.1±11.8, p<0.01) and had higher fibrinogen level (2.53[2.20-2.93] vs 2.40[2.10-2.79], p=0.001) at baseline. There was no difference in gender or smoking status. On multivariate analysis, baseline fibrinogen remained to be an independent predictor for incident MS with age-adjusted HR 1.92 (1.03-3.55, p=0.039) per log unit increase in fibrinogen.
Conclusion: Our findings confirmed plasma fibrinogen level, an indicator of inflammation, is an independent predictor of metabolic syndrome in this community-based Chinese cohort.

Polymorphisms of the AGER gene are related to serum levels of soluble receptor for advanced glycation end products and autoantibody frequencies in children with type 1 diabetes

K.M. Salonen[1], S. Ryhänen[1], J.M. Forbes[2], A.-P. Laine[3], J. Ilonen[3,4], P.-H. Groop[5,6], M. Knip[1,5], The Finnish Pediatric Diabetes Register; [1]Children´s Hospital, University of Helsinki, Finland, [2]Baker IDI Heart & Diabetes Institute, Melbourne, Australia, [3]Immunogenetics Laboratory, University of Turku, Finland, [4]Department of Clinical Microbiology, University of Eastern Finland, Finland, [5]Folkhälsan Research Center, Helsinki, Finland, [6]Department of Nephrology, Department of Medicine Helsinki University Central Hospital, Biomedicum Helsinki, Finland.

Background and aims: The receptor for advanced glycation end products (RAGE) is a multiligand receptor involved in inflammatory and immune responses. RAGE and the encoding gene AGER are associated with the pathogenesis of type 1 diabetes (T1D) and the development of its complications. Strong linkage disequilibrium has been described earlier between AGER polymorphisms and HLA class II genes.
Materials and methods: The subjects (n=1444) were derived from the Finnish Pediatric Diabetes Register and Biobank. We analyzed three single nucleotide polymorphisms (SNPs) of the AGER gene associated with HLA-DR/DQ independent risk for T1D (rs2070600, rs9469089 and rs17493811) for possible associations with serum levels of soluble RAGE (sRAGE).
Results: T1D risk associated variants of two studied SNPs were found to correlate with lower levels of soluble RAGE. The mean level in subjects with the TT genotype of the rs2070600 (n=14) was 475 pg/ml compared to 932 pg/ml in CT (n= 309) and 1241 pg/ml in CC (N=1121) carriers [p<0.001 (ANOVA)], and the mean levels among subjects with various rs9469089 genotypes were 1140 pg/ml in GG homozygotes (N=980), 1214 pg/ml in CG heterozygotes (N=436) and 1401 pg/ml in CC homozygotes (N=28) [p<0.001 (ANOVA)]. Carrying the minor allele of the rs2070600 correlates with the frequency of IAA [54% vs. 43%, p<0.001(χ2)], whereas the protective minor allele of the rs9469089 is positively related to ZnT8A frequency [68% vs. 59%, p=0.009(χ2)] and inversely with IAA frequency [39% vs. 48%, p=0.001(χ2)]. Correlations between SNPs and autoantibody frequencies remained significant after controlling for the effect of age, sex and HLA genotype with logistic regression.
Conclusion: The association of two T1D risk affecting AGER gene SNPs with lower levels of soluble RAGE in children with newly diagnosed disease implies that polymorphisms of the gene influence the serum sRAGE levels. Studies in prediabetic children will be needed to assess the role of sRAGE levels in the development of T1D. The observed association between AGER gene polymorphisms and humoral autoimmunity suggests that the RAGE genotype might influence the autoimmune process leading to T1D.

The serum activity of p53 in people with and without type 2 diabetes mellitus and its relation to the diabetes duration

J. Drzewoski[1], J. Kasznicki[1], M. Kosmalski[1], I. Majsterek[2], A. Śliwinska[1];
[1]Department of Internal Disease, Diabetology and Clinical Pharmacology, Medical University of Lodz, Zgierz, [2]Department of Chemistry and Clinical Biochemistry, Medical University of Lodz, Poland.

Background and aims: Growing evidence indicates that ageing is associated with cellular senescence that is manifested by irreversible cell growth arrest. Previously, cellular senescence was thought to be a results of shortening of the telomeres with each cell division. However, recently it has become clear that cellular senescence can be also induced by various stresses that damage DNA independently of cell replication. This complex process is controlled by tumor suppressor proteins, including p53 and pRb. T2DM patients reveal increased level of oxidative stress induced DNA damage. Since, the activity of p53 is associated with oxidative stress that accompanies T2DM we performed the analysis of serum activity of p53 in relation to the T2DM duration.

Materials and methods: The study population consisted of 241 unrelated Caucasians, recruited between 2008 and 2012, matched for sex and age enrolled into two groups: 165 T2DM patients and 76 control subjects with normal glucose homeostasis. All patients were not supplemented by any antioxidants. The study was approved by the Bioethical Committee of the Medical University of Lodz and met the tenets of the Declaration of Helsinki. Written consent was obtained from each patient. Assessment of anthropometric and biochemical parameters was performed. Plasma glucose, HbA1c and lipids were assayed by routine automated laboratory methods. The serum activity of p53 [U/mL] was determined in duplicate with competitive ELISA kits. All data were expressed as mean ± SD. Differences between mean values were tested using One-Way Anova test. P-value less than 0.05 were considered statistically significant.
Results: We noted that the serum activity of p53 calculated for the entire group of people with T2DM was significantly higher than in subjects without T2DM (2.49 ± 0.14 v 1.96 ± 0.13; p=0.019). However, the highest activity of p53 was found in patients with T2DM duration >10 years (3.32 ±2,54 vs 1.96±1.17; p≤0.001). Results and clinical characteristic of T2DM patients and control subjects are presented in Table 1.
Conclusion: In this study we show that the serum activity of p53 is significantly higher in people with than without T2DM. In addition, we found that the level of p53 activity appears to be associated with T2DM duration. Both of these findings may at least partially support hypothesis that p53 plays a role in cellular aging associated with diabetes and its duration.

Retrospective analysis of the Japanese diabetes risk score for incident diabetes and urinary albumin excretion in 2084 subjects and comparison with fatty liver markers

S. Katoh[1], H. Takahashi[1], M. Kaji[1], M. Zeniya[1], Y. Sakamoto[1], K. Utsunomiya[2]; [1]Jikei University Harumi Triton Clinic, [2]Department of Internal Medicine, Jikei University School of Medicine, Tokyo, Japan.

Background and aims: The Finnish Diabetes Risk Score is a questionnaire used for detecting Europeans at high risk of developing type 2 diabetes. We modified it to create the Japanese Diabetes Risk Score (JPDRISC). Fatty liver and urinary albumin excretion (UAE) are risk factors for incident diabetes and cardiovascular disease, respectively. Variables of fatty liver are not included in the above scores. Moreover, the association between the above risk scores and UAE has yet to be sufficiently investigated. We retrospectively examined the odds ratio of JPDRISC for incident diabetes and compared it with fatty liver markers including serum cholinesterase (ChE). We also examined associations among JPDRISC, ChE and UAE.
Materials and methods: Study periods I and II were defined as January 2007 to May 2009 and June 2009 to December 2011, respectively. A total of 2084 subjects (1389 men, 695 women; mean age: 46 years) who underwent an annual medical check-up including blood sampling after an overnight fast in Periods I and II were assigned to JPDRISC analysis. They were accumulated as representatives of the regional population. In this study, diabetes was diagnosed by prescription of antidiabetic agents, fasting plasma glucose (FPG) ≥ 6.8 mmol/l, HbA1c (NGSP) ≥ 6.5% and/or a past history of diabetes in those not yet treated with antidiabetic agents.
Results: A total of 103 subjects were diagnosed with diabetes in Period I and excluded from analysis. The mean observation period was 2.23 years, with 42 subjects with newly developed diabetes from Periods I to II. The remaining 1939 subjects were nondiabetic. In logistic regression analysis, both JPDRISC (p=0.0003) and ChE (p=0.0169) in Period I were significantly associated with incident diabetes. In receiver operating characteristic analysis, the specific cut-off point in JPDRISC for detecting incident diabetes was 5.5 points (AUC 0.76, p<0.001, sensitivity 68%, specificity 0.71). In those with a JPDRISC ≥ 5.5 points (n=497), the odds ratio for incident diabetes was 5.2 (95%CI 2.5-10.1, $\chi 2$ p<0.0001) compared with others (n=1179). In those with a ChE ≥ 369 U/l (n=503), the odds ratio for incident diabetes was 4.1 (95%CI 2.2-7.9, $\chi 2$ p<0.0001) compared with others (n=1006). The UAE in Period II was significantly associated with fasting plasma glucose (FPG) and HbA1c in Period I (p<0.0001, r=0.3, both), but only very weakly with JPDRISC and systolic BP in Period I (p<0.05, r<0.1, both). The UAE in Period II was not significantly associated with ChE in Period I (p=0.2, r<0.1). In linear regression analysis, HbA1c (β=0.17, p<0.0005), systolic BP (β=0.20, p=0.02) and serum creatinine (Cr) (β=0.25, p<0.0001) in Period I were significantly associated with UAE in Period II.
Conclusion: The JPDRISC is more useful than ChE alone. UAE in period II was associated with HbA1c in Period I, but only very weakly with JPDRISC and not associated with ChE in Period I. Both JPDRISC and ChE affect incident diabetes, with elevated HbA1c being associated with increased UAE.

Fatty liver disease accompanies loss of glycaemic control on the 5 years follow-up of a previously non-diabetic population

R.T. Ribeiro[1,2], M.P. Macedo[1,3], L. Gardete-Correia[1,2], R. Duarte[1,2], J.M. Boavida[1], I. Correia[1,2], Z. Peerally[1], F.O. Martins[3], J.F. Raposo[1,3]; [1]ERC - Education and Research Center, APDP - Diabetes Portugal, [2]SPD - Portuguese Society of Diabetologia, [3]CEDOC - Faculty of Medical Sciences, Lisboa, Portugal.

Background and aims: Diabetes and fatty liver disease are rising epidemics. PREVADIAB, the first Portuguese nationwide study on the prevalence of diabetes, showed that 11,7% of the population had diabetes; and nearly 25% presented at least one kind of defect of glycemic profile encompassed by IFG, IGT, or both ("prediabetes"). Five years after the initial study, we aimed to evaluate the evolution of glycemic control and the prevalence and impact of fatty liver on a follow-up study.
Materials and methods: People evaluated on the first PREVADIAB as non-diabetics (either designated "normal" or "prediabetes" based on both fasting glycaemia and 2h post-load challenge) were called for reassessment. Thus, subjects aged 23-83 years, from 33 Health Centers, were recruited 5 years after the original call. An OGTT was performed to evaluate glycemic control, and biochemical parameters were quantified. Fatty liver status, and peripheral and hepatic insulin sensitivity were estimated through surrogate indexes already validated on human studies (FLI, ISI, and HIR).
Results: The present cohort consisted of 519 people, representative of the overall distribution observed on the first study. The prevalence of diabetes, after only 5 years follow-up, was 9,6%. Additionally, IFG was 4,0%, IGT was 13,1%, and IFG+IGT was 3,3%, to a cumulative indication of "prediabetes" of 20,4%. In relation to the deterioration of glycemic control, 60% of individuals initially assessed as IFG+IGT have progressed to diabetes, while it happened in around 20% of IGT and IFG. Of normal individuals only 5% progressed to diabetes (T2D). Mean Fatty Liver Index (FLI) was found to be increasingly higher throughout disglycemic worsening, in comparison with normal glycemic control (FLI: 44.5±1.3 for normal subjects versus 56.4±3.1 for IGT, p<0.01; 62.5±4.5 for IFG, p<0.05; 64.3±5.6 for IFG+IGT, p<0.05; 70.2±3.4 for T2D, p<0.001). In terms of prevalence, fatty liver condition was identified on 66.0% of individuals with diabetes, and in almost half of people with "prediabetes" (47.0% of IFG+IGT, 47.6% of IFG, and 44.1% of IGT). Surprisingly, fatty liver was nonetheless identified on 28.9% of people with normal glycemic control. Hepatic insulin resistance was shown to correlate directly with FLI progression (r=0.631). Also, it showed a correlation with fasting hyperglycaemia (r=0,330), and, even stronger, with 2h post-OGTT hyperglycaemia (r=0.543), p<0.0001 for all. This seems consistent with the decrease in peripheral insulin sensitivity observed in all disglycemic groups in relation to normal individuals (from 271.6±6.1 for normal to 200.4±20.1 for IFG, p<0.05; 143.0±3.0 for IGT, p<0.001; 121.5±7.2 for IFG+IGT, p<0.001; and 122.5±5.3 for T2D, p<0.001).
Conclusion: The liver has a central role in energy homeostasis, and should be expected to influence not only hepatic glucose fluxes but also whole-body

glucose homeostasis. Here, we have shown that fatty liver is a prevalent condition in a previously non-diabetic population, and that it is strongly related to a worsening in glycemic control, both fasting and postprandial. This leads us to believe that one third of the normoglycemic population may be particularly prone to develop disglycaemia due to a present condition of fatty liver.

Metabolomic profiling identifies biomarkers associated with dysglycaemia and incident type 2 diabetes in the METSIM study
J. Cobb[1], H. Cederberg[2], K. Pappan[1], M. Mitchell[1], K.-P. Adam[1], P. Gunst[1], J. Kuusisto[2], M. Laakso[2];
[1]Metabolon, Durham, USA, [2]Department of Medicine, University of Eastern Finland and Kuopio University, Finland.

Background and aims: Type 2 diabetes can be delayed or prevented with lifestyle or drug interventions in at risk subjects. There remains a need to better identify these at risk patients as they would be expected to benefit the most from early intervention. The aim of this work was to identify candidate biomarkers of dysglycaemia and for the prediction of type 2 diabetes.
Materials and methods: Age-matched case (N=220) and control (N=440) subjects (mean age: 60 years) were taken from the METSIM (Metabolic Syndrome in Men) Study including Finnish men. All subjects in this observational study were non-diabetic at baseline by both OGTT and A1C criteria. Case subjects were diagnosed with type 2 diabetes within the 5 year follow-up period and displayed this glycemic profile at baseline: 45% IFG, 7% IGT, and 38% combined IFG/IGT. Control subjects displayed normal fasting glucose and normal glucose tolerance at both baseline and at the 5 year follow-up. Non-targeted metabolomic profiling was carried out on fasted plasma samples using gas chromatography or ultrahigh performance liquid chromatography coupled with tandem mass spectrometry to identify metabolites whose levels differed in the case and control groups.
Results: A total of 404 named, identified metabolites were measured semi-quantitatively. Two-way ANOVA with contrasts and decision tree analysis was used to identify and stratify metabolites on their ability to separate cases from controls. All metabolites listed below have ANOVA p values $<5x10^{-6}$ (cases vs controls at baseline). Not surprisingly, given the high rate of dysglycaemia in the case group, glucose was the most significant metabolite found. The results replicated reports for several metabolites previously linked to incident type 2 diabetes: branched-chain amino acids (leucine, isoleucine, and valine), tyrosine, glycine, 2-hydroxybutyrate, and 1-linoleoylglycerophosphocholine (LGPC). A number of other metabolites associated with dysglycaemia and incident T2D were also identified. These include several compounds linked to branched-chain amino acid catabolism (3-methyl-2-oxovalerate, 4-methyl-2-oxopentanoate, 3-hydroxyisobutyrate, isovalerycarnitine, 2-methylbutyrylcarnitine). A number of fatty acids were also found: arachidonate, palmitate, stearidonate, oleate. Other compounds of interest include the Krebs cycle intermediate, alpha-ketoglutarate, the monosaccharide mannose, two compounds involved in energy metabolism: carnitine and creatine, and the purine xanthine. All of these metabolites were elevated in the cases with the exception of glycine and LGPC. Random Forest classification ranked the top 5 metabolites (after glucose) for distinguishing cases versus controls as mannose, alpha-ketoglutarate, 3-methyl-2-oxovalerate, 2-hydroxybutyrate, and 4-methyl-2-oxopentanoate.
Conclusion: A number of metabolites have been identified that associate with incident type 2 diabetes in Finnish men and which may also serve to distinguish normal glycemic control from IGT or IFG. These metabolites represent a variety of different metabolic pathways which may be perturbed prior to developing overt type 2 diabetes. In particular, dysregulation of branched-chain amino acid metabolism is replicated and highlighted by this work.

Low serum total osteocalcin levels is associated with high risk of metabolic syndrome in Korean men
C.-H. Park[1,2];
[1]Preventive Medicine, Chungbuk University, Cheongju, [2]Eulji University, Daejeon, Republic of Korea.

Background and aims: Osteocalcin may play an important role in regulating insulin secretion and sensitivity, and fat metabolism. Evidence on the association of osteocalcin with metabolic syndrome(MS), however, is very limited. Therefore we investigated the relationship of serum osteocalcin levels and MS in Korean men.

Materials and methods: This study was a cross sectional study including 470 Korean adults who visited a health promotion center in a university hospital from January 2010 to May 2011. MS was defined according to the NCEP-ATP lll criteria. MS and its individual components were assessed as well as serum osteocalcin levels with multiple logistic regression analysis.
Results: The overall prevalence of the MS in participants of this study was 22.2%. Compared with the highest quantile serum osteocalcin level group (16.84-36.70 ng/dL), the odds ratio for MS in the lowest level group (13.73-16.80 ng/dL) was 4.62 (95% CI=2.24-9.51), in the lower level group (11.54-13.69 ng/dL) was 3.32 (95% CI=1.59-6.91), and in the intermediate level group (4.81-11.53 ng/dL) was 1.95 (95% CI=0.90-4.21). Among the components of metabolic syndrome, the odds ratios for abdominal obesity, impaired fasting glucose, elevated blood pressure, low HDL cholesterol level, and high triglyceride level in the lowest serum osteocalcin level group were 4.68 (1.82-12.03), 3.22 (1.74-5.95), 1.88 (1.11-3.20), 3.82 (1.83-7.96), and 1.46 (0.84-2.54), respectively.
Conclusion: We found that a low serum osteocalcin level is significantly associated with a high risk of MS and negative effect for some metabolic components, especially the abdominal obesity, impaired fasting glucose, elevated blood pressure, and low HDL cholesterol level in Korean male.

Advanced glycation end products (AGEs) increases renal lipid accumulation: a pathogenic factor of diabetic nephropathy (DN)
H. Sun[1], Y. Yuan[2];
[1]Medical School, [2]Department of Endocrinology, Zhongda Hospital Southeast University, Nanjing, China.

Background and aims: Advanced glycation end products (AGEs) is one of the pathogenic factors of diabetic nephropathy, and our previous work has suggested that AGEs may play a central role in the pathogenesis of glomerulosclerosis. The aim of this study is to further investigate the molecular mechanisms of glomerulosclerosis induced by AGEs.
Materials and methods: For the *in vitro* study, human renal mesangial cells (HMCs) were incubated with Nε-(carboxymethyl) lysine (CML; a member of the AGEs family) and low density lipoprotein (LDL) for 24h. On *in vivo* level, animal model with diabetic nephropathy was developed by high fat/sucrose diet feeding plus streptozotocin injection. Two weeks after STZ injection, rats were divided into three groups, namely, control, diabetic and diabetic treated with AminoguanidineHydrochloride (AG; an inhibitor of AGEs; 100 mg/kg/day) by gavage for 8 weeks. The effects of cholesterol accumulation were examined by Oil Red O staining and a quantitative intracellular cholesterol assay. Serum AGEs was determined by High performance liquid chromatography analyzer. 24-hour urine protein was measured by Coomassie brilliant blue protein assay. The gene and protein expression were analyzed by quantitative RT-PCR, western blot and immunohistochemistry .
Results: 1. CML increased Oil Red O staining in HMCs. 2. Intracellular cholesterol ester was increased in CML-treated cells. 3. CML upregulated both mRNA and protein expression of HMG-CoAR, LDLr, SREBP-2 and SCAP. 4. The level of serum AGEs was higher in diabetic rats than that in control rats, and AG treatment reduced serum AGEs. 5. 24-hour urine protein of the diabetic group was significantly increased compared with control group, and AG treatment improved this alteration. 6. There was very strong staining of Oil Red O in the glomerular of the diabetic group, less staining in the AG treated group, and almost no staining in the control group. 7. Immunohistochemistry showed the overexpression of LDLr, SREBP-2, and SCAP in the glomerular of the diabetic rats, which was suppressed by AG treatment. 8. RT-PCR and western blot showed the overexpression of HMG-CoAR, LDLr, SREBP-2, and SCAP in the renal of the diabetic rats was ameliorated after the AG treatment.
Conclusion: For the *in vitro* study, we demonstrated CML increased lipid accumulation in HMCs by disrupting the SCAP-mediated feedback regulation of HMG-CoAR and LDLr. On *in vivo* level, we also found this SCAP-mediated feedback regulation was disrupted in the renal of type 2 diabetic rats, but inhibiting AGEs producing improved the feedback regulation. These data demonstrated that AGEs (CML) caused glomerulosclerosis via disturbing the intracellular feedback regulation of cholesterol, and inhibiting AGEs-induced lipid accumulation have a potential renoprotective role in the progression of DN.

Effect of fasting plasma glucose combined advanced glycation endproducts-peptide on screening for diabetes mellitus and pre-diabetes in Chinese high-risk population
J. He, Z. Sun, Z. Xie, S. Qiu, Y. Zhou;
Endocrinology, Institute of Diabetes, Zhongda Hospital, Nanjing, China.

Background and aims: Diabetes mellitus (DM) has now become an epidemic disease worldwide which needs effective screening methods. This study evaluated the utility of combined use of fasting plasma glucose (FPG) and Advanced Glycation Endproducts -peptide (AGEsP) in DM screening among Chinese high-risk population.
Materials and methods: 1020 subjects with high-risk factors of DM were recruited from eight community health service centers for the measurements of FPG, haemoglobin A1c (HbA1c), AGEsP and 2h-plasma glucose (2h-PG) following 75g-oral glucose tolerance test (OGTT). 857 participants finished the screening procedure and completed all data collection. AGEs-specific fluorescence immunoassay (FIA) was used to measure total AGEsP content. Combined use of FPG and AGEsP was compared against either FPG alone, 75 g-OGTT alone or HbA1c for detection of DM. DM was diagnosed according to 2010 Chinese type 2 diabetes prevention guide. The appropriate cut-off points of AGEsP for DM was assessed. Sensitivity, Specificity, area under the curve (AUC) of receiver-operating characteristics (ROC) for DM detection were computed for FPG, 2h-PG, HbA1c and AGEsP.
Results: The incidence of both pre-DM and DM in the study population was 27.1% and 25.1% respectively. AGEsP was positively correlated with FPG, 2h-PG, and HbA1c (r = 0.602, 0.609, 0.751, $P = 0.000$ for each by Spearman Analysis). The AUC of the ROC curve for AGEsP predicting undiagnosed DM was similar to that of FPG, 2h-PG and the cut-off point of AGEsP 10.22 μg/ml was optimal for predicting DM, with a sensitivity of 84.2%, and a specificity of 88.5%. Compared to FPG alone, combined use of FPG and AGEsP had higher sensitivity for detecting DM (FPG ≥ 7.0 mmol/L and/or AGESP ≥10.22 μg/ml vs. FPG ≥ 7.0 mmol/L: 90.7% vs. 59.1%, $P < 0.001$). No significant difference exists between the AUC of AGEsP evaluated against FPG or 2h-PG alone in detecting DM. For pre-DM screening, combined FPG ≥ 6.1 mmol/L and/or AGEsP ≥ 5.18 μg/ml performed better than either FPG alone, OGTT alone or combined measurements of FPG and HbA1c (FPG ≥ 6.1 mmol/L and/or AGEsP ≥ 5.18 μg/ml vs. FPG ≥ 6.1 mmol/L vs. OGTT 2h-PG ≥ 7.8 mmol/L vs. FPG ≥ 6.1 mmol/L and/or HbA1c ≥ 5.9 mmol/L: 90.5% vs. 25% vs. 75% vs. 81.0%, $P < 0.001$).
Conclusion: This study identified that the utinity of AGEsP may be a practical and convenient tool for screening undiagnosed DM and pre-DM. The combined use of FPG ≥ 7.0 mmol/L and/or AGEsP ≥ 10.22 μg/ml, and FPG ≥ 6.1 mmol/L and/or AGEsP ≥ 5.18 μg/ml substantially improves the sensitivity of detecting DM and pre-DM relative to FPG alone, and may represent an efficient early detection of DM and pre-DM. This has implied a new efficient approach for current and future DM screening programmes, especially among high-risk population.

Serum peroxiredoxin 4 as novel biomarker of oxidative stress and the risk of incident type 2 diabetes: the PREVEND study
A. Abbasi[1], E. Corpeleijn[1], D. Postmus[1], R.T. Gansevoort[2], R.O.B. Gans[2], L.T.W. de Jong-van den Berg[3], J. Struck[4], H.L. Hillege[1], P. van der Harst[5], R.P. Stolk[1], G. Navis[2], S.J.L. Bakker[2];
[1]Epidemiology, University Medical Centre Groningen, Netherlands, [2]Internal Medicine, University Medical Centre Groningen, Netherlands, [3]Social Pharmacy, University Medical Centre Groningen, Netherlands, [4]Research, Thermo Fisher Scientific/ BRAHMS GmbH, Hennigsdorf, Germany, [5]Cardiology, University Medical Centre Groningen, Netherlands.

Background and aims: Oxidative stress plays a major role in the development of type 2 diabetes. It is unknown whether serum peroxiredoxin 4 (Prx4), as a potent antioxidant biomarker, predicts the risk of incident type2 diabetes (T2D).
Materials and methods: From the Prevention of Renal and Vascular End-stage Disease (PREVEND) study, we included 3909 men and 4063 women (aged 28-75 years). Prx4 was measured by a novel immunoluminometric assay in baseline samples.
Results: Prx4 levels were significantly higher in men than in women (median [IQR], 0.71(0.45-1.16)U/l and 0.42(0.66-1.08)U/l resp.;P<0.001). During me-

dian (IQR) follow-up of 7.7 (7.4-8.0) years, 288 men and 208 women developed T2D. In a model adjusted for age, smoking, BMI and parental diabetes, OR for T2D risk per doubling of Prx4 levels was 1.31 (1.13-1.52) in men and 1.07 (0.90-1.27) in women (P<0.01 for sex-interaction). Further adjustment for glucose, HDL-cholesterol, triglyceride, hs-CRP, procalcitonin and urine albumin excretion did not materially change the association. The addition of Prx4 to the DESIR (data from the Epidemiological Study on the Insulin Resistance Syndrome) clinical model for prediction of diabetes improved discrimination (C-statistic change +0.010; P<0.001) and reclassification (integrated discrimination improvement = 0.004; P< 0.01) in men. We observed no improvement in women.
Conclusion: Elevated Prx4 levels are associated with a higher risk of incident T2D. This association was stronger in men than in women. Prx4 significantly improved prediction for risk of future T2D when added to a clinical model, but only in men. Further studies are warranted to confirm our findings and to investigate the underlying mechanisms for this gender disparity.

Fasting plasma neurotensin and risk of type 2 diabetes according to dietary fat content
U. Ericson[1], C.-A. Schulz[1], A. Bergmann[2], O. Melander[1], M. Orho-Melander[1];
[1]Department of Clinical sciences in Malmö, Lund university, Malmö, Sweden, [2]Sphingo Tec GmbH, Hohen Neuendorf, Germany.

Background and aims: Proneurotensin is a precursor of the regulatory peptide neurotensin involved in gut motility, gastric acid secretion and appetite regulation. Blood levels are elevated postprandially, and the secretion seems above all to be stimulated by fat intake, but may also depend on type of fat. High fasting plasma proneurotensin concentrations have been associated with development of type 2 diabetes (T2D) in individuals from the Malmö diet and cancer (MDC) cohort. We examined if dietary fat content modifies the association between fasting concentrations of proneurotensin and risk of T2D.
Materials and methods: This study included 3602 men and women, aged 46-68 years, from the population based MDC cohort with baseline examinations between 1991 and 1994. The included participants were without prevalent diabetes, and had measured fasting plasma proneurotensin concentrations and dietary data collected with a modified diet history method (combining a 7-day food record of cooked meals with a 168-item dietary questionnaire covering other meals). Cox proportional hazard models were used to calculate hazard ratios of incident T2D according to tertiles of fasting proneurotensin and energy adjusted intakes of total fat, saturated fat, monounsaturated fat and polyunsaturated fat. The mean time of follow-up was 13 years.
Results: We observed a significant statistical interaction between tertiles of proneurotensin and tertiles of dietary fat energy percent on incident T2D (P for interaction= 0.03) showing a significantly increased incidence of T2D with higher fasting proneurotensin among individuals in the lowest tertile of fat intake (P for trend <0.001), whereas no significant associations were seen among those in the higher tertiles of fat intake. Similar to our observations for total fat, we observed tendencies of stronger risk increasing associations among those with the lower intakes of saturated and monounsaturated fat than among those with higher intakes, but significant interactions were not detected (P=0.06 and P=0.17).
Conclusion: Our results suggest that dietary fat content could modify the association between fasting plasma proneurotensin and risk of T2D. High fasting proneurotensin may in particular be associated with increased risk among individuals with diets low in fat.

Differential role of chronic inflammation in the development of glucose intolerance: relationship between HbA_{1c} and lower adiposity or insulin secretory function in women
S. Okahata[1], K. Sakamoto[1], M. Yano[2], T. Mitsumatsu[1], Y. Ishizaka[2], M. Yamakado[2], T. Shiba[1];
[1]Toho University Ohashi Medical Center, [2]Department of health care center for multiphasic health testing and services Mitsui Memorial Hospital, Tokyo, Japan.

Background and aims: Local or systemic low-grade inflammation has been reported to increase the risk of the development of type 2 diabetes mellitus (DM). Helicobacter pylori (HP) can infect the mucosal lining of the stomach, induce chronic superficial gastritis, and decrease the serum pepsinogen 1(P1) level (ng/ml) and the ratio of pepsinogen 1 to pepsinogen 2 due to chronic inflammation. Some studies have shown an association between HP infection and DM. Our group conducted a cross-sectional study to clarify how chronic inflammation in gastric mucosa contributes to the development of glucose intolerance.
Materials and methods: The study subjects were 6,126 individuals (40-59 years) assessed for P1 and P2 levels, HbA1c (%, NGSP), IRI, and CRP in general health screenings performed at the Mitsui Memorial Hospital, in 2011. Gastritis was classified into four categories based on the serum level of P1 and the ratio of serum P1 to P2 (P1/2): Severe (P1 < 30 and P1/2 < 2.0), Moderate (P1 < 50 and P1/2 < 3.0), Mild (P1 < 70 and P1/2 < 3.0), and None(other values : P1≧70 orP1/2≧3.0). Gender difference was also examined.
Results: In females, the HbA1c levels were (n=2,640) 5.7±0.31 in the Severe group (n=67), 5.6±0.28 in Moderate (n=126), 5.6±0.33 in Mild (n=86), and 5.6±0.29 in None (n=847). The level in Severe was significantly higher than that in None (p=0.015). No differences in HbA1c were found between other categories in the females or between any categories in the males. Next an examination of the risk factors for diabetes on female revealed that BMI and body fat percentage (BFP; %) were significantly smaller (p<0.001) in Severe than in None: 19.7±2.8 and 22.5 ± 6.2 in Severe vs. 21.2±3.2 and 23.4±5.8 in None, respectively. There was no significant difference in insulin resistance, but the Severe group exhibited a significant impairment in insulin secretory function and a lower HOMA -β (47.3±15.5 compared to 58.4±29.4 in Neutral (p=0.007)). No significant differences were observed in the evaluation of the effects of CRP. In the univariate analysis, BMI was significantly correlated with HbA1c. The multivariate analysis of model 1 (P1/2, BMI, and age) and model 2 (P1/2, BMI, age, and HOMA -β) identified P1/2, BMI, age, and HOMA -β as independent risk factors for increment of HbA1c.In males, there was no significant difference in HbA1c between the Severe (n=87) and None (n=3,087) groups: 5.6±0.37 and 5.6±0.34, respectively. HOMA -β in the Severe group (55.6±33.7) was smaller than that in the N group (62.6±38.2), but the difference fell short of significance due to the large variability.
Conclusion: In the female subjects of this study, chronic inflammation with superficial gastritis represented by lower P1 and P1/2 induced a small but significant elevation in HbA1c without increasing either insulin resistance or adiposity, two common features of glucose intolerance caused by chronic inflammation in visceral adipose tissue. No such effect was observed in the male subjects of this study. Furthermore, subjects with severe gastritis were less adipose and had lower insulin secretory function. This suggests that chronic inflammation contributes differently to the development of DM in different tissues. The mechanism of gender difference should be further elucidated.

Serum protein concentration predicts incident diabetes: the Insulin Resistance Atherosclerosis study
S.M. Haffner[1], A.J.G. Hanley[2,3], C. Lorenzo[1];
[1]Medicine, University of Texas Health Science Center, San Antonio, USA, [2]Departments of Nutritional Sciences and Medicine and the Dalla Lana School of Public Health, University of Toronto, Toronto, Canada, [3]Leadership Sinai Centre for Diabetes, Mt. Sinai Hospital, Toronto, Canada.

Background and aims: A number of acute phase reactants have been associated with insulin resistance syndrome and have shown to predict type 2 diabetes. Since albumin concentration tends to be stable in the absence of co-morbidities, we hypothesized that total protein concentration (TP) could predict future development of diabetes. Therefore, the aim of this study was to examine the relationship between TP and incident diabetes.

Materials and methods: Population data were obtained from the Insulin Resistance Atherosclerosis Study, which includes data from 864 participants who were non-diabetic at baseline. Using the 2003 American Diabetes Association criteria, incident diabetes was ascertained after a 5-year follow-up period. Insulin sensitivity index (S_I) and acute insulin response (AIR) were directly measured by the frequently sampled intravenous glucose tolerance test. Logistic regression analysis was used to assess the relationship between TP and incident diabetes.
Results: In cross-sectional analysis, TP had a significant relationships with BMI (r = 0.14, p <0.001), S_I (r = - 0.22, p <0.001), AIR (r = 0.17, p <0.001), C-reactive protein (r = 0.14, p <0.001), fibrinogen (r = 0.18, p <0.001), and albumin (r = 0.49, p <0.001). We performed a logistic regression to model incident diabetes with a restricted cubic polynomial spline for TP to estimate the varying effects of TP over its full range (Figure). This relationship was linear (Wald test, p >0.2) and statistically significant (p = 0.033). In contrast, serum albumin concentration modeled also by a smooth function was not associated with incident diabetes (p = 0.766). TP was an independent predictor of diabetes (OR x 1 SD, 1.32 [95% CI: 1.04 - 1.66]) after adjusting for age, sex, ethnicity, clinic, family history of diabetes, BMI, plasma glucose levels, S_I, AIR, C-reactive protein, alcohol intake, and smoking, and albumin excretion.
Conclusion: TP predicts the development of type 2 diabetes independently of multiple risk factors including plasma glucose, insulin sensitivity, and insulin secretion.

Higher serum bilirubin level as a protective factor for the development of diabetes in healthy Korean men: a 4 year retrospective longitudinal study
M. Lee, J. Jang, C. Jung, W. Lee, K.-U. Lee, J.-Y. Park;
Department of Internal Medicine, Asan Medical Center, Seoul, Republic of Korea.

Background and aims: Bilirubin is a natural product of heme catabolism by heme oxygenase, one of key antioxidant enzymes. Recently, it has been recognized as a substance with potent antioxidant and cytoprotective properties. So far, there have been several studies which showed the significant negative relationship between serum bilirubin levels and the risk of metabolic disorders including cardiovascular diseases, type 2 diabetes, metabolic syndrome, arterial hypertension, and obesity. Regarding type 2 diabetes, however, most of the studies have been confined to the cross-sectional nature. In light of these findings, we designed this study to investigate the longitudinal effects of baseline serum bilirubin concentrations on the development of type 2 diabetes during a 4 year follow-up period in middle aged Korean Men.
Materials and methods: This 4 year retrospective longitudinal observational study was conducted at our medical center. The study population consisted of 5,960 men without type 2 diabetes who underwent routine health examination in 2007 (baseline) and 2011 (follow-up). Baseline serum bilirubin concentrations were determined by the vanadate oxidation method.
Results: During a 4 year period, 409 incident cases of diabetes (6.9 %) were identified. Incident type 2 diabetes decreased across the baseline bilirubin quartile categories (*P* for trend <0.001). In multivariate-adjusted model, the odds ratio for the development of type 2 diabetes was significantly lower in highest (i.e., 1.30-2.00 mg/dl) compared with the lowest bilirubin quartile category (i.e., ≤0.90 mg/dl), even after adjustment for confounding variables including homeostasis model assessment of insulin resistance (odds ratio=0.69, 95% confidence interval 0.48-0.99, *P* for trend=0.041).
Conclusion: The results indicate that serum total bilirubin level may provide additional information for predicting future development of type 2 diabetes, especially in subjects without chronic liver diseases.

437

Circulating levels of selenoprotein P predict future hyperglycaemia in non-diabetic Japanese people
H. Misu[1], T. Kanamori[1], Y. Takeshita[1], Y. Saito[2], M. Tanaka[3], S. Kaneko[1], T. Takamura[1];
[1]Department of Disease Control and Homeostasis, Kanazawa University, Kanazawa, [2]Department of Medical Life Systems, Faculty of Medical and Life Sciences, Doshisha University, Kyotanabe, [3]Diagnostic R&D, Development & Production Headquarters, Alfresa Pharma Corporation, Ibaragi, Japan.

Background and aims: We have recently identified selenoprotein P (SeP) as a hepatokine that induces insulin resistance and hyperglycaemia by using animal and cellular experiments. The aim of this study is to examine whether circulating levels of SeP predicts future hyperglycaemia in nondiabetic people.
Materials and methods: We followed 76 nondiabetic Japanese who went to a hospital for a complete physical examination for 4 years (age 52 ± 10; BMI 22.7 ± 3; A1c 5.2 ± 0.3%). Baseline levels of serum SeP were measured by a sol particle homogeneous immunoassay. 75 g oral glucose tolerance tests (OGTT) were performed before and after the follow-up period.
Results: (1) Baseline SeP levels correlated positively with baseline age and plasma glucose levels at 30 min and 60 min, and negatively with baseline insulinogenic index (r = 0.252, p = 0.028; r = 0.241, p = 0.036; r = 0.326, p = 0.004; r = -0.293, p = 0.010, respectively), but not with HOMA-IR. (2) Levels of plasma glucose at 0 min, 60 min, and 120 min significantly increased before and after the follow-up period (from 93 ± 8 to 97 ± 10, p < 0.0001; from 131 ± 41 to 144 ± 45, p = 0.004; from 109 ± 25 to 116 ± 26, p = 0.022, respectively). (3) Baseline SeP levels significantly correlated with plasma glucose at 0, 30, 60, and 120 min measured at the end of the follow-up period (r = 0.303, p = 0.008; r = 0.264, p = 0.021; r = 0.451, p < 0.0001; r = 0.230, p = 0.045, respectively). (4) A multiple regression analysis showed that baseline A1c and SeP predicted the fasting plasma glucose 4 years later independently of the other clinical markers such as age and insulinogenic index (β = 0.375, p = 0.001; β = 0.246, p = 0.024, respectively).
Conclusion: Circulating levels of SeP predicted the future hyperglycaemia independently of the other clinical parameters in nondiabetic healthy subjects. Our observation, combined with emerging functional and genetic evidence, support the concept that hepatokine SeP has a causal role in the development of type 2 diabetes.

CARING: diabetes mellitus and risk of cancer - a systematic review and meta-analysis

J. Starup-Linde[1], P. Vestergaard[2], O. Karlstad[3], S.A. Eriksen[4], H.K. Bronsveld[5], F. de Vries[6], A. de Boer[6], M.L. de Bruin[6];
[1]The Osteoporosis Clinic, Aarhus University Hospital, Aarhus C, Denmark, [2]Clinical Institute, Aalborg University, Denmark, [3]Department of Pharmacoepidemiology, Norwegian Institute of Public health, Oslo, Norway, [4]Clinical Institute, Aalborg University, Denmark, [5]Department of Molecular Pathology, Netherlands Cancer Institute, Amsterdam, Netherlands, [6]Division of Pharmacoepidemiology & Clinical Pharmacology, Utrecht University, Faculty of Science, Institute for Pharmaceutical Sciences, Netherlands.

Background and aims: Patients suffering from diabetes mellitus (DM) may experience an increased risk of cancer, but results are conflicting. The aim is to examine the association between DM and cancer by a meta-analysis.
Materials and methods: A systematic review and meta-analysis was performed according to the PRISMA guidelines. The systematic literature search included Pubmed, Embase, Cinahl, Bibliotek.dk, Cochrane library, Web of Science and Svemed+ with the search terms: "Diabetes mellitus", "Neoplasms", "Prospective study" and "Risk of cancer". Odds ratios, relative risks, risk ratios, hazard ratios, prevalence ratios, incidence ratios and standardized incidence ratios were used in the pooled analysis. Statistical analysis was performed using random effects models.
Results: A total of 1,785 records were screened by title and abstract and 253 records were subsequently assessed by full text, of which 195 records fulfilled the criteria for the systematic review. The cancer types studied showed significant heterogeneity across studies by Chi-square test.Compared to non-diabetic controls, DM patients had an increased risk of any cancer (RR=1.14, 95 % CI [1.01-1.28], 26 records). Diabetics seemed especially at risk of liver (RR=2.27, [1.86-2.78], 47 records), pancreas (RR=2.21 [1.86-2.62], 47 records) and endometrial cancer (RR=1.9, [1.67-2.16], 24 records), although an increased risk was also seen for biliary tract, stomach, colon, rectum, kidney, bladder, breast and thyroid gland cancer. In contrast, DM patients appeared to experience a decreased risk for prostate cancer (RR= 0.87 [0.81-0.93], 44 records).
Conclusion: DM patients were at higher risk of cancer than non-diabetics, especially digestive tract cancers and hormone/related cancers (breast, endometrial). However, an apparent protective effect against prostate cancer was present. The observed effects could be due to confounding by factors not adequately adjusted for in the studies like obesity.

Autonomic neuropathy, sexual dysfunction and urinary incontinence in women with type 1 diabetes: findings from the DCCT/EDIC

J.M. Hotaling[1], A. Sarma[2], R. Pop-Busui[3], P. Cleary[4], R. Dunn[2], H. Wessells[5];
[1]Urology, University of Illinois Chicago, [2]Urology, University of Michigan, Ann Arbor, [3]Neurology, University of Michigan, Ann Arbor, [4]Biostatistics Center, George Washington University, Washington, [5]Urology, University of Washington, Seattle, USA.

Background and aims: Cardiovascular autonomic neuropathy (CAN) may play an important role in the pathophysiology of male diabetic erectile dysfunction but the impact of CAN on female sexual dysfunction (FSD) and urinary incontinence (UI) in women with T1DM remains unknown. We evaluated the association of cardiovascular autonomic neuropathy (CAN) and FSD and UI in women participating in the Diabetes Control and Complications Trial/Epidemiology of Diabetes Intervention and Complications Study (DCCT/EDIC).
Materials and methods: Measures of CAN (R-R response to deep breathing, Valsalva maneuver, change in postural blood pressure), FSD and UI were obtained in 580 DCCT/EDIC female subjects, 16-to-17 years after DCCT closeout. Mean age was 50.6±7.2 years, mean diabetes duration 29.6±5.1 years, and mean DCCT/EDIC HbA1c 8.0±0.9%. CAN was defined as 1) R-R variation<15 or 2) R-R variation between 15-19.9 and a Valsalva ratio≤1.5, or 3) postural drop of 10 mm Hg in diastolic blood pressure. UI was defined by the Sandvik Index categories of dry/mild (0-2) versus moderate/severe (3-12) and FSD was defined by the abbreviated Female Sexual Function Index (FSFI-R) score ≥22.75 defining presence of FSD at EDIC year 17. Multivariable logistic regression estimated the associations between CAN and FSD and UI, after adjusting for DCCT cohort, DCCT/EDIC HbA1c, DCCT/EDIC systolic blood pressure, age, smoking status, and drinking status at EDIC year 17.
Results: At EDIC year 17, FSD and UI were present in 26% and 30% of women, respectively. Subjects with FSD had significantly lower R-R variation (p=0.002) and Valsalva ratio (p=0.003) at EDIC year 16/17. (Table 1) Likewise, those with UI had similar findings. Forty seven percent of participants with FSD and 44% of participants with UI also had confirmed CAN at EDIC year 16/17 (p=0.02 and p=0.20, respectively). Participants with CAN had OR= 1.58, 95%CI (1.07-2.34) greater odds of FSD and 1.28 (0.88-1.85) greater odds of UI on univariate analysis. In adjusted analyses, participants with CAN had a 1.30 (0.83-2.02) greater odds of FSD and 1.02 (0.67-1.54) greater odds of UI. Although the trends remained consistent, they were no longer significant.

Table 1. Neuropathy measures at DCCT closeout and EDIC year 16/17 by FSD or UI status

	No FSD N=408	FSD N=146	p-value	No UI N=399	UI N=172	p-value
Neuropathy Measures¶	Mean±Std or N (%)					
At DCCT Closeout						
R-R Variation	41.50±21.01	40.04±22.63	0.4677	41.30±21.92	40.35±20.06	0.8031
Valsalva Ratio	2.05±0.40	1.98±0.38	0.1564	2.03±0.42	2.03±0.37	0.6931
Abnormal CAN	27 (7)	23 (17)	0.0014	36 (10)	15 (9)	0.8620
At EDIC Year 16/17						
R-R Variation	26.17±17.25	21.92±17.11	0.0021	25.48±17.24	22.58±16.45	0.0542
Valsalva Ratio	1.74±0.35	1.62±0.30	0.0028	1.72±0.34	1.64±0.32	0.0168
Abnormal CAN	138 (36)	65 (47)	0.0223	142 (38)	72 (44)	0.1986

Data are Mean±Std or N (%). P-values based the difference between those with and without FSD or UI using the Wilcoxon rank-sum test for quantitative variables or the Contingency chi-square for qualitative variables. Sample sizes may vary due to missing data.

Conclusion: The association between CAN and LUTS in the DCCT/EDIC cohort indicates that CAN may be a useful surrogate biomarker of more generalized autonomic neuropathy that plays a role in urologic complications in women with long-standing type 1 DM or vice versa. Further studies with longitudinal assessments to elucidate temporal sequence are warranted.

The risk of acute pancreatitis with GLP-1 receptor agonists and DPP-4 inhibitors: a retrospective observational cohort study

C.E. Koro[1], M.O. Sowell[2], M. Stender[3], P. Chhabra[4], J.K. Allen[5], H.J. Krzywy[5];
[1]Worldwide Epidemiology, GlaxoSmithKline, Collegeville, USA, [2]Global Clinical Safety and Pharmacovigilance, GlaxoSmithKline, Collegeville, USA, [3]Worldwide Epidemiology, GlaxoSmithKline, Stockley Park, UK, [4]University of Maryland, Baltimore, USA, [5]Worldwide Epidemiology, GlaxoSmithKline, Research Triangle Park, USA.

Background and aims: To evaluate the association between GLP-1 receptor agonists (GLP-1RA), DPP-4 inhibitors (DPP-4I) and acute pancreatitis compared to the association observed between this outcome and the use of other antidiabetic agents (OADA). In contrast to other published observational studies, this study includes both exenatide and liraglutide users and has a longer follow-up time.
Materials and methods: A retrospective cohort study was conducted in the Truven Health Marketscan® Commercial Claims and Encounters Database from 2005 to 2011. The Type 2 diabetes study population was classified as GLP-1RA user, DPP-4I user or OADA user based on the antidiabetic prescription received on the index date. Acute pancreatitis in the study groups was identified in the post-index follow up period by hospitalization claims with a primary discharge diagnosis of ICD-9 code 577.0 (acute pancreatitis). Cox Proportional Hazards model was used to compare the adjusted (refer to Table 1 for a list of adjusters) risk of acute pancreatitis among subjects treated with GLP-1RA and DPP-4I as compared to OADAs (reference group).
Results: We identified 124,925 GLP-1RA users, 208,683 DPP-4I users, and 1,187,502 OADA users 18-64 years old. The majority of subjects in these 3 cohorts were 55- 64 years old. The GLP-1RA cohort had a higher proportion of subjects who were obese (10.8%) compared to the OADA group (7.3%; p<0.001) and a higher proportion of females (57.6%) compared to the OADA

group (47.8%; p<0.001). We identified 5871 cases of acute pancreatitis in over 3 million person-years of follow-up. The unadjusted incidence rate of pancreatitis per 100,000 person-years was 1.92 (95% CI = 1.75 - 2.09) among the GLP-1RA cohort, 1.88 (95% CI = 1.74-2.04) among the DPP-4I cohort and 1.93 (95% CI = 1.88-1.99) among the OADA cohort. The adjusted hazard ratio for acute pancreatitis was 0.95 (95% CI = 0.86-1.04) for GLP-1RA and 0.92 for DPP-4I (95% CI = 0.85-1.00) compared to OADA (Table 1).

Conclusion: In this study neither the unadjusted incidence rates nor the adjusted hazards ratios demonstrated an increased risk of acute pancreatitis among patients prescribed GLP-1RA or DPP-4I compared to other antidiabetic agents. A follow-up analysis will be conducted when additional data from the last quarter of 2011 becomes available.

Table 1: Adjusted* risk of acute pancreatitis

Cohort Group	Adjusted HR (95% CI)	p-value
GLP-1RA (ref=OADA)	0.946 (0.860, 1.04)	0.251
DPP-4I (ref=OADA)	0.921 (0.847, 1.001)	0.0532

Serum levels of pancreatic regenerating protein indicate the development of type 2 diabetes and diabetic chronic complications

J. Yang[1,2], Z. Sun[1], R. Graf[3], L. Li[1];
[1]Department of Endocrinology, Zhongda Hospital of Southeast University, Nanjing, China, [2]Department of Endocrinology, Affiliated Hospital of Nantong University, China, [3]Department of Visceral and Transplantation Surgery, University Hospital of Zurich, Switzerland.

Background and aims: Type 2 diabetes mellitus (T2DM) is one of the most common non-communicable diseases globally, and its complications result in increasing disability, reduced life expectancy and enormous health costs. However, it is frequently not diagnosed until complications occur. Pancreatic regenerating protein (*reg*) is mitogenic to islet β-cells and associated with inflammation, while no data exist regarding the prognostic value of reg among T2DM patients. The aim of this pilot study was to evaluate the quantity of reg in different clinical stages of T2DM and its correlation with diabetic complications.

Materials and methods: We analysed serum reg and its correlation with clinical and biochemical parameters in 1004 subjects with T2DM at different clinical phases. A group of healthy control subjects was also analysed. reg values were measured by a newly developed ELISA.

Results: Reg was correlated with the duration of diabetes (spearman's rank correlation coefficient 0.319 p<0.001). Compared to healthy controls, reg levels were elevated in high-risk patients (18.7[15.0-26.4] vs 16.4[13.9-20.8], p=0.014), and patients with long-term diabetic mellitus (without complications: 26.4[17.4-38.2] vs 16.4[13.9-20.8] p<0.001; with complications: 32.1[22.1-55.5] vs 16.4[13.9-20.8] p<0.001). Interestingly, there is no statistically significant differences among the population of high-risk, IGR and incipient diabetic patients. The area under the curve (AUC) of reg for incidence of diabetes-onset and chronic complications were 0.640 and 0.754, separately. Two reg cut-offs potentially allow to identify individuals with a high risk to develop T2DM and its chronic complications. reg levels above 22 ng/ml in nondiabetes were associated with a high risk to develop T2DM in future, levels above 29 ng/ml among T2DM were the most significant parameter to predict the occurrence of diabetic chronic complications.

Conclusion: Reg might evolve as a promising new marker to predict the occurrence, development of T2DM and diabetic chronic complications.

442

Haemorrheological approach for early detection of diabetic angiopathy

S. Lee;
Endocrinology, Yonsei University, Seoul, Republic of Korea.

Background and aims: Several key hemorheological parameters, such as erythrocyte deformability, erythrocyte aggregation are altered in patients with diabetes mellitus. Because erythrocytes remain in hyperglycemic environment throughout their life span and thus are subjected to series of compositional changes. These changes of erythrocyte in turn make whole blood more viscous and may play an important role on the pathogenesis of vascular complications of diabetes mellitus. So in this study, we intended to examine erythrocyte deformability and aggregation in patients with type 2 diabetes, and assess the differences of these parameters compared with healthy controls.

Materials and methods: 204 subjects were enrolled and their blood and urine samples were obtained. Also, they had a carotid IMT test and their eye's examination. The erythrocyte deformability was measured in terms of elongation index (EI) with microfluidic ektacytometer, RheoScan, which was very sensitive to detect changes in EI of erythrocytes due to hyperglycemic process. The aggregation index (AI) was measured with RheoScan, too. The hemorheological analyses including EI measurement were completed within 36 hours after blood collection. All subjects were divided by five groups according to their past history and test results as follows: Healthy control (n=32), prediabetes (pre-DM, n=38), diabetes without vascular complications (DM-no Cx, n=83), diabetes with microvascular complications (DM-microCx, n=24) and diabetes with macrovascular complications (DM-macroCx, n=27). The statistical analysis was performed using Kruskal Wallis test and Pearson's correlation coefficients with SPSS, version 20.

Results: A significant reduction of erythrocyte deformability was observed in DM-microCx group and DM-macroCx compared with healthy control (0.329 & 0.323 vs. 0.354 p<0.05). Also, EI was significantly decreased in the group of higher HbA1c level (a1c≥9%) compared with in the group of lower HbA1c level (a1c<7%, 0.322 vs. 0.337, p<0.05). The factors that had negative correlation with EI were DM duration, HbA1c, FPG, serum creatinine, triglyceride, HOMA-IR, calcium and results of PWV/ABI (no adjusted, p<0.05). Whereas, AI was observed significant decrease in DM-microCx and DM-macroCx group compared with healthy control (38.54 & 37.72 vs. 39.96, p<0.01) and these results implied that reduced cell deformability caused to decrease RBC aggregation even for increased fibrinogen concentration.

Conclusion: EI is a sensitive parameter to detect impairment of erythrocyte in diabetic process. The results in this study suggest that significant reduction in the EI may have correlation with diabetic vascular complications, and furthermore could be one of the indicators of these complications.

443

Semi-automatic analyses of skin capillary density: proof of principle and validation

Ü. Karaca[1], E.H.B. Gronenschild[2], D.M.J. Muris[1], M.T. Schram[1], C.D.A. Stehouwer[1], A.J.H. Houben[1];
[1]Internal Medicine, [2]Psychiatry and Neuropsychology, Maastricht University Medical Centre (MUMC+) and Cardiovascular Research Institute Maastricht (CARIM), Netherlands.

Background: It is increasingly being recognized that microvascular dysfunction may be a key feature in the development of both obesity-related hypertension and insulin resistance. Skin capillaroscopy has been proven to be a valid tool to study microvascular function non-invasively in humans. Unfortunately, the analysis of capillary density from video-clips is very time-consuming, since this is done manually. This impedes the use of this technique in large-scale studies. We aimed to develop a (semi-)automated assessment of skin capillary density.

Methods: CapiAna (Capillary Analysis) is a newly developed semi-automatic image analysis application. The technique involves four steps: 1) movement correction, 2) positioning of the region of interest (ROI) and selection of the frame range, 3) automatic detection of capillaries, and 4) manual correction of detected capillaries. We assessed accuracy, reproducibility, and time-savings of the semi-automatic method as compared to the manual counting procedure (MCP). For this purpose, finger skin capillary density was measured in 10 healthy participants (6 women; mean age 55.7 (49 - 68) years). First, to investigate agreement between the semi-automatic image analysis application (CapiAna) and the classic MCP, we used weighted Deming regression and

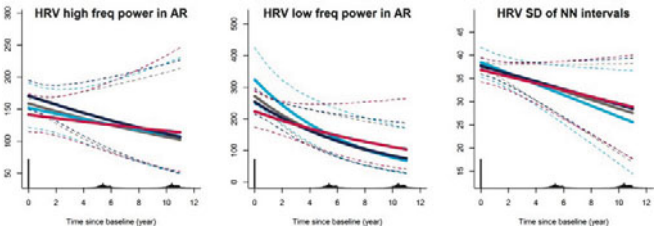
Bland-Altman analysis. Second, intra- and interobserver reproducibility of the semi-automatic method was assessed by calculating coefficients of variation (CV). To this end, an experienced investigator counted the number of capillaries twice with a two week interval. In addition, a second experienced investigator counted the number of capillaries in exactly the same ROI. Finally, the difference in analysis-time between the semi-automatic and the manual method was assessed.
Results: We found a Pearson`s correlation coefficient of 0.88 ($P < 0.001$) between both methods. Weighted Deming regression analysis resulted in the equation $y = 0.87x + 16.16$. The comparison between CapiAna and the MCP by the Bland-Altman analysis showed a bias of -3.9 capillaries/mm^2 (<5%) and limits of agreement (± 1.96 SD) of +13.6 to -21.4 capillaries/mm^2 (approximately 17%). The intra- and interobserver CVs of CapiAna were 2.0% and 5.4%, respectively (as compared to MCP data from literature: 4.5% and 7.2%, respectively). Finally, the analysis time for CapiAna ranged between 25 - 35 minutes versus 80 - 95 minutes for the MCP.
Conclusion: We have developed a semi-automatic image analysis application for the assessment of skin capillary density. The results indicate that CapiAna is in good agreement with the MCP. In addition, CapiAna is more reproducible as compared to the MCP. Finally, analysis time was significantly reduced with CapiAna. As a result, skin capillaroscopy can be used in large-scale studies, which importantly extends the possibilities to perform microcirculation research in humans.

444

Natural history of heart rate variability by glycaemic status in the Whitehall II cohort

C.S. Hansen[1], E.J. Brunner[2], A. Tabák[2], M. Kivimäki[2], A. Britton[2], D.R. Witte[3], J. Fleischer[4], M.E. Jørgensen[5], D. Vististen[1];
[1]Dept. of Epidemiology 469, Steno Diabetes Center, Gentofte, Denmark, [2]Department of Epidemiology and Public Health, University College London, UK, [3]Centre for Health Studies, CRP-Santé, Strassen, Luxembourg, [4]Medical Research Laboratories, Clinical Institute of Medicine, Aarhus, Denmark,

Background and aims: People with pre-diabetes and diabetes have an increased risk of cardiovascular disease (CVD). This increased morbidity and mortality is associated with adverse changes in cardiac autonomic tone which may be reflected in reduced heart rate variability (HRV) measures. Little is known about the natural history of HRV indices. We characterized changes in HRV indices in relation to baseline glycaemic state over ~12 years of follow-up.
Materials and methods: Data from 3,634 participants (7,290 person-examinations) without known diabetes at baseline (Phase 5) from the Whitehall II Cohort were used. 5-minute HRV recordings were collected at three phases approximately 5 years apart. HRV was analysed in the time domain (SD of intervals between R waves with normal-to-normal conduction (SDNN)) and in the frequency domain using an autoregressive method computing two power spectrum components: Low frequency power (LFP) and High frequency power (HFP). Individuals were divided into four subgroups based on glycaemic state at baseline: normal glucose tolerance (NGT)(n=3,110), isolated impaired fasting glucose (iIFG) (n=90), impaired glucose tolerance (IGT) (n=302), screen detected diabetes (SDM) (n=132). Trajectories of HRV recordings from baseline (time=0) and up to approximately 12 years later were estimated using multi-level longitudinal modelling adjusted for age, sex ethnicity, anti-hypertensive treatment and study phase. Participants with self-reported ischemic heart disease or use of nitrates were excluded.
Results: Preliminary results show a trend towards a decrease in all HRV indices over time in all subgroups (figure 1), with less decline in the SDM group. Baseline LFP measures are significantly lower (p=0.0244) in the SDM subgroup compared to baseline measures in the iIFG subgroup. No significant differences in HFP or SDNN values were found.
Conclusion: We show a decrease in SDNN, LFP and HFP over time in people with NGT, IFG, IGT and SDM which is in part related to ageing. Baseline values of LFP are lower in the SDM group compared to iIFG group suggesting an early imbalance in autonomic tone which could be the result of hyperglycaemia. The diminishing difference in HRV over time could be caused by convergence in ageing effects.

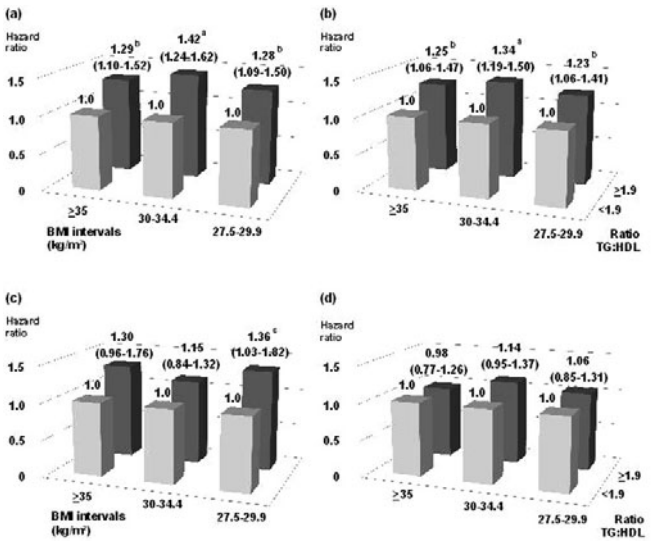


445

The triglycerides-to-HDL-cholesterol ratio and cardiovascular disease risk in obese patients with type 2 diabetes: a report from the Swedish national diabetes register

K. Eeg-Olofsson[1], S. Gudbjörnsdottir[1], B. Eliasson[1], B. Zethelius[2], J. Cederholm[2];
[1]Department of Medicine, University of Gothenburg, Göteborg, [2]Department of Public Health and Caring Sciences, Uppsala University, Sweden.

Background and aims: Studies in patients with type 2 diabetes (T2D) have shown both positive and negative results for the association between increasing BMI and cardiovascular disease (CVD) and mortality. We assessed the association between BMI and risk of coronary heart disease (CHD), CVD and mortality in T2D, also with regard to higher or lower levels of the ratio triglycerides-to-HDL-cholesterol (TG:HDL) as a marker for insulin resistance.
Materials and methods: 54,061 T2D patients, aged 30-74 years, with BMI ≥18.5 kg/m^2, mean age 61.5±8 years, diabetes duration 6.9±6 years, 14% with a history of CVD, from the Swedish National Diabetes Register, were included and followed for mean 4.8 years.
Results: Adjusting at Cox regression for characteristics not directly linked to BMI (age, sex, smoking, history of CVD), hazard ratios (HR) for fatal/nonfatal CHD and CVD were significantly ($p<0.001$) increased with baseline obesity (BMI 30-34.9 kg/m^2), 1.34 and 1.30, and prominent obesity (BMI ≥35 kg/m^2), 1.46 and 1.42, compared to normal weight (BMI 18.5-24.9 kg/m^2). With a second adjustment model including also BMI-linked covariates, as blood lipids, blood pressure, HbA1c, albuminuria, HR for these outcomes were significant only with prominent obesity, 1.19 ($p=0.01$) and 1.17 ($p=0.009$). Stratifying by 75th percentile of TG:HDL, with normal weight and TG:HDL <1.9 as reference and full adjustment, baseline obese and prominently obese with TG:HDL ≥1.9 had considerably increased HR around 1.7 for fatal/nonfatal CHD and 1.6 for CVD ($p<0.001$), while obese and prominently obese with TG:HDL <1.9 only had HR 1.2-1.3 for CHD and CVD ($p=0.003-<0.01$). A similar picture was found using updated mean BMI and TG:HDL. In each of the higher BMI categories, risks for CHD and CVD were increased by 25-40% with high TG:HDL compared to lower (Figure 1. Adjusted HR (95% CI) for outcomes with categories of baseline BMI and TG:HDL, a. fatal/nonfatal CHD; b. fatal/nonfatal CVD; c. fatal CVD; d. non-CVD mortality. Significance levels: a $p<0.001$, b<0.01, c<0.05). The risk for non-CVD mortality was not affected by lower or higher TG:HDL.
Conclusion: Obese T2D patients with high TG:HDL, associated with increased insulin resistance, had considerably increased risk of CHD and CVD. The TG:HDL ratio is clinically available and could add valuable information when assessing the individual patient risk.



PS 022 Prediction of complications in type 1 and type 2 diabetes II

446

Short term mortality in people with diabetes: results from the national diabetes audit in England and Wales

N. Holman[1], B. Young[2];
[1]National Diabetes Information Service, York, [2]Salford Royal Infirmary, Salford, UK.

Background and aims: Research studies have provided a wealth of information on the associations between patient characteristics and mortality for those with diabetes but research populations often differ from clinical populations. The National Diabetes Audit (NDA) in England and Wales provides an opportunity to assess the independent association between patient demographic characteristics, treatment targets and diabetic complications on mortality in a 'real world' cohort.
Materials and methods: The NDA extracts data from primary care records on patient characteristics (age, sex, type of diabetes, ethnic group, social deprivation, body mass index - BMI) and treatment targets (HbA1c, blood pressure, cholesterol). The patients were matched to Hospital Episode Statistics and Patient Episode Data for Wales (databases containing a record of every hospital admission in England and Wales respectively) to identify hospital admissions for diabetic ketoacidosis, angina, heart failure, myocardial infarction, stroke, renal replacement therapy, minor amputation (below the ankle) and major amputation (above the ankle). They are also matched to nationally collated death records. A regression model was created to assess the risk of people aged 30 years and older with diabetes included in the 2009/10 audit dying in 2011.
Results: The risk of one year mortality increased with age (OR per additional year 1.082 95% CI 1.081-1.084) and male sex (OR 1.349 95% CI 1.316-1.382). People with Type 1 diabetes had a higher risk of dying than those with Type 2 diabetes (OR 1.222 95% CI 1.152-1.295). There was a statistically significant social deprivation gradient in the risk of one year mortality. People from South Asian and Black ethnic groups had lower mortality than those from white ethnic groups (OR 0.533 95% CI 0.504-0.563 and OR 0.529 95% CI 0.487-0.574 respectively). Having a very low BMI (<18.5) was associated with a significantly higher risk of dying (OR 2.372 95% CI 2.171 - 2.591 compared to BMI 18.5-24.9 (reference group). However, the lowest mortality were found in those with a BMI of 30-34.9 (OR 0.625 95% CI 0.604 - 0.648) and a BMI of 35-39.9 (OR 0.647 95% CI 0.618 - 0.677). This analysis found that there was a J shaped relationship between HbA1c and one year survival. Compared to those with a HbA1c of 42-53mmol/l (reference group) people with a HbA1c of <42mmol/l had an OR of 1.302 (95% CI 1.255 - 1.350). There was no significant difference in one year mortality for people with a HbA1c of 54-64mmol/l (OR 1.010 95% CI 0.980 - 1.041). Higher mortality was found in people with a HbA1c of 65-74mmol/l and 75+mmol/l (OR 1.145 95% CI 1.101 - 1.191 and OR 1.441 95% CI 1.385 - 1.498 respectively). A hospital admission for heart failure was associated with an OR of dying of 4.587 (95% CI 4.411 - 4.769) compared to 3.439 (3.232 - 3.660) for stroke and 1.991 (95% CI 1.853 - 2.138) for myocardial infarction. One or more minor amputations resulted in an OR of 1.709 (95% CI 1.415 - 2.065) and one or more major amputations was associated with an OR of 3.248 (95% CI 2.638 - 4.089). One or more hospital admissions for diabetic ketoacidosis were associated with an OR of 3.701 (95% CI 3.134 - 4.369).
Conclusion: This analysis has highlighted the risk factors for short term mortality in a real world cohort. Notable findings include the lower mortality risk in people from non white ethnic groups and in those with higher BMIs. It also identified the considerable additional risk of dying following a hospital admission for heart failure.

Does the association of diabetes with mortality vary by sex? Results from a pooled cohort analysis

A.P. Carson[1], S.E. Badon[2], L. Zhao[2], C.E. Lewis[1], M.L. Biggs[3], S.H. Golden[4], J.S. Pankow[5], C.S. Fox[6], V.G. Vimalananda[7], L.H. Kuller[8], P.D. De Chavez[2], M.R. Carnethon[2];
[1]University of Alabama at Birmingham, [2]Northwestern University, Chicago, [3]University of Washington, Seattle, [4]Johns Hopkins University, Baltimore, [5]University of Minnesota, Minneapolis, [6]National Heart, Lung, and Blood Institute, Bethesda, [7]Boston University, [8]University of Pittsburgh, USA.

Background and aims: Diabetes is associated with an increased risk of mortality. Whether this association varies by sex is unknown; findings from previous studies have been inconsistent and have mostly assessed prevalent diabetes without accounting for diabetes duration. The objective of this study was to investigate the association of incident diabetes with all-cause and CHD mortality and evaluate whether associations vary by sex.
Materials and methods: This pooled analysis included data from 35,665 participants, free of diabetes at baseline, from 5 epidemiologic cohort studies: Atherosclerosis Risk in Communities Study (1990-2006); Cardiovascular Health Study (1992-2008); Coronary Artery Risk Development in Young Adults Study (1985-2011); Framingham Offspring Study (1979-2007); and Multi-Ethnic Study of Atherosclerosis (2002-2011). Incident diabetes was defined as fasting glucose ≥ 7.0 mmol/l or use of diabetes medications. All-cause mortality and CHD mortality were determined from adjudicated event surveillance. Cox proportional hazards models with time-dependent exposure and covariates were used to assess the association of incident diabetes with mortality and determine whether this association varied by sex in models adjusted for socio-demographics (age, race, and education), cardiovascular disease (CVD) risk factors (BMI, smoking, hypertension, and hyperlipidemia), and prior CHD. Hazard ratios from cohort-specific analyses were pooled together using fixed-effects meta-analysis.
Results: Median age at baseline was 52 years. Over a median 17.9 years of follow-up, all-cause and CHD mortality rates were 173.5 and 35.5 per 1000 person-years, respectively. Diabetes was associated with an increased risk of all-cause and CHD mortality after adjustment for socio-demographics and a statistically significant interaction by sex was noted for all-cause mortality (Table). After additional adjustment for CVD risk factors and prior CHD, diabetes remained associated with all-cause and CHD mortality overall and within sex-groups, but the interaction between diabetes and sex was not statistically significant.
Conclusion: Incident diabetes was associated with an increased risk of all-cause and CHD mortality. The association of incident diabetes with all-cause mortality was greater among women compared with men, but this excess risk was explained by differences in CVD risk factors. Ongoing efforts to address modifiable CVD risk factors are needed to reduce the risk of all-cause and CHD mortality associated with incident diabetes.

	Overall	Men	Women

Total mortality by elevated transferrin saturation and haemochromatosis genotype in individuals with diabetes from two general population studies

C. Ellervik[1], T. Mandrup-Poulsen[2], A. Tybjærg-Hansen[1], B.G. Nordestgaard[1];
[1]Institute of Clinical Medicine, Faculty of Health and Medical Sciences, University of Copenhagen, [2]Department of Biomedical Sciences, Faculty of Health and Medical Sciences, University of Copenhagen, Denmark.

Background and aims: Iron overload and hemochromatosis genotype confer risk of diabetes. Mortality is increased in patients with clinically overt hereditary hemochromatosis, in individuals from the general population with increased transferrin saturation (TS) independent of hemochromatosis genotype, and also in patients with diabetes and increased TS or hemochromatosis genotype from a highly specialised diabetes clinic. Thus, we have recommended targeted screening for TS in specialised diabetes clinics. Whether mortality is also increased in patients ascertained from the general population with diabetes and increased TS or hemochromatosis genotype is unknown.
Materials and methods: In two Danish population-based follow-up studies, we examined mortality according to baseline TS(N=3346) or hemochromatosis genotype(N=1865) in individuals with diabetes (type 1 diabetes, N=118; type 2 diabetes, N=3228; total, N=3346). During a median of 4 years of follow-up, 541 patients with diabetes died.
Results: The cumulative survival was reduced in patients with diabetes with TS≥50% versus <50% (log-rank P<0.0001). Age-and sex adjusted hazard ratios for total mortality for TS≥50% vs <50% were 2.0 (95% CI 1.3-2.8; P =0.0004) overall, 1.8 (1.2- 2.8; P=0.003) in men, and 3.2 (1.2-8.8; P=0.02) in women; for neoplasms 2.6(1.3-5.4; P=0.008) and for endocrinological causes 4.8(2.0-12;P=0.0003); death due to cardiovascular causes was not different. Overall median survival time was 66 years (TS≥50%) and 79 years (TS<50%). Hazard ratio for total mortality in individuals with diabetes and hemochromatosis genotype C282Y/C282Y vs. wild type/wild type was 3.2(1.0-10;P=0.04) overall. Multifactorially adjusted hazard ratios and analyses for type 2 only or excluding hemochromatosis genotypes showed similar results. A stepwise increased risk of total mortality was observed for stepwise increasing levels of TS (log-rank P=0.0001), with the highest risk conferred by TS≥70% vs TS<20% with a hazard ratio of 4.8 (2.0-12; P =0.0006). Seven percent of premature death among diabetics in the general population can possibly be avoided by early screening for TS or hemochromatosis genotype.
Conclusion: Patients with diabetes, ascertained in the general population, with increased TS or hemochromatosis genotype have a 2-5-fold increased risk of premature death. Thus, we also recommend targeted screening with TS or hemochromatosis genotype in patients with diabetes in the general population.

Prosomatostatin and mortality in patients with type 2 diabetes mellitus (ZODIAC-35)

H. Joosten[1], L. van Essen[2], P.R. van Dijk[2], K.H. Groenier[3], S.J.L. Bakker[1], H.J.G. Bilo[2,1], N. Kleefstra[2,4];
[1]University Medical Center Groningen, [2]Diabetes centre, Isala clinics, Zwolle, [3]University Medical Center Groningen, Zwolle, [4]Langerhans Medical Research Group, Zwolle, Netherlands.

Background and aims: Prosomatostatin, the prohormone of somastatin, is suggested to be involved in glucose metabolism by inhibiting the secretion of glucagon and insulin. Prosomatostatin also influences the growth hormone-insulin-like growth factor-1 (GH-IGF-1) axis, by inhibiting the secretion of GH, the subsequent low IGF-1 concentrations are associated with an increased cardiovascular risk. Aim of this study is to investigate whether prosomatostatin is related to cardiovascular and all-cause mortality in patients with type 2 diabetes (T2DM).
Materials and methods: A total of 1687 primary care patients with T2DM participated in this prospective observational study, as part of the ZODIAC project. EDTA-plasma was stored at -80°C, until assessment of prosomatostatin by sandwich immunoassay. Cox proportional hazards models were used to investigate the relationship between the serum concentration prosomatostatin and mortality with adjustment for the selected confounders. Three models were chosen: model 1 included only prosomatostatin, model 2 included age and gender and model 3 included nine risk factors as additional potential confounders (diabetes duration, smoking, macrovascular complications, BMI, systolic blood pressure, HbA1c, serum creatinine, cholesterol-HDL ratio and albuminuria). Harrell's C statistic was used to investigate the capability of each model to predict mortality.
Results: Prosomatostatin was assessed in baseline serum samples of 1326 patients (78.6%) with a median (interquartile range) concentration of 591.5 (449.8-783.3) pmol/L. During median follow-up of 6.0 (3.2-10.0) years, 413 (31.1%) patients died, of which 176 (42.6%) were attributed to cardiovascular causes. As depicted in table 1, high prosomatostatin is significantly associated with cardiovascular and all-cause mortality, both in the crude analyses and after adjustment for age and gender. However, in model 3 the association of log prosomatostatin with mortality lost significance. There were no significant differences in Harrell's C statistics for the models with and without prosomatostatin.
Conclusion: High levels of prosomatostatin are significantly associated with increased cardiovascular and all-cause mortality in patients with T2DM, also after adjusting for age and gender. However, after adjustment for established cardiovascular risk factors this significant association is no longer observed.
Table 1. Results of the Cox proportional hazards models

	Log PSS HR (95% CI)	Harrell's C (95 % CI)	Harrell's C (95 % CI)*
All-cause mortality			
Model 1	2.80 (2.17-3.60)	0.62 (0.59-0.65)	-
Model 2	1.48 (1.14-1.93)	0.77 (0.75-0.80)	0.77 (0.75-0.80)
Model 3	1.09 (0.81-1.46)	0.79 (0.77-0.82)	0.79 (0.77-0.82)
Cardiovascular mortality			
Model 1	3.86 (2.64-5.62)	0.65 (0.60-0.70)	-
Model 2	2.21 (1.49-3.28)	0.76 (0.72-0.80)	0.75 (0.71-0.79)
Model 3	1.08 (0.69-1.68)	0.81 (0.77-0.84)	0.80 (0.77-0.84)

*Log prosomatostatin expressed in Hazard Ratio's and the capacity of the different models to predict mortality using the Harrell's C statistic. * Values of the Harrell's C statistic for the models without PSS. PSS: prosomatostatin, HR: Hazard ratio, 95% CI: 95% Confidence interval.*

Predicting macro- and microvascular complications in type 2 diabetes: the Japan diabetes complications study / the Japanese elderly diabetes intervention trial risk engine

S. Tanaka[1], S. Tanaka[2], S. Iimuro[3], H. Yamashita[4], S. Katayama[5], Y. Akanuma[6], N. Yamada[7], A. Araki[8], H. Ito[8], H. Sone[9], Y. Ohashi[3];
[1]Department of Pharmacoepidemiology, Graduate School of Medicine and Public Health, Kyoto University, [2]EBM Research Center, Kyoto University Graduate School of Medicine, [3]Department of Biostatistics, School of Public Health, University of Tokyo, [4]Department of Ophthalmology, Yamagata University Faculty of Medicine, [5]Department of Endocrinology and Diabetes, School of Medicine, Saitama Medical University, [6]The Institute for Adult Diseases Asahi Life Foundation, Tokyo, [7]Department of Internal Medicine, University of Tsukuba Institute of Clinical Medicine, [8]Tokyo Metropolitan Geriatric Hospital, , [9]Department of Hematology, Endocrinology and Metabolism, Niigata University Faculty of Medicine, Japan.

Background and aims: To develop and validate a risk engine that calculates the risks of macro- and micro-vascular complications in type 2 diabetes.
Materials and methods: We analyzed pooled data from two clinical trials on 1,748 Japanese type 2 diabetic patients without diabetes complications other than mild diabetic retinopathy with a median follow-up of 7.2 years. Endpoints were coronary heart disease (CHD), stroke, non-cardiovascular mortality, overt nephropathy defined by persistent proteinuria, and progression of retinopathy. We fit a multi-state Cox regression model to derive an algorithm for prediction. The predictive accuracy of the calculated 5-year risks was cross-validated.
Results: Sex, age, HbA1C, years after diagnosis, BMI, systolic blood pressure, non-HDL cholesterol, albumin-to-creatinine ratio, atrial fibrillation, current smoker and leisure time physical activity were risk factors for macro- and micro-vascular complications and were incorporated into the risk engine. The observed-to-predicted ratios for each event were between 0.93 and 1.08 and Hosmer-Lemeshow tests showed no significant deviations between observed and predicted events. In contrast, the UKPDS risk engine overestimated CHD risk (observed-to-predicted ratios: 0.30 for CHD and 0.72 for stroke). C statistics in our Japanese patients were high for CHD, non-cardiovascular mortality, and overt nephropathy (0.696 to 0.767) but moderate for stroke and progression of retinopathy (0.636 and 0.614). By combining macro- and micro-vascular risks the classification of low- and high-risk patients was improved by a net reclassification improvement of 5.7% (p=0.02).
Conclusion: The risk engine accurately predicts macro- and micro-vascular complications and would provide helpful information in risk classification and health economic simulations.

PS 022 Prediction of complications in type 1 and type 2 diabetes II

451

Association between sodium and potassium urinary concentrations and cardiovascular and renal complications in a French cohort of type 2 diabetes patients

P. Saulnier[1], R. Roussel[2], A. De Hauteclocque[1], R. Marechaud[3], P. Sosner[4], S. Ragot[1], S. Hadjadj[1];
[1]CIC0802, CHU Poitiers, [2]CHU Bichat, Paris, [3]Endocrinology, CHU Poitiers, [4]Cardiology, CHU Poitiers, France.

Background and aims: In type 1 diabetes and in the general population, epidemiological data suggest that sodium intake is associated with cardiovascular outcomes with a J-shape curve. However no data examined the association between urinary sodium and cardiovascular or renal complications in type 2 diabetes patients. We performed an observational evaluation in an inception cohort of 1467 type 2 diabetes patients focusing on sodium and potassium urinary concentrations (U_{Na} and U_K).
Materials and methods: Baseline urinary sodium and potassium concentrations were measured by indirect potentiometry on morning spot urine. Our primary outcome is a composite of cardiovascular death, non fatal acute myocardial infarction, cerebrovascular stroke, hospitalization for congestive heart failure or end-stage renal disease (dialysis or renal transplantation). We used Kaplan-Meier survival analysis, log-rank test and Cox proportional hazard model to estimate associations between predictors and complication outcome.
Results: Median follow-up was 56 months during which 386 primary outcomes and 193 cardiovascular deaths occurred. The mean value of U_{Na} and U_K were 88.5±41.3 mmol/day and 52.2±25.2 mmol/day respectively. Cumulative incidence of primary outcome increased significantly with decreasing tertiles of U_{Na} and U_K (Figure; all log-rank P <0.0001): lower tertile U_{Na} [7-68 mmol/l] : 9.67 %/pt-yr ; intermediate tertile U_{Na} tertile [69-103 mmol/l] : 6.41 %/pt-yr ; higher U_{Na} tertile [104-240 mmol/l]: 3.97 %/pt-yr. Lower tertile U_K [6-38 mmol/l] : 8.74 %/pt-yr ; intermediate U_K tertile [39-59 mmol/l] : 7.56 %/pt-yr higher U_K tertile [60-163 mmol/l]: 3.42 %/pt-yr. A similar relationship was found when considering cardiovascular death (all log-rank P <0.0001). This association remained significant after adjustment on age, sex, diabetes duration, estimated glomerular filtration rate, urinary albumin excretion, prior history of myocardial infarction, systolic blood pressure and use of diuretics (primary outcome : U_{Na}, P=0.0004:U_K, P <0.0001; cardiovascular death : U_{Na}, P =0.0041 and U_K, P <0.0036).
Conclusion: In type 2 diabetes patients, lower sodium and potassium concentrations are associated with higher cardiovascular and renal complications.

Albuminuria and renal function as predictors of cardiovascular events and mortality in type 2 diabetes: nationwide observational study

B. Eliasson[1], J. Cederholm[2], B. Zethelius[2,3], M. Svensson[1], S. Gudbjornsdottir[1];
[1]Department of Medicine, Gothenburg, [2]Department of Public Health and Caring Sciences, Uppsala, [3]Medical Products Agency, Uppsala, Sweden.

Background and aims: Reduced renal function and albuminuria predict cardiovascular (CV) events and mortality in type 2 diabetes (T2D). We examined the role of these and several other cardiovascular risk factors including co-existing congestive heart failure (CHF) on cardiovascular (CV) events in a large observational population-based cohort of T2D patients.
Methods: We included 68 156 patients with T2D reported to the National Diabetes Register (NDR) in Sweden in 2003-06 with a mean follow-up of 5.6 years, censor date 31 December 2010. Data on outcomes were collected from the Cause of death and Hospital discharge registers.
Results: Ten per cent of patients experienced a CV event of which 3.7% were fatal. Increasing levels of albuminuria and renal impairment were independently associated with increasing risk of CV events and all-cause mortality, also when adjusting for CHF. In normoalbuminuric patients, a reduction in renal function was an important predictor of CV events and all-cause mortality. Glycemic control and smoking had important effects on risk for CV events in patients with albuminuria but not in patients with normoalbuminuric renal impairment.
Conclusion: Albuminuria and renal impairment are independent risk factors for cardiovascular outcomes and mortality in type 2 diabetes, albuminuria being the strongest risk factor and relevant at all levels of renal function. In normoalbuminuric patients, a reduction in renal function is an important predictor of CV events and all-cause mortality.

453

Type 2 diabetes and risk of recurrent cardiovascular event following acute coronary syndrome (ACS): longitudinal analysis 2006-2011

V.S. Reddy[1], R. Luthra[2], Y. Xu[1], M. Fisher[2], T. Power[3], K. Wilhelm[1], M. Cziraky[2];
[1]Genentech Inc., South San Francisco, CA, USA, [2]HealthCore Inc, Wilmington, [3]AIM Specialty Health, Deerfield, USA.

Background and aims: Cardiovascular disease (CVD) is the leading cause of mortality worldwide, resulting in extensive morbidity and mortality in patients with T2D. This study evaluated the effect of multiple risk factors on time to first subsequent CV event in patients with and without T2D following ACS.
Materials and methods: ACS patients hospitalised with an ICD-9 code for acute myocardial infarction (MI) (410.xx) or unstable angina (411.1x) were identified from the HealthCore Integrated Research Database (HIRD^{SM}) from 2006–2011. Patients with T2D were defined as ≥ 2 ICD-9 codes for T2D (250.x0, 250.x2) at least 30 days apart; or ≥ 1 claim for T2D and ≥ 1 claim for oral or injectable anti-diabetics; or ≥ 2 prescriptions of oral anti-diabetic (OAD) or glucagon-like peptide 1 medication. Patients without T2D were defined as not meeting the above criteria and having no type 1 diabetes diagnosis (250.x1, 205.x3). Multivariable Cox proportional hazards models were used to evaluate the effect of risk factors on time to first subsequent CV event (defined as stroke, MI or coronary heart disease-related mortality) in patients with and without T2D, adjusting for baseline demographic characteristics, comorbidities, treatment utilisation and index ACS characteristics.
Results: Of the 140,903 ACS patients identified, 38,553 (27.6%) had T2D at baseline. Mean (median) follow-up length was 1.82 (1.40) and 1.84 yrs (1.41) for patients with and without T2D, respectively. Patients with T2D were on average older (mean age 68.2 vs. 65.6 yrs) with more baseline comorbidities (Deyo-Charlson Index score 3.15 vs. 1.11) vs. patients without T2D. Mean (median) length of stay of the index ACS hospitalisation was longer in patients with T2D (7.62 [4.00] vs. 5.20 [3.00] days). Following discharge, 26.2% of patients with T2D had a subsequent CV event vs. 15.4% of patients without T2D during the follow-up period. After adjusting for baseline differences, patients with T2D had significantly increased hazard (all P-values < 0.05) of a subsequent CV event if older (adj HR = 1.30 in ≥ 65 vs. < 65 years), history of chronic renal dysfunction (adj HR = 1.36), heart failure (adj HR = 1.35), hypertension (adj HR = 1.10), baseline insulin use (adj HR = 1.19), or index STEMI and NSTEMI vs. UA (adj HR STEMI = 1.59, NSTEMI = 1.62). Patients with T2D had significantly lower adjusted hazards (all P-values <

0.05) with baseline statin (adj HR = 0.94), OAD agent use (adj HR = 0.95), or CABG during the index ACS event (adj HR = 0.83).
Conclusion: Following an ACS event, patients with T2D had increased hazard of a subsequent CV event if older, had more comorbidities or MI at index, or insulin use at baseline, while a lower hazard with statin, OAD use, or CABG during the index hospitalisation. These findings reinforce the need for aggressive management of known CV risk factors to reduce the risk of subsequent CV events in patients with T2D.

Table: Risk of Subsequent CV Event Following ACS Hospitalisation, by Diabetes Status

Parameter	Patients with T2D (n = 38,553)			Patients without T2D (n = 81,845)

PS 023 Receptor regulation of islet function

454

The chemokine CCL5 is expressed by islets and regulates beta cell function through activation of GPR75

Z. Hassan, B. Liu, S. Amisten, G.C. Huang, S.A. Amiel, P.M. Jones, S.J. Persaud;
Diabetes Research Group, Kings College London, UK.

Background and aims: Chemokine ligand 5 (CCL5) activates the chemokine receptors CCR1, CCR3, CCR5 and the atypical CCL5 receptor GPR75, which shares only 12-16% amino acid sequence homology with conventional chemokine receptors. It is known that GPR75 activation promotes inositol 1,4,5-trisphosphate (IP_3) formation, stimulates intracellular calcium ($[Ca^{2+}]_i$) and protects neurons against apoptosis. We have previously demonstrated that mouse and human islets express CCL5, that GPR75 is the most abundant receptor for this chemokine in mouse and human islets, and that CCL5 stimulates insulin secretion from mouse islets. The current study investigated the cellular localisation of CCL5 and GPR75 in mouse and human islets, the effects of exogenous CCL5 on insulin secretion and apoptosis in human islets and the requirement of GPR75 in mediating the effects of CCL5 in mouse β-cells.
Materials and methods: CCL5 and GPR75 localisation within mouse and human islets was detected by immunohistochemistry. Dynamic insulin secretion from human islets perifused in the absence or presence of exogenous CCL5 was quantified by radioimmunoassay. Apoptosis of human islets was induced by exposure to a cytokine cocktail (IFNγ:1000U/μl, TNF-α:1000U/μl and IL-1β:100U/μl) and detected by measuring caspase 3/7 activities using a luminescent assay. Changes in $[Ca^{2+}]_i$ were measured by single cell microfluorimetry of fura-2-loaded MIN6 β-cells transiently transfected with non-coding RNAs (ncRNAs) or with GPR75 siRNAs. The extent of GPR75 knockdown by siRNAs treatment was determined by quantification of GPR75 mRNA levels by qPCR.
Results: CCL5 was present in glucagon-secreting α-cells in mouse and human islets, and it was also expressed by β-cells of human islets, but not by mouse islet β-cells. CCL5 did not co-localise with somatostatin-secreting δ-cells of either species. The CCL5 receptor GPR75 was abundantly expressed by β-cells of mouse and human islets. Exogenous CCL5 (10nM) potentiated glucose-induced insulin secretion from human islets (peak stimulation above glucose plateau: 259±92%, n=4, P<0.05), and decreased cytokine-induced caspase-3/7 activities in human islets (luminescence units, control: 256,577±47,811; +1nM CCL5: 145,892±19,934, n=5-7, P<0.05). CCL5 stimulated $[Ca^{2+}]_i$ in MIN6 β-cells in a concentration-independent manner (% tolbutamide response, 0.25nM CCL5: 65.7±1.6%; 2.5nM CCL5: 50.5±1.4%; 25nM CCL5: 60.6±2.1%, n=34, P<0.01). Exposure of MIN6 β-cells to GPR75 siRNAs caused a significant reduction in GPR75 mRNA expression (non-coding RNAs, GPR75 mRNA expression: 0.48±0.07% of β-actin mRNA; siRNAs: 0.29±0.01%, n=3, P<0.05) and when GPR75 expression was down-regulated the $[Ca^{2+}]_i$ response to CCL5 was significantly diminished (0.25nM CCL5: 19.0±0.5%; 2.5nM CCL5: 28.4±0.9%; 25nM CCL5: 18.9±0.6% tolbutamide response, n=45, P<0.01 versus responses in ncRNA-treated cells).
Conclusion: GPR75 is expressed by mouse and human islet β-cells and it may be activated in a paracrine manner by islet cell-derived CCL5. Exogenous CCL5 stimulates insulin secretion from human islets and protects them from apoptosis, as we have previously found for mouse islets. Down-regulation of β-cell GPR75 diminishes $[Ca^{2+}]_i$ elevations in response to CCL5, suggesting that CCL5 may primarily exert its effects in β-cells via GPR75 activation.

Fractalkine, a new factor protecting beta cell function and survival

R. Dusaulcy[1], S. Rutti[1], P. Plomgaard[2], B.K. Pedersen[3], P.A. Halban[1], K. Bouzakri[1];
[1]Department of Genetic Medicine and Development, Geneva University, Switzerland, [2]Department of Clinical Biochemistry, Rigshospitalet, Copenhagen, Denmark, [3]Rigshospitalet, Centre of Inflammation and Metabolism and Department of infectious Diseases, Copenhagen, Denmark.

Background and aims: Fractalkine (CX3CL1) is a membrane bound chemokine with a soluble form generated by enzymatic shedding. Biological

actions of fractalkine are mediated through a specific G-protein coupled receptor, CX3CR1. We have previously shown the existence of a muscle-pancreas intercommunication axis in which fractalkine produced by skeletal muscle cells could be implicated. The aim of the study was to explore the impact of fractalkine on islets and sorted beta cells.
Materials and methods: Human islets and sorted beta and non-beta cells were used to measure, CX3CL1 and CX3CR1 mRNA expression. Glucose stimulated insulin secretion (GSIS: 1h 2.8 mmol/l followed by 1h 16.7 mmol/l glucose) was measured using human beta cells exposed to 1-50 ng/ml fractalkine for 24h or rat beta cells exposed to 1-100ng/ml fractalkine for 24h alone or with TNFα (20ng/ml) or cytomix (20 ng/ml each TNFα, IFNγ, IL1-β). Glucagon secretion (1h 16.7 mmol/l followed by 1h 2.8 mmol/l glucose) was measured on human islets exposed to 1-50 ng/ml fractalkine for 24h. Rat beta cell apoptosis (TUNEL assay), and proliferation (BrdU incorporation) were measured after 24h exposure to 1-100 ng/ml fractalkine alone, or to 20 ng/ml fractalkine for 48h with addition of cytomix for the last 24h. Data are mean +/- SE (5 independent experiments).
Results: CX3CL1 and CX3CR1 are both expressed in human islets. Within the islet, fractalkine seems to be principally expressed by non-beta cells while its receptor is more expressed in the beta cells. Treatment with fractalkine for 24h had no significant impact on GSIS or insulin content in human and rat sorted beta cells. In human islets, fractalkine treatment blocked stimulation of glucagon secretion at low glucose (e.g. 0.49+/-0.06% content/h fractalkine 25ng/ml vs. 2.23+/-1.09% control; $p<0.05$) without any effect on glucagon content. In rat beta cells, fractalkine treatment had no direct impact on proliferation or apoptosis. To test the hypothesis that fractalkine could protect against the negative effects of cytokines, rat sorted beta cells were treated with fractalkine in combination with TNFα or cytomix. Fractalkine completely blocked the adverse effect of TNFα on GSIS (1.46+/-0.11% content/h TNFα vs. 3.19+/-0.12% $p<0.05$ and 2.62+/-0.04% $p<0.05$ TNFα + 10 or 25 ng/ml fractalkine). Interestingly, fractalkine treatment was not able to block the effects of cytomix on GSIS, proliferation or apoptosis in rat sorted beta cells.
Conclusion: Taken together our results show that fractalkine could have a positive impact on beta cells via a paracrine and/or endocrine axis. Fractalkine can also directly regulate glucagon secretion. Moreover, fractalkine protects beta cells from the adverse effects of TNFα while offering no protection against cytomix treatment. This suggests a specific interaction between TNFα and fractalkine signalling pathways in beta cells.

Epigenetic regulation of chemokine CXCL12 gene transcription influences its prosurvival effect on pancreatic beta cells

M. Vidakovic[1], A. Tolic[1], J. Markovic[1], N. Grdovic[1], S. Dinic[1], A. Uskokovic[1], M. Djordjevic[1], J. Arambasic[1], M. Mihailovic[1], G. Poznanovic[1], N. Martinet[2];
[1]Institute for Biological Research, University of Belgrade, Serbia, [2]Institut de Chimie de Nice, UMR 7272 CNRS, Université de Nice-Sophia Antipolis, France.

Background and aims: The CXC chemokine ligand 12 (CXCL12/SDF-1) promotes the expression of the proliferative phenotype that improves the resistance of pancreatic beta cells (b-cells) to diabetogenic stimuli. Our aim was to demonstrate the positive impact of chemokine CXCL12 expression on increased survival of b-cells, to provide a novel insight into the epigenetic regulation of CXCL12 gene (*Cxcl12*) transcription and to initiate a screening study designed to test whether certain compounds present in the Epigenetic Compound Library (ECL-COST-TD0905) possess a DNMT1 inhibitory potential.
Materials and methods: The RIN-5F rat pancreatic b-cell line (wt), its counterpart that possesses a stably integrated human gene for CXCL12 (#1) and MIN6 cells were exposed to increasing concentrations of streptozotocin. The prosurvival potential of CXCL12 was assessed by the viability assay (MTT). For the DNA methylation studies, DNA was isolated from: rat RIN-5F wt and #1 cells, rat Langerhans islets and mouse MIN6, NIH 3T3 wt and PARP-1 knockout cells. DNA methylation of the rat and mouse *Cxcl12* was assessed using real-time methylation-specific PCR (MSP) with primers designed for each CpG island predicted within the promoter, the first exon and intron of *Cxcl12*. Each component from ECL-COST-TD0905 was used at 15 μM concentration for demethylation studies (5-aza-2'-deoxycytidine, was used as positive control).
Results: Our results confirmed that the ıncreased presence of CXCL12 improves pancreatic b-cell survival during oxidative stress induced by a diabetogenic stimulus. The CpG island analysis of the rat and mouse *Cxcl12* promoter, first exon and intron revealed the same number and very similar distribution of CpG islands in both species. MSP showed that the CpG-rich regions within the *Cxcl12* promoter, first exon and intron are semi-methylated in the rat Rin-5F cells. In the rat Langerhans islets, the core promoter is unmethylated, while the first exon exhibited methylation of both alleles. In mouse cells, large differences in methylation patterns of the core promoter were observed: wt cells possess a unmethylated and PARP-1 knockout cells a fully methylated core promoter. One of the eight analysed compounds from the ECL-COST-TD0905 possesses potential to inhibit DNMT1 *in vitro*.
Conclusion: We confirmed that CXCL12 exerts a prosurvival effect on pancreatic b-cells. The differences observed in the methylation status of the *Cxcl12* gene, points to decreased gene responsiveness to external stimuli. The clear differences in the methylation status of the promoter and the first exon in the rat insulinoma cell line and *ex vivo* isolated Langerhans islets have to be underlined. Furthermore, observed hypermethylation of mouse *Cxcl12* in PARP-1 knockout cells, points to the involvement of PARP-1 in the inhibition of the methylation *in vivo*.

Role of GPR55 in the regulation of insulin secretion and islet survival

S. Song[1], B. Liu[1], J.E. Bowe[1], D. Baker[2], G.C. Huang[1], S.A. Amiel[1], P.M. Jones[1], S.J. Persaud[1];
[1]Diabetes and Nutritional Sciences Division, King's College London, [2]Barts and the London School of Medicine and Dentistry, Blizard Institute, UK.

Background and aims: We have recently shown that the novel cannabinoid receptor GPR55 is expressed by islets and that its pharmacological activation stimulates insulin secretion and protects islets from apoptosis. To further understand the role of GPR55 in islets, this study evaluated the effects of two GPR55 agonists (10μM O-1602 and 5μM LPI) on insulin secretion from islets isolated from GPR55 knockout (KO) mice and age-matched wildtype (WT) mice. The effects of the GPR55 antagonist cannabidiol (1μM CBD) on insulin secretion from isolated mouse and human islets, and on islet apoptosis, were also investigated.
Materials and methods: Islets were isolated from mouse and human pancreas by collagenase digestion and purified by density gradient centrifugation. Dynamic insulin secretion was quantified by radioimmunoassay following perifusion of islets from WT and GPR55 KO mice, and from human organ donors. Apoptosis of islets was induced by exposure to mixed cytokines (1U/μl IFNγ, 1U/μl TNFα, 0.05U/μl IL-1β) for 20 hours and caspase 3/7 activities were measured using a luminescent assay.
Results: 10μM O-1602 significantly stimulated insulin secretion from WT mouse islets at 2mM glucose (peak stimulation: 488±80%; n=3, $P<0.05$) and potentiated glucose-induced insulin stimulation (peak stimulation above 20mM glucose plateau: 232±53 %; n=3, $P<0.05$). The stimulatory effects of O-1602 on insulin secretion were abolished in islets isolated from GPR55 KO mice (n=4, $P<0.05$ versus response to O-1602 in WT islets). However, 10μM LPI significantly potentiated glucose-induced insulin secretion from islets isolated from both WT and GPR55 KO mice (peak stimulation above 20mM glucose plateau: WT: 142±11%; KO: 179±42%; n=4, $P<0.05$ versus 20mM glucose alone for WT and KO islets). Unexpectedly, the GPR55 antagonist CBD significantly stimulated insulin secretion from mouse islets at 2mM glucose (peak stimulation: 334±87%; n=4, $P<0.05$) and at 20mM glucose (peak stimulation above 20mM glucose plateau: 194±68%; n=4, $P<0.05$). Stimulatory effects in response to CBD were also observed in perifusion experiments using human islets, with increases over basal secretion at 2mM glucose (peak stimulation: 415±84%; n=4, $P<0.05$) and potentiation of glucose-stimulated insulin secretion (peak stimulation above 20mM glucose plateau: 255±50%; n=4, $P<0.05$). In addition, exposure of mouse islets to 1μM CBD for 20 hours protected against apoptosis (reduction in caspase 3/7 activities, basal: 39±6%; cytokine-induced: 45±2%; n=11, $P<0.01$).
Conclusion: These data indicate that the pharmacological GPR55 agonist O-1602, and the endogenous lipid LPI, stimulate insulin secretion from mouse islets, but only the effect of O-1602 is dependent on the presence of GPR55. In addition, the GPR55 antagonist CBD unexpectedly increased insulin secretion and promoted islet survival. Our results therefore suggest that GPR55 plays an important role in the regulation of islet physiology, but LPI and CBD exert their effects on islet function by a GPR55-independent pathway(s).

Effect of in vitro and in vivo hyperglycaemia on muscarinic M3 receptor expression and activation in islets

A.C. Hauge-Evans, Z. Franklin, A. Kerby, S. Amisten, A.J.F. King, S.J. Persaud, P.M. Jones;
Diabetes Research Group, King's College London, UK.

Background and aims: Islets are innervated by parasympathetic nerves which release acetylcholine (ACh) during feeding. In beta cells the effect of ACh is mediated primarily via muscarinic M3 receptors (M3R) leading to amplification of glucose-induced insulin secretion from the islets. Beta cell specific knock-out of M3R results in reduced insulin secretion and impaired glucose tolerance and we have previously shown that M3R expression and secretory sensitivity to muscarinic agonists are down-regulated in islets isolated from *ob/ob* mice. Here we investigate *in vitro* and *in vivo* whether this change is a consequence of the local hyperglycaemic environment of the islets.
Materials and methods: To provide an *in vivo* hyperglycaemic/diabetic environment lacking direct islet innervation, alginate-encapsulated mouse islets were transplanted intraperitoneally into streptozotocin-induced diabetic mice and retrieved after 7 days, and encapsulated islets were also transplanted into control, normoglycaemic mice. In the *in vitro* study, isolated mouse or human islets were maintained in the presence of 5.5 or 16 mmol/l glucose for 3 or 7 days. Blood glucose levels were assessed by commercial glucose meter, islet hormone secretion and content by RIA and M3R mRNA levels by qPCR.
Results: Blood glucose levels of diabetic mice remained high following minimal mass (200) transplantation of encapsulated islets (day -1: 28.6±1.3 mmol/l glucose, day 7: 22.5±3.5, n=5, P>0.2). Islets retrieved from both control and diabetic mice responded to glucose with release of insulin (control: 1 mmol/l glucose: 13.9±2.0 pg/islet/h, 20 mmol/l glucose: 79.2±20.8, P<0.05; diabetic: 1 mmol/l glucose: 18.4±1.8 pg/islet/h, 20 mmol/l glucose: 116.1±7.8, P<0.001, n=3-4), but enhancement of glucose-induced insulin secretion by the acetylcholine analogue, carbachol (CCh, 0.5 mmol/l), was reduced by 71±7% in islets from diabetic mice compared to controls (339±79% secretion at 20 mmol/l glucose vs 1156±346%, n=5-6, P<0.05). Maintenance of islets in the presence of 16 mmol/l glucose for 3 days significantly reduced the expression of M3R mRNA by 50±12% compared to islets maintained at 5.5 mmol/l glucose (n=8, P<0.001). Potentiation of glucose-induced insulin secretion by CCh was reduced by 33±7% (P<0.05) and 58±3% (P<0.001) following culture in 16 mmol/l glucose for 3 and 7 days, respectively, compared to 5.5 mmol/l glucose. In addition, CCh stimulated glucose-induced secretion from human islets that had been maintained at 5.5 mmol/l glucose for 7 days, but not those that had been exposed to 16 mmol/l glucose for 7 days (P<0.001 vs. 5.5 mmol/l glucose).
Conclusion: These results indicate that down-regulation of islet M3R and reduced insulin secretory sensitivity to muscarinic agonists is likely to be a consequence of the hyperglycaemic environment and suggests that M3 receptors could be potential targets in the treatment of type 2 diabetes.

Receptor-mediated effects of melatonin on insulin secretion in INS-1 832/13 beta cells

P. Singh, H. Mulder;
Department of Clinical Sciences, Unit of Molecular Metabolism, Lund University Diabetes Centre, Malmö, Sweden.

Background and aims: The vital role of the hormone melatonin on glucose homeostasis was highlighted by the discovery of the single nucleotide polymorphisms (SNPs) of the human Mtnr1b and more recently of Mtnr1a associated with impaired glucose metabolism. Despite several advances, the exact mechanism of melatonin actions on insulin release and its receptor involvement is still unclear. To unveil this issue, we examined the impact of melatonin receptor signaling on insulin secretion by using a knockdown approach in INS-1 832/13 β-cells.
Materials and methods: To generate knockdown of Mtnr1a and Mtnr1b receptors, the INS-1 832/13 β-cells were transfected with siRNA against these receptors. To examine the magnitude of receptor-mediated effects of melatonin on glucose-stimulated insulin secretion (GSIS), the transfected cells were stimulated with glucose in the absence or presence of melatonin (1μM). Moreover, the effect of silencing its receptors on cAMP-evoked insulin release was also studied considering the established cAMP-lowering effects of its receptors.
Results: Robust knockdown of both Mtnr1a and Mtnr1b receptors was achieved at the mRNA as well as at the protein level. The knockdown of either Mtnr1a or Mtnr1b did not affect GSIS in INS-1 832/13 β-cells (3.2±0.01 or 3.8±1.24 vs. 2.8±0.25 fold respectively). Melatonin decreased GSIS in control cells (2.8±0.25 vs. 1.8±0.11 fold respectively, P<0.05), while, in Mtnr1a knockdown cells no melatonin-induced reduction in GSIS was observed compared to negative control cells (2.7±0.09 vs. 2.8±0.25 fold respectively). Interestingly, melatonin only marginally lowered insulin secretion in Mtnr1b knockdown cells compared to Mtnr1a knockdown cells (2.2±0.12 vs. 2.7±0.09 fold respectively). However, fold changes in GSIS in melatonin-treated Mtnr1b knockdown cells were still significantly higher than the melatonin-treated negative control cells (2.2±0.12 vs. 1.8±0.11 fold respectively, P<0.05). This reflects that even though both receptors are involved in the insulin-lowering effect of melatonin, Mtnr1a exerted a stronger effect than Mtnr1b. No melatonin-mediated reduction in GSIS was observed in forskolin-stimulated Mtnr1a or Mtnr1b knockdown cells (5.9±0.62 vs. 6.1±1.00 or 6.6± 0.57 vs. 6.1±0.33 fold respectively). This supports previous reports of the involvement of cAMP signaling in melatonin receptor-mediated effects on insulin secretion.
Conclusion: Our results revealed that in the paucity of its receptors, melatonin failed to inhibit glucose- or cAMP-stimulated insulin release. This emphasizes the significant role of both of its receptors and cAMP signaling in this course.

460

Inhibition of small-Maf function in pancreatic beta cells attenuates the effect of GLP-1 receptor agonist on improvement of glucose tolerance

H. Nomoto, T. Kondo, N. Fujimori, H. Miyoshi, T. Atsumi;
Medicine II (Immunology and Metabolism), Hokkaido University, Sapporo, Japan.

Background and aims: GLP-1 possesses protective effects on beta cells and increases both amount of insulin secretion on demand and beta cell proliferation. In addition, anti-oxidative and anti-inflammatory effects have been reported in some incretin-related agents. MafA, one of large-Maf factors, is a major regulator of insulin gene expression and beta cell function. On the other hand, small-Maf factors lack N-terminal transactivation domain and therefore act as a negative regulator of insulin expression. We previously reported that mRNA and protein levels of small-Maf factors were increased under oxdative or lipotoxic conditions, and concomitantly insulin gene expression was diminished in beta cell lines. Moreover, transgenic (Tg) mice with beta cell specific expression of dominant-negative small Maf factor (DN-MafK) on C57BL/6J background showed improvement of glucose tolerance under feeding high-fat diet (HFD), in spite of similar MafA expression pattern as compared with wild-type (Wt) mice. Here, to clarify the incretin effects on small-Maf factors under the lipotoxic condition, we evaluate the effects of liraglutide to HFD-fed Tg mice.
Materials and methods: Both Wt and Tg male mice were fed on HFD from 6 weeks of age and injected liraglutide (at a dose of 200μg/kg) or vehicle daily from 8 weeks. Body weight, food consumption and blood glucose were measured. At 16 weeks, insulin tolerance test and oral glucose tolerance test were performed, and then pancreatic sections were obtained for immunohistochemistry to evaluate beta cell mass using insulin staining. Proliferation of beta cell was evaluated by PCNA staining.
Results: Body weight and food intake were reduced in liraglutide-treated mice than in vehicle, but there were no significant differences between Wt and Tg mice. Treating with liraglutide resulted in significant lower levels of random blood glucose in Wt mice, not in Tg mice. Glucose tolerance test showed liraglutide-treated Wt mice and vehicle-treated Tg mice improved in blood glucose AUC as compared with vehicle-treated Wt mice (p<0.05, p<0.001 respectively) and, however, there was no significant difference between vehicle-treated Tg mice and liraglutide-treated Tg mice. In immunohistochemistry analyses, there were tendencies to increase beta cell mass and proliferation in liraglutide-treated Wt mice and Tg mice
Conclusion: The effect of GLP-1 in HFD-fed Tg mice seems to be focal. These data suggest a possibility that GLP-1 receptor signal in beta cells might be at least partially mediated by small-Maf factors.

Cannabinoid CB1 receptors and mTORC1 signalling pathway interact to modulate glucose homeostasis

F.J. Bermudez-Silva[1,2], S.Y. Romero-Zerbo[1], M. Haissaguerre[2,3], I. Ruz-Maldonado[1], A. Tabarin[2,3], G. Marsicano[2,3], D. Cota[2,3];
[1]Investigacion, Hospital Carlos Haya, Malaga, Spain, [2]U862, Neurocentre Magendie, Inserm, Bordeaux, France, [3]Universite Bordeaux 2, France.

Background and aims: The endocannabinoid system is an inter-cellular signalling mechanism that has been described to play a role in the islets of Langerhans in the modulation of insulin secretion as well as beta cell mass expansion. CB1 antagonism has been reported to ameliorate the metabolic profile, including glucose homeostasis, in diabetic patients. However, the downstream signalling proteins mediating these effects are poorly understood. The mammalian target of rapamycin complex 1 (mTORC1) is a key intra-cellular signalling pathway involved in energy homeostasis and has an important role in pancreatic islet's physiology. Recent reports have described a functional interaction between both systems in the central nervous system, but this aspect is still unexplored in the endocrine pancreas.
Materials and methods: We explored the possible interaction between the ECs and mTORC1 signalling by pharmacologically manipulating the CB1 or mTORC1 pathway in C57Bl/6 mice and used mice genetically lacking the CB1 receptor or the downstream target of mTORC1, p70S6K1 protein. In vitro static secretion experiments on islets, western blotting and in vivo glucose tolerance tests were performed.
Results: CB1 antagonism decreased glucose-stimulated insulin secretion (GSIS) and specific pharmacological blockade of mTORC1 by rapamycin, as well as genetic deletion of p70S6K1 protein, impaired the CB1-mediated decrease in GSIS. Phosphorylation of p70S6K1 protein within islets was increased after CB1 antagonism. In vivo experiments showed that CB1 antagonism decreased insulin levels and induced glucose intolerance; this effect was prevented by i.p. injection of low doses of rapamycin not increasing per se plasma insulin levels.
Conclusion: These findings suggest a functional molecular interaction between the ECS and the mTORC1 pathway within the endocrine pancreas and at the whole body level, which could have implications for the development of new therapeutic approaches for pancreatic beta cell diseases.

Angiogenic factors regulate beta cell function

P. Shah[1], J. Olerud[2], J. Kerr-Conte[3], P.-O. Carlsson[2], K. Maedler[1];
[1]University of Bremen, Germany, [2]Uppsala University, Sweden, [3]INSERM/ Universite` de Lille, France.

Background and aims: Angiogenic factors play an important role in organ vasculature during development, quiescence as well as pathological conditions. The highly vascularised islets of Langerhans are in a close network with the islet endothelial cell (EC), which regulates blood supply as well as islet endocrine function. The Angiopoietin-Tie system is one such family of angiogenic factors consisting of Angiopoietin-1 (Ang-1)-the agonist, expressed by perivascular cells and β-cells, Angiopoietin-2 (Ang-2)-the antagonist, expressed by endothelial cells as well as β-cells and their common receptor Tie-2 expressed by endothelial cells. In this study we hypothesized that reduced islet vessel density under diabetogenic conditions occurs together with changes in the Angiopoietin-Tie system, which directly regulates β-cell function.
Materials and methods: Islet vessel density was quantified by immunostaining islets with CD31, and EC marker and insulin. The vessel density was expressed as a ratio of CD31:Insulin area. To investigate the effect of Ang-2 on islet function, human and mouse islets and INS-1E -cells were treated with 0.2 ug to 0.8 ug/ml of recombinant Ang-2. After treatment duration of 2-4 days the islets were subject to a glucose stimulated insulin secretion assay (GSIS).
Results: Endothelial cell area was reduced under diabetogenic conditions with 61% reduction ($p>0.05$) in mouse islets and a 46% reduction in human islets in response to glucotoxicity (22.2 mM glucose/palmitate for 4 days). Ang-1 and Tie-2 mRNA levels were decreased by 70% and 80% respectively whereas there was a 3-fold induction in Ang-2 mRNA in treated human islets, similar changes in Ang-1, Tie-2 and Ang-2 also occurred in mouse islets isolated from high fat diet fed mice. Such increased Ang-2 levels led to direct impairment in β-cell function. Glucose stimulated insulin secretion (GSIS) was depleted in human and mouse islets amd INS-1E cells upon exposure to recombinant-Ang-2.
Conclusion: The Ang/Tie angiogenic system plays an important role in the regulation of islet function, with Angiopoietin-2 causing its impairment under diabetogenic conditions.

FFAR1 is involved in both the acute and chronic effects of palmitate on insulin secretion

H. Kristinsson[1], D. Smith[2], P. Bergsten[1], E. Sargsyan[1];
[1]Medical Cell Biology, Uppsala University, [2]AstraZeneca, Mölndal, Sweden.

Background and aims: Free fatty acids (FFAs) have pleiotropic effects on pancreatic beta cells. While acute exposure to FFAs stimulates glucose-stimulated insulin secretion (GSIS), prolonged exposure impairs GSIS and causes apoptosis. FFAs exert their effects via intracellular metabolism and interaction with the free fatty acid receptor 1 (FFAR1/GPR40). Here, we studied the role of FFAR1 in the acute and long-term effects of palmitate on GSIS and insulin content in isolated human islets.
Materials and methods: The role of FFAR1 in the acute effect of palmitate on GSIS was investigated by perifusing human islets with 20 mM glucose with and without palmitate (0. 5 mM, 0.5% BSA) in the presence or absence of the FFAR1 agonist TAK-875 (2μM), or the antagonist ANT203 (2μM). The role of FFAR1 in the chronic effect of palmitate was addressed by culturing human islets with and without palmitate (0.5 mM, 0.5 % BSA) in the presence or absence of the FFAR1 agonist TAK-875 (2μM), or the antagonist ANT203 (2μM) for 7 days. After culture GSIS and insulin content were measured.
Results: Acute palmitate exposure potentiated GSIS ~3-fold, whereas addition of FFAR1 antagonist decreased this potentiation to ~2-fold ($p<0.05$ n=4). In the absence of palmitate, FFAR1 agonist caused only a ~1.4-fold increase in GSIS ($p<0.05$, n=4). Treatment with palmitate for 7 days decreased GSIS to 70 % and insulin content to 25 % of control level ($p<0.05$, n=5). These negative effects of long-term exposure to palmitate were ameliorated by FFAR1 inhibition ($P<0.05$, n=5) and further aggravated by additional stimulation of the receptor ($P<0.05$, n=3). In the absence of extracellularly applied palmitate long-term treatment with the agonist caused a modest increase in GSIS.
Conclusion: We conclude that FFAR1 plays a substantial role not only in the acute potentiation of GSIS by palmitate, but also in the negative long-term effects of palmitate on GSIS and insulin content.

Inhibition of the mitogen activated protein kinase pathway accentuates the pro-apoptotic effect of fatty acids but does not alter the fatty acid-induced insulin secretion

M. Panse[1], F. Gerst[1], G. Kaiser[1], C.-A. Teutsch[1], E. Christiansen[2], T. Ulven[2], H.-U. Häring[1], S. Ullrich[1];
[1]Internal Medicine IV, University Hospital Tübingen, Germany, [2]Department of Physics, Chemistry and Pharmacy, University of Southern Denmark, Odensee, Denmark.

Background and aims: The mitogen activated protein kinase (MAPK) pathway is involved in a variety of physiological processes such as proliferation, differentiation and, more intriguingly, apoptosis. MAPK is activated by growth factors including IGF-1 and insulin but also by metabolites such as glucose and fatty acids. The role of the MAPK pathway in insulin secreting cells is controversially discussed. Both, pro- and anti-apoptotic effects have been shown upon inhibition of extracellular signal-regulated protein kinases 1 and 2 (ERK1/2). Also, reduced ERK1/2 activity affects insulin secretion. The stimulation of ERK1/2 primarily results in an induction of transcription factors. The activation of early genes, c-fos and myc, induces cell cycle proteins, such as cyclin D and cyclin dependent kinases, and promotes cell cycle progression. Furthermore, stimulation of ERK1/2 controls neuronal differentiation through paired box protein PAX6, a transcription factor also essential for differentiation of pancreatic endocrine cells. This study aims to understand the role of ERK1/2 during acute and chronic exposure of insulin secreting cells to fatty acids.
Materials and methods: In isolated islets from C57BL/6 and free fatty acid receptor 1 (FFAR1) knockout mice as well as in INS-1E cells, ERK1/2 was stimulated with palmitic acid (600 μmol/l in the presence of 0.6% albumine or 50 μmol/l in the presence of 0.05% albumine); with oleic acid (50 μmol/l in the presence of 0.05% albumine) and with a specific FFAR1 agonist (TUG-469, 10 μmol/l in the presence of 0.05% albumine); and inhibited by PD98059 (10 μmol/l). Insulin secretion was assessed after static incubation of the cells by radioimmunoassay. Apoptotic cell death was assessed using the TUNEL assay. Activation of ERK1/2 was evaluated on Western blot using phospho-specific antibodies.
Results: Palmitic and oleic acid transiently induced phosphorylation of ERK1/2 in INS-1E cells. This effect did not depend on FFAR1 as palmitic acid increased phoshorylation of ERK1/2 in wild type as well as FFAR1-deficient islets. Furthermore the FFAR1 agonist TUG-469 did not mimic the effect of fatty acids. Palmitic acid induced beta cell death, but oleic acid and TUG-469 did not. Although the ERK1/2 inhibitor PD98059 was neither apoptotic under control culture conditions, i.e. in the presence of 11 mmol/l glucose nor in the presence of TUG-469, it augmented palmitic acid-induced cell death. When insulin secretion was examined, inhibition of ERK1/2 by PD98059 did not affect basal secretion (i.e. at 2.8 mmol/l glucose) but significantly increased (by 50%) glucose-induced insulin secretion. PD98059 did not influence secretion in the presence of palmitic and oleic acid. Both fatty acids augmented 2-fold glucose (12 mmol/l)-induced secretion but had no effect at 2.8 mmol/l glucose.
Conclusion: These observations suggest that FFAR1 does not mediate fatty acid-dependent stimulation of ERK1/2. Inhibition of ERK1/2 augments fatty acid-induced cell death but does not affect fatty acid-induced insulin secretion, suggesting that ERK1/2 exerts primarily anti-apoptotic effects in beta cells.

Prolonged exposure to palmitate deteriorates glucose-induced cAMP generation and pulsatile insulin secretion

G. Tian, E.-R.M. Sol, Y. Xu, A. Tengholm;
Medical cell biology, Uppsala University, Sweden.

Background and aims: Type 2 diabetes is often associated with increased plasma concentrations of free fatty acids. Indeed, prolonged exposure of β-cells to the fatty acid palmitate induces lipotoxic effects with deterioration of glucose-stimulated insulin secretion, but the underlying mechanisms have not been fully clarified. Insulin secretion is triggered by a rise of the cytoplasmic Ca2+ concentration ([Ca2+]i) and is further amplified by elevation of cAMP. Glucose induces synchronous oscillations of [Ca2+]i and the subplasma membrane cAMP concentration ([cAMP]pm) in β-cells, which result in pulsatile insulin secretion. The aim of the present study was to investigate how [Ca2+]i and [cAMP]pm signalling in β-cells and insulin secretion are affected by long-term exposure to palmitate.
Materials and methods: Islets isolated from C57Bl mice were pre-incubated with 0.5 mM palmitate in 1% BSA for 48 hours. [Ca2+]i was measured with Fura-PE3 and epifluorescence microscopy. A translocation biosensor based on fluorescence-tagged subunits of protein kinase A was used to monitor [cAMP]pm in β-cells within intact islets. The time-course of insulin secretion was monitored using a translocation sensor for PtdIns(3,4,5)P3, a lipid formed in the β-cell plasma membrane following autocrine insulin receptor activation. Changes in localization of the reporters were detected with total internal reflection fluorescence microscopy. Insulin-secreting β-cells were identified by their large size and [cAMP]pm-lowering effect of adrenaline.
Results: In control β-cells, an increase of glucose from 3 to 20 mM induced a pronounced [cAMP]pm elevation, often with oscillations (frequency 0.09-0.27/min) whereas addition of 100 nM GLP-1 triggered stable [cAMP]pm increase. After 48 h exposure to palmitate, 91% of the β-cells failed to respond to glucose with rise of [cAMP]pm and the remaining cells showed only a modest and transient [cAMP]pm elevation. In contrast, the GLP-1-induced [cAMP]pm response was unaffected by palmitate treatment (amplitude 0.46±0.12 ratio units vs 0.38±0.04 in control). Basal [Ca2+]i in the presence of 3 mM glucose was slightly elevated after palmitate exposure (67±1 nM vs 48±0.8 nM in control; $P<0.05$), but the fatty acid did not influence the amplitude of the [Ca2+]i oscillations induced by 20 mM glucose (130±11 nM vs 132±10 nM in control) or the [Ca2+]i elevation triggered by 30 mM K+ (209±11 nM vs 220±22 nM in control). ¬¬¬¬Control islet cells responded to 20 mM glucose with pronounced PtdIns(3,4,5)P3 oscillations, reflecting pulsatile insulin secretion. This glucose-induced PtdIns(3,4,5)P3 response was lost in 93% of the palmitate-treated cells, and the remaining cells showed only a transient increase or minute stable elevation of PtdIns(3,4,5)P3.
Conclusion: Prolonged exposure of mouse islets to palmitate results in deterioration of glucose-stimulated insulin secretion with loss of pulsatility. While [Ca2+]i signalling is essentially unaffected, the secretory defect is associated with impaired generation of cAMP.

Acute exposure of beta cells to low concentrations of IL-1beta improves insulin secretion through focal adhesion and actomyosin remodelling

C. Arous, P.A. Halban;
Dpt. Genetic Medecine and Development, University Medical Center, University of Geneva, Switzerland.

Background and aims: Defective insulin secretion in type 2 diabetes is associated with low-grade systemic and islet inflammation governed in part by IL-1beta. This cytokine is known to exert both negative and positive effects on beta cells. Numerous publications have documented the deleterious effects on beta cell function and survival of longer term (>24h) exposure to a high concentration (20ng/ml) of IL-1beta. While exposure to much lower concentrations of IL-1beta for >24h has been shown to improve beta cell function and survival, the acute effects of low concentrations of IL-1beta has been less well studied. We have recently demonstrated that focal adhesion (FA) and actomyosin II remodelling, and activation of the ERK1/2 signalling pathway occur rapidly in beta cells after glucose stimulation; this is crucial for insulin granule recruitment to the basal membrane. We hypothesized that IL-1beta might modulate these dynamic pathways leading to glucose-induced insulin secretion.
Materials and methods: All studies were performed using sorted rat primary beta cells cultured in monolayer on extracellular matrix. Beta cells were exposed to IL-1beta and insulin secretion (radioimmunoassay) measured during 1h at low glucose (2.8mmol/l), followed by 1h at high glucose (16.7mmol/l). Protein levels and phosphorylation were determined by western blot following 2h at low glucose and 10 min at high, in the continued presence of IL-1beta. Immunofluorescence was used to study dynamic changes in localization and appearance of FA proteins, focal adhesion kinase (FAK) and paxillin (PAX), and actin cytoskeleton. Data are mean±SE (n=3 unless mentioned otherwise).
Results: A low concentration of IL-1beta (0.1 ng/ml) for 2h increased glucose-stimulated insulin secretion (GSIS) by 42.6 ± 7.6% (p=0.028) whereas 20 ng/ml was without significant effect. Glucose stimulation led to remodelling of actin into filaments, with FAK and PAX phosphorylation and their localization in small newly formed FA. Presence of 0.1 ng/ml IL-1beta increased the length of FAs at the basal membrane measuring >2.5μm by 47.7 ± 16.6% (p=0.015) and glucose-induced phosphorylation of PAX and ERK1/2 by 39.8 ± 13.1% (p=0.031) and 37.06 ± 11.8% (p=0.024) respectively. By contrast, 20 ng/ml IL-1beta had no effect on glucose induced FA remodelling or protein phosphorylation. In order to determine whether 0.1 ng/ml IL-1beta also affects basal insulin secretion, beta cells were treated for 2h with the cytokine at 2.8mmol/l glucose. This led to a 19.8 ± 8.8% decrease in (basal) secretion (n=2) associated with actin restructuring into thick bundles.
Conclusion: Acute exposure of beta cells to 0.1 ng/ml IL-1beta improves beta cell function. The increase in GSIS was accompanied by changes in focal adhesion remodelling and intracellular signalling previously shown to be critical for insulin secretion. It is concluded that low-dose IL-1beta can act rapidly, directly and positively on insulin secretion through FA and actin remodelling.

Relationship between islet angiogenesis and the positive effect of islet neogenesis-associated protein pentadecapeptide (INGAP-PP) upon beta cell function

L.E. Flores, C.L. Román, B. Maiztegui, J.J. Gagliardino;
CENEXA – Centro de Endocrinología Experimental y Aplicada (UNLP-CONICET LA PLATA, Centro Colaborador OPS/OMS para Diabetes) Facultad de Ciencias Médicas, Universidad Nacional de La Plata, Argentina.

Background and aims: Islet neogenesis-associated protein pentadecapeptide (INGAP-PP) administration to normal rats increases their β-cell mass and function, but its mechanism of action remains unclear. On the other hand, embryonic β-cell differentiation needs the presence of endothelial cells, the vascular endothelial growth factor-A (VEGF-A) and integrin β. The aim of the present work was to study whether the effect of INGAP-PP upon β-cell mass and function is associated to a similar effect upon islet angiogenesis.
Materials and methods: Adult male Wistar rats were intraperitoneally injected for 10 days with saline solution (control group, C) or INGAP-PP (500 μg/day; intervention Group, I). At the end of the treatment period, glucose tolerance test (GTT) was performed in some animals from both groups while other rats were sacrificied and bled to measure plasma glucose, insulin and trilgliceryde (TG) concentration. Homeostatic model assessment-insulin resistance (HOMA-IR) and - β cell function (HOMA- β) were also calculated. Glucose-stimulated insulin secretion (GSIS), DNA content and levels of gene expression (qPCR and western blot) of Pancreatic and duodenal homeobox 1 (Pdx1), neurogenin 3, integrin β1, VEGF-A, VEGF-Receptor 2 (VEGF-R2), laminin β1 and insulin were measured on islets isolated from both experimental groups. Statistical data analysis was performed using the Students T-test and differences were considered significant when P value <0.05 (*).
Results: INGAP-PP did not affect significantly GTT (area under the curve: 2898 ± 649 vs. 2854 ± 525 mmol/L/120 min), plasma glucose (107 ± 2.5 vs. 113 ± 2.8 mg/dl), TG (122.6 ± 8.8 vs. 115.4 ± 7.9 mg/dl) and insulin (0.57 ± 0.08 vs. 0.63 ± 0.07 ng/ml) levels. Consequently, it did not affect HOMA-IR (4.01 ± 0.5 vs. 4.06 ± 0.6) and HOMA- β (52.4 ± 6.2 vs. 41.7 ± 7.1) values. However, I rats showed less islet DNA content than C animals (26 ± 1.3 vs. 18 ± 1.2* ng/islet) and higher GSIS at 16.7 mM glucose (10 ± 0.1 vs. 20 ± 0.1* ng ins/pg DNA). Their islets also showed increased mRNA levels of PDX1 (100 ± 1.82 vs. 221 ± 77* %), insulin (100 ± 0.09 vs. 134 ± 21* %), integrin β1 (100 ± 3.15 vs. 698 ± 29* %), laminin β1 (100 ± 3.05 vs. 201 ± 72* %) and VEGF-A (100 ± 0.22 vs. 149 ± 34* %) as well as protein concentration of integrin β1 (100 ± 28 vs. 191.9 ± 19.5* %) and VEGF-A (100 ± 16.78 vs. 154.79 ± 22.5* %).
Conclusion: These results suggest that the mechanism by which INGAP-PP exerts its effect upon β-cell mass and function in adult rats, mimics the normal process observed during the embryonic period where vascular neogenesis preceeds islet neogenesis.

INGAP effect on pancreatic islet function: its potential molecular mechanism

B. Maiztegui, C. Román, J. Gagliardino;
CENEXA. Center of Experimental and Applied Endocrinology (National University of La Plata-National Research Council), La Plata, Argentina.

Background and aims: Islet neogenesis associated protein (INGAP-PP) increases insulin secretion and B-cell mass in normal rats but it is not clear the mechanism by which produces its effects. Thus, the aim of the present work is to study *in vitro* the effect of INGAP-PP on insulin secretion and on several enzymes and mediators involved in glucose metabolism and in PI3-K/Akt pathway.
Materials and methods: Islets isolated by collagenase digestion from adult normal rats were cultured for 4 days in RPMI with 2 g/L $NaHCO_3$, 5% FBS, 1% penicillin/streptomycin and 10 mM glucose (G), in the absence (controls) or presence of 10 μg/mL INGAP-PP, with/without addition of Wortmannin (150 and 300 nM), or LY294002 (10 and 25 mM) to the medium. Islets were preincubated in 3 mM G for 45 min and then incubated with different glucose concentrations to study: insulin secretion/content (radioimmunoassay), HK/GK activity (G-6-P production), glucose oxidation and utilization ($^{14}CO_2$ and ^3H_2O production, respectively), GK, IR, IRS-1/2 and PI3K quantification (Western blotting) and PI3K/IRS-1 association (immuneprecipitation and Western blotting). Results were statistically analyzed using ANOVA and Student´s t-test for independent samples.
Results: (C vs. INGAP-PP; *p<0.05): Insulin secretion (ng/islet/h): 3 mM G: 0.3 ± 0.03 vs. 0.3 ± 0.04; 8 mM G: 1.6 ± 0.2 vs. 2.4 ± 0.3*; 16 mM G: 2.4 ± 0.2 vs. 4.7 ± 0.3*; 16 mM +W 150 nM: 1.7 ± 0.3 vs. 1.8 ± 0.3; 16 mM G + W 300 nM: 0.9 ± 0.1 vs. 0.9 ± 0.3 (% inhibition respect to 16 mM G: C, 64 ± 6 and INGAP-PP, 81 ± 6*). Glucose oxidation $^{14}CO_2$ (pmol/ islet/ 120 min): 3 mM G: 0.3 ± 0.04 vs. 0.5 ± 0.07; 8 mM G: 0.4 ± 0.06 vs. 0.7 ± 0.1*; 16 mM G: 0.6 ± 0.1 vs. 1.4 ± 0.1*. Glucose utilization ^3H_2O (pmol/ islet/ 120 min): 3 mM G: 1.3 ± 0.2 vs. 1.8 ± 0.3; 8 mM G: 1.9 ± 0.3 vs. 3.2 ± 0.4*; 16 mM G: 3.3 ± 0.4 vs. 5.8 ± 0.6*. GK activity (pmol/islet/h): 2.4 ± 0.6 vs. 4.8 ± 0.3*. Protein levels (INGAP-PP % above control): GK 91.7 ± 3.8*; IR 75 ± 1.5*; IRS-2 170.8 ± 4.7*; PI3K 155 ± 15*; PI3K-IRS-1 complex 76 ± 5*; pIR 149 ± 5.6*; pIRS-1 138 ± 2.6*. Wortmannin and LY294002 significantly decreased the INGAP-PP-induced increase of GK protein concentration to levels similar to those measured in C.
Conclusion: Our data suggest that the positive modulatory effect of INGAP-PP on insulin release could be partly ascribed to its effect upon GK activity and glucose metabolism and it is mainly mediated by the PI3K/AKT pathway. All these INGAP-PP-mediated changes would elicit a more robust B-cell secretory function and result in a more sensitive B-cell to extracellular regulators such as insulin (increased protein IR level and phosphorylation). These results should be further investigated to prove the potential use of INGAP-PP to maintain/enhance the secretory capacity of cultured islets previous to

their transplant and also as an alternative therapy for diabetes prevention and treatment.

Increased hexosamine biosynthetic pathway flux alters cell-cell adhesion in INS-1E cells and murine islets

B. Di Jeso[1], S. Turco[1], V. La Pesa[1], A.S. Treglia[1], D.D. Lofrumento[1], F. De Nuccio[1], L. Ulianich[2], C. Miele[2], M. Longo[3], R. Spinelli[3], L. Parrillo[2], G. Nicolardi[1], C. Garbi[4], F. Beguinot[3];
[1]DiSTeBA, University of Salento, Lecce, [2]IEOS, CNR, Napoli, [3]Dip. Scienze Mediche Traslazionali, University of Naples, [4]Dip. Medicina Molecolare e Biotecnologie Mediche, University of Naples "Federico II", Lecce, Italy.

Background and aims: In type 2 Diabetes, beta cell failure is caused by loss of cell mass, mostly by apoptosis, but also by simple dysfunction (decline of glucose-stimulated insulin secretion, downregulation of specific gene expression). Apoptosis and dysfunction are caused, at least in part, by lipoglucotoxicity, in which increased flux of glucose in the hexosamine biosynthetic pathway (HBP) plays a role. In this study we sought to clarify whether increased HBP flux affects beta cell-beta cell adhesion and if this may participate in beta cell dysfunction and altered islet physiology.
Materials and methods: We used INS-1E cells and ex vivo murine islets. INS-1E cells and murine islets were subjected to glucosamine (GlcN) (5 and 7.5 mM) and high glucose (20 and 30 mM) treatments to increase the HBP flux. E-cadherin and beta-catenin expression was evaluated by WB, their intracellular localization by confocal immunofluorescence, Trypsin-Ca2+/Trypsin-EGTA digestions and sub-cellular fractionation. E-cadherin assembly into adherens junctions by TX-100 solubility assay. Cell-cell adhesion was evaluated by morphological examination of isolated and treated murine islets.
Results: We focused on cell-cell homotypic interactions. E-cadherin expression was not changed by increased HBP flux, however, there was a decrease of cell surface, and an increase in intracellular E-cadherin, detected by Trypsin-Ca2+/Trypsin-EGTA digestions (intracellular E-cadherin increased from 6±;1.8% to 18±;4% following a treatment of 7.5 mM GlcN for 48 hrs) and a change of intracellular E-cadherin distribution, from a prevalent Golgi to a prevalent endoplasmic reticulum distribution, detected by confocal immunofluorescence. Beta-catenin alterations were found to parallel those of E-cadherin, showing a dislocation from the plasmamembrane (where beta-catenin is bound to E-cadherin) to the cytosol, detected by confocal immunofluorescence and sub-cellular fractionation (cytosolic beta-catenin increased from undetectable levels to 16±;3.7% following a treatment of 7.5 mM GlcN for 48 hrs). Moreover, following increased HBP flux, there was a decrease in E-cadherin found in the Triton X (TX)-100-insoluble cell fractions, suggesting a defect of the assembly of E-cadherin into adherens junctions (a treatment of 7.5 mM GlcN for 48 hrs, in cells 50% confluent, decreased insoluble E-cadherin from 41±;6% to 26±;4% and, in cells 80% confluent, decreased insoluble E-cadherin from 76Ã‘±;8% to 28±;4%). Lastly, we measured cell-cell adhesion, by morphological examination of murine islets. Following increased HBP flux by both GlcN and high glucose treatments, there was a disaggregation of islet structure.
Conclusion: These results suggest that increased HBP flux changes the intracellular distribution of E-cadherin and beta-catenin and the ability of E-cadherin to assemble into adherens junctions. These changes were accompanied by decreased cell-cell adhesion, which may easily impact on beta cell function.

Effects of the inhibitor of anoctamin 1, tannic acid, on insulin-producing cells

W.J. Malaisse[1], R. Crutzen[2], N. Bulur[1], M. Virreira[2], A. Rzajeva[1], P.E. Golstein[2], A. Sener[1], R. Beauwens[2];
[1]Laboratory of Experimental Hormonology, [2]Laboratory of Cell and Molecular Physiology, U.L.B., Brussels, Belgium.

Background and aims: We recently reported that anoctamin 1 mRNA and protein are expressed in human, rat and mouse insulin-producing cells, and proposed that anoctamin 1 acts as a volume-regulated anion channel in these cells. The present study concerns further investigations on the effects of the inhibitor of anoctamin 1, tannic acid, on insulin-producing cells.
Materials and methods: Cell volume was measured in BRIN-BD11 cells and dispersed rat islet cells. Insulin release, D-[5-^{3}H]glucose utilization and D-[U-^{14}C]glucose oxidation were measured in rat pancreatic islets over 90 min incubation at 37°C. Voltage measurements were performed in zero-current nystatin-perforated patch-clamp experiments conducted in mice pancreatic islets.
Results: In both BRIN-BD11 and dispersed rat islet cells, tannic acid (100 μM) suppressed the regulatory volume decrease otherwise occurring during exposure to a hypotonic extracellular medium. Tannic acid (10 to 100 μM) inhibited insulin release evoked by 16.7 mM glucose, with a threshold value close to 3 μM, an ED_{50} close to 57 μM and a mean decrease of 43 ± 4% at a 100 μM concentration. However, in the presence of 8.3 mM glucose, tannic acid (100 μM) did not affect significantly insulin output. In islets exposed to 16.7 mM glucose, tannic acid (100 μM) decreased D-[5-^{3}H]glucose utilization by 45 ± 7%, whilst increasing D-[U-^{14}C]glucose oxidation by 40 ± 12%. Assuming that the difference between D-[5-^{3}H]glucose utilization and D-[U-^{14}C]glucose oxidation corresponds to the production of lactic acid, the ATP generation attributable to the catabolism of glucose was virtually identical in the absence of tannic acid (995 ± 98 pmol/islet) and in its presence (998 ± 77 pmol/islet). As judged from the changes provoked by tannic acid (100 μM) in the duration, action potential height and action potential rate of the active bioelectrical phase in mice islets exposed to 16.7 mM glucose and assuming that the action potential height is proportional to the amount of Ca^{2+} entering into cells, it was calculated that the influx of Ca^{2+} only represented in the presence of tannic acid about 44% of the control value found in its absence.
Conclusion: These findings support the view that inhibition of anoctamin 1 by tannic acid decreases in islet cells both lactate output and Ca^{2+} influx independently of any change in the energy yield resulting from glucose catabolism, with a prevalent inhibition of insulin release at high concentrations of the hexose.

Sphingosine kinase 1 interacting protein (SKIP) inhibits insulin secretion from beta cells through regulation of protein kinase A activity

Y. Wang, S.-I. Harashima, S. Yamane, K. Suzuki, N. Harada, Y.-Y. Liu, N. Inagaki;
Department of Diabetes and Clinical Nutrition, Kyoto University, Japan.

Background and aims: Compartmentalization of PKA (protein kinase A) is mediated by A-kinase anchoring proteins (AKAPs). The AKAP family consists of over 70 molecules and most AKAPs bind RII subunit of PKA. Several dual-function AKAPs can bind both RI and RII subunits; SKIP (sphingosine kinase 1 interacting protein, also called Sphkap) and MGC13057 are AKAPs that tether only PKA-RI subunit in human. PKA has been shown to be important in the insulin secretory process. Recent study on PKA-RI subunit-deleted mice reported a dramatic increase in glucose-stimulated and exendin-4-enhanced insulin secretion from beta cells. Because our preliminary data showed that SKIP is highly expressed in beta cells, we examined whether SKIP is involved in glucose-stimulated and exendin-4-enhnaced insulin secretion.
Materials and methods: Endogenous SKIP expression was detected by quantitative real time PCR, western blot analysis, and immunohistochemiscal study in several mouse and rat beta cell lines and islets isolated from Wister rats, C57BL/6 mice, and human. SKIP and PKA-RI interaction was confirmed by immunoprecipitation. Glucose-stimulated and exendin-4-enhanced insulin secretion was examined in SKIP-overexpressed and knock down INS-1D cells, a rat beta cell line, using SKIP expression vector or SKIP siRNAs, respectively. PKA activity was measured by PepTag assay for non-radioactive detection of PKA. Phosphorylation of CREB was detected by western blot analysis.
Results: Quantitative real time PCR showed that SKIP was highly expressed in beta cells, weakly expressed in heart and spinal cord, and was not detected in kidney, liver, gastrointestinal tract, testis, and skeletal muscle. Western blot showed that SKIP was strongly expressed in beta cells but not in spinal cord, heart or the other tissues. Immunohistochemical study revealed that SKIP was co-localized with insulin in INS-1D cells and was localized in pancreatic beta cells and not in alpha-cells of human, Wistar rat, and C57BL/6 mice. Immunoprecipitation showed that SKIP interacted with PKA-RI subunit but not with PKA-RII subunit in SKIP-overexpressed HEK293 and INS-1D cells. Overexpression of SKIP decreased PKA activity and CREB phosphorylation, while knock down of SKIP increased PKA activity and CREB phosphorylation in INS-1D cells. Overexpression of SKIP decreased glucose-stimulated insulin secretion by 60% ($P<0.05$) and exendin-4-enhanced insulin secretion

by 66% (p<0.05). In contrast, knock down of endogenous SKIP resulted in a 1.8-fold increase in glucose-stimulated (P<0.05) and a 1.3-fold increase in exendin-4-enhanced insulin secretion (P<0.05). However, insulin content did not differ between controls and SKIP-overexpressed or SKIP-knocked down INS-ID cells.
Conclusion: SKIP is specifically expressed in pancreatic beta cells. This molecule binds only PKA-RI subunit and modulates PKA activity. Overexpression of SKIP inhibited glucose-stimulated and exendine-4 enhanced insulin secretion, while knock down of SKIP increased glucose-stimulated and exendine-4-enhanced insulin secretion. These results demonstrate that SKIP inhibits insulin secretion through regulating PKA and CREB activity.

PS 025 Insulin secretion in vitro

473

Effects of high extracellular KCl on insulin secretion beyond plasma membrane depolarisation
M. Willenborg, M. Belz, K. Schumacher, I. Rustenbeck;
Institute of Pharmacology and Toxicology, Technical University of Braunschweig, Germany.

Background and aims: The depolarization of the beta cell plasma membrane by a high extracellular K+ concentration stimulates insulin secretion without a preceding increase of the energy metabolism or changes in the KATP channel open probability. Also, the depolarizing strength can be predicted by the Goldman-Hodkin-Katz equation and, in contrast to depolarizing KATP channel blockers, the involvement of intracellular binding sites can be ruled out. Recently, however, the question arose as to whether the consequences of K+ depolarization differ from those of depolarization by KATP channel closure as occurs during glucose-induced insulin secretion.
Materials and methods: Membrane potentials and currents of isolated NMRI mouse beta cells were measured in the perforated patch mode of patch-clamp technique. The cytosolic Ca2+ concentration ([Ca2+]i) was measured using Fura-2/AM-loaded NMRI mouse islets. Insulin secretion was measured by batch perifusion of freshly isolated pancreatic islets.
Results: Using a voltage-clamp protocol, action currents were elicited in the presence of maximally effective concentrations of sulfonylurea and TEA to block all K+ conductance. These action currents were abolished by 10 μM nifedipine, demonstrating that the depolarization-induced action currents represent Ca2+ influx via L-type channels. Using the same protocol and raising the extracellular K+ concentration from physiological to 40 mM transformed the action current pattern into a continuous inward current after a short period of broadened action currents. This current could be abolished by 2.5 mM of the unspecific Ca2+ channel blocker CoCl2, partially reduced by 50 μM of the blocker of L-type Ca2+ channels, D600, but not by nifedipine. When the extracellular K+ concentration was only raised to 15 mM, the occurrence of significantly broadened action currents persisted. These currents could be completely antagonized by CoCl2 or nifedipine. To test the hypothesis that, in spite of the presence of a sulfonylurea and TEA, K+ currents are involved in the derangement of Ca2+ influx, the effects of 35 mM CsCl and 35 mM RbCl (each in addition to the physiological K+ concentration) were characterized. Rb+ is known to have practically the same permeability as K+, whereas that of Cs+ is only about 30%. In fact, Rb+ depolarized the beta cell like 40 mM K+, whereas the depolarization by Cs+ corresponded to that by 15 mM K+. Under voltage-clamp condition, Rb+ led to the same continuous inward current as 40 mM K+, whereas Cs+ produced broadened action current similar to 15 mM K+. Both, 40 mM K+ and 15 mM K+ were able to increase [Ca2+]i beyond the level established by a maximal sulfonylurea concentration. In both cases this increase correlated with a strong increase in secretion. The striking discrepancy between the near inability of 15 mM K+ to stimulate insulin secretion under basal condition and the ability to strongly augment the secretion by a maximal sulfonylurea concentration was also noted with 35 mM Cs+.
Conclusion: The presence of a high extracellular K+ concentration does not only depolarize the beta cell plasma membrane but also modifies the resultant activity of voltage-gated Ca2+ channels. Prolongation of the channel openings would explain the minimal insulinotropic property of 15 mM K+ under basal condition and the strong augmentation of secretion under depolarized condition.

Differential role of NO in the control of insulin secretion in human pancreatic islets
F. Castex[1], A. Chalançon[1], J. Leroy[1], K. Mezghenna[1], G. Parnaud[2], A. Wojtusciszyn[3], C. Broca[3], D. Bosco[2], R. Gross[1], A.-D. Lajoix[1];
[1]Faculte de Pharmacie, EA 7288, Montpellier, France, [2]Geneva University Hospital, Cell Isolation and Transplantation Center, Geneva, Switzerland, [3]Diabetes cellular therapy laboratory, Institut for Research in Biotherapy, Montpellier, France.

Background and aims: We have previously shown that rat pancreatic β-cells express an isoform of neuronal NO synthase (nNOS) that controls insulin

secretion through two catalytic activities: NO production and cytochrome c reduction. In humans, we also found the expression of nNOS in pancreatic β-cells. In the present study, we investigated whether nNOS, as observed in rats, is able to modulated insulin secretion in human pancreatic islets.
Materials and methods: Human islets were obtained from brain dead donors in the frame of the Gragil network (Geneva) and the IRB's isolation platform (Montpellier). Insulin secretion in response to glucose (2.8, 8.3, and 16.7 mM) was evaluated on pools of 10 islets during 90 minutes in the presence or not of pharmacological inhibitors of nNOS, Nω-nitro-L-arginine methyl ester (L-NAME) and 7-nitroindazole (7-NI), the NO donors, sodium nitroprusside (SNP) and hydroxylamine, and the scavenger of peroxynitrites, uric acid.
Results: Inhibition of nNOS by 10 mM L-NAME increased insulin secretion induced by 8.3 and 16.7 mM glucose (+35% et +33% respectively, P<0,001). In the presence of 100 μM 7-NI, a more selective inhibitor of nNOS, insulin secretion was stimulated by 20% in the presence of 8.3 mM glucose (P<0,01) and by 21% in the presence of 16.7 mM glucose (P<0,001). A substitutive treatment by the exogenous NO donor SNP (300 μM) was unable to normalize the amplificatory effect of L-NAME. At the opposite, SNP strongly stimulated insulin secretion induced by glucose + L-NAME (+76% with 8.3 mM and +70% with 16.7 mM glucose versus L-NAME alone, P<0,001), as well as that of glucose alone (+98% with 8.3 mM and +108% with 16.7 mM glucose, P<0,001). Moreover, hydroxylamine (300 μM), an endogenous NO donor, led to similar effects as SNP, as insulin secretion was increased in the presence of glucose + L-NAME (+43% with 8.3 mM and +57% with 16.7 mM glucose versus L-NAME alone, P<0,001) or glucose alone (+60% with 8.3 mM and +86% with 16.7 mM glucose, P<0,001). Conversely, we could demonstrate that uric acid (300 μM), a scavenger of peroxynitrites, was able to normalize the stimulating effect of SNP, with or without L-NAME, in the presence of 8.3 mM and partially in the presence of 16.7 mM glucose.
Conclusion: In human pancreatic islets, low amounts of NO modulate negatively insulin secretion, through S-nitrosylation of proteins involved in the metabolism, whereas, at higher concentrations, NO amplifies insulin secretion, probably via nitration of exocytotic proteins.

Regulation of miR-335 expression contributes to orchestrate insulin secretion at the level of exocytosis in insulin secreting INS-1 832/13 cells
V.A. Salunkhe, S.A. Andersson, J.L.S. Esguerra, I.G. Mollet, A. Wendt, L. Eliasson;
Lund University Diabetes Centre, Islet Cell Exocytosis, Clinical Research Centre Malmö, Lund University, Malmö, Sweden.

Background and aims: MicroRNAs (miRNAs) are small non-coding RNAs that negatively regulate gene expression. Many miRNAs are implicated in insulin secretion including the well-established miR-375. We have previously identified a number of miRNAs with dysregulated expression in the pancreatic islets of non-obese type-2 diabetes (T2D) model Goto-Kakizaki (GK) rats as well as in human islets from glucose intolerant donors. Among the up-regulated miRNAs in the GK-rat was miR-335 which we showed to target Munc18-1. The regulation of miRNAs is still elusive, but there are indications that some miRNAs are glucose-regulated. Here we aim to investigate the glucose- and time-dependent regulation of miR-335 and miR-375, and the influence on exocytosis and insulin secretion by these miRNAs.
Materials and methods: INS-1 832/13 cells were cultured for 1, 2, 6, 12 and 24 h and at different glucose concentrations (2.8, 11 and 16.7 mM) or transfected with LNA (locked nucleic acid)-based anti-mir-335 or anti-mir-375 for 48 h. MicroRNA and mRNA expression was analyzed by qPCR. Glucose stimulated insulin secretion (GSIS) was measured by RIA and exocytosis was detected as changes in membrane capacitance using patch-clamp.
Results: In 2.8 mM glucose miR-335 expression was significantly higher when cultured for ≥ 2h relative to 1 h (n=3; p<0.05). At higher glucose concentrations this was valid for 12 and 24 h culture in 11 mM glucose (n=3; p<0.05) and for 6 and 12 h in 16.7 mM glucose (n=3; p<0.05). Interestingly, peak expression was reached earlier when cultured at 16.7 mM glucose (after 6 h) as compared to 2.8 mM glucose (after 12 h). This was accompanied with a reduced glucose stimulated insulin secretion after culture for 2 and 6 h in 2.8 mM glucose (n=3; p<0.01). Expression of the target gene S*txbp1* (coding for Munc 18-1) was reciprocally expressed except after culture for 24 h. On the other hand, expression of miR-375 was stable and did not vary with time at the different glucose concentrations. Furthermore, it was confirmed that culture in 16.7 mM glucose impairs GSIS. This effect was visible already after 1 h in culture. To further characterize the role of miR-335 and miR-375 in regulated exocytosis, we performed electrophysiological measurements on cells transfected with anti-miR-335 and anti-miR-375, respectively. Reduction of miR-335 levels in the knockdown experiments lead to Munc18-1 up-regulation. Exocytosis initiated by a train of ten 500-ms depolarizations from -70 to 0 mV was significantly increased by ~50% (n=8-10 cells; p<0.01) in the anti-miR-335 transfected cells, but there was no significant change in exocytotic response in the anti-miR-375 transfected cells. There were no changes in the voltage-dependent Ca^{2+} current after transfection with either of the anti-miRs.
Conclusion: We conclude that miR-335 influence exocytosis through the regulation of Munc18-1, and that low expression of this miRNA appears beneficial for enhanced exocytosis. The time shift in peak miR-335 expression suggests involvement of this miRNA in acceleration of impaired insulin secretion at hyperglycaemia.

Involvement of heparan sulfate proteoglycan syndecan-4 in the mouse beta cell proliferation and insulin secretion
I. Takahashi, S. Sato, W. Sakai, K. Ohashi, K. Nata;
Dept of Medical Biochemistry, Iwate Medical University, Shiwa-gun, Japan.

Background and aims: Heparan sulfate proteoglycans (HSPGs) are composed of a core protein to which extracellular glycosaminoglycan chains are attached. Syndecans, one of the major heparin sulfate (HS)-containing core proteins, are distributed on the cell surface, where it interacts with various proteins, including growth factors, morphogens and extracellular matrix components to regulate their signalling. We recently found that HS is localized exclusively around beta cells in the islets of adult mice and is required for islet morphogenesis, beta cell proliferation and insulin secretion. Furthermore, we found that the 3-*O*-sulfate and 6-*O*-sulfate groups of HS are important for maintaining normal glucose-induced insulin secretion (GIIS) and beta cell proliferation, respectively. So far it is not known, however, which core proteins are crucial in this process and how they function to modulate beta cell function. The aim of this study is to clarify how the core protein including HS affects beta cell proliferation and insulin secretion.
Materials and methods: Subcloning of MIN6 cells, mouse pancreatic beta cell line, was performed by the limiting dilution method. The cells were then screened and selected by an index of GIIS, KCl-induced insulin secretion and HS expression. The expression of HS was analysed by western blot analysis. Semi-quantitative RT-PCR was used for analyzing mRNA expression of HS biosynthetic enzymes and HSPG core proteins. Expression of HSPG syndecan-4 was silenced, and cell proliferation and GIIS were examined in T3, insulin-secreting and HS-expressing cell line derived from the MIN6.
Results: MIN6 cells were subcloned, and 30 clones were obtained. Four sublines were selected for this study, designated T3, T5, T9 and T16. T3, T5 and T9 cells exhibit GIIS in a concentration-dependent manner, whereas T16 cells respond poorly to glucose. In the presence of KCl, T16 cells secreted almost the same amount of insulin as T3, T5 and T9. Next, we analysed the expression of HS in these subclones. HS was detected in T3, T5 and T9 cells. On the other hand, HS was not detected in T16 cells. The HS biosynthetic enzymes and HSPG core proteins such as Ext/Extl gene family, *N*-deacetylase/*N*-sulfotransferases, C5-epimerase, HS sulfotransferases, cell surface and secreted HSPG core proteins were almost expressed in all subclones, but syndecan-4, one of cell surface HSPG core proteins, was not expressed only in T16 cells. Silencing of a syndecan-4 by RNA interference reduced T3 cell proliferation to 85% of control treatment (p<0.005). Furthermore, GIIS was decreased in T3 cells with RNA interference of syndecan-4 to 52% of the control treatment (p<0.001).
Conclusion: Our data indicate that HSPG syndecan-4 plays important role(s) in the beta cell proliferation and insulin secretion.

Flavanol metabolites produced by colonic microbiota improve glucose-stimulated insulin secretion and protect pancreatic beta cells against oxidative damage

M.A. Martin[1,2], E. Fernández-Millán[2], C. Alvarez[2,3], L. Bravo[1], S. Ramos[1], L. Goya[1];
[1]ICTAN-CSIC, [2]CIBER de Diabetes y Enfermedades Metabólicas Asociadas (ISCIII), [3]Facultad de Farmacia (UCM), Madrid, Spain.

Background and aims: Oxidative stress is accepted as one of the causes of beta cell failure commonly observed in type 2 diabetes. Therefore, identification of natural antioxidant agents that enhance or preserve islet beta cell mass and function is considered an interesting strategy to prevent or treat diabetes. Dietary flavanols are natural occurring compounds abundant in fruits and vegetables. Oligomeric and polymeric flavanols are metabolised by the intestinal microbiota into various phenolic acids of low molecular weight, which are well absorbed in the colon. Recent evidences indicated that flavanol metabolites could possess biological properties and potential beneficial effects on various tissues. However, up to date, whether these compounds have a direct effect on pancreatic beta cells is unclear. The aim of this work was to establish the potential anti-diabetic properties of the microbial-derived flavanol metabolites 3,4-dihydroxyphenylacetic acid (DHPA), 2,3-dihydroxybenzoic acid (DHB) and 3-hydroxyphenylpropionic acid (HPP). To this end, we tested their ability to influence pancreatic beta cell function and to protect against oxidative stress-induced beta cell damage.
Material and methods: INS-1E beta cells and rat islets (isolated by collagenase digestion) were treated for 20h with physiological concentrations of DHPA, HPP and DHB (1-10 μM). Insulin content and insulin secretion in response to metabolites and metabolites plus glucose (4 and 10 mM) were quantified using an ELISA kit. Cellular signalling related to the effect of metabolites on glucose-stimulated insulin secretion (GSIS) was examined using specific inhibitors. Levels of the main protein kinases activated by metabolites were evaluated by Western Blot. In oxidative stress experiments, INS-1E cells were treated for 20h with the different phenolic compounds (5 μM) and further exposed to the pro-oxidant *tert*-butyl hydroperoxide (t-BOOH, 50 μM) for 2h. Generation of reactive oxygen species and carbonyl levels were evaluated by fluorimetric methods and cell viability by the crystal violet assay.
Results: We found that DHPA and HPP (but not DHB) amplified GSIS both in INS-1E beta cells and pancreatic islets without affecting insulin content. Experiments with pharmacological inhibitors suggest that enhancement of GSIS by DHPA and HPP is mediated by the activation of protein kinase C and ERK/MAPKs but is independent on the protein kinase A pathway. Furthermore, pre-treatment of cells with DHPA and HPP, and to a lesser extend DHB, was able to protect against beta cell dysfunction and death induced by the potent pro-oxidant t-BOOH.
Conclusion: These results suggest that the microbial-derived flavanol metabolites DHPA and HPP may have anti-diabetic potential by promoting survival and function of pancreatic beta cells. Further studies to evaluate their action *in vivo* are required.

Insulin secretion and ZnT8 gene expression are decreased by ZnT3 overexpression

K. Smidt[1], K.S. Sørensen[1], A. Larsen[1], J. Prætorius[1], P.M. Martensen[2], J. Rungby[1];
[1]Department of Biomedicine, [2]Department of Molecularbiology and Genetics, University of Aarhus, Denmark.

Background and aims: Insulin synthesis and processing rely on the presence of zinc. Zinc is abundantly present in pancreatic beta cells. The transport of zinc into beta cells is regulated by zinc transporting proteins (ZnTs). ZnT8 transport zinc into the insulin containing granules. Beta cell specific ZnT8 knockout mice show decreased insulin content, atypical insulin crystallization and reduced first phase insulin secretion. We have previously shown a transcriptional inverse correlation between ZnT8 and another zinc transporter protein, ZnT3. We found that ZnT3 knock down leads to a transcriptional up-regulation of ZnT8 and vice versa. Furthermore, ZnT3 knock down increases the apoptosis in beta cells and decreases the acute 2 hour-glucose stimulated insulin secretion. The aim of this present study was to investigate the effect of ZnT3 overexpression on beta cell functions including insulin secretion and beta cell survival.
Materials and methods: Insulin secreting INS-1E cells were stably transfected either with an empty pcDNA3.1 vector or with pcDNA3.1-hZnT3. Cells were treated with 5 mM, 11mM and 21 mM glucose for 24 hours prior to analysis. Gene expression analysis was performed by Q-PCR followed by normalization to three housekeeping genes (Beta-actin, Cltc, HSPcb). Glucose stimulated insulin secretion was analyzed by ELISA. Apoptosis was measured by DNA fragmentation analysis by Nucleo Counter NC3000. Immuno-gold EM analysis was performed on cryosections of cell pellets on a FEI Morgani microscope. Goat anti-rabbit IgG conjugated to 10-nm and 5-nm colloidal gold particles were used for visualization of ZnT3 and insulin, respectively.
Results: The gene expression of ZnT8 was significantly decreased by overexpression of ZnT3 at all tested glucose concentrations (5 mM, 11 mM and 21 mM). ZnT3 overexpression decreased the insulin transcription, insulin content and insulin secretion compared to the vector transfected cells. ZnT3 overexpression did not affect the level of DNA fragmentation in INS-1E cells after 24 hours of glucose treatment (5mM, 11 mM and 21 mM). EM analysis showed that ZnT3 was localized to some insulin-empty compartments in the cytosol. Interestingly, ZnT3 was primarily localized to insulin containing granules close to the plasma membrane.
Conclusion: We show that ZnT3 and ZnT8 expression levels are inversely correlated. ZnT3 overexpression reduces insulin synthesis and secretion. We show that ZnT3 is present in insulin-empty compartments in the cytosol but primarily located in insulin containing granules close to the plasma membrane.

Zinc buffering by exogenous Zn7-metallothionein-2A affects insulin production, insulin secretion and intracellular zinc regulation in beta cells

S.B. Nygaard, N. Lund, N. Pedersen, A. Larsen, J. Rungby, K. Smidt;
Biomedicine, Aarhus University, Denmark.

Background and aims: Preservation of beta cell mass and beta cell insulin secretion ability appears to be related to a balanced cellular zinc homeostasis as pancreatic beta cells depend on zinc for their primary function; insulin biosynthesis, insulin storage and insulin secretion. Metallothioneins are ubiquitously expressed proteins well-known for their metal-binding capacity and secures sufficient zinc for the cellular needs. The aim of the study was to examine how important zinc binding proteins are regulated at normal and high glucose concentrations and to investigate if increasing extracellular metallothionein levels by means of exogenous Zn7-MT-2A is beneficial for beta cell function and survival by contributing to an optimal zinc supply and regulation in the pancreas.
Materials and methods: INS-1E beta cells were pre-conditioned with +/- Zn7-MT-2A for 6 hours at standard 11 mM glucose and then stimulated with 6 or 21 mM glucose respectively for 24 hours. A concentration of 1 μg/mL (152 nM) Zn7-Metallothionein-2A (Zn7-MT-2A) was maintained throughout the stimulation period. Following stimulation cells were harvested for

gene expression analysis of Bax, Bcl-2, ZnT-8, ZnT-5 ZnT-3, MT-1A or MT-3 determined by RT-PCR and for measurements of insulin content and insulin secretion by ELISA.
Results: Zn7-MT-2A treatment induced a 2-fold increase in the level of insulin secretion and elevated the insulin content (2-fold) at 6.6 mM glucose (P=0.0001 and P=0.0325). Zn7-MT-2A exposure reduced the transcriptional regulation of the Bax/Bcl-2 ratio at both 6.6 and 21 mM glucose (P=0.0343 and P=0.0472). Furthermore, ZnT-5 and ZnT-8 gene expression was down-regulated (1.6 and 1.8 fold) by 21 mM glucose (P<0.0001 and P=0.0025) and by treatment with Zn7-MT-2A (1.2 fold) at the basal glucose concentration. Exposing INS-1E cells to 21 mM glucose lead to statistically significant (2-fold) down-regulation of MT-1A transcription (P=0.0037) and a further down-regulation of MT-1A was observed after exposure Zn7-MT-2A. The MT-3 gene expression was up-regulated (2-fold) at 21 mM glucose (P<0.0001) and at the basal glucose level MT-3 gene expression was down-regulated (1.15 fold, P=0.0199) when beta cells were exposed to Zn7-MT-2A. Unpaired T-test was used to determine statistical significance.
Conclusion: This study shows that Zn7-MT-2A can regulate important beta cell functions in INS-1E cells. The study suggests that there is a therapeutic potential of metallothionein administration for regulating beta cell insulin processing, cell death and zinc turnover. Exogenous metallothionein administration not only protects the INS-1E beta cells during glucose stress but also optimize the core function of the cells under normal glucose conditions.

Modulation of incretin actions in pancreatic beta cells by metformin
K. Shinmura[1], T. Negoro[2], Y. Nakano[2], T. Hirano[1];
[1]Department of Medicine, Division of Diabetes, Metabolism and Endocrinology, [2]Department of Pharmacogenomics, Showa University School of Pharmacy, Tokyo, Japan.

Background and aim: Metformin improves blood glucose concentration through activation of LKB1 and AMPK in liver and skeletal muscle. On the other hand, incretins, GLP-1 and GIP, directly raise intracellular Ca2+ and cAMP concentration in pancreatic β-cells, resulting in insulin secretion. We examined the effect of metformin on pancreatic β-cells and especially on the mechanisms of insulin secretion by incretins. We focused these Ca2+ response and cAMP production related with the mechanisms of insulin secretion.
Materials and methods: Amount of insulin secretion was measured by ELISA. For cAMP assay, pGloSensor™20F cAMP Plasmid was transfected into MIN6 cells by Neon™ Transfection System and cAMP production was measured by luminescence spectroscopy using GloSensorTM cAMP assay (Promega, USA) reagent. Intracellular Ca2+ concentration was measured by the Fura-2 fluorescence-imaging analytic method using Meta Fulora video image analyzer. LKB1 and phosphorylated LKB1 were detected by Western blotting.
Results: Ca2+ response by 10 nM GLP-1 was better than that by the same dose of GIP due to their receptors' mRNA expression in MIN6 cells and the peak response was dependent on glucose concentration because of significantly lower response in 0 mM glucose condition. 1 mM metformin pretreatment reduced to 78% of Ca2+ response by GLP-1 but concomitant metformin treatment with GLP-1 showed only 31% reduction. Moreover, inhibition of Ca2+ response by metformin occurred under 5.5 mM glucose as a physiological concentration but not 16.7 mM glucose condition. This inhibitory effect was time-dependent, 30 min (13 %), 60 min (30 %), 120 min (74 %) and 180 min (61 %). It showed that maximum inhibitory effect of Ca2+ response needed the pretreatment of metformin for 120 min. Metformin phosphorylated LKB1 and reached to maximum activation at 1hr under both glucose conditions. And also metformin modulated cAMP production in MIN6 cells by incretins under 5.5 mM glucose condition but not 16.7 mM glucose. Metformin affected in the similar way on insulin secretion by incretins. However, under high glucose concentration (16.7mM), metformin didn't show any effect on incretin functions (Ca2+ response and cAMP production).
Conclusion: Metformin reduced Ca2+ response by incretins under physiological glucose concentration and modulated on cAMP production by them. The peak of LKB1 activation by metformin did not correspond the time of maximum inhibitory effect against Ca2+ response. Glucose requirement was also different in these activities. Analysis of these mechanisms have still been investigating. As a result, it is suggested that metformin control the reaction of pancreatic β-cells to incretins under physiological glucose condition.

The DPP-IV inhibitor, sitgliptin enhances glucose-stimulated insulin secretion from mouse isolated islets
A. Clark, C.C.L. Baker, P. Rorsman, R. Ramracheya;
Diabetes Research Laboratories, University of Oxford, OCDEM, UK.

Background and aims: The action of DPP-IV inibitors are considered to prevent degradation of glucagon-like peptide-1 (GLP-1) in the circulation thus enhancing the effects of GLP-1 on glucose-stimulated insulin secretion (GSIS). DPP-IV activity has been identified in several tissues but its presence and role in pancreatic islets have not been determined. The aims were to determine the direct effects of DPP-IV inhibitor, sitagliptin on GSIS in isolated mouse islets and identify DPP-IV in islet cells.
Materials and methods: Mouse or rat islets, isolated by collagenase digestion were incubated with glucose, 1 or 12mM (60min) with and without sitagliptin (5nM). Long term effects were tested by overnight culture of islets with the DPP-IV inhibitor (5nM) followed by measurements of GSIS (1 or 8mM glucose). Insulin secretion was measured by radioimmunoassay and GLP-1 production by ELISA. DPP-IV and GLP-1 receptors were identified in islets cells by immunohistochemistry.
Results: GSIS (1-12mM glucose) was enhanced by 30% compared to GSIS without sitagliptin, from 0.12±0.01 to 0.16±0.01% of insulin content/h (n=6, p<0.05). Overnight pretreatment of islets with sitagliptin (5nM) resulted in a doubling of GSIS, from 0.05±0.008%/h to 0.10%±0.01 (n=3, p<0.05). Immunolabelling demonstrated DPP-IV to be present in mouse jejunum and mouse islet alpha and beta cells. GLP-1 receptor was detected in mouse beta cells but absent from alpha cells. In rat islets, GLP-1 was co-released with glucagon at molar ratios 1:4.
Conclusion: The presence of DPP-IV in pancreatic islets and the direct enhancing effects of sitagliptin on GSIS suggest that DPP-IV inhibitors can act directly on islets raising the possibility that GLP-1 could be released and act locally in islets.

Anti-diabetic effect of oral borapetol B, isolated from the plant tinospora crispa, by stimulating insulin release in type 2 diabetic Goto-Kakizaki rats
E.F. Lokman[1], H.F. Gu[1], W. Wan Mohamood[2], M. Yusof[3], L. Meng[3], C.-G. Östenson[1];
[1]Department of Molecular and Surgery, Karolinska Institutet, Stockholm, Sweden, [2]Department of Diabetes and Endocrinology, Institute for Medical Research, Kuala Lumpur, Malaysia, [3]Faculty of Industrial Sciences and Technology, University Malaysia Pahang, Malaysia.

Background and aims: *Tinospora crispa* (*T.crispa*) has been used in traditional medicine for the treatment of diabetes mellitus but the exact mechanism of its anti-diabetic effect is unknown. From *T.crispa* extract, we have isolated a biologically active small compound, Borapetol B (C1). The current study was undertaken to evaluate the anti-diabetic properties of C1 compound.
Materials and methods: The effect of C1 on the blood glucose and serum insulin was assessed by an oral glucose tolerance test in normoglycaemic control Wistar (W) and spontaneously type 2 diabetic Goto-Kakizaki (GK) rats. For *in vitro* studies, the stimulation of insulin secretion was assessed by performing batch incubation and perifusion experiments using isolated W and GK pancreatic islets.
Results: C1 (10 μg/100 g) which was administrated orally by gavage 30 minutes prior to an oral glucose challenge significantly improved blood glucose levels in treated compared to placebo group with areas under the glucose curves 0-120 min being 72 ± 17 vs 344 ± 10 mmol/L (P<0.001) and 492 ± 63 vs 862 ± 55 mmol/L (P<0.01) in W and GK rats respectively. Plasma insulin levels were significantly enhanced by 2-fold in treated W and GK rats at 30 min compared to the placebo group with mean values of 27 ± 4 vs 61 ± 9 μU/mL (P<0.05) and 30 ± 4 vs 63 ± 8 μU/mL (P<0.05) respectively. For the *in vitro* study, C1 dose-dependently increased insulin secretion from W and GK isolated islets in both low (3.3 mM) and high glucose (16.7 mM). In W, incubation of islets at 0.1, 1 and 10 μg/ml of C1 significantly stimulated insulin release by 6.2-fold (15.1 ± 2.2; P<0.01), 8.1-fold (19.5 ± 4; P<0.05) and 9.2-fold (21.9 ± 2; P<0.001) in low glucose and 1.5-fold (48.8 ± 6; P<0.05), 1.9-fold (63.1 ± 8.9; P<0.05) and 5.0-fold (164.5 ± 11.3; P<0.001) in high glucose respectively compared to the control group. In GK, islets treated with C1 at 0.1, 1 and 10 μg/ml significantly stimulated insulin secretion by 3.9-fold (4.7

± 0.3), 6.3-fold (7.5 ± 0.9) and 8.8-fold (10.5 ± 1.8) (all P<0.05) respectively in low glucose and by 1.5-fold (20.6 ± 1.1), 2.3-fold (30.9 ± 3.8) and 4.2-fold (57.3 ± 6.3) (all P<0.05) respectively compared to the control group. The perifusions of W and GK rat islets with 10 μg/ml of C1 increased insulin secretion in low (0-16 min) and high (16-30 min) glucose. In W, insulin secretion increased by 5.5-fold (1.1 ± 0.16 μU/islet/min)(12 min) and 7.5-fold (1.5 ± 0.16 μU/islet/min)(22 min). There was a significant difference observed from 2 min to 32 min (P<0.001). In GK rat, insulin secretion increased by 2.5-fold (0.43 ± 0.05 μU/islet/min)(2 min) (P<0.001) and 4.7-fold (0.8 ± 0.03 μU/islet/min) (20 min) (P<0.001). There was a significant difference observed between (2-4 min) and (20-30 min) (all P<0.001). The insulin secretion returned to basal level in both W and GK when C1 was omitted from the perifusate indicating that the compound did not cause leakage of insulin by damaging islet beta cells.

Conclusion: This study provides evidence that Borapetol B (C1) isolated from *Tinospora crispa* has anti-diabetic properties mainly due to its stimulation of insulin release. Further studies are needed to understand the mechanisms involved by which C1 induce insulin release from pancreatic islets.

Nutrient regulation of thiols redox state in the mitochondrial matrix of rat pancreatic islet cells: dynamic measurements using redox-sensitive GFP2 fused to GRX-1

H.K. Takahashi, L.P. Roma, J. Duprez, J.-C. Jonas;
Pôle d'endocrinologie, diabète et nutrition, Institut de Recherches Expérimentale et Clinique, Université Catholique de Louvain, Brussels, Belgium.

Background and aims: Both reactive oxygen species and NADPH production are putative metabolic coupling factors in pancreatic β cells. Through a network of oxidation-reduction reactions, they exert opposite effects on protein thiols redox state that may play a role in the control of β cell function and survival. So far, little is known about nutrient-induced changes in β cell thiols redox state, and even less about their changes in subcellular compartments. Here, we used the redox-sensitive GFP2 fused with glutaredoxin (GRX) 1 to investigate the acute nutrient regulation of glutathione redox potential, a good indicator of thiols redox state, in the cytosol and mitochondrial matrix of rat β cells.

Methods: Male Wistar rat islet cell clusters were cultured on glass coverslips in RPMI medium containing 10mM glucose (G10) and 10% FBS. They were infected with an adenovirus encoding cytosolic GRX1-roGFP2 or mitochondrial mt-GRX1- roGFP2. One to two days later, the fluorescence ratio of the probe (exc 400/480nm; em 535nm) was measured every 30s during perifusion with a Krebs solution containing various glucose concentrations and test substances. The results (mean±SE for 8-11 clusters from at least 3 islet isolations) were normalized to the fluorescence ratio measured in the presence of 10mM dithiothreitol (set to 0%) and that measured in the presence of 1mM H_2O_2 (set to 100%). The significance of differences between groups was assessed by one-way ANOVA and a post-test of Newman-Keuls.

Results: Coinfection with Ad-RIP-DsRed showed that 90% of mt-GRX1-roGFP2 positive cells were β cells. The correct expression of the probes in the cytosol and mitochondria was confirmed by confocal microscopy using Mitotracker Red. In the presence of G10, the fluorescence ratio of cytosolic GRX1-roGFP2 was low (1.5±0.3% of min-max difference) and unaffected by stepwise changes in glucose concentration between G0 and G30. In comparison, the fluorescence ratio of mitochondrial mt-GRX1-roGFP2 was higher and significantly affected by the glucose concentration, ranging from 31±1% in G0 to 27±1% in G2, 21±1% in G5, 17±1% in G10, and 10±1% in G30. The fluorescence ratio of mt-GRX1-roGFP2 was also significantly reduced by addition of various metabolic substrates (α-ketoisocaproic acid, succinate methylester, Leu with Gln) to G5. These nutrient effects, which were opposite to previously reported nutrient-induced changes in NAD(P)H autofluorescence, were not due to changes in pH, as addition of 30 mM NH_4Cl or sodium acetate to G10 only slightly affected mt-GRX1-roGFP2 fluorescence ratio. They were also independent from changes in Ca^{2+} influx, as mt-GRX1-roGFP2 fluorescence ratio was not affected by addition of 500μM tolbutamide to G5 or 250μM diazoxide to G10. The glucose reduction of mt-GRX1-roGFP2 fluorescence ratio was similar when β cells were depolarized with 30 mM extracellular K^+ in the presence of 250μM diazoxide than under control conditions.

Conclusion: Acute nutrient stimulation rapidly reduces thiols (mainly glutathione) redox state in the mitochondrial matrix but not the cytosol of rat islet cells. These changes could play a role in the nutrient stimulation of insulin secretion (triggering and metabolic amplifying pathways), or in the long-term effects of glucose on the functional β cell mass.

Influence of K_{ATP} channel inhibition on ROS production in pancreatic beta cells

A. Edalat[1,2], C. Bauer[1], P. Krippeit-Drews[1], G. Drews[1], M. Düfer[2];
[1]Pharmacology, Toxicology, and Clinical Pharmacy, University of Tübingen, [2]Pharmacology, University of Münster, Germany.

Background and aims: In pancreatic beta cells glucose metabolism represents a major source for reactive oxygen species (ROS) and it is well known

that oxidative stress induces beta cell failure. Sulfonylureas (SUs) have been used in the treatment of diabetes mellitus type 2 for decades and their effects on stimulus-secretion coupling are well documented. In previous studies we showed that SUs upregulate antioxidative enzymes and protect beta cells against oxidative stress. Our current aim was to investigate short and long-term effects of SUs on mitochondrial metabolism and ROS levels in beta cells.
Materials and methods: Cytosolic Ca^{2+} concentration $[Ca^{2+}]_c$ was measured by fura-2, mitochondrial membrane potential (ΔΨ) was determined by Rh-123, FAD and NAD(P)H concentrations were analyzed by changes in autofluorescence and intracellular ROS were captured with 2',7'-dichlorofluorescein.
Results: In glucose-stimulated beta cells elevation of Ca^{2+} influx by a SU partly depolarised the mitochondrial membrane potential (ΔΨ) (15 mM glucose: 418±19 a.u., + 100 μM tolbutamide: 428±20 a.u., n=31, p≤0.05). The L-type Ca^{2+} channel blocker nifedipine completely prevented this effect (15 mM glucose + 5 μM nifedipine: 414±16 a.u., + 100 μM tolbutamide: 406±16 a.u., n=22, p≤0.05). To investigate the influence of SUs on the concentration of reduction equivalents, changes in NAD(P)H and FAD were determined. As expected NAD(P)H concentration was increased by elevating glucose (0.5 mM glucose: 479±14 a.u., 15 mM glucose: 504±14 a.u., n=16, p≤0.001). SU application reduced NAD(P)H autofluorescence by 5±1 a.u. and the L-type Ca^{2+} channel blocker gallopamil reversed this effect (n=16). FAD autofluorescence that could be increased by the specific complex II inhibitor 3-nitropropionic acid (3-NPA) (15 mM glucose: 422±7 a.u., + 1 mM 3-NPA: 440±7 a.u., n=40, p≤0.001) was unaffected by SU (4 mM glucose: 687±39 a.u., + 100 μM tolbutamide: 682±41 a.u., n=8, n.s.). 1 h incubation of beta cells with 15 mM glucose led to ROS accumulation (0.5 mM glucose: 315±19 a.u., 15 mM glucose: 789±46 a.u., n=56-63, p≤0.001). At 15 mM but not at 0.5 mM glucose SUs increased ROS. This effect could be reversed by gallopamil (1 h: 15 mM glucose + 100 μM tolbutamide: 996±56 a.u., + 50 μM gallopamil: 649±34 a.u., n=47-72, p≤0.001). 3-NPA did not elevate ROS indicating that the effect of SUs is independent of complex II (1 h: 15 mM glucose: 434±31 a.u., + 1 mM 3-NPA: 248±26 a.u., n=26-37, p≤0.001). Interestingly, oxidative stress induced by long-term incubation of islet cells in a glucolipotoxic milieu (2 days: 25 mM glucose, 100 μM palmitate) was not increased but drastically ameliorated by co-administration of a SU (25 mM glucose + 100 μM palmitate: 1192±298 a.u., + 10 μM gliclazide: 783±216 a.u., n=250-251 of 4 independent preparations, p≤0.05).
Conclusion: Beside their insulinotropic effect SUs are able to modulate ROS accumulation in metabolically active beta cells. Acute stimulation of Ca^{2+} influx by SUs accelerates respiratory chains and favours ROS formation possibly by interacting with mitochondrial structures like complex I. In agreement with upregulated antioxidative defense our data show that prolonged exposure to SUs reverses this situation and protects beta cells against metabolic stress by reducing intracellular ROS formation.

The role of the reactive oxygen species producing NADPH oxidase 5 (NOX5) as a regulator of islet function
I. Szanto[1], K. Bouzakri[2], D. Bosco[3], T. Berney[3];
[1]Dpt. of Cellular Physiology and Metabolism, [2]Medical Genetics and Development, [3]Department of Visceral Surgery and Transplantation, University of Geneva, Switzerland.

Background and aims: Production of reactive oxygen species (ROS) is a well-known modulator of islet beta cell insulin secretion and apoptosis. Different isoforms of the family of NADPH oxidase enzymes (NOX-es) are major intracellular sources of ROS. The goal of our study was to characterize NOX isoform expression in human islets and to investigate their role in islet insulin secretion and survival in a systematic way.
Materials and methods: We analyzed isolated human islets by real-time PCR, Western blot analysis and immunofluorescens labeling.
Results: We detected NOX2, NOX4 and NOX5 mRNA expression in whole islets and in isolated beta cells using an RT-PCR approach. In the following part we focused our attention on NOX5 as this isoform has not yet been described in islets. NOX5 is expressed in humans but has no rodent homologue. NOX5 produces reactive oxygen species (ROS) in a calcium-dependent manner and regulates cell proliferation in diverse cell types. When isolated islets were stimulated with high (16.7mM) glucose concentration, NOX5 protein displayed a two-fold increase compared to basal (5.6mM) glucose concentrations. Immunofluorescens co-localization experiments in islets demonstrated an intriguing pattern for NOX5 expression. In basal condition, we detected few, but highly NOX5-positive cells which were also labeled for somatostatin. By contrast, in glucose-stimulated islets NOX5 labeling was detected in insulin positive cells with lower intensity and a punctuated expression pattern. NOX5 did not directly co-localize with insulin-containing vesicles. To extend our investigations we analyzed DNAchip data and found increased NOX5 expression in islets of Type 2 diabetic subjects.
Conclusion: Taken together, our data imply NOX5 as a novel modulator of islet beta cell function and a potential regulator of intra-islet crosstalk. Therapeutic alteration of different NOX isoforms is considered a novel and viable approach in different pathologies. Our data suggest that modulation of NOX5 activity might be envisioned in the context of islet function and survival.

Oxidative stress and activation of the intrinsic pathway of apoptosis cause beta cell loss in Friedreich's ataxia
M. Igoillo-Esteve[1], E. Gurgul-Convey[2], S. Lenzen[2], D.L. Eizirik[1], M. Cnop[1,3];
[1]Laboratory of experimental Medicine, Université Libre de Bruxelles, Belgium, [2]Institute of Clinical Biochemistry, Hannover Medical School, Germany, [3]Division of Endocrinology, Erasmus Hospital, Brussels, Belgium.

Background and aims: Friedreich's ataxia (FRDA) is a neurodegenerative disease caused by reduced expression of the mitochondrial protein frataxin (Fx). In addition to the neurological manifestations, FRDA patients have a high prevalence of impaired glucose tolerance and diabetes as a consequence of β-cell demise. We have previously shown that Fx deficiency sensitizes β-cells to apoptosis induced by metabolic or endoplasmic reticulum stress. Moreover, we found that cAMP induction by incretin analogs is β-cell protective and may have therapeutic potential in FRDA. The activation of the intrinsic or mitochondrial pathway of apoptosis is controlled by the balance between anti- and pro-apoptotic proteins of the BCL-2 family. The aim of this study was to elucidate the molecular mechanisms of β-cell demise in FRDA.
Materials and methods: Fx was silenced by RNA interference (siFx) in stable clones of INS-1E cells expressing the HyPerCyto or HyPerMito vectors, to monitor H2O2 production in the cytosol or mitochondria, respectively, and in INS-1E cells overexpressing catalase in the mitochondria. RNA interference was used to silence BAD, DP5, Puma or Bim (≥ 50% knockdown) together with siFx. 48h after transfection cells were exposed for 24h to oleate (0.5 mM) or the endoplasmic reticulum stressor brefeldin-A (0.1 μg/ml), with or without the cAMP inducer forskolin (20 μM) or the reactive oxygen species scavenger MnTMPyP (25 μM). β-cell apoptosis was examined by Hoechst 33342/propidium iodide staining, caspase-3 activation and immunofluorescence for cytochrome c release. Protein and gene expression was analyzed by Western blot and real-time PCR.

Results: Fx silencing increased SOD2 expression and mitochondrial H2O2 production in β-cells. MnTMPyP protected Fx-deficient β-cells from oleate (40±4% apoptosis for siFx oleate vs 21±2% for siFx oleate + MnTMPyP, n=3, p<0.05) and brefeldin (47±3% for siFx brefeldin vs 37±2% for siFx brefeldin + MnTPyP, n=4, p<0.05). Mitochondrial catalase overexpression also protected Fx-deficient β-cells from brefeldin (n=3, p<0.05). Fx deficiency activated the intrinsic pathway of apoptosis in β-cells, as indicated by mitochondrial cytochrome c release, induced the pro-apoptotic proteins DP5, Puma and Bim (around 60% increase in mRNA expression, n=9-14, p<0.05), and reduced BAD phosphorylation. Silencing of DP5, BAD and Bim but not Puma protected Fx-deficient β-cells in control condition and after oleate and brefeldin exposure (n=4, p<0.05). Forskolin protected Fx-deficient β-cells by restoring BAD phosphorylation and reducing Bim expression (n=4, p<0.05).
Conclusion: β-Cell death in FRDA is mediated by enhanced mitochondrial oxidative stress and activation of the intrinsic pathway of apoptosis. The pro-apoptotic BCL-2 proteins BAD, DP5 and Bim are key mediators of β-cell death. cAMP inducers protect Fx-deficient β-cells via BAD phosphorylation and reduced Bim expression. Selective modulation of pro-apoptotic BCL-2 proteins by incretin analogs may have therapeutic potential to prevent β-cell loss in FRDA.

Glucose causes a pronounced activation of ATP-synthase dependent respiration in pancreatic beta cells
A. Wiederkehr;
Diabetes and Metabolism, Nestlé Institute of Health Sciences, Lausanne, Switzerland.

Background and aims: Mitochondria are essential for metabolism-secretion coupling in pancreatic beta cells. Glucose stimulation accelerates mitochondrial oxidative metabolism and respiration to increase the cytosolic ATP/ADP ratio, which initiates plasma membrane electrical activity and thereby insulin granule exocytosis. Cytosolic calcium signals occurring as a result of plasma membrane depolarization are sensed by mitochondria and serve as a potentiating signal during second phase insulin secretion. The proposed main target of mitochondrial calcium signals are pyruvate dehydrogenase, α-ketoglutarate dehydrogenase and isocitrate dehydrogenase. Their activation will increase TCA cycle activity and the formation of NADH. Here the effect of beta cell calcium signaling on the regulation of glucose-induced NAD(P)H formation and ATP-synthase dependent respiration were assessed.
Materials and methods: Glucose-induced respiration was studied in INS-1E cells or groups of intact human islets. Mitochondrial respiration was calculated as the difference before and after addition of rotenone (complex I inhibitor) in combination with antimycinA (complex III inhibitor). ATP-synthase dependent respiration was determined similarly using oligomycin. Oxidative metabolism in human islets was followed by measuring NAD(P)H autofluorescence on a two-photon confocal microscope. Cytosolic calcium signals were analyzed at the single cell level in INS-1E and primary beta cells using the calcium sensitive probe YC3.6.
Results: Glucose stimulates mitochondrial respiration in INS-1E and human beta cells. We find that in insulin secreting cells a surprisingly large fraction of total respiration under resting conditions is ATP-synthase independent. Following glucose stimulation this fraction of the total respiratory rate remains constant while ATP-synthase dependent respiration is strongly induced. This activation of ATP-synthase is almost completely suppresses when calcium signaling is prevented. Under similar conditions, NAD(P)H levels rapidly increase in response to glucose. At this point the NAD(P)H/NAD(P) ratio is in a new steady-state determined by on the one side enhanced oxidative metabolism and on the other re-oxidation by the respiratory chain. Consistent with this view, when glucose is removed the NAD(P)H signal rapidly decreases while inhibition of respiration further augments the NAD(P)H/NAD(P) ratio. Interestingly, calcium signaling had no impact on the NAD(P)H steady-state signal.
Conclusion: Glucose-induced calcium signaling is required to stimulate ATP-synthase dependent respiration in pancreatic beta cells. In contrast calcium signaling does not influence steady-state NAD(P)H levels, which are determined mainly by the glucose concentration. The data are consistent with the hypothesis that calcium accelerates oxidative metabolism (NADH formation) and respiration (NADH oxidation) about equally.

MICU2 modulates nutrient-sensing and insulin secretion in INS-1 832/13 cells
A. Bagge[1], B. Valtat[1], V.K. Mootha[2], H. Mulder[1];
[1]Unit of Molecular Metabolism, Lund University Diabetes Centre, Malmö, Sweden, [2]Broad Institute, Cambridge, USA.

Background and aims: The Mitochondrial Calcium Uniporter (MCU) is a low affinity Ca^{2+} channel-complex. It is responsible for mitochondrial Ca^{2+} (Ca^{2+}_m) influx during metabolic activation. Ca^{2+}_m influx potentiates mitochondrial metabolism by the activation of dehydrogenases in the TCA-cycle, which increases metabolic flux and hence NAD(P)H availability. The molecular composition of the MCU-complex was recently resolved. Thus, the proteins MCU and MICU1 (mitochondrial calcium uptake 1) are potential regulators of nutrient-stimulated ATP generation and insulin secretion in beta cells. Recently, MICU2 (EFHA1) was reported to be part of the MCU complex. Here, we investigated the role of MICU2 in glucose-stimulated insulin secretion (GSIS) and mitochondrial function in the clonal beta cell line INS-1 832/13.
Materials and methods: *MICU2* mRNA expression in human islets was determined by microarray analysis in islets from 85 donors. GSIS (at 2.8 or 16.7 mM glucose) was determined 72 h after siRNA-mediated knock-down (KD) of *Micu2* in INS-1 832/13 cells. ATP content was determined by luciferase-dependent luminescence. The Seahorse XF24 instrument was used to measure respiration.
Results: *MICU2* mRNA expression in human islets was negatively correlated with fold change in insulin secretion (p=0.0160). KD of *Micu2* in INS-1 832/13 cells for 72 h decreased basal insulin secretion by 33 ± 4.0% (p = 0.0003). There was a trend towards decreased GSIS. Both basal and glucose-stimulated respiration were decreased in *Micu2* KD cells by 44 ± 9% (P=0.0257) and 33 ± 7% (p=0.0364), respectively, compared to control cells. While KD of *Micu2* did not affect basal nor glucose-stimulated total ATP levels, respiration-driven mitochondrial ATP generation (oligomycin-sensitive respiration) and proton leak (oligomycin-insensitive respiration) were decreased by 27 ± 7% (p=0.0229) and 57 ± 11% (p=0.0156), respectively. Interestingly, KD of *Micu2* abolished spare respiratory capacity (FCCP-induced uncoupling) by decreasing the maximal respiration rate by 43 ± 6% (p=0.0047).
Conclusion: MICU2 seems to modulate nutrient-sensing and insulin secretion in INS-1 832/13 cells. This modulation awaits full elucidation but likely involves Ca^{2+}_m influx leading to activation of dehydrogenases in the TCA-cycle and production of NAD(P)H. This is supported by our findings of decreased metabolic flux and the abolishment of spare respiratory capacity by *Micu2* KD. It may limit availability of electrons, causing the mitochondria to run out of reducing equivalents when respiration is uncoupled from ATP-generation.

The mitochondrial fission proteins Fis1 and Drp1 are important for proper glucose-induced insulin secretion in INS1 832/13 cells
J. Schultz, F. Reinhardt, R. Waterstradt, M. Tiedge, S. Baltrusch;
Institut of Medical Biochemistry and Molecular Biology, Rostock, Germany.

Background and aims: Mitochondria in living cells exist as a dynamic network that continuously cycle through fusion-fission events. Dysfunctional parts of the network were sorted out by mitophagy to support mitochondrial vitality. Mitofusin 1 and 2 (Mfn1 and Mfn2) and the optic atrophy 1 (Opa1) are essential for mitochondrial fusion, whereas the fission protein 1 (Fis1) and the dynamin related protein 1 (Drp1) control fission. It is currently being discussed if both fission proteins, Fis1 and Drp1, are essential to maintain mitochondrial function and glucose-induced insulin secretion of pancreatic beta cells. Thus, the aim of this study was to investigate changes in mitochondrial dynamics and cellular function after knockdown of Fis1 and Drp1 in glucose-responsive INS1 832/13 cells.
Materials and methods: Down-regulation of Fis1 and Drp1 were achieved using the GIPZ Lentiviral short hairpin RNAmir expression system. INS1 832/13 cells were infected with lentiviral particles containing shRNA for Fis1 or Drp1, or a non-silencing shRNA as control. Gene and protein expression were analysed by Real-Time PCR, western blot, and immunofluorescence analyses, respectively. The ATP content was measured using the ATPlite assay. Glucose-induced insulin secretion was determined by ELISA. Mitochondrial morphology and membrane potential were determined by MitoTracker and TMRE staining.

Results: Knockdown of Fis1 and Drp1 in INS1 823/13 cells resulted in a significantly reduced gene expression compared to control cells. Immunofluorescence and western blot analyses showed that Fis1 and Drp1 protein expression was likewise decreased. The mitochondrial membrane potential was significantly reduced in shFis1 and shDrp1 cells compared to control cells by 40 and 20 %, respectively. We observed a homogenous mitochondrial network structure in INS1 823/13 control cells. Knockdown of Fis1 and Drp1 resulted in a significantly higher mean mitochondrial area compared to control cells. However, whereas the Fis1 knockdown especially increased the value of elongated mitochondria in INS1 823/13 cells, after Drp1 knockdown also a number of clumped mitochondria were detectable. The ATP content and glucose-induced insulin secretion was significantly reduced, both in shFis1 and shDrp1 cells compared to control INS1 823/13 cells.
Conclusion: Our results suggest that both proteins, Fis1 and Drp1 are important for the stimulus secretion coupling in INS1 823/13 cells. Because the reduced expression of Drp1 and Fis1 evoked a different mitochondrial morphology, we propose for both proteins independent mechanisms on mitochondrial dynamics and cellular function in pancreatic beta cells.

Activation of glutamate dehydrogenase stimulates insulin secretion and implicates a metabolic pathway in beta cell stimulus-secretion coupling
B. Valtat[1], I. Göhring[1], A.P. Danielsson[1], S.G. Straub[2], G.W.G. Sharp[2], P. Spégel[1], H. Mulder[1];
[1]Clinical Sciences, Lund University Diabetes Centre, Malmö, Sweden, [2]Molecular Medicine, Cornell University, Ithaca, USA.

Background and aims: Leucine is an amino acid that stimulates insulin release under physiological conditions through the activation of glutamate dehydrogenase (GDH). GDH catalyzes the oxidative deamination of endogenous glutamate. Previous studies have shown that leucine and 2-aminobicyclo [2.2.1]heptane-2-carboxylic acid (BCH), a nonmetabolizable leucine analog, are activators of GDH and largely mimic the effects of glucose on insulin release from pancreatic islets. To better understand stimulus-secretion coupling in pancreatic β-cells, the functional, secretory and metabolic responses to glucose and BCH are compared in INS-1 832/13 clonal β-cells, as well as in human islets.
Materials and methods: INS-1 832/13 clonal β-cells and human islets were stimulated with 16.7 mM glucose or 20 mM BCH. Glucose- and BCH-stimulated insulin secretion was measured, as well as mitochondrial and plasma membrane potentials. Metabolite profiles were determined by gas chromatography-mass spectrometry and compared at 2.8 and 16.7mM glucose as well as 20 mM BCH, using multivariate statistics.
Results: Similar to 16.7 mM glucose, BCH provoked insulin release in INS-1 832/13 β-cells in a biphasic manner. This was associated with a depolarization of plasma membrane and an increase in the cytosolic Ca^{2+} level. Conversely, metabolite profiles in INS-1 832/13 β-cells kept in 2.8 and 16.7 mM glucose or 20 mM BCH were perfectly separated by multivariate statistical analysis. Notably, glucose or BCH increased α-ketoglutarate levels while glutamate levels decreased in response to BCH stimulation in either INS-1 832/13 β-cells or human islets.
Conclusion: BCH through the activation of GDH induces the same effects as high glucose on insulin secretion and plasma membrane potential in INS-1 832/13 β-cells. Notwithstanding this activation of GDH by BCH involves other metabolic pathways, mainly anaplerotic, in β-cell stimulus-secretion coupling.

DNA methylation of the glucagon-like peptide-1 receptor (GLP1R) in human pancreatic islets
E. Hall[1], T. Dayeh[1], C.L. Kirkpatrick[2], C.B. Wollheim[2], M. Dekker Nitert[3], C. Ling[1];
[1]Department of Clinical Sciences, Epigenetics & Diabetes, Lund University Diabetes Centre, Lund University, Malmö, Sweden, [2]Cell Physiology and Metabolism, University Medical Center, Geneva, Switzerland, [3]School of Medicine, Royal Brisbane Clinical School, University of Queensland, Herston, Australia.

Background and aims: Glucagon-like peptide-1 (GLP-1) is an incretin hormone which exerts its effects via the glucagon-like peptide-1 receptor (GLP1R) located on several different cell types and organs including pancreatic beta cells. Binding of GLP-1 to its receptor on beta cells will enhance the exocytosis of insulin. GLP1R protein expression is reportedly reduced in pancreatic islets from patients with type 2 diabetes. However, whether epigenetic mechanisms e.g. DNA methylation affect *GLP1R* in human islets remains unknown. Here, we examined if DNA methylation of the *GLP1R* gene is associated with *GLP1R* mRNA expression in pancreatic islets from human donors. We further examined if pancreatic islets from patients with type 2 diabetes show differential DNA methylation of the *GLP1R* gene compared with non-diabetic donors.
Materials and methods: DNA methylation of 12 CpG sites located both upstream and downstream of the transcription start site of *GLP1R* were analysed in human pancreatic islets of 55 non-diabetic donors and 10 donors with type 2 diabetes. DNA methylation of the *GLP1R* promoter was also analysed in FACS sorted alpha and beta cells from pancreatic islets of three human donors.
Results: DNA methylation of one CpG site of the *GLP1R* promoter correlated negatively with islet gene expression (rho=-0.34, p=0.008) and positively with BMI (rho=0.30, p=0.02) and HbA_{1c} (rho=0.30, p=0.03). This specific CpG site is positioned in an area previously shown to have SP1 and SP3 transcription factor binding sites, suggesting that methylation of this specific site could influence the binding of these factors and thereby the transcription of the gene. We also found significantly higher levels of DNA methylation of this CpG site in human alpha cells compared with beta cells (p=0.009). Furthermore, one CpG site showed nominally increased DNA methylation in pancreatic islets from patients with type 2 diabetes compared with non-diabetic controls (p=0.022).
Conclusion: Our results suggest a mechanism where obesity and/or hyperglycaemia influence DNA methylation and eventually gene expression of *GLP1R* in human pancreatic islets.

Targeting pancreatic alpha and beta cells with adeno-associated viruses (AAVs)
E. Tudurí[1], M.M. Glavas[1], A. Asadi[1], G. Soukhatcheva[2], R.K. Baker[1], C.B. Verchere[2,3], T.J. Kieffer[1,3];
[1]Department of Cellular and Physiological Sciences, [2]Department of Pathology and Laboratory Medicine, [3]Department of Surgery, University of British Columbia, Vancouver, Canada.

Background and aims: Adeno-associated viruses (AAVs) are useful gene therapy vectors and are being tested clinically in various diseases. We have designed AAV8s containing the rat glucagon promoter (700 bp) or the rat insulin I promoter (410 bp) to specifically target pancreatic alpha- and beta cells, respectively. These novel vectors may allow for the acute expression or knockout of a desired gene and for the development of gene therapies targeted to these cell types.
Materials and methods: Constructs with the glucagon promoter driving enhanced green fluorescent protein (GCG-EGFP) or with the insulin promoter driving Cre recombinase (RIP-Cre) were used to produce the vectors. AAV8s were delivered by intraperitoneal or intraductal injection to wild type and mT/mG reporter mice. Transgene expression and function of the targeted

cells were analyzed at different time points post-injection. Additionally, body weight and several metabolic parameters were examined.
Results: AAV RIP-Cre delivery resulted in specific beta cell Cre expression within the islets. Cre activity was confirmed by delivery of AAV RIP-Cre to reporter mT/mG mice, in which EGFP was expressed upon Cre-mediated recombination. Administration of AAV RIP-Cre up to the dose of 1x10^12 viral genomes did not produce alterations in body weight, blood glucose, glucose tolerance, glucose-stimulated insulin secretion or plasma hormone levels. AAV GCG-EGFP delivery allowed for exclusive EGFP expression in alpha-cells, which exhibited normal [Ca2+]i when stimulated with low and high glucose and adrenaline, and did not produce alterations in body weight, blood glucose, arginine and glucose tolerance, or plasma hormone levels. Moreover, preliminary data showed that AAV GCG-EGFP could be used to successfully sort alpha-cells from a pancreatic cell population.
Conclusion: We conclude that AAV8s may be suitable vectors to specifically and acutely target gene expression in alpha- and beta cells.

Microelectrode array (MEA) technology allows functional analysis of human and mouse pancreatic islets
S. Schönecker[1,2], U. Kraushaar[1], W. Barthlen[3], U. Lendeckel[3], R. Walther[3], M. Düfer[4], E. Guenther[1], G. Drews[5], P. Krippeit-Drews[5];
[1]Natural and Medical Science Institute at the University of Tübingen, Reutlingen, Germany, [2]University of Tübingen, [3]University Medicine Greifswald, [4]Universtity of Münster, [5]University Tübingen, Germany.

Background and aims: Electrical activity of beta cells in intact mouse islets consists of membrane potential oscillations that couple blood glucose levels to insulin release. We have shown before that the oscillations measured with MEAs are an excellent marker of beta cell activity and metabolic integrity. We aimed 1) to apply the MEA technology to human islets in order to elucidate whether human islets exhibit oscillatory activity similar to that described in mice, and 2) to demonstrate in mice that the MEA is suitable for the long-term assessment of islet functionality in vitro.
Materials and methods: Oscillations of V_m were recorded from whole islets as field potentials using MEA technique. They were quantified by calculating the fraction of plateau phase (FOPP = percentage of time with burst activity). Mouse islets were cultured on MEAs. Electrical activity from human islets, obtained from biopsies during pancreatic surgery, was recorded on MEA electrodes in tissue slices or individual islets.
Results: We can show for the first time that the membrane potential of human islets is able to oscillate in a similar manner as observed in mouse islets (n=1). The islet within a tissue slice covered two electrodes (200 µm distance) of a MEA. The oscillations appeared at a glucose concentration of 10 mM and could only be followed for 2'30 min because of a fast decay of signal amplitude. The apparent FOPP was 48 % which closely resembles the EC_{50} value for glucose stimulation of mouse islets which is at 12±1 mM glucose (n=5-10). In another human islet electrical activity occurred in 10 mM glucose after 4 d in culture. The signal was too noisy to resolve oscillations properly, but responded to diazoxide and tolbutamide. In a further approach, mouse islets were kept up to 34 days in culture (DIC) and five to ten islets were usually recorded in parallel with MEA electrodes. The FOPP was summarized for the experiments performed at DIC 6 and 7, and compared to those at DIC 33 and 34. Similar to acute recordings obtained previously* islets were silent at 3 mM glucose and the FOPP amounted to 32±3 % (n=8) and 36±2 % (n=7) at 10 mM glucose and to 70±6 % (n=8) and 72±5 % (n=7) in 15 mM glucose at DIC 6/7 and DIC 33/34, respectively. This long-term experiment shows for the first time that beta cells in culture keep unchanged oscillatory activity and responsiveness to glucose over weeks.
Conclusion: This study presents for the first time that human islets show membrane potential oscillations comparable to those found in mice. It discloses the proof-of-principle that MEA technology can be used to evaluate the functionality of human islets. Further investigations will elucidate whether this technique is suited for quality control of islet transplants. Moreover, we show for the first time, that MEA technology is suitable to assess the functional properties of individual islets over weeks. As the glucose-dependent FOPP did not change with time, this opens numerous possibilities for complete new concepts and designs of in vitro studies on islets of Langerhans which may contribute to reduce the number of laboratory animals, too.

Syndapin I is a key regulator of beta cell endocytosis and plasma membrane protein homeostasis
Y. Shi[1], G. Yang[1,2], J. Yu[1], B. Qualmann[3], M. Kessels[3], L. Yu[1], P.-O. Berggren[1], S.-N. Yang[1];
[1]Molecular Medicine and Surgery, Karolinska Insititutet, Stockholm, Sweden, [2]Jilin Academy of Traditional Chinese Medicine, Changchun, China, [3]Institutet for Biochemistry I, Friedrich Schiller University Jena, Germany.

Background and aims: Syndapin was originally identified as a synaptic dynamin-associated protein in the brain. Later, this neuron-specific isoform was named syndapin I since other isoforms, syndapin II and syndapin III, were detected in other tissues. All these three isoforms participate in the regulation of endocytosis. The best understood one is syndapin I, which plays a crucial role in dynamin-mediated endocytosis in neuronal tissue. Like other secretory cells, the highly specialized secretory pancreatic β cell undergoes profound exocytosis in both constitutive and regulated fashions. Such profound exocytosis is inevitably followed by effective endocytosis to preserve β cell integrity and plasma membrane homeostasis in particular. Significant efforts have been devoted to the understanding of insulin exocytosis, the central function of the β cell. However, β cell endocytois is much less understood. The molecular details of the endocytic machinery in the β cell have not been well clarified. The present work dissects mechanistically the role of syndapin I in constitutive and regulated endocytosis as well as plasma membrane protein homeostasis in the pancreatic β cell.
Materials and methods: We combined patch-clamp techniques, confocal microscopy, FM1-43 staining, siRNA transfection, immunoblot analysis, immunocytochemistry and cell culture for characterizing the role of syndapin I in endocytosis and plasma membrane protein homeostasis in the mouse islet β cells and insulin-secreting RINm5F cells.
Results: Immunoblot analysis shows that syndapin I siRNA transfection significantly decreased syndapin I expression at the protein level. Confocal microcopy reveals that syndapin I knockdown effectively abrogated internalization of the fluorescent endocytosis marker dye FM 1-43 into β cells under basal conditions, exposed to D-glyceraldehyde/D-glucose or stimulated with KCl. In addition, intracellular application of inositol hexakisphosphate ($InsP_6$) evoked a significant reduction in β cell capacitance and activated β cell CK2 resulting in the elevation of syndapin I phosphorylation in β cells. Furthermore, CK2 inhibition not only reduced the $InsP_6$-induced phosphorylation, but also decreased $InsP_6$-induced capacitance reduction in β cells. Importantly, syndapin I knockdown appreciably increased L-type Ca^{2+} channel density in the β cell plasma membrane.
Conclusion: The results reveal that syndapin I serves as a key regulator of both constitutive and regulated endocytosis in β cells. This key endocytic protein also mediates $InsP_6$-induced β cell endocytosis via its CK2-dependent phosphorylation. Importantly, it plays a crucial role in the maintenance of plasma membrane protein homeostasis, as exemplified by the L-type Ca^{2+} channel. Overall, syndapin I is a key regulator of β cell endocytosis and plasma membrane protein homeostasis. These findings provide a better understanding of β cell endocytosis and its physiological importance.

Stimulus secretion coupling in a human beta cell line - EndoC-betaH1
L.E. Andersson[1], B. Valtat[1], V.V. Sharoyko[1], D.G. Nicholls[2], P. Spégel[1], H. Mulder[1];
[1]Department of Clinical Sciences in Malmö, Unit of Molecular Metabolism, Lund University Diabetes Centre, Malmö, Sweden, [2]Buck Institute for Research on Aging, Novato, USA.

Background and aims: Clonal cell lines have been extensively used in investigations of ß-cell metabolism as they are accessible at large quantities, and as opposed to the islet, contain only one cell-type. Thus far, most research has been conducted in rodent ß-cell lines due to the lack of stable human ß-cell lines. However, findings from rodent models cannot generally be directly translated into humans. Here we examine and compare stimulus-secretion coupling in a recently developed human ß-cell line (EndoC-ßH1) with a widely used rodent ß-cell line (INS-1 832/13).
Materials and methods: EndoC-ßH1 and INS-1 832/13 clonal ß-cells were challenged with various secretagogues after which insulin secretion, insulin content, metabolite profiles, glucose utilization, ATP, oxygen consumption rate, plasma membrane potential and cytoplasmic free calcium were analyzed.

Results: Overall, the patterns of responses in the measured parameters were similar in the two cell-lines when stimulated with glucose, pyruvate and KCl. Basal insulin secretion, however, was higher in the human than in the rat cells. Conversely, the fold difference in the response to secretagogues and the plasma membrane potential was lower in the human cells. Metabolite profiling revealed clear similarities, but also differences in e.g. metabolites associated with mitochondrial shuttling.
Conclusion: To this end, the response in metabolism to glucose stimulation was found to be largely similar in human EndoC-ßH1 cells and rat INS-1 832/13 ß-cells. Hence, previous knowledge generated from studies on stimulus-secretion coupling in the INS-1 832/13 ß-cell line may to a large extent translate into human ß-cell biology.

Interaction of incretin and sulfonylurea through Epac2A signalling in insulin secretion
H. Takahashi[1], T. Shibasaki[1], S. Hidaka[1], A. Ono[1], T. Takahashi[1,2], S. Seino[1,3];
[1]Division of Cellular and Molecular Medicine, [2]Division of Diabetes and Endocrinology, [3]Division of Molecular and Metabolic Medicine, Kobe University, Kobe, Japan.

Background and aims: Incretin hormones such as glucagon-like peptide-1 (GLP-1) and glucose-dependent insulinotropic polypeptide (GIP) potentiate glucose-induced insulin secretion by increasing the intracellular cAMP level. This potentiation is mediated by both protein kinase A (PKA)-dependent and PKA-independent pathways, the latter involving Epac2A, a protein possessing guanine nucleotide exchange factor activity towards the small G-protein Rap. Recently, we found that Epac2A is directly activated by sulfonylurea (SU) and is important in SU-induced insulin secretion. Thus, Epac2A is a target of both cAMP and SU. To investigate the interaction of incretin and SU through Epac2A in insulin secretion, we examined the effects of combination of SU with incretin or cAMP analog on insulin secretion and activation of Epac2A/Rap1 signaling.
Materials and methods: We examined the effects of combination of SUs with GLP-1 on insulin secretion from isolated mouse pancreatic islets. We also examined dynamics of insulin secretion from perfused pancreases stimulated with combination of GLP-1 and SUs using wild-type and Epac2A-deficient mice. Activation of Epac2A by SUs and 8-pCPT-2'-*O*-Me-cAMP (8-pCPT), an Epac-selective cAMP analog, in insulin-secreting MIN6 cells was examined by fluorescent resonance energy transfer (FRET) system using Epac2A FRET sensor. Activation of Rap1 by SUs and 8-pCPT in MIN6 cells was examined by GTP-Rap1 pull-down assay. The effect of Rap1 activation on insulin secretion was examined using MIN6 cells infected with adenovirus carrying constitutive-active Epac2A mutant (CA-Epac2A), which lacks both cAMP-binding domains.
Results: In MIN6 cells, Epac2A was activated by glibenclamide (GLB) or glimepiride (GLM) but not gliclazide (GLC). In pancreatic islets, combination of GLP-1 with GLB or GLM augmented insulin secretion at both 4.4 and 8.8 mM glucose. Combination of GLP-1 with GLC augmented insulin secretion but the extent is smaller than that by combination of GLP-1 with GLB or GLM. In perfusion experiment, GLB and GLM induced insulin secretion in a biphasic manner: a transient increase immediately after stimulation (early phase), followed by sustained release (late phase). In the presence of GLP-1, GLB-induced insulin secretion was markedly potentiated in both early and late phases in wild-type mice. In contrast, potentiation of both phasic GLB-induced insulin secretion by GLP-1 was markedly reduced in Epac2A-deficient mice. On the other hand, there was no significant difference in the potentiation of GLC-induced insulin secretion by GLP-1, which was observed predominantly in late phase, between wild-type and Epac2A-deficient mice. In MIN6 cells, Epac2A was synergistically activated by combination of GLB and 8-pCPT. Activation of Rap1 was enhanced by combination of 8-pCPT with GLB or GLM but not GLC. We next examined the association of enhancement of Rap1 activation and insulin secretion, using CA-Epac2A. Introduction of CA-Epac2A into MIN6 cells induced strong activation of Rap1 in the absence of cAMP and significant potentiation of GLB- and glucose-induced insulin secretion.
Conclusion: Incretin and SU synergistically augment insulin secretion through Epac2A/Rap1 signaling. This synergistic effect depends upon SU structure.

Central role of osteopontin in pancreatic islets: regulation by glucose and incretin hormones
Y. De Marinis[1], M. Cai[1], A. Balhuizen[2], J.R. Acosta[1], M. Laakso[3], L. Groop[1];
[1]Diabetes and endocrinology, Lund University, Malmö, Sweden, [2]Diabetes and Celiac Unit, Lund University, Malmö, Sweden, [3]Diabetes and endocrinology, University of Eastern Finland and Kuopio University Hospital, Finland.

Background and aims: In diabetes, metabolic memory refers to a situation where the body can remember glycemic control years later, emphasizing the need for initial optimal metabolic control to prevent late complications. Elevated glucose levels can turn on genes with deleterious effects, among which we in this project focused on osteopontin (OPN). In patients with type 2 diabetes, circulating concentrations of OPN are elevated, and over expression of OPN has been associated with inflammation and accelerated diabetic complications. Previous studies have revealed that OPN is up-regulated in the serum of type 1 diabetic patients as well as in diabetic vascular walls and kidneys. Recent publication from our own group showed that in insulin-secreting cells, OPN could stimulate cell proliferation and prevent cytokine-induced apoptosis. These data suggest that OPN plays an important role in pancreatic islets. We therefore aimed at determining the function of OPN in pancreatic islet and how hyperglycaemia and incretins regulate the expression and function of OPN under normal and diabetic conditions.
Materials and methods: We conducted our study on diabetic mouse models and human pancreatic islets, involving methods as islet hormone secretion assay, immunohistochemistry, quantitative PCR and ELISA.
Results: Our data showed that in isolated single mouse islets, high glucose significantly increased OPN secretion about threefold ($p<0.001$) and elevated expression level by fivefold ($p<0.05$). GLP-1 upregulated OPN secretion by 1.5 fold ($p<0.001$) when islets are exposed to high glucose (16.7 mM) but has no effect at low glucose (1 mM), while GIP stimulated twofold OPN secretion at low glucose ($p<0.001$), but not at high glucose. We also observed that OPN exerts direct inhibitory effect on glucose-stimulated insulin secretion (GSIS) in both mouse (~50%, $p<0.05$) and human islets (~50%, $p<0.01$). Interestingly, in diabetic human islets, GSIS was elevated about 1.5 fold ($p<0.01$) by OPN. In addition, we explored the role of OPN in diabetic SUR1-E1506K mutant mice, in which an excessive secretion of OPN was found in islets. We observed that OPN is present in both pancreatic beta- and alpha-cells by confocal microscopy, and high glucose is able to upregulate OPN expression and secretion in islets from wild type C57Bl (1.5 fold, $p<0.05$), but not in SUR1-E1506K mutant mice. However, OPN secretion is significantly upregulated in SUR1-E1506K mice islets compared to wt when challenged by high glucose ($p<0.001$).
Conclusion: Our study shows that OPN inhibits GSIS in both human and mouse islets, but stimulated GSIS in diabetic human islets. The secretion and expression of OPN is regulated by glucose and incretins. When exposed to high glucose, diabetic mouse islets secreted more OPN compare to its wildtype.

Effects of glucose and potassium depolarisation on the granule mobility in the submembrane space of insulin-secreting MIN6 cells
K. Schumacher, M. Matz, K. Baumann, I. Rustenbeck;
University of Braunschweig, Germany.

Background and aims: Physiologically, insulin secretion is initiated by an increase of the glucose concentration. This involves a depolarization-induced

Ca^{2+} influx, which is experimentally often mimicked by raising the K^+ concentration in the medium. It has come into doubt, however, whether the stimulatory effect of a strong K^+ depolarization, which produces a first phase-like insulin secretion, is based on the same mechanisms as the first phase of glucose-induced secretion.

Materials and methods: Granules in the immediate vicinity of the plasma membrane were visualized by transient transfection of insulin-secreting MIN6 cells with an insulin-EGFP fusion protein and imaged by TIRF microscopy. The cells were continuously perifused with HEPES-buffered Krebs-Ringer medium (saturated with 95% O_2 and 5% CO_2) at 37.0 °C. The TIRF field had a calculated decay constant of 84 nm. The image files (1 sequence = 200 images = mean duration of 25 seconds) were evaluated by an in-house written program (MATLAB 7.6.0) to achieve an observer-independent quantification. The insulin secretion of MIN6 pseudoislets was measured by perifusion with ELISA of the fractionated efflux.

Results: Insulin release from perifused MIN6 pseudoislets was elicited by 30 mM glucose followed by 40 mM K^+ after an interval of 10 min with basal glucose. These stimuli were also applied in the reversed sequence. Under each condition 40 mM K^+ produced a robust increase of secretion whereas glucose was markedly less effective when following the K^+ depolarization. The same experimental protocol was used to measure the mobility of insulin granules in the submembrane space of perifused single MIN6 cells. Depending on the duration of their presence in the submembrane space, insulin granules were classified as either short-term (presence < 1 s) or long-term residents (presence for the entire image sequence ≥ 25 s). In a typical sequence ca. 80 % of all the granules that were identified were short-term residents and 30 to 40 % of the granules identified in the first image were still visible in the last image and were classified as long-term residents. Additionally, arrivals at and departures from the submembrane space were quantified, which represent the bidirectional mobility in the z-direction, i.e. orthogonal to the plasma membrane. Independently of the sequence of exposure 30 mM glucose and 40 mM K^+ led to an increase of arrivals and departures within 2 min. During the next 7 min there was a further slight increase with high glucose but not with 40 mM K^+. The increase of arrivals and departures was reversible upon wash-out of the stimuli. The increased rates of arrivals and departures led to a transient increase of the total number of granules in the submembrane space and a transient decrease of the number of long-term resident granules. None of these effects was seen with a constant basal glucose concentration.

Conclusion: High glucose and K^+ depolarization exert similar effects on the mobility of submembrane insulin granules in MIN6 cells, suggesting a role for depolarization-induced Ca^{2+} influx. However, increased mobility and secretion coincided only with K^+ depolarization, but were separable with glucose stimulation, suggesting the control of exocytosis by additional regulatory elements further downstream.

Autocrine signals mediate plasma membrane translocation of protein kinase C in insulin-secreting cells

A. Tengholm, A. Wuttke;
Department of Medical Cell Biology, Uppsala University, Sweden.,

Background and aims: Activation of protein kinase C (PKC) typcially involves Ca^{2+}- and/or diacylglycerol (DAG)-dependent translocation of the kinase from the cytoplasm to the plasma membrane. In insulin-secreting β-cells, PKCs have been implicated in the regulation of metabolism, cell death, proliferation and secretion. In the present study we investigated PKC translocation to the plasma membrane in response to transient increases in plasma membrane DAG after autocrine activation of $P2Y_1$-purinoceptors by ATP co-released with insulin.

Materials and methods: MIN6 β-cells were transfected with different fluorescent-protein-tagged PKC isoforms and a fluorescent translocation biosensor for DAG. The cytoplasmic Ca^{2+} concentration ($[Ca^{2+}]_i$) was measured with the fluorescent indicator Fluo-4. Changes of fluorescence in the sub-plasma membrane space were recorded with total internal reflection microscopy.

Results: Glucose stimulation of MIN6 β-cells triggered brief (<10 s), repetitive DAG elevations ("spiking"), which were perfectly mirrored by rapid recurring translocation of the novel PKC isoforms PKCδ, -ε, and -η. The conventional PKCβI and βII isoforms showed a more complex response with both the rapid and a slower translocation pattern. Depolarization with K^+ also induced parallel DAG spiking and PKC translocation. Whereas PKCε dissociated from the membrane between the K^+-induced DAG spikes, PKCβI dissociation was incomplete and the sustained component due to $[Ca^{2+}]_i$ elevation. Inhibition of $P2Y_1$-purinoceptors interrupted both DAG spiking and the intermittent translocation of the PKCs, but did not affect $[Ca^{2+}]_i$ or the associated sustained PKCβI translocation.

Conclusion: Exocytosis from β-cells induces transient increases of DAG, which translate into recurring translocation of conventional and novel PKCs to the plasma membrane, indicating that PKC signalling is involved in the autocrine regulation of β-cell function.

The clock gene Rev-erb alpha regulates glucagon secretion in mouse pancreatic alpha cells

E. Vieira[1,2], L. Marroquí[2], A. C. Figueroa[3], B. Merino[2], R. Fernández Ruiz[1], A. Nadal[2], T. Burris[4], R. Gomis[3], I. Quesada[2];
[1]Diabetes and Obesity Laboratory, CIBERDEM, Barcelona, Spain, [2]Instituto de Bioingeniería, Universidad Miguel Hernandez, Elche, Spain, [3]Diabetes and Obesity Laboratory, IDIBAPS, Barcelona, Spain, [4]The Scripps Research Institute, La Jolla, USA.

Background and aims: Disruption of pancreatic clock genes impairs pancreatic beta cell function, leading to the onset of diabetes. Specifically, the clock gene Rev-erbalpha was shown to regulate insulin secretion and proliferation. Despite the importance of alpha-cells in the regulation of glucose homeostasis and diabetes pathophysiology, nothing is known about the role of Rev-erbalpha in these cells. Therefore, the aim of the present work was to study the role of the clock gene Rev-erb alpha in the regulation of glucagon secretion.
Materials and methods: Pancreatic mouse alpha TC1-9 and mouse primary alpha cells were used. Gene expression and protein levels were measured by RT-PCR and western blot respectively. Gene silencing was done by siRNA technique. Intracellular calcium levels were measured by fluorescence microscopy. Purification of primary mouse alpha cells were done by FACS and glucagon secretion was measured by ELISA.
Results: Rev-erb alpha gene and protein down-regulation by siRNA in alphaTC1-9 cells inhibited glucagon secretion ($p<0.01$). The Rev-erb alpha agonist GSK4112 increased glucagon secretion (1.6 fold) and intracellular calcium signals in alphaTC1-9 cells and mouse primary alpha-cells, whereas the Rev-erb alpha antagonist SR8278 produced the opposite effect. AlphaTC1-9 cells exhibited intrinsic circadian Rev-erb alpha expression oscillations at 0.5mM glucose that were inhibited by 11mM glucose. In mouse alpha-cells, glucose induced similar effects ($p<0.001$). High glucose inhibited key genes controlled by AMPK such as Nampt, Sirt1 and PGC-1alpha ($p<0.01$). AMPK activation by metformin completely reversed the inhibitory effect of glucose on Nampt-Sirt1-PGC-1alpha and Rev-erb alpha genes. The Nampt inhibitior FK866 decreased Sirt1, PGC-1alpha and Rev-erb alpha mRNA expression and inhibited glucagon release ($p<0.01$).
Conclusion: Rev-erb alpha is as a new intracellular regulator of glucagon secretion via AMPK/Nampt/Sirt1 pathway. Strategies to target the Nampt-Sirt1-Rev-erb alpha in pancreatic alpha-cells can be useful for the treatment of hyperglucagonemia present in diabetes.

Roles of the type 2 diabetes-associated gene products Arap1 and StarD10 in the control of insulin secretion

G.R. Carrat, G. Meur, G.A. Rutter;
Medicine, Imperial College London, UK.

Background and aims: Investigation of the function of genes identified by genome-wide association studies for Type 2 diabetes may bring a better understanding of disease aetiology and ultimately provide new therapeutic targets. Recently-identified common genetic variants in the ARAP1 locus affect fasting proinsulin levels (rs11603334) and glucose-induced insulin secretion (rs1552224) in man. Two genes are implicated at this locus: ARAP1 and STARD10. To determine which of these might confer altered disease risk, and to explore the molecular mechanisms involved, we have studied the effect on insulin secretion of manipulating Arap1 and StarD10 levels in mouse islets and rodent beta cell lines.
Materials and methods: Arap1 and StarD10 expression was silenced by siRNA and proteins overexpressed via a coding plasmid transfected by Lipofectamine 2000 (cell lines) or adenoviral infection (mouse islets). Insulin secretion was measured by radioimmunoassay.
Results: Western (immuno-) blot analysis revealed that both Arap1 and StarD10 are expressed in mouse and human islets and in beta cell lines. Confocal immunocytochemistry demonstrated chiefly extranuclear localisation of both proteins. Forced over-expression of StarD10 cDNA in MIN6 cells decreased insulin secretion provoked by 30 (versus 3.0) mM glucose (control: 2.54 ± 0.21-fold; StarD10: 1.55 ± 0.10-fold; $p<0.01$) or 30mM KCl (control: 5.20 ± 0.35-fold, StarD10: 2.63 ± 0.14-fold; $p<0.0001$). Over-expression of the full-lengh variant of Arap1 (variant 3) exerted no apparent effect on insulin secretion in response to either 30mM glucose (control: 2.31 ± 0.28-fold; Arap1-V3: 2.22 ± 0.25-fold; NS) or 30mM KCl (control: 4.24 ± 0.48; Arap1-V3: 4.13 ± 0.72; NS). Although overexpression of a shorter form of Arap1 (variant 1), lacking an N-terminal inhibitory domain and thus supposed to be more active, had no significant effect on insulin secretion, we observed a strong tendency toward an inhibition of insulin secretion provoked by 30 mM glucose (control: 4.01 ± 0.63-fold; Arap1-V1: 2.84 ± 0.53-fold; NS) or 30mM KCl (control: 3.68 ± 0.28; Arap1-V1: 2.90 ± 0.32; $p=0.083$). siRNA-mediated silencing of either gene exerted no significant effect on stimulated insulin secretion
Conclusion: These data suggest that StarD10, implicated in phospholipid transfer between intracellular organelles, may act downstream of glucose metabolism to modulate insulin granule trafficking and/or exocytosis. Increased levels of StarD10 in beta cells from risk allele carriers may thus lead to diminished insulin secretion.

Identification of mitochondrial targets in human islets exposed to high glucose or fatty acids

T. Brun[1], N. Li[1], D. Bosco[2], T. Berney[2], P. Maechler[1];
[1]Department of Cell Physiology and Metabolism, University of Geneva, [2]Cell Isolation and Transplantation Center, Department of Surgery, Geneva University Hospital, Switzerland.

Background and aims: Exposure of pancreatic beta cells to metabolic stresses, such as chronic high glucose, fatty acids and oxidative stress, alters mitochondria and interrupts the transduction of signals normally coupling glucose metabolism to insulin secretion. However, it remains unclear what are the respective contributions of different diabetes-associated stresses on human beta cell dysfunction and death. Here, we aimed at identifying putative mitochondrial targets of beta cell injuries secondary to metabolic stresses.
Materials and methods: Freshly isolated human islets from three different donors, who had provided written informed consent, were cultured for 3 days in different conditions: 1) in control 5.6mM glucose 2) at high 25-30mM glucose 3) with 0.4mM palmitate 4) with 0.4mM oleate and 5) at 5.6mM glucose after a transient oxidative stress (200μM H2O2 for 10 min at day 0). Effects of the different metabolic stresses on expression profiles were repeatedly investigated in the three independent islet preparations. The NanoString-based molecular screening allowed absolute quantification of mRNAs of 57 mitochondrion-associated genes. The expression profile was compared to non-endocrine human HeLa cells. Molecular targets of interest were further evaluated at the protein level by immunoblotting.
Results: We first established the transcriptome of 30 mitochondrial inner membrane proteins, including the recently identified pyruvate carriers MPC1 and MPC2. Then, we observed that the different stresses induced specific responses in terms of expression profiles. Chronic exposure of human islets to high glucose impaired glucose-stimulated insulin secretion, decreased insulin content, promoted caspase-3 cleavage and cell death. High glucose specifically reduced transcript levels of the energy sensor SIRT1, of key transcription factors (HNF4α, PPARα, TFAM), and of mtDNA-encoded respiratory chain subunits (MT-ND3, MT-ATP6). Conversely, transcript levels of the uncoupling protein UCP2 and of the dicarboxylate transporter DIC and the aspartate/glutamate carrier AGC2 were increased by high glucose, a profile compatible with important mitochondrial anaplerotic/cataplerotic activities and NADPH-generating shuttles. All tested metabolic stresses down-regulated IPF1, MAFA, and the pyruvate carboxylase PC. Three days after acute oxidative stress, no significant alteration or apoptosis were detected in human islets. Immunoblotting revealed complex regulation of protein expression, not necessarily correlating with mRNA levels. Interestingly, absolute transcripts levels of PC, TFAM and UCP2 were lower in human islets compared to HeLa cells.
Conclusion: NanoString data provided first insights into absolute transcript levels in human islets, both in safe and metabolically stressful conditions. Expression profile of mitochondrion-associated genes was selectively modified by glucose in human islets, delineating a glucotoxic-specific signature.

TCF7L2* is the master regulator or proinsulin expression through *ISL1, MAFA* and *NEUROD1

Y. Zhou[1], J. Su[2], E. Ottosson-Laakso[1], T. Thevenin[1], E. Zhang[1], A. Brazma[3], J. Rung[2], L. Groop[1], E. Renstrom[1], O. Hansson[1];
[1]Lund University Clinical Resarch Center, Malmö, Sweden, [2]Functional Genomics, European Bioinformatics Institute, Hinxton, UK, [3]European Bioinformatics Institute, Hinxton, UK.

Background and aims: Type 2 Diabetes is characterized by elevated glycaemia as a consequence of reduced insulin secretion along with compromised insulin sensitivity. Genetic variants in the*TCF7L2*, shows the strongest association with type 2 diabetes (T2D) by affecting various aspects of beta cell function, including reduced insulin secretion.
Materials and methods: The screening of downstream pathways of TCF7L2 was performed using transcriptome RNA-seq in *Tcf7l2* depleted INS-1 832/13 cells. Pathway analysis was performed using Ingenuity IPA. Downstream targets were verified using Real-Time PCR, Western Blot, immuno histo chemistry imaging, and measurement of glucose stimulated insulin secretion.
Results: Knockdown of *TCF7L2* using siRNA reduced the expression of proinsulin gene expressionas well as of *Isl-1*, *MafA*, and *NeuroD1* expression in INS1 831/13 cells, and consequently glucose stimulated insulin secretion. *Isl1* was identified as a direct target of TCF7L2 and ISL1 is a known enhancer of proinsulin gene expression. In human pancreatic islets from cadaver donors, siRNA mediated *TCF7L2* depletion caused down regulation of *Isl1*, *MAFA* and *NEUROD1* mRNA expression. In addition, expression of *ISL1, MAFA* and *NEUROD1* correlate significantly with the *INS-IGF2* mRNA in human islets. Both NEUROD1 and MAFA were bound to the proinsulin promoter.
Conclusion: We report a novel pathway by which TCF7L2 can influence insulin synthesis (proinsulin) and secretion, by regulating the expression of ISL1, NEUROD1 and MAFA in adult pancreatic islets.

cAMP mediated regulation of miR-212/132 expression in insulin secreting cells acts through CREB-regulated transcription co-activator 1 (CRTC1)

H.A. Malm, I. Mollet, J.L.S. Esguerra, M. Orho-Melander, L. Eliasson;
Dept Clinical Sciences in Malmö, Lund University Diabetes Centre, Sweden.

Background and aims: MicroRNAs (miRNAs) are small non-coding RNAs controlling gene expression. We have previously demonstrated miR-212 and miR-132 to be regulated by glucose in Wistar rat islets. Others have demonstrated that the transcription factor CREB binds to CRE-sites on the miR-212/132 promotor. Here we aim to investigate mechanisms involved in cAMP-mediated transcriptional regulation of the miR-212/132 cluster in insulin secreting cells.
Materials and methods: INS-1 832/13 cells were cultured for 2, 6 and 24 h in 2.8, 5.0 and 16.7 mM glucose in the absence or presence of 1 μM forskolin (FSK) and 100 μM IBMX. To investigate the role of co-activators of CREB, INS-1 832/13 cells were transfected with siRNA against CRTC1, 2 and 3. Glucose stimulated insulin secretion (GSIS) was determined as the fold-increase in insulin released during 1 h incubation at 16.7 as compared to 2.8 mM glucose. The release at the different conditions was measured using RIA. Relative expression of miRNAs and mRNAs was determined by qPCR. Western Blot was performed to verify phosphorylated CREB.
Results: Expression of miR-212 and miR-132 was significantly increased after 2h culture in 16.7 mM as compared to 2.8 mM glucose ($p<0.05$; n=3 for each miRNA). A more pronounced increase in expression of miR-212 and miR-132 was observed after incubation in FSK/IBMX (3-and 4-fold, respectively; $p<0.01$) as compared to glucose alone and this increased to 5- and 7-fold and 6- and 8-fold after 6 and 24 h, respectively. GSIS was 3-fold ($p<0.01$; n=3) after culture in 2.8 mM glucose for 2h, which was significantly reduced (to 2-fold increase; $p<0.05$) after culture in the simultaneous presence of FSK/IBMX. The reduction in GSIS was more pronounced after culture for 6 an 24 h. Increased level of phosphorylated CREB was observed at 16.7 mM glucose, which was further enhanced in the presence of FSK. Transfection of INS-1 832/13 cells with siRNA against the three CRTCs separately reduced each of them significantly (>50%). Expression of miR-212 and miR-132 ($p<0.05$; n=3) and GSIS were significantly decreased ($p<0.01$; n=3) in cells transfected with siRNA against CRTC1, whereas expression of miR-212 and miR-132 was unaffected after silencing of CRTC2 and 3.
Conclusion: We confirm our previous observation that expression of miR-211 and miR-132 is glucose dependent in insulin secreting cells. Moreover, our data suggests that the miR-212/132 cluster is strongly regulated by cAMP in insulin secreting cells and that this is, at least in part, mediated through CREB and its co-activator CRTC1.

GLP-1 rescued dysregulated miRNA by hyperglycaemia in diet-induced obese mice

I. Lee, K. Park, K.-J. Yang, J. Lee, Y. Jang, H. Kim;
Daejeon St. Mary's Hospital, Deajeon, Republic of Korea.

Background and aims: GLP-1 has shown direct beneficial effects on beta cells, such as anti-apoptotic effect, increasing beta cell mass, and improvement of beta cell function. However, its mechanism is still not fully understood. MicroRNAs could be involved in insulin secretion, pancreatic development, and

beta cell differentiation. This study investigated the role of microRNA in beta cell development with GLP-1 in obesity-associated diabetes.
Materials and methods: We administered GLP-1 to diet-induced obese mice fed high fat diet(HFD) for 2 weeks. Body weight, food intake were monitored regularly throughout the treatment. beta cell mass, islet size, plasma glucose, and plasma insulin were measured after 2 weeks of dosing. We have selected 6 microRNAs(miR-15a, 29c, 34a, 124a, 146a, and 375), as candidate according to literature data and to a computational analysis and analysed the microRNA expression by real-time quantitative PCR in serum and pancreas.
Results: The HFD Mice receiving GLP-1 had a body weight gain similar to that of the HFD mice. The HFD Mice receiving GLP-1 were significantly increased beta cell mass relative to the HFD mice. The HFD Mice receiving GLP-1 were significantly decreased both plasma glucose and insulin levels relative to the HFD mice. The HFD mice were significantly increased miR-15a, 29c, and 375 levels in pancreas relative to the low fat diet mice. Expression of miR-15a, 29c, 146a, and 375 was significantly decreased by administration of GLP-1 in pancreas of the HFD mice. The HFD mice ware significantly decreased serum miR-15a, 29c, 34a, 124a, 146a, and 375 levels relative to the low fat diet mice. Expression of serum miR-15a, 29c, 34a, 124a, 146a, and 375 was significantly increased by administration of GLP-1 in the HFD mice.
Conclusion: Our results provide experimental evidence that dysregulated miRNA contributes to development of obesity-induced insulin resistance. miR-15a, 29c, 34a, 124a, 146a, and 375 play an important role for beta cell development with GLP-1 in obesity-associated diabetes and are a potential target for the treatment of obesity-associated diabetes.

Differences in microRNA expression between embryonic stem cells and induced pluripotent stem cells during differentiation to a pancreatic lineage

N.A. Francis[1,2], M. Moore[1], G.A. Rutter[2], C.J. Burns[1];
[1]Biotherapeutics, National Institute Of Biological Standards And Control, Potters Bar, [2]Department Of Medicine, Imperial College London, UK.

Background and aims: Type 1 diabetes mellitus (T1DM) results from autoimmune destruction of pancreatic ß cells. Islet transplantation has shown proof of principle for cell replacement therapy to treat T1DM. Insulin-expressing cells have been produced in vitro from embryonic stem cells (ESCs), however problems associated with ESCs, primarily ethical concerns & immunogenicity, mean an alternative cell source is needed. Induced pluripotent stem cells (iPSCs) are an alternative source of pluripotent stem cells which can be derived in a patient-specific manner. iPSCs have been shown to differentiate into insulin-expressing cells in vitro but it is unknown whether iPSCs are equivalent to ESCs, since important differences have been shown to exist between ESCs & iPSCs which may affect the ability of iPSCs to give rise to cells of a pancreatic lineage & thus limit their usefulness for treatment of T1DM. MicroRNAs (miRNAs) are small non-coding RNAs that regulate gene expression. They are differentially expressed depending on cell type & stage of differentiation. A unique miRNA signature characterises pancreas development at the definitive endoderm (DE) stage. Given the recognised differences in miRNA expression between iPSCs & ESCs, we have investigated the profiles of miRNA expression at the DE stage, a critical step in the in vitro differentiation of these cells toward an insulin-expressing phenotype.
Results: Multiple iPSC & ESC lines were differentiated into DE using an Activin A-based protocol. Individual cell lines showed different propensities to form DE. As a result, microarray analysis was carried out on undifferentiated & differentiated iPSCs & ESCs in order to compare miRNA expression. Microarray analysis allowed identification of miRNAs that are up- or down-regulated upon differentiation to DE, & which may therefore play a role in this process. The 10 miRNAs that are most upregulated in DE are miR-375, miR-708-5p, miR-744-5p, miR-4792, miR-4530, miR-26b-5p, miR-4472, miR-27b-3p, miR-4289 & miR-30b-5p. The 10 miRNAs that are most downregulated in DE are: miR-5002-5p, miR-378a-3p, miR-3941, miR-4451, miR-516b-5p, miR-4436b-5p, miR-4732-3p, miR-32-3p, miR-124-5p & miR-4285. Several of these miRNAs have been previously implicated in pancreas development. Comparison of undifferentiated iPSCs & ESCs showed that they share a miRNA signature, with no miRNAs differentially expressed ($p<0.05$). However, upon differentiation, 91 miRNAs were differentially expressed in iPSCs vs. ESCs. This suggests that miRNA expression may play an important role in the ability of iPSCs & ESCs to differentiate into DE. Further elucidation of the role of these miRNAs may be useful for improving the efficiency of differentiation into a pancreatic lineage. Microarray results have subsequently been validated by qRT-PCR. We are now investigating the role of miRNAs that are involved in DE formation & that are differentially expressed between ESCs & iPSCs through the identification of putative targets & the manipulation of miRNA expression in differentiating cells.
Conclusion: iPSCs are a promising alternative to ESCs for the treatment of T1DM. However, differences in miRNA expression between these two cell types may affect their ability to differentiate into the pancreatic lineage, which may be important for any future clinical application of these cells.

Dual modal MR/fluorescent zinc sensing probes for in vivo beta cell imaging

G.J. Stasiuk[1], F. Minuzzi[2], M. Sae-Heng[1], N.J. Long[1], G.A. Rutter[2];
[1]Chemistry, [2]Medicine, Imperial College London, UK.

Background and aims: Changes in pancreatic beta cell mass contribute to the development of both Type 1 and Type 2 diabetes. At present, however, robust approaches to following these changes prospectively *in vivo* are lacking. Compared with other modalities, Magnetic Resonance (MR) imaging has excellent anatomical resolution but suffers, at the molecular scale, with low intrinsic low sensitivity. To produce a detectable change in water signal intensity, a relatively high concentration of contrast agent (0.01 - 0.1 mM) is required. This creates problems when imaging at the molecular level, as the most interesting targets are present at much lower concentrations, typically in the nano-molar range. In order to overcome the inherent sensitivity problem of the MRI, dual modal contrast agents show great promise for use both in experimental models and potentially in the clinic. Given the high concentration of zinc ions in insulin granules, and relative scarcity of these ions throughout the rest of the pancreas, we hypothesised that MRI-active agents capable of binding zinc may be used to quantify beta cell mass in vivo. Specifically, we have modified DOTA to allow both zinc binding and the incorporation of fluorescent sensors. Coordination with gadolinium yields novel dual-modal, MR/fluorescent zinc sensing probes.
Materials and methods: DOTA was modified with various organic fluorophores, AQA (Gd.1) and Dansyl (Gd.2), and zinc sensing motifs, to create zinc sensing agents. Probes were tested using both pancreatic beta cell-derived (MIN6, INS1(832/13) and non-beta (HEK293, HeLa) cell lines and in vivo after injection into CD1 mice. Fluorescence was monitored by confocal or multiphoton microscopy and MRI using a 9.4T magnet.
Results: Of compounds synthesised, Gd.1 showed ratiometric fluorescence changes upon zinc binding with a Stokes shift, from λem = 410 nm to λem = 500 nm upon zinc chelation, and a Kd = 22 μM. Gd.1 has an r_1 = 4.2 $mM^{-1}s^{-1}$, which increased to 6.2 $mM^{-1}s^{-1}$ (9.4T) upon zinc binding. Gd.2 shows an increase in fluorescence intensity at λem = 520 nm, with a Kd = 44 μM, Gd.2 has an r_1 = 3.7 $mM^{-1}s^{-1}$, which decreases to 3.4 $mM^{-1}s^{-1}$ (9.4T) upon zinc chelation. Examined in beta cell lines, both agents also showed localisation to secretory granules identified by co-expression of granule-resident protein phogrin, and relatively poor uptake into non beta cells. Injection of Gd.1 into mice also revealed uptake into islets with modest staining of other tissues.
Conclusion: We describe dual modal imaging agents that sense zinc, with excellent fluorescent and MRI properties, which may be used to monitor beta cell mass in vivo.

^{111}In-exendin for non-invasive quantification of beta cell mass in patients with type 1 diabetes and healthy controls

W. van der Weg[1], M. Brom[1], M.J.R. Janssen[1], M. Béhe[2], W.J.G. Oyen[1], C.J. Tack[3], O.C. Boerman[1], M. Gotthardt[1];
[1]Dept. of Nuclear Medicine, RUNMC, Nijmegen, Netherlands, [2]Center for Radiopharmaceutical Sciences, Paul Scherrer institute, Villingen-PSI, Switzerland, [3]Dept. of Internal Medicine, RUNMC, Nijmegen, Netherlands.

Background and aims: To date, many questions remain concerning the role of beta cell mass (BCM) in the pathophysiology and course of type 1 and type 2 diabetes (T1D and T2D). Various tests exist to quantify beta cell (BC) function (insulin secretion), but do not necessarily provide information on BCM, while BCM seems the most important predictor of future BC failure. A method that reliably can quantify BCM would be a tremendous asset to better elucidate the pathophysiology of T1D and T2D, and to determine the effects of therapeutic interventions. We developed a non-invasive imaging technology based on targeting of ^{111}In-labelled Exendin to the glucagon-like peptide-1 (GLP-1) receptor, which is specifically expressed on beta cells. In previous studies in animal models we showed that the pancreatic uptake of this tracer correlates with BCM. Here, we report the first results of an ongoing clinical trial using single photon emission computed tomography (SPECT) with ^{111}In-Exendin for BCM quantification in patients with T1D and in healthy controls.
Materials and methods: Patients with long standing T1D (no measurable C-peptide after glucagon stimulation, BMI below 27, age 21-60 yr) and healthy controls (normal glucose tolerance, matched for age, gender and BMI) are eligible for the study. 24 hours after i.v. injection of 150 MBq ^{111}In-Exendin-4, SPECT/CT scans were acquired for quantitative assessment of pancreatic BC targeting. A volume of interest (VOI) of the pancreas was delineated on SPECT/CT images and counts within this VOI were corrected for administered activity and time after injection.
Results: So far, 5 T1D patients and 5 matched healthy volunteers were studied. The pancreatic uptake of ^{111}In-Exendin (see figure) varied widely among these subjects. In healthy volunteers, it ranged from 0.9x10^5 to 3.8x10^5 counts/MBq (mean 2.3x10^5 counts/MBq). The uptake was decreased in T1D patients, but interestingly not completely absent in all, ranging from 0.5x10^5 to 1.5x10^5 counts/MBq (mean 1.0x10^5 counts/MBq). Our main observations are: a) pancreatic uptake in T1D patients is up to 8-fold lower than in healthy volunteers, b) pancreatic uptake varied by a factor of 3-4 amongst individuals within one group, and c) in some T1D patients, the radiotracer uptake suggests a substantial residual BCM.
Conclusion: Our results suggest that quantification of BCM with ^{111}In-Exendin SPECT is feasible. The data show large differences between T1D patients and healthy controls, as well as a high inter-individual variability in pancreatic uptake. Our *in vivo* imaging data are in line with autopsy data from the literature, suggesting that T1D patients may have a relevant remaining BCM, and that large inter-individual differences in BCM exist. ^{111}In-Exendin SPECT seems a valuable tool for non-invasive determination of BCM.

Towards clinical imaging with ^{18}F-labelled exendin-4, synthesised via click chemistry

K. Mikkola[1], C.-B. Yim[1], P. Lehtiniemi[1], V.-V. Elomaa[1], T. Ishizu[1], J. Rajander[2], P. Nuutila[1], O. Solin[1,2];
[1]Turku PET Centre, University of Turku and Turku University Central Hospital, [2]Accelerator Laboratory, Åbo Akademi University, Turku, Finland.

Background and aims: The glucagon like peptide-1 receptor (GLP-1R) is abundantly expressed in pancreatic beta cells and is a candidate molecular

target for beta cell imaging. Click chemistry (Cu(I)-catalysed alkyne/azide cycloaddition) was explored for the ^{18}F-labelling of GLP-1R specific exendin-4 peptide. We aim to develop [^{18}F]exendin-4 tracer for clinical imaging of beta cells with PET.

Materials and methods: Synthesis of [^{18}F]exendin-4 was started by reacting alkyne tosylate precursor with ^{18}F-fluoride-Kryptofix complex in DMSO. Subsequently, exendin-4 azide was added to react with [^{18}F]alkyne in the presence of $CuSO_4$/Na-ascorbate. Radiochemical analysis and isolation of [^{18}F]exendin-4 was performed using HPLC. *Ex vivo* biodistribution of [^{18}F]exendin-4 was evaluated in male Sprague-Dawley rats (N = 1-3 per time point). Rats (250-300 g) were injected intravenously with 6 ± 1 MBq (mean ± SD) [^{18}F]exendin-4 (mass 0.10 ± 0.04 nmol, specific activity 66 ± 24 MBq/nmol) and sacrificed at 15 min, 1 h, 2 h or 4 h after injection. The organ-specific radioactivity was reported as a percentage of the injected dose per gram of tissue (%ID/g). Intrapancreatic distribution of radioactivity was assessed with autoradiography and islet-to-exocrine tissue ratios were analyzed. For PET scans, one rat was imaged twice (dynamic 0-1 h, static 3.5-4 h) using Inveon Multimodality PET/CT.

Results: The radiochemical yield of the Click reaction was 40-45 %, and the specific activity of [^{18}F]exendin-4 was 80-140 MBq/nmol after synthesis. Most of the radioactivity was observed in the kidneys (Fig. 1B). Renal clearance was high (3 %ID/g 4 h p.i.), while radioactivity was nearly constant in the pancreas and stomach wall over the course of the study (Fig. 1A and B). The islet-to-exocrine tissue ratio in pancreas was 10 in one study using [^{18}F]exendin-4 with a specific activity of < 1 MBq/nmol, and increased to a maximum of 130 (*modus:* 60-70) with a specific activity of 140 MBq/nmol. Radioactivity in bone was low, indicating low defluorination. In PET images, the highest tracer uptake was found in kidney, lung and stomach wall.

Conclusion: To be clinically applicable for beta cell imaging, a sensitive radiotracer with high specific activity (> 1 GBq/nmol) is required. We have established a synthetic route towards ^{18}F-labelled exendin-4 based on Click chemistry. Our preliminary results of [^{18}F]exendin-4 showed specific and sustained uptake in pancreatic islets with an islet-to-exocrine tissue ratio of up to 130. Although far from clinically viable, these indications are promising for the development of an ^{18}F-labelled exendin-4 analogue with a specific activity that would render clinical imaging of beta cells.

^{19}F-mannoheptuloses as contrast agents for the non-invasive imaging of GLUT2-expressing cells: in vivo and ex vivo MRI studies

K. Louchami[1,2], S. Liang[2], E. Hupkens[1], W.J. Malaisse[1], J. Thimm[3], A. Sener[1], U. Himmelreich[2];
[1]Laboratory of Hormonology, Université Libre de Bruxelles, Belgium, [2]Department of Imaging and Pathology, Katholieke Universiteit Leuven, Belgium, [3]Department of Chemistry, University of Hamburg, Germany.

Background and aims: Suitable analogs of D-mannoheptulose are currently considered as possible tools for the non-invasive imaging of pancreatic islet insulin-producing cells. In the present studies, we examined whether ^{19}F-heptuloses could be used for non-invasive imaging of GLUT2-expressing cells. It was previously shown that the GLUT-2 transporter is expressed in both β-cells and hepatocytes and that mannoheptulose has high uptake specificity for the GLUT-2 transporter .

Materials and methods: *In vivo* ^{19}F MRI was used to confirm an extracellular concentration of 10 mM of either 1-^{19}F or 3-^{19}F fluoro-deoxy-mannoheptulose (FMH) after injection. Male BL6 mice were anesthetized using isoflurane according to the ethical committee's recommendations. For the *in vivo* ^{19}F MR imaging experiments, a Bruker Biospec 9.4T small animal MR scanner was used in combination with an in-house build, single loop, saddle-shape surface coil (42 mm x 66 mm). The animals were sacrificed immediately after the final imaging session (2 to 5 hours after the ^{19}FMH injection). The pixelwise ^{19}F signal was considered significant if larger than 2*SD of background noise ($p<0.025$) at post-processing stage. Hereby, ^{19}F NMR spectra of homogenized tissue samples were acquired by using an NMR spectrometer (Bruker Avance II, 9.4T) after addition of a known concentration of 5-fluorocytosine as an external concentration and chemical shift reference. The effect of fluorinated heptoses, D-mannoheptulose and 2-fluoro-2-deoxy-glucose administrated as indicated above upon blood glucose and insulin concentrations was examined at 5, 15, 30, 60, and 120 min after intraperitoneal glucose injection.

Results: Using an in-house build ^{19}F MRI coil resulted in reproducible, sensitive and quantifiable 19F MR images with a detectability limit of approximately 10^{15} atoms per pixel. *In vivo* images show clear signals of 1-FMH and 3-FMH from the bladder, kidney, liver and potentially from the pancreas. Repeated MRI scans indicate rapid clearance of 1-^{19}FMH and 3-^{19}FMH from the circulation (kidney, bladder) and only low retention in the liver and pancreas. ^{19}F NMR spectroscopy of excited tissue confirms the presence of ^{19}F FMH in these organs (1 to 5 mM). Both *in vivo* MRI and *ex vivo* NMR show almost complete clearance of ^{19}F FMHs 24 hours after injection. The effect of the ^{19}FMH on the IPGTT was comparable to that of unlabeled D-mannoheptulose. Indeed, 30 min after injection of high concentration of D-glucose (1mg/g of mice) and coinjection of these heptoses, the glycaemia remained higher than in the control experiments.

Conclusion: *In vivo* experiments using the different FMH derivatives indicate rapid clearance of the compound. While the FMH signal remaining in the liver and pancreas is potentially sufficient for in vivo β-cell and hepatocyte imaging, the sensitivity has to be improved for applications in models of diabetes. The IPGTT experiments demonstrate that the fluorinated mannoheptuloses exert the same effect as the unlabeled heptose. These results support the hypothesis that these fluorinated mannoheptuloses could be suitable candidates in the perspective of their use as non-invasive imaging tools.

Are we overestimating the loss of beta cells in type 2 diabetes?

L. Marselli, M. Suleiman, M. Masini, M. Bugliani, F. Olimpico, F. Syed, P. Masiello, F. Filipponi, U. Boggi, P. Marchetti;
Department of Clinical and Experimental Medicine, University of Pisa, Italy.

Background and aims: Decreased beta cell mass (-30/40% on average) is a consistent finding in human type 2 diabetes (T2D), and increased apoptosis is considered the major driving mechanism. However, recent work has shown that beta cell dedifferentiation, could also lead to beta cell failure in T2D. In addition, clinical findings such as the rapid recovery of insulin secretion after bariatric surgery suggests the presence of a relevant beta cell mass even in long-standing T2D patients. We therefore hypothesized that beta cell loss, as assessed so far, may be overestimated in T2D subjects, and performed morphological, morphometric, ultrastructural and functional studies with

pancreatic samples and isolated islets from non-diabetic (ND) and T2D individuals.
Materials and methods: We studied pancreas tissue samples and/or isolated islets from 6 ND (age: 69±3.5 years; gender: 3 males and 3 females; body mass index, BMI: 26.5±1.5 kg/m^2) and 7 T2D (age: 63±8 years; gender: 3 males and 4 females; BMI: 26.2±2.2 kg/m^2; known duration of diabetes: from 3 to 15 years) subjects. Immunocytochemical staining for insulin, glucagon and chromogranin, and electron microscopy analyses were performed, together with insulin secretion evaluations.
Results: By light microscopy, islet insulin-positive area was approximately 25% lower (p<0.001) in T2D (55.7±5.6%) than ND (74.3±8.7%). However, when islet beta cells were counted by electron microscopy, the 13% decrease in T2D (61.0±8.7% vs 70.3±6.4%) was barely significant (p=0.054). Beta cell amount as measured by light and electron microscopy differed significantly in T2D (p=0.036), but not in ND (p=0.41), and insulin granule density volume was lower (p<0.01) in T2D cases. Chromogranin expression was similarly detected in ND and T2D islets, including in cells negative for insulin. Glucagon containing cells, as quantified by both light and electron microscopy, did not differ between ND and T2D islets. When ND isolated islets were studied after 24h exposure to 22.2 mmol/l glucose, a marked reduction of insulin positive area by light microscopy assessment (non-treated: 74±8%; treated: 49±11%, p=0.03), but not upon electron microscopy (67±5% vs 71±7%, p=0.5) was found, together with marked insulin degranulation (p<0.05). Again, chromogranin staining detected cells negative for insulin. Acute glucose and glibenclamide-stimulated insulin release was 50% lower (both p=0.01) from T2D isolated islets.
Conclusion: These results show that the loss of beta cells in T2D islets may be currently overestimated due to insulin degranulation, and support the concept that insulin secretion defects play a key role. If so, rescuing beta cell function in T2D could be more realistic than pursuing regeneration.

Effects of altered insulin sensitivity on islet morphology in humans
T. Mezza[1,2], G. Muscogiuri[2], G. Sorice[2], G. Clemente[2], A. Giaccari[2], R.N. Kulkarni[1];
[1]Islet Cell & Regenerative Medicine, Joslin Diabetes Center, Boston, USA, [2]Catholic University, Rome, Italy.

Background and aims: Type 2 diabetes develops when insulin secretion fails to cope with worsening insulin resistance. It is becoming evident that insulin resistance can also impact non-classical tissues including the pancreatic β-cells. For example, obese insulin resistant patients exhibit an enhanced β-cell mass as an adaptive response although the underlying mechanism(s) is not fully understood.
Materials and methods: To explore the alterations that occur in islet morphology, as part of the adaptive mechanism, we performed hyperinsulinemic euglycemic clamps in 18 Caucasian nondiabetic patients, dividing them into insulin resistant (IR, n=9) or insulin sensitive (IS, n=9) (10 F/8 M, 51±15 yrs., BMI 27.9±5.3 kg/m2) groups according to glucose uptake (GU), incretins were evaluated during a Mixed Meal Test and insulin secretion were evaluated during Hyperglicemic Clamp, before and then after the surgery. Subsequently, all patients underwent duodeno-pancreatectomy, and pancreases were collected for immunohistochemistry for glucagon, insulin and somatostatin+ cells to assess islet morphology. Apoptosis was evaluated by TUNEL, proliferation by Ki67, and ductal cells by CK19 immunostaining.
Results: Assessment of the entire group revealed a direct correlation between GU and islet size (r= -0.74; p<0.001), and between GU and % glucagon area expressed as a fraction of the total pancreas (%GLUCA, r=-0.65; p=0.003). IR group displayed a significant reduction in β/α ratio and increased islet size (2456±332.2 vs 5156±944.8 μm2, p<0.01). While no differences were evident in proliferation, apoptosis or β cell area, the IR group displayed increased insulin+CK19+ cells (p<0.001),scattered islets (<8 cells)(p=0.04), insulin+glucagon+ double cells (p<0.01) and a larger β-cell nuclear area (p=0.03). Further, GLP1 levels correlated with %GLUA (r=0.63, p=0.04) and we detected GLP-1 immunoreactivity in α-cells. After the 50% pancreatectomy, We observed that the IRs experience an higher reduction of insulin secretion capacity compared to ISs (IS, 924.2± 900.3 vs. IR 6952±1951 ΔAUC insulin secretion tot, p=0.04). Moreover, greater increase in the glucagon secretion after pancreatic mass reduction have been described in insulin resistance status (IS 112.5±101.2 vesus IR 1812±326.3, p=0.02).
Conclusion: Our data suggest that neogenesis from duct cells and potential transdifferentiation of α cells towards the β-cell lineage could contribute towards a compensatory increase in β cells production in insulin resistance. This may be, in part, driven by the presence of GLP-1 immunoreactivity in the α cells. Together these data indicate that a failure of compensation in patients with insulin resistance leads to the development of overt diabetes following partial pancreatectomy.

513

Islet number rather than islet size may be a major determinant of beta cell mass in non-diabetic humans
K. Kou[1], Y. Saisho[1], S. Sato[1], T. Yamada[2], H. Itoh[1];
[1]Internal Medicine, [2]Pathology, Keio University School of Medicine, Tokyo, Japan.

Objective: Both type 1 and type 2 diabetes are characterized by a deficit of β-cell mass(BCM). Although enhancing endogenous β-cell regeneration is considered to be a potential therapeutic strategy to cure diabetes, little is known about factors determining BCM in humans. Both islet number and islet size(IS) contribute to BCM, however, the relative contribution of both factors in humans is unclear. Therefore in this study we examined associations between islet density(ID), mean IS and BCM in human pancreas.
Methods: We obtained autopsy pancreas from 72 Japanese adults aged from 20 to 70 years(age 47 ± 12 (mean ± SD), BMI 24.1 ± 5.0). To be included, cases were required to have 1) had a full autopsy within 24 h of death and 2) pancreatic tissue stored that was of adequate size and quality, 3) no history of diabetes, pancreatitis or pancreatic surgery, 4) no use of glucocorticoids. Cases were excluded if pancreas tissue showed autolysis or any abnormal change such as pancreatitis. Pancreas tissues were stained for insulin or glucagon, and fractional β-cell area(%BCA) and α-cell area(%ACA) to the total pancreas area were measured, respectively. Since pancreas weight was not available in the most cases, to determine BCM or α-cell mass(ACM), the pancreas weight in each case was estimated by use of equations based on the population data. Then estimated BCM or ACM were calculated as a product of %BCA or %ACA and reference values of pancreas parenchymal mass. ID, IS and β-cell turnover(i.e., replication, neogenesis and apoptosis) were quantified in randomly selected areas of pancreas that contained more than 100 islets in each case. Islet was defined as a cluster of four or more β-cells and a total of 7,778 islets were assessed. Islet number per section was calculated as a product of ID and total pancreas area. Replication and apoptosis were quantified by immunohistochemistry for insulin and Ki-67 or single-stranded DNA staining, respectively. Neogenesis was evaluated by the frequencies of scattered β-cells within the acinar tissue and insulin(+) duct cells.
Results: Islet morphometric analysis revealed that there was a considerable variation in ID(5.28 ± 2.73 /mm^2) and IS(7,342 ± 2,729 μm^2) among individuals. There was a negative correlation between ID and IS($r = -0.25$, $p = 0.03$). %BCA was not correlated with IS($p = 0.6$), while %BCA was positively correlated with ID($r = 0.63$, $p < 0.01$). These results did not change even when BCM was used in the analysis and there was a positive correlation between BCM and ID($r = 0.63$, $p < 0.01$), but not IS($p = 0.5$). Islet number per section was also associated with %BCA and BCM($r = 0.63$ and 0.64, both $p < 0.01$). The frequency of scattered β-cells was positively correlated with ID($r = 0.68$, $p < 0.01$) and negatively correlated with IS($r = -0.36$, $p < 0.01$). There was no correlation between the frequency of insulin(+) duct cells and ID or IS($p > 0.05$). The frequency of replication was correlated with IS ($r = 0.26$, $p = 0.03$), whereas there was no correlation between replication and ID($p = 0.2$). Apoptosis was not detectable in all cases. %ACA and ACM were also correlated with ID($r = 0.39$ and $r = 0.38$, both $p < 0.01$), whereas there was no correlation between IS and %ACA or ACM($p > 0.05$).
Conclusion: We report that there was a considerable variance in islet morphology in non-diabetic human pancreas and ID, but not IS was significantly correlated with BCM in humans. Our findings imply that islet number rather than IS is a major determinant of BCM in human.

Slow and minimal decline of beta cell mass associated with ageing in non-diabetic Japanese and lack of compensatory islet hyperplasia in obesity

H. Mizukami[1], K. Takahashi[1], W. Inaba[1], K. Kamata[1], K. Tsuboi[1], O. Uehara[2], S. Yagihashi[1];
[1]Pathology and Molecular Medicine, Hirosaki University, Hirosaki, [2]Medicine, Kuroishi Municipal Hospital, Kuroishi, Japan.

Background and aims: Reduced beta cell mass is established to be a major pathological finding in type 2 diabetic subjects. Since the population of diabetes increases in the aged, it may be hypothesized that enhanced aging process may account for the reduced beta cell mass. It remains unclear, however, how beta cell mass is influenced by aging or obesity in Japanese subjects who are prone to type 2 diabetes in the environment of westernization. In this study, we therefore examined islet and beta cell masses in different ages in Japanese non-diabetic subjects and their relationship to body mass index (BMI) and cell proliferation activity.
Materials and methods: Pancreata obtained from 115 autopsied cases (male 69, female 49) were subjected to morphometric analyses of masses of islet and beta cells after immunostainings of chromogranin A, and insulin. To explore underlying mechanism of the islet changes, immunohistochemical expressions of Ki67, pancreatic duodenal homeobox (PDX)-1, cell cycle inhibitor P16, and oxidative stress marker γH2AX were also examined. The values of immunopositive reactions were estimated at decile age levels.
Results: The largest islet volume density (Vi)(%) was evident in a group of age below 10 years old (y.o.)(4.33±1.0, mean±SE). Thereafter, Vi was sharply reduced until 20 y.o. and consistent throughout the rest of life. In contrast to Vi, beta cell volume density (Vb) was gradually reduced with aging without any peak, yielding a significant difference between groups of below 10 y.o. (2.26±0.45) and 70ties (1.93±0.23). BMI did not influence on the changes of Vb ($p=0.07$). During maturation until 10 y.o., beta cell proliferation activity was gradually decreased ($p<0.05$) and reached a low plateau (<0.5%), which was independent of BMI. PDX-1 expressions were robust in the young, but equivocal after maturation, while expressions of P16 and γH2AX in the adults or seniles were more intensitied compared to those in the young.
Conclusion: We found that age-associated decline of beta cell mass was marginal after maturation and the reduction of beta cell mass encountered in type 2 diabetes may be a specific process. In Japanese, there was no evidence that increased BMI was associated with beta cell hyperplasia.

Beta and alpha cell trajectories during development and after high fat programming in neonate, weanling and adolescent Wistar rats

M.E. Cerf, C.S. Chapman, J. Louw;
Diabetes Discovery Platform, Medical Research Council, Cape Town, South Africa.

Background and aims: Islet cell populations fluctuate over the early life course and are influenced by nutritional programming. Previous studies revealed that exposure to high fat diets during fetal and early postnatal life induced immediate, transient and durable changes in islet cell structure and function in progeny throughout life. This study assessed beta and alpha cell trajectories in neonate, weanling and adolescent Wistar rats during development (physiology) and after exposure to a high fat diet.
Materials and methods: Pancreata from neonatal (one-day-old), weanling (three-week-old) and adolescent (three-month-old) Wistar rats were double immunolabeled with insulin and glucagon in control (10% fat as energy) progeny (physiology) and progeny maintained on a high fat (40% of mainly saturated fat as energy) diet during fetal, lactational and/or postnatal life (high fat programming). Beta and alpha cell number, size and volume, beta cell:alpha cell and alpha cell:beta cell ratios were assessed with data presented as means ± SEM and significance established at $p < 0.05$.
Results: Beta cell hyperplasia presented in adolescent rats (659 ± 37.80, n = 8) compared to neonate rats (115 ± 41.83, n = 7) and after postnatal high fat maintenance at weaning (640 ± 112.80, n = 7) that was preserved at adolescence (1189 ± 61.30, n = 7). Postnatal high fat maintenance induced beta cell hypertrophy at adolescence (182 ± 11.72 μm^2, n = 7 compared to 115 ± 15.47 μm^2, n = 5 in neonates) and was mirrored in adolescent rats maintained on a high fat diet during fetal life (116 ± 7.66 μm^2, n = 6 compared to 85 ± 10.03 μm^2, n = 12 in neonates). Physiologically and more markedly after postnatal high fat maintenance, alpha cell numbers increased with age, emerging at weaning and prevailing in adolescence. Further, alpha cell hyperplasia was maintained after fetal and postnatal high maintenance at weaning (224 ± 32.68, n = 6) and adolescence (226 ± 29.76, n = 5; both compared to 102 ± 20.26, n = 10 in neonates). Physiologically, alpha cell hypertrophy presented in adolescence (125 ± 11.82 μm^2, n = 8 relative to neonates 55 ± 4.43 μm^2, n = 5). However, after postnatal high fat maintenance, alpha cell hypertrophy emerged earlier at weaning (92 ± 7.35 μm^2, n = 6) and persisted in adolescence (137 ± 7.29 μm^2, n = 7). Physiologically, after fetal, lactational or fetal and lactational high fat maintenance, alpha cell volume was enhanced at weaning.
Conclusion: Beta and alpha cell populations vary in number, size and volume throughout development and are altered in response to high fat programming. Preserving beta and alpha cell populations (islet cell numbers that constitute islet cell volumes) will maintain islet cell function to regulate glucose homeostasis.

Molecular mechanism of pancreatic islet proliferation during the neonatal development in mice

X. Wu, J. Zhu, X. Wang, Y. Xu, Y. Lv, J. Zhang, Q. Zhang;
Department of Endocrinology, First Affiliated Hospital of Nanjing Medical University, China.

Background and aims: Pancreatic islet cells undergo a transient burst of proliferation immediately after birth, followed by substantial remodeling of cell mass in the neonatal period, with a progressive decrease in cell replication. The different rates of cell proliferation are thought to be due to differences in the percentage of cells recruited for entry into the cell cycle. To understand this adaptation at the molecular level, we undertook a time course analysis of β/α cell mass, cell proliferation and cell cycle genes expression in mice.
Materials and methods: Mice islet β/α cell mass and the expression of pocket protein family (Rb, p107, p130), E2F1, cdk1 and cyclinB1 at 1-, 3- to 8-week after birth were detected by immunohistochemistry. Pancreatic islets were isolated by collagenase. Cell cycle was detected by flow cytometry. The expression of cell cycle genes were detected by real-time quantitative PCR and Western blotting.
Results: 1) Compared with 1w, islet β/α cell mass significantly increased at 3w and 8w ($P<0.05$); cell size increased 1.7 times at 8w ($P<0.01$); cell number increased nearly 3.5/3.7 times at 3w ($P<0.01$). Rb, p107, p130, E2F1, Cdk1 and cyclinB1 were dynamically expressed in nucleus and cytoplasm of islet cells. 2) Compared with 8w, there were less islet cells in the G0/G1 phase and more cells in the G2/M phase at 1w and 3w ($P<0.05$), and the proliferation index were significantly higher at 1w and 3w ($P<0.05$). 3) The mRNA level of Rb, p107, E2F1/2, cyclin D1/E1/A1/A2/B1/B2, cdk1/2/6, cdc25b/c and Wee1 at 8w were much lower than that at 1w ($P<0.05$), whereas the level of p130 and cdc25a were much higher than that at 1w ($P<0.05$). The level of cdk4 expressed more at 3w than that at 1w and 8w ($P<0.05$). 4) Compared with 1w, the protein level of Rb, p107, E2F1, cyclinB1 and cdk1 were much lower, but the level of p130 was significantly increased at 8w ($P<0.05$).
Conclusion: Islet β/α cell mass increased significantly during neonatal development in mice, primarily in cell numbers and proliferation. Cell cycle genes were dynamically expressed. The higher level of Rb, p107, E2F1/2, cyclin D1/E1/A1/A2/B1/B2, cdk1/2/6, cdc25b/c and Wee1 might be involved in the regulation of islet cell proliferation.

Modulation of C/EBP beta expression via AMPK regulates pancreatic beta cell mass

H. Takahashi[1], T. Matsuda[2], Y. Mieda[1], S.-I. Asahara[2], E. Terashi[2], A. Kanno[2], M. Koyanagi[2], A. Bartolomé[1], S. Seino[2], Y. Kido[1,2];
[1]Division of Medical Chemistry, Department of Biophysics, [2]Division of Diabetes and Endocrinology, Department of Internal Medicine, Kobe University Graduate School of Medicine, Kobe, Japan.

Background and aims: The endoplasmic reticulum (ER) is often compared to a quality control plant. ER homeostasis is maintained by the unfolded response induced by environmental conditions, which leads to instability of the ER, known as ER stress. During the development of type 2 diabetes, ER stress can lead to not only insulin resistance but also pancreatic β-cell failure. We have recently reported that accumulation of the transcription factor C/EBPβ in β-cells causes ER stress and reduced β-cell mass, leading to β-cell failure. We established β cell-specific C/EBPβ transgenic (TG) mice, which had a non-fasting glucose level of approximately 200 mg/dL, and showed reduced β-cell mass. Therefore, we considered TG mice to be mild diabetes model mice. Next, we examined whether the DPP-4 inhibitor vildagliptin (Vilda) could preserve pancreatic β-cell mass in the TG mice owing to reduced C/EBPβ expression, which was concomitant with reduced ER stress and amelioratied insulin signaling. We investigated the mechanism through which Vilda suppresses C/EBPβ expression.
Materials and methods: MIN6 cells, pancreatic β cell lines, were treated in vitro with tunicamycin, Exendin-4, Metformin (Met) and AICAR. We evaluated the relationship between AMPK and C/EBPβ in an in vitro assay; TG and wild-type (WT) mice were orally administered Vilda with or without Met, starting at 4 weeks of age.
Results: Incubation of MIN6 cells with Exendin-4 or Met resulted in the activation of AMPK, which suppresses C/EBPβ expression. Furthermore, co-expression of dominant-negative AMPK increased C/EBPβ expression, whereas co-expression of constitute-active AMPK decreased C/EBPβ expression. Therefore, we assumed that modulation of C/EBPβ expression by AMPK regulates pancreatic β-cell mass. In vivo treatment with Vilda markedly ameliorated hyperglycaemia in TG mice and increased AMPK activity in pancreatic β cells. On the other hand, Met treatment in conjunction with Vilda did not considerably affect fed blood glucose levels. However, an oral glucose tolerance test revealed that treatment with Vilda and Met (Vilda, Met-TG) significantly improved glucose tolerance compared with only Vilda alone (Vilda-TG), with a further increase in AMPK activity. Immunostaining analyses of pancreatic islets showed that Vilda, Met-TG mice exhibited an increase in pancreatic β-cell mass compared with Vilda-TG mice; this result is consistent with the reduced C/EBPβ expression observed in this study.
Conclusion: Vilda might activate AMPK in pancreatic β-cells. Furthermore, treatment with Met in conjunction with Vilda led to a greater increase in AMPK activity compared with Vilda alone. As a result, C/EBPβ expression was suppressed to the proportion of AMPK activity. Therefore, these findings suggest that the modulation of C/EBPβ expression by AMPK could regulate pancreatic β-cell mass.

The in-vitro effects of glucagon-like peptide-1 (GLP-1) and gastrin combination therapy on pancreatic beta cell proliferation and islet cell survival

J. Skarbaliene[1], T.S.R. Neerup[1], K. Fosgerau[1], N. Billestrup[2];
[1]Zealand Pharma A/S, Glostrup, [2]Department of Biomedical Sciences, University of Copenhagen, Denmark.

Background and aims: Combination therapy with GLP-1 and gastrin has been shown to control hyperglycaemia in diabetic mice. This improvement in glycemic control was shown to be accompanied by a significant increase in beta cell mass for combination treatment. Here we investigated the *in-vitro* effects of exendin-4 (Ex-4) + h[Leu15]gastrin17 (G-17) combination therapy in regulation of pancreatic beta cell proliferation and islets cell survival in isolated neonatal rat islets.
Materials and methods: Isolated neonatal rat islets from pancreases of 3-5 day-old Wistar rat pups were used in this study. The islets were incubated for 4 days (proliferation study) or for 2 days (apoptosis study) with either the combination of Ex-4 + G-17 (10 nM + 40 nM), or reference compounds Ex-4 (10 nM), or G-17 (40 nM). Human growth hormone (hGH, 20nM) was used as a positive control in the proliferation study. Proliferation was measured by 5-ethynyl-2'-deoxyuridine (EdU) incorporation in islets and calculated as the percentage of EdU^+ Pancreatic duodenal homeobox-1^+ (PDX1) cells of total $PDX1^+$cells. Apoptosis was induced with either cytokines (IL-1β, 150 pg/ml; IFN-γ, 100 pg/ml) or palmitate (1 mM) and measured by the presence of histone-associated DNA fragments in cell lysate (apoptosis) and supernatant (necrosis).
Results: As expected hGH significantly increased beta cell proliferation ($PDX1^+$) (4-fold increase, $^{***}p < 0.001$ vs. control islets). Neonatal rat islets cultured with Ex-4 + G-17 combination significantly increased the proliferation of beta cells (140 %, $^{***}p < 0.001$ vs. control islets). Treatment with G-17 or Ex-4 alone showed no significant increase in the proliferation of beta cells. The changes in the level of apoptosis can be seen in Figure 1. There was a 5-fold increase in the level of apoptosis in islets incubated with IL-1 β and IFN-γ. The effect of tested compounds on cytokine-induced apoptosis was not statistically significant; nonetheless there was a 33 % reduction in the level of apoptosis in islets cultured with Ex-4 + G-17 combination. Also, treatment with G-17 or Ex-4 alone decreased the level of cytokine-induced apoptosis by 14 % and 16 %, respectively. In response to palmitate, there was a 7-fold increase in the level of apoptosis in control islets. The combination treatment with Ex-4 + G-17 decreased palmitate-induced apoptosis by 47 %, as did treatments with Ex-4 (48 %) and G-17 (43 %) alone; however this reduction was not statistically significant.
Conclusion: In conclusion, the combination treatment with Ex-4 + G-17 significantly increased beta cell proliferation, and showed a trend toward reducing the levels of cytokine- and palmitate-induced apoptosis in neonatal rat islets, suggesting that beta cell regenerating and protective effects of GLP-1-gastrin dual agonism may provide an attractive option for the treatment and/or prevention of Type 2 diabetes.

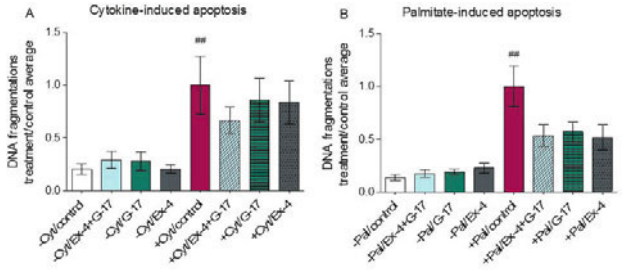

Figure 1. Effects of the combination treatment with Ex-4 and G-17 on pancreatic islets cell survival. A) Cytokine-induced apoptosis, B) Palmitate-induced apoptosis. All treatment conditions were normalized to the control condition in the presence of cytokines or palmitate. Data were analyzed using one-way ANOVA test followed by Dunnett's multiple comparison test, vs. +Cyt/control or +Pal/control; or Mann Whitney test ##p < 0.01 vs. -Cyt/control or -Pal/control. n=5-6. Data are mean ± SEM.

Dopamine could be involved in the maintenance of rat pancreatic beta cells controlling insulin secretion and cellular proliferation

M.J. Garcia-Barrado[1], E.J. Blanco[1], M.C. Iglesias-Osma[1], M. Carretero-Hernandez[1], D.J. Burks[2], J. Carretero[1];
[1]Laboratory of Neuroendocrinology INCYL and IBSAL, University of Salamanca, [2]Laboratory of Neuroendocrinology, Institut of Reseach Principe Felipe, Valencia, Spain.

Background and aims: Dopamine is a neurotransmitter that plays a critical role in neurological and psychiatric disorders and it is implicated in various physiological functions, including endocrinological modulation. In isolated islets, dopamine and its analogs have shown contradictory results on insulin release. These findings suggest that beta cells might be directly responsive to dopamine. Recent studies have shown the presence into beta cells of the enzymes responsible on synthesis or metabolization of dopamine. Thus it could be accepted that dopamine exerts an auto-paracrine regulation of insulin secretion from pancreatic beta cells. The aim of this study is to analyze whether dopamine is a regulator of proliferation of rat pancreatic beta cells in pancreatic isolated islets after glucose induced secretion of insulin.
Materials and methods: In order to analyze if dopamine inhibitory effect on secretion of insulin whether related to changes in the pancreatic beta cells populations an in vitro study on isolated pancreatic islets, obtained from adult and old rats, was carried out analyzing the effects of 10 µmol/l and 1 µmol/l dopamine from 1 to 12 hours. The secretion of insulin was determined by RIA, and the cellular proliferation of beta cells by double immunocytochemical labelling for PCNA (proliferating cell nuclear antigen) and insulin. Data were analyzed using the GraphPad Prism and ImageJ software.
Results: Without significant differences between both doses of dopamine assayed, dopamine inhibits significantly ($p<0.05$) the secretion of insulin from isolated islets as early as 1 hour after treatment. In adult and old rats, the percentage of insulin-positive cells in the islets decreases significantly ($p<0.05$) after 1 hour of treatment. These effects were sustained until 12 hours of treatment. However, the effects were significantly ($p<0.05$) more evident after treatment with 10 µmol/l dopamine than 1 µmol/l dopamine. The proliferation of insulin-positive cells in the islets decreased significantly ($p<0.01$) after treatment with dopamine. The higher effect was observed after 3 hours of treatments. After 6 and 12 hours of treatment with 1 µmol/l dopamine the inhibitory effects were significantly ($p<0.05$) lower that those observed after 3 hours. The inhibitory effects of 10 µmol/l dopamine were similar after 3 and 6 hours of treatment, so with this treatment the effect was more sustained in time than those observed after treatment with 1 µmol/l.
Conclusion: The results obtained in this study demonstrate that dopamine could modulate the proliferation of pancreatic beta cells and suggest that dopamine could be involved in the maintenance of pancreatic islets.

Differentiation of human adult pancreatic duct cells into insulin-producing cells

M. Pairó[1,2], N. Téllez[1,2], C. García[1,2], M. Núñez[1], M. Nacher[1,2], E. Montanya[1,2];
[1]IDIBELL, Hospital Universitari Bellvitge, University of Barcelona, [2]CIBERDEM, Barcelona, Spain.

Background and aims: Adult human pancreatic duct cells have been reported to differentiate *in vitro* into insulin-producing cells. Glucagon-like peptide-1 (GLP-1) induces islet neogenesis in animal models, but little information is available on the effects of GLP-1 on human duct cells. The aim of this study was to investigate whether liraglutide, a human long-acting GLP-1 analog, could enhance the differentiation of human adult pancreatic duct cells into insulin-producing cells *in vitro*.
Materials and methods: Pancreas from 12 human cadaveric organ donors, 4 male, 56±3 y.o. (range: 33-79), BMI 27.8±1.62 (Kg/m^2), were processed as for islet isolation and the exocrine fraction was collected and dispersed into single cells. Duct cells were purified by magnetic cell sorting with CA19.9 antibody, and cultured in suspension for one month in differentiation serum-free medium with liraglutide (300nM) or without (control), and/or EGF (20ng/mL). Gene expression was determined by real time RT-PCR. Replication (BrdU) and protein expression were analysed by immunohistochemistry. Insulin and C-Peptide content and insulin secretion in response to glucose (20mM) were determined by ELISA.
Results: After 2-3 days in culture, the sorted cell population (82.7±1.01% duct cells, 0.40±0.11% beta cells) clustered into pancreatospheres (92.4±0.45% $PanCK^+$ cells; 0.19±0.07% $C\text{-}Peptide^+$ cells). Gene expression of *krt19* was reduced on days 3, 7 and 30 compared with post-sorting day ($P<0.05$). Duct cell replication was similar in liraglutide and control groups at all time points, and was similarly increased by EGF in both groups ($P<0.05$). After 30 days in culture, the expression of the islet hormone genes *ins* ($P<0.01$), *sst* ($P<0.001$), and *gcg* ($P<0.01$), and of *Pdx-1* ($P<0.01$) was increased compared with post-sorting day and culture day 3 in both groups. No significant differences were found between liraglutide and control treated groups. Insulin and C-Peptide content (corrected per DNA) was significantly increased on day 30 compared with post-sorting day ($P<0.05$), but remained very low compared with human islets (≈1%). It was similar in liraglutide and control groups. Insulin secretion did not increase in response to glucose stimulation.
Conclusion: The results support the hypothesis that adult human pancreatic duct cells can differentiate into insulin-producing cells. The GLP-1 analog liraglutide did not increase the efficiency of human adult duct cell differentiation into insulin-positive cells, and did not exert a mitogenic effect in human adult duct cells.

DPP-4 (CD26) is expressed by ductal and islet cells in human adult pancreas

P. Augstein[1,2], G. Naselli[2], T. Loudovaris[3], P. Campbell[3], E.M. Bandala-Sanchez[2], P. Heinke[1], W.J. Hawthorne[4], L.C. Harrison[2];
[1]Institute of Diabetes, Karlsburg, Germany, [2]The Walter and Eliza Hall Institute for Medical Research, Melbourne, Australia, [3]St. Vincent's Institute of Medical Research, Fitzroy, Australia, [4]Westmead Hospital, University of Sydney, Australia.

Background and aims: Dipeptidyl peptidase-4 (DPP-4) or CD26 is a membrane glycoprotein and serine exopeptidase that cleaves X-proline dipeptides from the N-terminus of polypeptides. DPP-4 plays a major role in glucose metabolism by degrading incretins such as GLP-1 that enhance insulin release and, at least in rodents, promotes growth of endocrine progenitor cells and insulin gene transcription. The class of oral anti-hypoglycemic drugs called DPP-4 inhibitors works by prolonging incretin action in vivo. DPP-4 is a marker of various cancers including pancreatic adenocarcinoma and it has been argued that its long-term inhibition may predispose to pancreatitis and pancreatic cancer. Expression of DDP-4 in situ has not been reported in the human adult pancreas. To identify the target cells of DDP-4 inhibition we measured its expression in organ donor pancreata.
Materials and methods: Pancreata were obtained, with informed consent of next-of-kin, from heart beating, brain dead organ donors. From each donor tissue a comparable region was cleaned of fat, embedded in OCT and snap-frozen. Cryosections from tissue of non-diabetic (n=15), type 2 diabetic (n=2) and type 1 diabetic (n=6) organ donors were stained with a DPP-4

monoclonal antibody (clone M-A261) using the APAAP technique. Beta cells were identified with the biotinylated anti-human proinsulin monoclonal antibody GS-9A8 and detected using horseradish peroxidase labelled streptavidin. Alpha cells were identified with the glucagon monoclonal antibody K79bB10. For co-localisation studies, sections were double stained for DPP-4 and proinsulin or glucagon and scanned using a Leica SP2 Confocal Microscope. Image analysis was performed with the ImageJ software.
Results: DPP-4 expression by both ductal and islet cells was detected in all specimens. 85% of islets (from 17 donors) contained cells expressing DPP-4, even in the absence of proinsulin expression. To identify DPP-4-positive cells, alpha and beta cells were visualised in the consecutive sections. DPP-4-positive cells had the same intra-islet location and morphology as glucagon-positive cells. In type 1 diabetic donors all remaining islet cells were DPP-4-positive. Co-localisation studies revealed overlapping expression of DPP-4 and glucagon.
Conclusion: Our findings show that ductal and alpha cells are potential direct target cells for DPP-4 inhibition. Expression of DPP-4 by alpha cells, which in humans are in proximity to beta cells, suggests a paracrine mechanism of incretin action on beta cells in human islets.

Effects of pharmacological glucokinase activation on beta cell survival and function in rat islets cultured for one week in a low, intermediate or high glucose concentration
J.-C. Jonas, L.P. Roma, J. Duprez;
Pôle d'endocrinologie, diabète et nutrition, Université catholique de Louvain, Brussels, Belgium.

Background and aims: The long-term effects of glucose on β cell survival and function in cultured rat islets are complex, a rise in glucose being beneficial between 5 and 10 mM and deleterious between 10 and 30 mM. The aim of this study was to evaluate the effects of moderate pharmacological glucokinase activation during prolonged culture at low, intermediate and high glucose concentrations on rat β cell gene expression, survival and function.
Materials and methods: Male Wistar rat pancreatic islets were cultured in RPMI medium containing 5g/L BSA and 5, 10 or 30 mM glucose (G5, G10, G30) with 3 μM of the glucokinase activator Ro 28-0450 (Ro) or vehicle alone (DMSO 1/1000). After culture, preproinsulin (*Ppi*), *Gadd153* and metallothionein 1a (*Mt1a*) to *Tbp* mRNA ratios were measured by real-time RT-PCR. Mitochondrial redox-sensitive GFP (mt-roGFP) oxidation was measured as a marker of oxidative stress. β cell apoptosis was measured by TUNEL assay on islet sections stained for insulin. The intracellular Ca^{2+} concentration (fura-PE3 microspectrofluorimetry) and the rate of insulin secretion (RIA) were measured in islets perifused with increasing glucose concentrations. Results are means±SE for at least 3 islet preparations. The significance of differences between groups was assessed by 2-way ANOVA and a post-test of Bonferroni.
Results: One week culture in G5, G10 and G30 affected rat β cell gene expression, survival and function as expected. While *Ppi/Tbp* mRNA ratio increased ~10-fold in G10 *vs*. G5 and only slightly decreased in G30 *vs.* G10, *Gadd153* and *Mt1a/Tbp* mRNA ratio decreased by 83% and 97% in G10 *vs.* G5 and were not different in G30 *vs.* G10. The proportion of TUNEL+ β cells after one week culture decreased from 12±1% in G5 to 3±1% in G10, but then increased to 6±1% in G30. Parallel changes in mt-roGFP oxidation were detected after 18h culture under the same conditions. In comparison with culture in G10 that optimally preserved glucose-induced Ca^{2+} rise and insulin secretion, culture in G5 lead to loss of glucose responsiveness. In contrast, culture in G30 increased the acute Ca^{2+} and secretion responses to 6 mM glucose while reducing those to 20 mM glucose. These functional alterations by culture in G5 and G30 were not corrected by addition of 3 μM Ro during the perifusion, despite the ability of the drug to acutely increase the glucose sensitivity of islets previously cultured in G10. In contrast, long term treatment with 3 μM Ro during culture in G5 fully mimicked the beneficial effect of culture in G10 on rat β cell insulin gene expression, survival and function, in parallel with a large reduction of mt-roGFP oxidation and of *Gadd153* and *Mt1a* mRNA levels. However, treatment with 3 μM Ro during culture in G10 mimicked the deleterious effect of culture in G30 on rat β cell survival and function, except for a lack of increase in mt-roGFP oxidation. No significant effect of Ro was observed on any parameter during long term culture in G30.
Conclusion: Pharmacological glucokinase activation during long term culture shifts to the left the glucose-response curve for changes in β cell gene expression, survival and function. Glucokinase activators may improve β cell survival under stress conditions leading a reduction of β cell glucose sensitivity, but they may also increase β cell glucotoxicity in normal β cells.

Pancreatic stellate cells induce beta cell failure in vivo
M. Zha, L.Z. Sun;
Endocrinology, Institute of Diabetes, Medical School, Southeast University, Nanjing, China.

Background and aims: Beta cell failure plays a crucial role in T2DM, but the mechanisms have not been fully explained. Recently, several studies report that pancreatic stellate cells (PSCs) are observed in the islets of patients and animal models with T2DM. However, the exact effects remain unclear. In this study, we investigated the effects of PSCs on islets in vivo.
Materials and methods: PSCs were isolated from Wistar rats, and cell purity was assessed by morphology and cytofilament staining of vimentin, α-SMA and desmin. PSCs were transplanted into the pancreas of normal Wistar (untreated: WU, sham operation: WS and transplanted: WT) and diabetic GK rats (GU, GS, GT) by multi-point injection. 16W after transplantation, oral glucose tolerance test (OGTT) was performed and insulin and HbA1c were assayed. The area under the curve for glucose (AUC_g) and insulin (AUC_i) were calculated using a trapezoidal estimation from the values. The beta cell mass and islet fibrosis were showed by insulin immunofluorescent staining and Masson's trichrome staining respectively. Statistical significance was determined by one-way variance (ANOVA). $P<0.05$ was considered to be statistically significant.
Results: In the GT group, the peak blood glucose level was observed at 30 min, showing a statistical difference compared to the GU and GS group (GT: 30.06±4.52 vs. GU: 22.44±4.10 and GS: 23.20±1.92 mmol/l, P< 0.05). In addition, PSC transplantation significantly increased the AUC_g (GT: 2953.20±296.07 vs. GU: 2474.40±374.01 and GS: 2525.40±273.27 mmol/l·min, P<0.05), but decreased the AUC_i (GT: 0.551±0.156 vs. GU: 1.424±0.545 and GS: 1.283±0.279 mmol/l·min, P<0.05). HbA1c in the GT group was significant higher than the controls (GT: 9.80±1.37 vs. GU: 8.30±1.06 and GS: 8.34±1.00 %, P<0.05). The relative beta cell mass was the least in the GT group (GT: 0.085±0.032 vs. GU: 0.132±0.05 and GS: 0.129±0.05, P<0.05). And the islet fibrosis was aggrevated followed by transplantation (GT: 29.6±6.7% vs. GU: 22.4±7.6 and GS: 23.2±4.3, P<0.05). However, in our present study, PSCs transplantation did not influence the Wistar rats.
Conclusion: Our present study demonstrates that PSCs transplantation deteriorate the islet dysfunction, beta cell loss and islet fibrosis in GK rats, and the effects are environment dependent. Our data suggest PSCs may be the promoters, rather than initiators of beta cell failure in T2DM.

Unfermented aqueous honeybush extract (*Cyclopia maculata*) attenuates STZ-induced beta cell cytotoxicity
N. Chellan[1,2], C.J.F. Muller[1], E. Joubert[3,4], H.G. Strijdom[2], J. Louw[1];
[1]Diabetes Discovery Platform, Medical Research Council South Africa, [2]Biomedical Science, Stellenbosch University, [3]Post-Harvest and Wine Technology Division, Infruitec-Nietvoorbij, Agricultural Research Council, [4]Food Science, Stellenbosch University, Cape Town, South Africa.

Background and aims: Streptozotocin (STZ), a glucosamine-nitrosourea, is commonly used to induce diabetes in rodents. The mechanism of STZ-induced β-cell cytotoxicity involves mitochondrial and cell dysfunction with increased oxidative stress (due to increased NO and ROS), ATP depletion, DNA alkylation and apoptosis. Several studies have demonstrated the ability of antioxidants [e.g. N-acetyl cysteine (NAC), and vitamins C and E] to preserve β-cell function. Plant-derived polyphenols have been described as possessing both anti-inflammatory and anti-oxidative properties and may protect against or ameliorate β-cell cytotoxicity. The aim of this study was to determine if an aqueous extract of unfermented honeybush (*Cyclopia maculata*) protects against STZ-induced β-cell cytotoxicity.
Materials and methods: Forty-eight adult, male Wistar rats were randomized into six groups, i.e. vehicle control, STZ control, metformin (125 mg/kg/d), NAC (125 mg/kg/d) and two extract-treated groups (30 and 300 mg/kg/d). The rats were pretreated with honeybush extract, metformin, NAC or vehicle

for 21 days. On day 16rats were injected with STZ (30 mg/kg i.p). An oral glucose tolerance test was performed prior to euthanisation on day 21. Blood was collected at termination and the following parameters assessed: plasma glucose, total serum triglycerides, serum insulin and plasma nitrite levels. To assess the *in vitro* effect of the extract on β-cell viability, ATP and MTT assays were performed on RIN-5F insulinoma cells exposed to 10 mM STZ.
Results: Treatment with both concentrations of honeybush extract reduced the OGTT glucose area under the curve compared to the STZ control (5264.38 ± 396.14 vs. 3114.13 ± 752.23, p<0.05; 2824.38 ± 536.00, p<0.01, respectively). The 300 mg/kg/day honeybush treated group showed a reduction in total triglycerides compared to the STZ control (1.48 mmol/l ± 0.48 vs. 0.40 mmol/l ± 0.04, p<0.05). Honeybush treated rats showed a reduction in the glucose:insulin ratio at the 300 mg/kg/day treated group (12.70 ± 2.34 vs. 2.89 ± 0.70, p<0.05) as well as plasma nitrite concentration at 30 and 300 mg/kg/day (0.563 ± 0.08 vs. 0.422 ± 0.01, p<0.05 and 0.421 ± 0.02, p<0.05, respectively) when compared to the STZ controls. *In vitro,* the honeybush extract improved the viability of RIN-5F insulinoma cells exposed to STZ, as measured using an MTT assay and by measuring cellular ATP (56.80% ± 1.49 vs. 91.03% ± 3.41, p<0.05; and 51.70% ± 2.32 vs. 112.84% ± 12.64, p<0.001, respectively).
Conclusion: Unfermented honeybush extract (*Cyclopia maculata*) demonstrated some protection against STZ-induced β-cell toxicity, hyperglycaemia and associated oxidative stress-induced nitrite production. This protective effect against STZ-induced β-cell cytotoxicity was verified *in vitro* using RIN-5F insulinoma cells.

Effect of liraglutide on apoptosis and tissue factor activity on Rin-m5f, in response to microparticles: interest in islet transplantation
C. Gleizes[1], A.A. Constantinescu[1], F. Zobairi[1], F. Moreau[2], F. Toti[3], L. Kessler[2,1];
[1]EA 7293 : Stress vasculaire et tissulaire en transplantation, [2]Service d'endocrinologie, diabète et nutrition, [3]UMR-CNRS 7213, Strasbourg, France.

Background and aims: IBMIR (Instant Blood Mediated Inflammatory Reaction) follows islet transplantation and is characterized by drastic cytokine secretion and the expression of tissue factor (TF) at islet vicinity. Microparticles (MPs) are plasma membrane fragments shed from stressed cells that act as cellular effectors. Recently, islet cytoprotection by incretinomimetics was proposed. We evaluate the protective effect of Liraglutide on β cell dysfunction mediated by MPs, using oxidative and inflammatory cell stress model.
Materials and methods: Rat β cells, Rin-m5f, were stimulated by 100µM H2O2 or 50U/ml IL-1β combined to 1000U/ml TNF-α. MPs generated by oxidative and cytokinic stress were isolated and applied to naive Rin-m5f for 24h. Effects of 1µM Liraglutide were assessed on insulin secretion, apoptosis by hypodiploïd DNA quantification and, MP release and TF activity by ELISA (n=9). MP cell membrane integration was probed by fluorescent dye.
Results: Direct protection by Liraglutide is revealed by a significant decrease in oxidative stress-induced apoptosis (10% vs. 18%) and by restored insulin secretion (oxidative stress: +55%, cytokinic stress: +25%). Indirect protection of β cell occurs through reduced MP shedding (oxidative: -25%, p=0,006; cytokinic -18%, p=0,01) and by counteracting the decrease in insulin secretion induced by MPs. By fluorescence probing, 50% of Rin-m5f integrate MPs and this integration is not modified by Liraglutide. Liraglutide reduces oxidative and cytokinic TF-induced activity with a significant decrease at Rin-m5f (oxidative: -18%; cytokinic: -17%) and MP surfaces (respectively: -31%; -15%).
Conclusion: In conclusion, Liraglutide shows a protective effect on β cell survival at different levels, on apoptosis, insulin secretion and TF activity. Furthermore, Liraglutide limits the deleterious message conveyed by MPs. Our data bring new hints on the mechanisms of cytoprotection by Liraglutide in islet transplantation and particularly during IBMIR.

Chaperones ameliorate hIAPP-induced ER stress in beta cells
L. Cadavez[1,2], J. Montane[1,2], G. Alcarraz-Vizán[1,2], M. Visa[1,2], R. Gasa[1,2], A. Novials[1,2];
[1]Diabetes and Obesity Laboratory, IDIBAPS, [2]Spanish Biomedical Research Centre in Diabetes and Associated Metabolic Disorders (CIBERDEM), Barcelona, Spain.

Background and aims: In type 2 diabetes, loss of beta cell function is thought to be due to several causes, one being the formation of toxic protein aggregates called islet amyloid, formed by accumulations of misfold human islet amyloid polypeptide (hIAPP). In many cases, misfolding is a natural consequence of protein biogenesis, but in T2D, it may contribute to β-cell dysfunction. In addition, accumulation of misfolding proteins perturbs the endoplasmic reticulum (ER) homeostasis activating the unfolded protein response (UPR). Molecular chaperones have been described to be important for regulation of ER signaling in response to ER stress, among others. The aim of the present work is to investigate the role of chaperones in ER stress response induced by hIAPP overexpression.
Materials and methods: Freshly isolated hIAPP transgenic mouse islets and rat pancreatic beta cell line INS1E stably expressing hIAPP (INS1E_hIAPP cells) were cultured with pharmacological (0.5µM thapsigargin) and non-pharmacological (25 mM glucose and 400µM palmitic acid) ER stress inducers in a time-dependent manner. To mimic the plausible protective role of endogenous chaperone BiP/GRP78 during ER stress, hIAPP transgenic mouse islets and INS1E_hIAPP cells were pre-treated with the chemical chaperone taurine-conjugated ursodeoxycholic acid (TUDCA) and phenylbutyric acid (PBA). Adenovirus mediated BiP/GRP78 overexpression was performed in isolated hIAPP transgenic mouse islets and INS1E_hIAPP cells. Gene expression and protein levels of ER stress markers (CHOP, ATF3 and spliced XBP1) and BiP/GRP78 were analyzed by real-time RT-PCR and Western Blot.
Results: Stressed beta cells showed a reduction in BiP/GRP78 protein levels when compared to control cells after exposure to 0.5µM thapsigargin or a combination of palmitic acid and high glucose. Interestingly, the expression of ER stress genes was higher in INS1E_hIAPP (CHOP 11.2-fold, ATF3 42.3-fold and spliced XBP1 8.3-fold) over untreated cells (p<0.001) compared to INS1E cells (CHOP 5.9-fold, ATF3 18.5-fold and spliced XBP1 4-fold) over untreated cells (p<0.001). The addition of 400µM palmitic acid to 25 mM glucose induced an increase of ATF3 and spliced XBP1 mRNA expression levels of 4.2-fold, and 3.5-fold, respectively compared to basal conditions. Overexpression of BiP/GRP78 in hIAPP-expressing beta cells, previously treated with thapsigargin or a combination of palmitic acid and high glucose, showed a reduction of ER stress genes such as spliced XBP1. In addition, treatment of stressed beta cells with chemical chaperones TUDCA or PBA showed a markedly decrease in protein levels of ATF3, spliced XBP1 and CHOP, and a significant reduction in ATF3 and spliced XBP1 genes (13%, p<0.05 and 18%, p<0.05 respectively) when compared to hIAPP-expressing controls treated with ER stress inducers.
Conclusion: Overexpression of hIAPP is sensed by ER and ultimately decreases chaperone BiP/GRP78 expression. In that way, overexpression of BiP/GRP78 or addition of chemical chaperones TUDCA and PBA ameliorates ER stress, suggesting that improving chaperone capacity can be important for the folding of hIAPP.

The translocon, a functional reticular calcium leak channel in human islets: towards a new way of protecting pancreatic beta cells from lipotoxicity
R. Cassel[1,2], F. Van Coppenolle[3,2], S. Ducreux[3,2], M.-A. Chauvin[1], J. Rieusset[1], C. Thivolet[1,2], A.-M. Madec[1,2];
[1]Faculte de Medecine Lyon-Sud, INSERM 1060, Oullins, France, [2]UCBL Lyon1, [3]Faculte de Medecine Rockefeller, INSERM 1060, Lyon, France.

Background and aims: Accumulating evidence suggests that palmitate mediates beta cell dysfunction in vivo and in vitro by inducing endoplasmic reticulum (ER) stress and [Ca2+] perturbation. However, not many treatments are able to efficiently protect beta cells from lipotoxicity. [Ca2+]ER store de-

pletion by itself can induce both ER stress and apoptosis. A recent study on prostatic cancerous cells demonstrated that [Ca2+]ER depletion ocurred via a passive [Ca2+] leak channel, the translocon, an ER multiprotein complex involved in translation. We explored in this study the role of translocon in pancreatic beta cells. We further analysed the effects of its modulation on calcium homeostasis and insulin secretion after palmitate treatment.
Materials and methods: Using the FURA-2 AM probe, we measured on human islets and MIN6B1 murine beta cells, the resting [Ca2+] and [Ca2+]ER by addition of thapsigargin (1μM). Functional translocon was determined by [Ca2+]ER measurements after addition of anisomycin (200μM), a translocon inhibitor, and/or puromycin (200μM), a translocon activator. We further analysed the modulation of translocon on MIN6B1 treated by BSA or palmitate (200 mM) during 24h. Glucose stimulated insulin secretion (GSIS) was determined by ELISA, ER stress markers, Serca2 - a [Ca2+]ER pump- and SEC61a - a major translocon protein - by RT-qPCR and western-blot.
Results: Puromycin induced a significant [Ca2+]ER release (p=0.05 vs resting calcium), and anisomycin counteracted totally this effect in human islets (p<0.001) and MIN6B1 cells (p<0.001). Anisomycin reduced the total [Ca2+] ER release induced by thapsigargin in human islets (p<0.01) and MIN6B1 (p<0.01). These results demonstrated that the translocon is implicated in [Ca2+]ER leak in beta cells. Palmitate treatment induced in MIN6B1, mRNA overexpression of ER stress markers such as GRP78 (p<0.05 vs BSA), CHOP (p<0.001), and XBP-1S (p<0.05); puromycin and anisomycin were not able to prevent these effects. Palmitate increased protein expression of Grp78 (p<0.05 vs BSA), CHOP (p<0.05), pJNK (p<0.05), and decreased Serca2 protein levels (p<0.05). Moreover, we observed in presence of palmitate, higher mRNA and protein levels of SEC61a (p<0.05 vs BSA) proving that palmitate enhanced the translocon expression. Palmitate markedly reduced [Ca2+]ER (p<0,001 vs BSA) in MIN6B1 and addition of anisomycin totally prevented this effect (p=NS vs BSA). GSIS, not modified by addition of anisomycin and puromycin in basal conditions, was reduced after palmitate treatment (p<0.05) but was restored by anisomycin (p<0.05).
Conclusion: We demonstrate for the first time that the translocon is implicated in the calcium regulation in human and murine beta cells. We also point out that inhibition of the translocon is able to protect beta cells from lipotoxicity by restoring insulin secretion and calcium homeostasis, without significant decrease of ER stress. These results highlight the role of translocon in beta cell function and supported the hypothesis that inhibition of the translocon opens a new potential way of treatments in type 2 diabetes.

Endoplasmic reticulum stress induces ATF4 and CHOP expression independently of PERK/eIF2alpha pathway in pancreatic beta cells
X. Zhao, O. Omikorede, T.P. Herbert;
Department of Cell Physiology and Pharmacology, University of Leicester, UK.

Background and aims: Chronic endoplasmic reticulum (ER) stress causes an increase in the expression of the transcription factor C/EBP homologous protein (CHOP), which has been implicated in pancreatic β-cell dysfunction and death and hence in the development of type-2 diabetes mellitus (T2DM). It has been proposed that this increase in CHOP expression is mediated by activating transcription factor-4 (ATF4), whose expression is up-regulated by the PERK-dependent phosphorylation of eIF2α. The aim of this project was to re-examine the role of eIF2/PERK in ER stress induced ATF4 and CHOP expression in pancreatic β-cells.
Materials and methods: MIN6 cells and primary rat islets were treated with thapsigargin to induce ER stress. Changes in the expression of ATF4 and CHOP were determined using qRT-PCR, luciferase reporter assays and Western blotting. The role of individual UPR transducers and eIF2α phosphorylation in ER stress induced ATF4/CHOP expression were explored using pharmacological inhibitors, expressing dominate-negative (DN) mutants of PERK and IRE1, and expressing GADD34ΔN, which promotes the dephosphorylation of eIF2α. All results are representative of at least three independent experiments. Statistical analysis was carried out using 1 way ANOVA Bonferroni's Multiple Comparison Test.
Results: Chronic ER stress causes an increase in both ATF4 and CHOP mRNA and protein expression in clonal pancreatic β-cells. However, the inhibition of PERK activation or eIF2α phosphorylation had no significant effect on the expression of ATF4 and CHOP but chronic eIF2α de-phosphorylation led to a significant increase in β-cell death. On the other hand pharmacological inhibition of inositol requiring enzyme 1 (IRE1) or expression of dominant negative IRE1 led to a decrease ATF4/CHOP protein expression and a decrease in CHOP promoter activity.
Conclusion: It has been proposed that pharmacological inhibitors of PERK/eIF2α may have therapeutic potential in the treatment/prevention of T2DM. However, according to the results presented here we question the value to developing drugs which target PERK/eIF2α in the treatment of diabetes and are thus currently seeking alternative drug targets by determining how ER stress up-regulates CHOP and ATF4 expression via an IRE1-dependent pathway in pancreatic β-cells.

HDAC3 inhibition rescues pancreatic beta cells from glucolipotoxicity and improves insulin secretion in obese diabetic rats
M. Lundh[1,2], T. Galbo[3], F.F. Wagner[4], D.P. Christensen[1], D. Walpita[2], J.P. Gale[4], Y.-L. Zhang[4], J.M. Hooker[5], G.I. Shulman[3], T. Mandrup-Poulsen[1,6], E.B. Holson[4], B.K. Wagner[2];
[1]Department of Biomedical Sciences, University of Copenhagen, Denmark, [2]Chemical Biology Program, Broad Institute of Harvard and MIT, Cambridge, USA, [3]Department of Internal Medicine, Yale University, New Haven, USA, [4]Stanley Center for Psychiatric Research, Broad Institute of Harvard and MIT, Cambridge, USA, [5]Department of Radiology, Massachusetts General Hospital, Cambridge, USA, [6]Department of Molecular Medicine and Surgery, Karolinska Institutet, Stockholm, Sweden.

Background and aims: Glucolipotoxicity activates oxidative-, endoplasmic reticulum- and inflammatory-stress pathways in pancreatic beta cells. Both inflammatory mediators (cytokines) and metabolites (acetyl CoA) affect gene expression by regulating epigenetic modifiers such as histone acetyl transferases (HATs) and deacetylases (HDACs). We have previously shown that inhibition of HDACs prevents cytokine-induced beta cell apoptosis. It is unknown if HDAC inhibition prevents beta cell glucolipotoxicity. Therefore we hypothesized that HDAC inhibition protects pancreatic beta cells against glucolipotoxicity in vitro and in vivo.
Materials and methods: Selective HDAC inhibitors were tested in INS-1E cells, primary rat and human islets and in Zucker diabetic fatty (ZDF) rats. High glucose (25mM) and palmitate (0.5mM) were used as in vitro glucolipotoxic condition.
Results: We screened 21 inhibitors with different selectivity against the classical HDACs 1-11 and novel HDAC3-selective small molecule inhibitors for their ability to protect beta cells against palmitate-induced apoptosis. Class I (HDAC1, -2, -3 and -8) and in particular HDAC3 selective inhibitors reduced palmitate-induced caspase-3 activity in INS-1E cells and glucolipotoxic apoptosis in INS-1E cells, rat and human islets. The protective effects of pharmacological HDAC3 inhibition were confirmed by siRNA-mediated HDAC3 knock-down in INS-1E cells. A novel HDAC3-selective small molecule inhibitor, BRD3308, also restored insulin-secretion in INS-1E cells exposed to glucolipotoxic conditions. Mechanistically, BRD3308 reduced JNK phosphorylation, CHOP transcription, reactive oxygen species (ROS) formation and caspase 9 activity, suggesting that HDAC3 mediates glucolipotoxic apoptosis via ER-stress-dependent activation of the intrinsic death pathway.
Conclusion: The HDAC3 inhibitor BRD3308 protects pancreatic beta cells against glucolipotoxicity in vitro and in vivo by interfering with ER stress-induced mitochondrial death pathways. These findings have considerable translational potential since orally active broad HDAC inhibitors are clinically well-tolerated and more specific HDAC inhibitors are being developed.

Suppression of NO-induced beta cell death by (-)-DHMEQ via activation of Nrf2-ARE pathway and alteration of MAPK activity
K. Umezawa[1], T. Ukaji[1], A. Ogasawara[2], S. Simizu[2], I. Takei[3];
[1]Molecular Target Medicine Screening, Aichi Medical University, Nagakute, [2]Faculty of Science and Technology, Keio University, Yokohama, [3]Ichikawa General Hospital, Tokyo Dental College, Ichikawa, Japan.

Background and aims: Pancreatic beta cells are considered to be degraded by inflammatory cytokines and mediators mainly secreted by activated macrophages in the onset of type-1 diabetes mellitus. These inflammatory reactions may be also important for type-2 diabetes mellitus. Among the inflammatory mediators excessive nitric oxide (NO) plays a pivotal role in the progression of beta cell apoptosis. Therefore, we have looked for the inhibi-

tors of NO-induced beta cell death using the beta cell like cell line, and also studied the mechanism of inhibition.
Materials and methods: We employed mouse insulinoma Min6 cells as a model of beta cells to screen low molecular weight compounds that inhibit NO-induced cell death. We prepared a luciferase reporter DNA for the evaluation of Nrf2 activity. Cell death was evaluated by Trypan blue dye exclusion and apoptosis by selective staining.
Results: We found that (-)-DHMEQ, an NF-kappa B inhibitor, rescued NO-induced apoptosis in Min6 cells. NO was shown to decrease the Akt activity and to increase the p38 activity. These changes were inhibited by (-)-DHMEQ. Moreover, (-)-DHMEQ activated Nrf2 and induced transcription of Nrf2-target genes following the increase of antioxidant response element (ARE) reporter activity. Similarly, tert-butyl hydroquinone (tBHQ), a known activator of Nrf2, inhibited NO-induced cell death activating Nrf2. RNAi-mediated knockdown of Nrf2 lowered the cytoprotective effect of (-)-DHMEQ against NO, suggesting that (-)-DHMEQ inhibited NO-induced cell death via Nrf2 activation. Bay11-7082, a known NF-kappa B inhibitor, also activated Nrf2. Furthermore, overexpression of Nrf2 rendered cells to be more resistant to NO, indicating that Nrf2 activation provides critical defense function against NO in Min6 cells.
Conclusion: (-)-DHMEQ inhibited NO-induced cell death in mouse beta cell-like Min6 cells. It may be a useful therapeutic agent for type-1 diabetes mellitus in the onset of disease protecting pancreatic beta cells from apoptosis.

531

PKBalpha but not PKBbeta can protect human islets from IL-1beta-induced apoptosis

M.G. Dietrich[1,2], R.A. Zuellig[1], B.A. Hemmings[3], G.A. Spinas[1,2], R. Lehmann[1], O. Tschopp[1,2], M. Niessen[1,2];
[1]Endocrinology, Diabetes & Clinical Nutrition, University Hospital of Zurich, [2]Competence Center for Systems Physiology and Metabolic Diseases, Swiss Federal Institute of Technology (ETH) Zurich, [3]Friedrich Miescher Institute (FMI) for Biomedical Research, Basel, Switzerland.

Background and aims: Loss of PKBα or PKBβ in mice results in increased or decreased glucose tolerance, respectively, whereas loss of PKBγ has no effect. The regulation of β-cell mass is normal in these mouse models indicating that no single isoform is required *in vivo* in pancreatic islets. The aim of this study is to test how gain-of-function for PKB isoforms affects regulation of proliferation, growth, apoptosis, and insulin production in human islets.
Materials and methods: Human islets (three donors) were obtained from the Juvenile Diabetes Research Fund (JDRF) and the European Consortium for Islet Transplantation's (ECIT) "Islets for Research Distribution Program". Intact or dissociated islets were cultured on extracellular matrix (ECM)-coated dishes. Gain-of-function was induced by overexpressing PKBα or PKBβ (GFP as control) from adenoviral vectors. Proliferation and apoptosis were assessed by BrdU incorporation and TUNEL. Insulin secretion (GSIS) and insulin content were assessed with intact islets. Insulin was measured by ELISA. β-cell size was determined after dissociation of islets. At least 50 islets or 2000 single cells in triplicate were evaluated. Data were normalised to GFP control and presented as mean ± SE and were analysed by student's t test.
Results: In intact islets, only PKBα increased proliferation significantly (3.21 ± 0.49 fold). Both isoforms increased β-cell proliferation significantly after dissociation of islets (PKBα: 4.2 ± 0.13 fold; PKBβ: 3.58 ± 0.69 fold). Proliferation of non-β-cells was not significantly increased. β-cell size was significantly increased by PKBα (1.34 ± 0.07 fold) and PKBβ (1.38 ± 0.06 fold). In intact islets IL-1β increased apoptosis 2.36 ± 0.33 fold ($p<0.01$). PKBα prevented the IL-1β-induced increase in apoptosis ($p<0.05$), whereas PKBβ had no effect. After dissociation of islets IL-1β did not affect apoptosis (n=1), however, the overall rate of apoptosis was increased significantly over intact islets. PKBα decreased basal apoptosis of β-cells by 80% whereas PKBβ decreased it only 20%. After dissociation, only PKBα increased the fraction of insulin-positive cells by 6.34 ± 1.4%. PKBα and PKBβ increased insulin content significantly (1.54 ± 0.19 and 1.6 ± 0.13 fold), whereas GSIS remained unchanged.
Conclusion: Our findings indicate significant differences between intact and dissociated human islets, both with respect to the role of PKB isoforms and the potency of IL-1β to induce apoptosis, possibly due to cellular interactions in intact islets. Overall PKBα appears to be more potent than PKBβ in regulating human islet mass as it protects β-cells from apoptosis and increases the percentage of β-cells to non-β-cells.

IL-17 increases the expression and release of pro-inflammatory chemokines by human pancreatic islets

F.A. Grieco[1,2], F. Moore[1], F. Vigneron[1], I. Santin[1], L. Marselli[3], D. Rondas[4], L. Overbergh[4], F. Dotta[2], C. Mathieu[4], P. Marchetti[3], D.L. Eizirik[1];
[1]Laboratory of Experimantal Medicine, ULB, Brussels, Belgium, [2]Department of Internal Medicine, Endocrine and Metabolic Sciences and Biochemistry, University of Siena, Italy, [3]Department of Endocrinology and Metabolism, Metabolic Unit, University of Pisa, Italy, [4]Laboratory of Clinical and Experimental Endocrinology, Campus Gasthuisberg, KUL, Leuven, Belgium.

Background and aims: Type 1 diabetes (T1D) is an autoimmune disease characterized by selective pancreatic beta cell destruction in the course of islet inflammation (insulitis). Cytotoxic T-cells and macrophages are the most prevalent cells during insulitis. These cells contribute to beta cell destruction at least in part through the production of pro-inflammatory cytokines such as IL-1β, IFN-γ TNF-α. IL-17-secreting $CD4^+$ T-cells (Th17) are implicated in several autoimmune diseases, and we have recently shown activation of the IL-17 pathway in both circulating T-cells and pancreatic islets of T1D patients. IL-17 exacerbates IL-1β+IFN-γ and TNF-α+IFN-γ-induced apoptosis in human islets. We have now evaluated whether IL-17 also contributes to the local production of chemokines, thus contributing to the build up and aggravation of insulitis.
Materials and methods: Human islets (12 donors) were isolated in Pisa, Italy and sent to Brussels for the experiments described below. Islets from wt and STAT-$1^{-/-}$ mice were studied in parallel. Dispersed islets cells were left untreated or treated with IL-17 alone or together with IL-1β+IFN-γ or TNF-α+IFN-γ. After 48h of treatment supernatants were collected for measurement of chemokine secretion by ELISA, whereas cells were used to evaluate mRNA expression by qRT-PCR. For histological studies whole human islets were treated with the same cytokine combination and then paraffin-embedded. RNA interference was used to knockdown (KD) STAT-1 in human islets.
Results: IL-17 augmented IL-1β+IFN-γ and TNF-α+IFN-γ-induced CXCL1, CCL20 and IL-8 mRNA expression in human islets ($P<0.05$). ELISA confirmed that IL-17 exacerbated IL-1β+IFN-γ and TNF-α+IFN-γ-induced CXCL1, CXCL10 and IL-8 secretion ($P<0.05$), while CCL20 was increased by IL-17 when combined with IL-1β+IFN-γ and CCL2 when combined with TNF-α+IFN-γ. IHC indicated detectable islet protein expression of CXCL1 and CXCL10 after cytokine + IL-17 treatment. Double immunofluorescence confirmed that beta cells are at least in part responsible for chemokine production. KD of STAT-1 in human islets prevented IL-17 + cytokine-induced apoptosis and expression of some (e.g. CXCL9 and CXCL10) but not other chemokines. Similar observations were made in islets isolated from STAT-$1^{-/-}$ mice. These concordant observations suggest that STAT-1 and other mechanisms that remain to be discovered contribute to the pro-inflammatory effects of IL-17.
Conclusion: The present findings indicate that IL-17 exacerbates pro-inflammatory chemokine expression and secretion by human islets exposed to IL-1β+IFN-γ and TNF-α+IFN-γ. For some chemokines this is mediated via STAT-1 activation. These observations suggest that IL-17 contributes to the pathogenesis of type 1 diabetes by two mechanisms, namely increased local production of chemokines (potentially aggravating insulitis) and exacerbation of beta cell apoptosis.

Background and aims: Activation of c-Jun amino terminal kinase (JNK) 1 and JNK2 is substantial for eliciting beta cells death in response to chronic exposure to diabetogenic stressors including pro-inflammatory cytokines and fatty acids. However, on the three JNKs present in beta cells, JNK3 is the most abundant and is rather required for protecting beta cells against pro-apop-

totic stimuli. The data suggests that the JNK signaling could also coordinate an anti-apoptotic signal under temporal and/or physiological circumstances. In this study we investigated the mechanism leading to JNK3 activation and the potential role of this signaling in beta cells under obese and pregnancy environment.
Material and methods: RNA and total protein were extracted from the insulin secreting INS-1E and MIN6 cells, isolated islets of pregnant rats at different stages, obese ob/ob mice and obese individuals with or without diabetes. Co-immunoprecipitation experiments were performed using MIN6 cells. The protein and mRNA contents were analyzed by Western blotting experiments and quantitative real-time PCR, respectively.
Results: We found that activation of JNK3 was orchestrated by the Dual Leucine bearing zipper Kinase (DLK) as the mitogen activated protein kinase kinase kinase within a module operated by the scaffold Islet brain 1 (IB1). DLK was only present in insulin-positive cells within islets and triggered PDX-1 activity. Suppression of DLK impaired JNK3 activation, leading to loss of PDX-1 activity, insulin expression and an increase in cytokines-induced apoptosis. Conversely, overexpression of DLK raised PDX-1 activity, resulting in an increase of expression and secretion of insulin, and protection of cells against cytokines-induced apoptosis. On the one hand, the DLK level was increased in isolated islets of pregnant rats, hyperinsulinemic obese mice and obese individuals without diabetes. The GLP-1 mimetic exendin 4 stimulated the expression of DLK and JNK3 activation, supporting a role of the signaling for adaptation of beta cells under obesity and pregnancy. On the other hand the expression of DLK was diminished in islets of obese with diabetes and in response to chronic incubation with palmitate or pro-inflammatory cytokines.
Conclusion: The DLK-JNK3 is required for beta cells tasks by controlling PDX-1 activity. This signaling could be a key for adaptation of islets triggered by GLP-1 under obesity and pregnancy. Dysfunction of this signaling could account for beta cells failure in diabetes.

Effect of angiotensin-(1-7) on apoptosis of insulin-secreting cell line NIT-1 induced by high glucose
W. Xiao-yun, X. Ming-tong, R. Meng, L. Xiu-hong, Y. Li;
Department of endocrinology, Sun Yat-sen Memorial Hospital,Sun Yat-sen University, Guangzhou, China.

Background and aims: The association of the renin-angiotensin system with diabetes has been demonstrated by studies. Angiotensin-(1-7) (Ang-(1-7)) an endogenous heptapeptide hormone formed by cleavage of angiotensinI and AngiotensinII (AngII), counter acts many actions of AngII. Recent findings suggested that Ang-(1-7) exerts positive physiological modulation of insulin actions. Earlier work from our team showed that Ang-(1-7) could reverse the inhibitory effect of AngIIon insulin-stimulated Akt-Ser phosphorylation in NIT-1 cells. The purpose of the present study was to examine the effects of Ang-(1-7) on the apoptosis of pancreatic β cell induced by high glucose.
Materials and methods: Mouse pancreatic β cell line NIT-1 was divided into five groups: control group, Ang-(1-7) (10^{-5}M) group, high glucose (HG, 35mM glucose) group, HG+Ang-(1-7) group and HG+Ang-(1-7) + A-779 (Mas receptor antagonist, 10^{-5}M) group. The cells apoptosis were evaluated by TUNEL and flow cytometry analysis (Annexin V/PI). The reactive oxygen species (ROS) was detected by DCFH-DA fluorescent staining assay. The malondialdehyde (MDA) was measured by TBA method. Western Blot was used for evaluating the expression of pro-apoptotic protein cleave caspase-3 and phosphorylation of JNK and p38MAPK. One way analysis of variance (ANOVA) and LSD test were used for data analysis.
Results: The results of TUNEL and flow cytometry analysis were showed as follows. Compared with control group, the percentage of apoptotic cells in HG group was significantly increased($p<0.05$), whereas there was no significant difference between Ang-(1-7) group and control group. The percentage of apoptotic cells in HG+Ang-(1-7) group was lower than that in HG group ($p<0.05$), but was higher than that in control group ($p<0.05$). The percentage of apoptotic cells in HG+Ang-(1-7) +A-779 group was significantly increased when compared with HG+Ang-(1-7) group ($p<0.05$), was not significantly different from that in HG group. Analogously, the expression of caspase-3 in HG group was significantly higher than that in control group ($p<0.05$). Whereas after co-incubated with Ang-(1-7) for 72 h, the expression of caspase-3 was significantly declined compared with that in high glucose treated cells ($p<0.05$). A-779 blocked the inhibitory effect of Ang-(1-7) on the expression of caspase-3($p<0.05$). Concentrations of ROS and MDA in HG group was higher than that in control group ($p<0.05$). Glucose-stimulated JNK and p38MAPK phosphorylation significantly increased in HG group compared to the control group($p<0.05$). After co-incubated with Ang-(1-7) for 72 h, both concentrations of ROS and MDA and phosphorylation of JNK and p38MAPK were significantly declined compared with those in high glucose treated cells HG group($p<0.05$). These inhibitory effect of Ang-(1-7) were reversed by the A-779 ($p<0.05$).
Conclusion: Our data indicated that Ang-(1-7) could attenuate the apoptosis of NIT-1 cells induced by high glucose. It also suggested that inhibitory effect of Ang-(1-7) on apoptosis mediated through Mas receptor,and probably through JNK and p38MAPK-mediated signaling pathways and blocking oxidative stress.

Role of muscle PGC-1α in the effects of resveratrol and exercise training on high fat diet induced changes in pancreas in mice
N. Brandt, S. Larsson, C.M. Kristensen, R.S. Biensø, J. Olesen, H. Pilegaard;
Molecular Integrative Physiology, University of Copenhagen, Denmark.

Background and aims: Obesity is associated with many adverse changes such as pancreatic dysfunction. It is suggested that both physical activity and resveratrol can prevent adverse metabolic effects of increased caloric intake, but the potential protective effects of physical activity and resveratrol on high-fat diet induced changes in pancreas have not been resolved. Furthermore, the molecular mechanisms underlying the beneficial effect of exercise training and resveratrol have not been fully elucidated, although muscle PGC-1α has been proposed to play a role. Therefore, the aim is to test the hypothesis that muscle peroxisome proliferator-activated receptor-Ɣ coactivator (PGC)-1α is required for mediating the beneficial effects of exercise and resveratrol on high fat diet (HFD) induced changes in pancreas in mice.
Materials and methods: Muscle-specific PGC-1α knockout (MKO) and littermate wildtype (WT) mice completed 16 weeks of intervention with either carbohydrate (chow), high-fat diet (HFD), HFD with resveratrol (RSV, 4g/kg), HFD+ exercise (EX) or HFD+RSV+EX. Glucose and insulin tolerance tests and magnetic resonance scans were performed at week 14-15. Mice were euthanized by cervical dislocation at week 16 and pancreases were removed.
Results: HFD worsened glucose tolerance (p≤0,05), but insulin tolerance was unaffected, which could indicate impaired glucose sensitivity of the pancreas. Neither RSV nor EX could prevent this change. The lack of muscle PGC-1α reduced glucose tolerance to the same level as for WT on HFD. HFD did not affect Cytochrome C (Cyt C) protein, but resulted in increased Cytochrome C Oxidase I (COXI) protein (p≤0,05) in pancreas. RSV enhanced this increase in COXI further (p≤0,05), but had no effect on Cyt C protein. EX alone and in combination with RSV had no effect. None of the interventions had an impact on PDH-E1α protein expression, while HFD increased PDK4 protein content (p≤0,05) in pancreas. HFD did not affect Bax protein, but increased Bcl2 protein (p≤0,05) in WT mice but not in PGC-1α MKO mice. EX in WT but not in PGC-1α MKO mice and RSV in both genotypes increased the Bcl2 protein (p≤0,05).
Conclusion: The main finding in the present study is that HFD induced impairment of glucose tolerance seemed to involve pancreatic changes opposite of expected this seemed to be associated with increased anti-appoptotic changes of pancreas, which may be due to compensatory regulation. RSV and EX training did not rescue HFD induced changes and muscle PGC-1α did not play a role.

c-Src regulates the phosphorylation status of STAT3 in pancreatic beta cells and modulates their response to interleukin-6

M.A. Russell, N.G. Morgan;
University of Exeter Medical School, Plymouth, UK.

Background and aims: Human type 2 diabetes is characterised by low grade systemic inflammation associated with elevated circulating levels of interleukin (IL)-6. Islet cells are responsive to IL-6 and this cytokine mediates its effects, in part, by promoting the phosphorylation of the transcription factor STAT3. Therefore, we have studied the regulation of STAT3 by IL-6 and, in particular, have considered the possibility that this may be influenced by the tyrosine kinase c-Src which is thought to modulate the activation of STAT3 in some cell types.
Materials and methods: INS-1E, HEK293T cells and isolated human islets were used. STAT3 phosphorylation was assessed in cell extracts by Western blotting with site-specific antisera. Transcriptional activity was measured using a STAT3 responsive dual-luciferase reporter construct. Cell viability was assessed by flow cytometry and nitrite levels were determined by Greiss assay.
Results: The IL-6 receptor comprises two subunits, IL-6Rα and GP130, and both were readily detected in INS-1E cells and human islets by RT-PCR. Exposure of INS-1E cells to IL-6 alone (20ng/ml) did not influence their viability but the cytokine enhanced the detrimental effects of a range of different cytotoxic stimuli, including IL-1β (IL-1β: 14.3 ± 0.2% dead cells; IL-1β + IL-6: 22.2 ± 0.7%, p<0.001), a pro-inflammatory cytokine mix (mix: 16.3 ± 0.3% dead cells; mix + IL-6: 22.7 ± 0.7%, p<0.001) and the saturated fatty acid, palmitate (palm: 37.4 ± 0.8% dead cells; palm + IL-6: 44.3 ± 0.3%, p<0.001). Nitrite production (an index of nitric oxide formation) was not elevated in cells treated with IL-6 alone, but the increase caused by IL-1β was potentiated in the presence of IL-6 (IL-1β alone: 17.5 ± 0.3 μM nitrite; IL-1β + IL-6: 21.8 ± 0.4 μM, p<0.001). These responses correlated with a rapid increase in the phosphorylation of STAT3 at Tyr705 upon addition of IL-6. The activity of a STAT3 responsive reporter was enhanced significantly in cells exposed to 20ng/ml IL-6 (by 59.9±24.6 fold above control; n=6; p<0.05). Phosphorylation of a second residue within STAT3, Ser727, was also detected under these conditions but this was seen in control cells and was only marginally influenced by IL-6. To study the possible role of the non-receptor tyrosine kinase, c-Src, cells were exposed to a selective inhibitor of the enzyme, Src-I (10μM). Upon exposure to IL-6, this agent reduced the phosphorylation of STAT3 at both Tyr705 and Ser727. Under these same conditions, STAT3 reporter activity was strongly inhibited (from 26.98±6.74 to 2.91±1.35; p<0.05). The inhibitor also markedly reduced STAT3 activity in control cells (to 0.18±0.04, relative to control; p<0.01) and this correlated with a selective attenuation of the phosphorylation of Ser727.
Conclusion: IL-6 augments the detrimental effects of various cytotoxic stimuli in pancreatic β-cells. This correlates with increased phosphorylation of STAT3 at Tyr705 and a rise in STAT3 transcriptional activity. STAT3 is also phosphorylated at a second site, Ser727, which is not enhanced upon exposure to IL-6. However, loss of the phosphate group from Ser727 occurred in cells exposed to a c-Src inhibitor, leading to attenuation of the response to IL-6. These data imply that the activity of c-Src may be required to facilitate the response of pancreatic beta cells to IL-6 and that inhibition of this enzyme attenuates the pro-inflammatory actions of IL-6.

Long-term overexpression of c-Kit negatively impacts beta cell function and survival via capillary and inflammatory recruitment in the islet

Z.-C. Feng[1], J. Li[1], J. Silverstein[1], A. Popell[1], S.-P. Yee[2], R. Wang[1];
[1]Children's Health Research Institute; Western University, London, Canada, [2]University of Connecticut Health Center, USA.

Background and aims: Diabetes progression is marked by a decline in pancreatic β-cell mass. We have shown that the receptor tyrosine kinase, c-Kit, plays an integral role in mediating beta cell mass, function and survival using c-KitWv/+ mutant and transgenic mice (c-KitβTg) overexpressing c-Kit specifically in beta cell. Our recent study demonstrated that c-KitβTg mice showed protective effect against short-term (4 weeks) high-fat diet (HFD) induced diabetes with significant activation of Phosphoinositide 3-kinase/Akt signaling pathway. However, this protective effect diminishes after a long-term HFD (20 weeks) and the mice developed progressive hyperglycaemia. This evidence suggests that overexpression of c-Kit in beta cells may affect its function and survival through a different regulatory mechanism under a long-term HFD. We propose that over-expression of c-Kit may promote HIF-1α and VEGF expression leading to capillary recruitment in the islets and an increase in inflammatory signals, which imposes a negative impact in beta cell function and survival.
Materials and methods: In vitro, insulinoma 832/13 (INS-1) cells were cultured with either stem cell factor (SCF) or c-Kit siRNA to examine the effect of SCF/c-Kit interaction in regulating HIF-1α and VEGF expression. In vivo, c-KitβTg and wild-type (WT) mice were fed with HFD for 20 weeks started at 6 weeks of age. Metabolic and morphological studies including islet microvasculature formation, islet inflammatory cytokines and beta cell function were characterized using qRT-PCR, western blot, ELISA and double immunofluorescence approaches.
Results: In vitro, SCF augmented VEGF production in INS-1 cell culture in a time-dependent manner. This up-regulation was significantly reduced after cells were transfected with c-Kit siRNA (P<0.05). A significant increase of HIF-1α (P<0.05) and VEGF (P<0.01) were detected in islets isolated from c-KitβTg mice, and decreased in c-Kitwv/+ islets, when compared to WT islets. Furthermore, isolated c-KitβTg islets cultured in 3D fibrin gel showed increased sprouting of endothelial-like cells and endothelial cell proliferation compared to WT islets. These results suggest that c-Kit upregulates expression of VEGF, which may lead to capillary recruitment. In vivo, c-KitβTg mice under long-term HFD showed a significant increase of body weight (P<0.05), elevated overnight fasting glucose level (P<0.05), together with glucose intolerance and reduced insulin secretion (P<0.05) as compared to WT mice. Significant increased beta cell mass was observed in the WT-HFD mice, but this HFD-induced compensation in c-KitβTg-HFD mice was diminished. In parallel, an increased islet capillary area and vascular dilation (P<0.05) in c-KitβTg-HFD mice was detected, which could result in the recruitment of macrophage and inflammatory cytokines in the islets.
Conclusion: The present study represents unique and integrated approaches to elucidate cellular mechanisms by which altered c-Kit expression in beta cell under the long-term HFD stress could negatively impact beta cell function and survival. This negative regulation is likely associated with VEGF-induced vascularization and subsequently leading to potent chemoattractant tracking for inflammatory process, which could induce the development and progress of type 2 diabetes.

538

Fibrin modulates αvbeta3 integrin expression and FAK signalling to mediate islet cell differentiation, function, proliferation and survival

M. Riopel[1,2], J. Li[1,3], W. Stuart[1,2], R. Wang[1,3];
[1]Children's Health Research Institute, London, Canada, [2]Pathology, Western University, London, Canada, [3]Physiology and Pharmacology, Western University, London, Canada.

Background and aims: Integrins are a class of cell adhesion molecules that integrate cells to the extracellular matrix (ECM). ECM-integrin interactions influence β-cell differentiation, function, proliferation and survival; yet, when ECM proteins are used in culture, progressive loss of islet function and structure occurs. Fibrin is a provisional ECM protein and contains Arg-Gly-Asp amino acid motifs that are bound by integrin receptors such as αvβ3. Fibrin has been used in multiple surgical specialties and supports human and rat adult islet function, but the molecular mechanisms by which this occurs is unknown. The present study examined the functional role of integrins and downstream signaling pathways during fibrin culture of human fetal islet progenitor cells and mature beta cells.
Materials and methods: Human fetal islet progenitor cells isolated from 2nd trimester of pregnancy and mature beta (INS-1) cells were cultured up to 4 weeks on tissue culture polystyrene (TCPS) and with fibrin in 2D and 3D. An anti-αvβ3 integrin blocking antibody was used to determine the necessity of integrins with respect to beta cell growth and intracellular signaling. Cultured cells were analyzed by scanning electron microscopy, quantitative RT-PCR, western blot, immunofluorescence and ELISA.
Results: Fibrin culture of human islet progenitors led to preserved expression of glucagon, insulin and PDX1 when compared to TCPS. Mature beta (INS-1) cells cultured with fibrin formed islet-like clusters and showed direct contacts with fibrin as determined by scanning electron microscopy. As well, fibrin improved basal insulin release (p<0.01), glucose-stimulated insulin secretion (p<0.05) and Pdx-1 expression (p<0.01) at 4 weeks of culture. Significant increases in integrin αvβ3 (p<0.01) and phosphorylated FAK, Akt and ERK1/2

protein levels (p<0.05-0.001) were observed in fibrin-cultured cells compared to controls. These changes were associated with significantly increased cyclin D1 expression levels and Ki67 labeling (p<0.01), as well as decreased cell apoptosis (p<0.05). Perturbation of αvβ3 integrin function affected beta cell spreading on fibrin gels and resulted in significantly decreased FAK phosphorylation and increased cleaved caspase-3 levels (p<0.05).
Conclusion: This study demonstrates that activation of FAK, Akt and ERK1/2 signaling pathways by fibrin-integrin interactions mediates differentiation, function, proliferation and survival of islet cells. Using fibrin during cell culture may assist in promoting long-term beta cell health, as well as supporting the differentiation of human fetal islet progenitor cells. In this manner, existing beta cell sources can generated and maintained for use in diabetic therapies.

AMPK regulates ER morphology and function in stressed pancreatic beta cells via phosphorylation of DRP1

G. Leibowitz, J.D. Wikstrom, T. Israeli, E. Bachar-Wikstrom, Y. Ariav, E. Cerasi;
Hebrew University-Hadassah Medical School, Jerusalem, Israel.

Background and aims: Lipotoxicity designates the functional and physical demise of β-cells induced by metabolic stress in obesity and type 2 diabetes. Fatty-acid excess induces ER stress, accompanied by ER morphological changes. The energy sensor AMPK regulates metabolic stress; however its impact on ER morphology and function is unknown. We studied the regulation of ER morphology by fatty acids and AMPK in relation to β-cell function and survival.
Materials and methods: Mouse and human islets and INS-1E β-cells were treated with and without palmitate and/or the AMPK activators AICAR and metformin. AMPK was inhibited using a dominant-negative AMPK adenovirus. ER and mitochondrial morphology were analyzed by super-resolution confocal and electron microscopy. Islet proinsulin and insulin content and secretion were analyzed by ELISA and RIA, respectively. Apoptosis was monitored by Western blot for cleaved caspase 3 and by nucleosome ELISA assay.
Results: Palmitate induced marked ER expansion and mitochondrial fragmentation. We demonstrate that DRP1, a key regulator of mitochondrial fragmentation, is an ER resident and plays an important role in this process. Adenoviral vector expression of a dominant-negative DRP1 (Ad-K38A) in β-cells attenuated fatty acid-induced ER expansion and mitochondrial fragmentation. Stimulating AMPK inhibited DRP1 by phosphorylating aminoacid Ser637 and completely prevented the alterations in ER and mitochondrial morphology. Confocal microscope imaging and sub-cellular fractionation of palmitate-treated cells showed that DRP1 was localized in mitochondrial fission sites and in the ER. Further, palmitate-induced ER enlargement was associated with proinsulin retention in the ER, resulting in impaired proinsulin trafficking and processing. Stimulation of AMPK prevented these alterations and attenuated palmitate-induced apoptosis.
Conclusion: AMPK-DRP1 is a novel pathway regulating ER and mitochondrial morphology, thereby controlling the response of β-cells to metabolic stress. DRP1 may function as a node integrating signals from stress regulators, such as AMPK, to coordinate organelle shape and function.

Pathways involved in the GLP-1-mediated protection against cytokine-induced beta cell dysfunction and death in human islets: a proteomic approach

D. Rondas[1], M. Bugliani[2], W. D'Hertog[1], M. Massini[2], E. Waelkens[3], P. Marchetti[2], C. Mathieu[1], L. Overbergh[1];
[1]Clinical and Experimental Endocrinology, KU Leuven, Belgium, [2]Endocrinology and Metabolism, University of Pisa, Italy, [3]Laboratory of Protein Phosphorylation and Proteomics, KU Leuven, Belgium.

Background and aims: Type 1 diabetes (T1D) is characterized by cytokine-mediated beta cell destruction, resulting in life-long insulin dependency for the patient. The incretin hormone glucagon-like peptide-1 (GLP-1) has been shown to protect pancreatic beta cells against cytokine-induced dysfunction and destruction, thereby maintaining glucose homeostasis. Incretin-based compounds have emerged as a new class of agents for treatment of T2D while few reports have also described the effects of incretin-based agents in T1D. However, the mechanisms through which GLP-1 exerts its effects are complex and still poorly understood. The aim of this study was to analyze the protein expression profiles of human islets of Langerhans treated with cytokines in the presence or absence of GLP-1 in order to better understand the molecular pathways involved in GLP-1-mediated beta cell protection.
Materials and methods: Whole human islets of Langerhans were incubated for 72 h with IL1β (50U/ml) and IFNγ (1000U/ml) either alone, or in combination with GLP-1 (10nM). Beta cell apoptosis was determined by electron microscopy and beta cell dysfunction was evaluated by means of glucose-stimulated insulin secretion measurements. In parallel alterations in protein expression profiles were identified by 2-dimensional difference gel electrophoresis (2D-DIGE) combined with sophisticated protein interactome network analysis. Interesting results were confirmed by Western blotting.
Results: Cytokines induced an almost two-fold decrease in glucose-stimulated insulin secretion (n=3, $p < 0.05$) and increase in apoptosis from 1 ± 0.6 to 18 ± 3.5 % (n=3, $p < 0.05$), an effect which was almost completely restored by co-incubation with GLP-1. 2D-DIGE (n=4) and interactome network analysis revealed that GLP-1 alters in an integrated manner protein networks in cytokine-exposed islets. This showed that the cytoprotective effects of GLP-1 are mainly executed through counteracting the effects of cytokines on proteins form different functional classes such as restoration of actin cytoskeleton organization (e.g. ARP3 and CAPZB), normalization of chaperones levels (e.g. EIF3I), metabolic proteins (e.g. ALDH) and islet regenerating proteins (REG1A and REG1B).
Conclusion: GLP-1 alters in an integrated manner protein networks in cytokine-exposed human islets while protecting them against cytokine-mediated cell death and dysfunction. These data illustrate the beneficial effects of GLP-1 on human islets under immune attack and lead to a better understanding of the underlying mechanisms involved, a prerequisite for improving therapies for diabetic patients.

Mechanisms underlying compensatory islet response to insulin resistance

A. El Ouaamari[1], J.-Y. Zhou[2], E. Dirice[1], C. Liew[1], J.-S. Kim[2], R. Smith[2], W.-J. Qian[2], R. Kulkarni[1];
[1]Joslin Diabetes Center, Boston, [2]Pacific Northwest National Laboratory, Richland, USA.

Background and aims: Compensatory islet response is a distinct feature of the pre-diabetic insulin resistant state in both rodents and humans. In this study, we aim to identify specific protein alterations in islet cell function, apoptosis and proliferation that characterize this adaptive response.
Material and methods: Islets from six-month-old male control, high-fat diet fed and obese Ob/Ob mice were analyzed by liquid chromatography coupled mass spectrometry (LC-MS). Accurate mass and time tag (AMT-Tag) and selected reaction monitoring (SRM) were applied to quantify and verify the proteomic response in islets.
Results: The LC-MS quantitative proteome profiling revealed ~1,700 islet proteins that were identified and quantified by at least two unique peptides with a false discovery rate <1%. Statistically significant alterations in protein abundances were observed for ~450 proteins between control and insulin resistant conditions. Our study reveals common exacerbated dysfunction in energy metabolism (e.g. ALDOA and PFKL), oxidative phosphorylation (e.g. ATP5I, COX5A and COX6A), hormone processing (e.g. PC1 and PC2) and secretory pathways (e.g. RAB7A and UCN3). Increased expression of actors involved in protein synthesis (such as EIF3 family members) and folding (e.g. ERP29 and ERP44) was observed and suggests endoplasmic reticulum stress response in insulin resistant islets. Compensatory cell survival and proliferation were revealed as the main mechanisms by which islet-cells compensate to increased metabolic needs during insulin resistance.
Conclusion: This study represents the first quantitative study of the islet proteome that is focused on the compensatory islet-cell growth in response to insulin-resistance without overt diabetes. The extensive dataset provides a resource of islet protein candidates to apprehend islet cell replenishment to increasing the number of beta cells in patients with diabetes.

Reduced availability of glucose during culture attenuates hypoxia-induced reduction in cellular viability and function in pancreatic beta cells

V. Grill[1,2], I. Hals[2], R. Singh[2], Z. Ma[3], A. Björklund[3];
[1]Dept Internal Medicine, University Hospital of Trondheim, Norway, [2]Institute of Cancer Research and Molecular Medicine, Trondheim, Norway, [3]Institute of Molecular Medicine and Surgery, Karolinska Institutet, Stockholm, Sweden.

Background and aim: To improve the success of islet transplantation in type 1 diabetes patients one needs to minimize hypoxia-induced beta cell death. Here we used clonal beta cells and rat pancreatic islets to test by viability and functional parameters if decreasing cellular metabolism by in vitro exposure to a low glucose concentration could reduce the impact of experimental hypoxia and hence be a potentially beneficial part of a pre-transplantation protocol. Further, we tested for evidence of lingering metabolic adaption to hypoxia.
Materials and methods: INS-1-derived 832/13 cells were cultured in medium containing either 5.5 or 11 mM glucose for three days under normoxic conditions before exposure to hypoxia for 8 or 18 h. Control cells were grown in parallel at continuous normoxia. Subsequent re-oxygenation (overnight) was always carried out at 11 mM glucose. Rat pancreatic islets were subjected to similar conditions.
Results: Reduction of cell viability after 18 h of hypoxia followed by re-oxygenation was assessed by the MTT assay, by cell counting and by measurement of apoptosis/necrosis. Reduction was less pronounced following culture at 5.5 mM glucose: for MTT 46 ± 2.7 vs. 62 ± 2.9 %, $p < 0.001$ (n = 4), for cell counting 32.7 ± 6.4 vs. 47.6 ± 6.1 %, $p < 0.002$ (n = 5), for incremental apoptotic DNA 1.52 ± 0.14 vs. 2.42 ± 0.19, $p < 0.02$ (n = 8), and necrotic DNA 1.54 ± 0.27 vs. 2.31 ± 0.26, $p < 0.08$ (n = 8). A favorable effect of pre-culture at low glucose (on MTT) was confirmed in rat pancreatic islets. Previous hypoxia tended to increase basal insulin secretion regardless of glucose concentration during culture. Previous hypoxia decreased an index of stimulation (ratio of insulin released at 16.7 to secretion at 3.3mM glucose) for cells cultured at 11 mM glucose , but did not affect this index in cells cultured at 5.5 mM glucose. Basal oxygen consumption in cells cultured at 11 mM glucose was not affected by 8 h of previous hypoxia and subsequent re-oxygenation, whereas respiration in 5.5 mM glucose-cultured cells was modestly increased. Previous hypoxia reduced the ratio of oligomycin-inhibited/FCCP-induced oxygen uptake in cells pre-exposed to any of the two glucose concentrations during culture, implying induction of a lesser degree of mitochondrial uncoupling.
Conclusion: Our findings provide evidence that culture at low glucose lessens the impact of experimental hypoxia on cell viability and function. Further they suggest that cellular adaption takes place in response to hypoxia.

Cytokines and histone deacetylase inhibition differentially regulate the expression of beta cell inflammasomes

M.S. Dahllöf[1], D.P. Christensen[1], L. Perruzza[2], M. Lundh[1], L. Chatenoud[3], F. Grassi[2], T. Mandrup-Poulsen[1,4];
[1]Department of Biomedicine, University of Copenhagen, Denmark, [2]Institute for Research in Biomedicine, Bellinzona, Switzerland, [3]Hôpital Necker-Enfants Malades, Institut National de la Santé et de la Recherche Médicale, Paris, France, [4]Department of Molecular Medicine and Surgery, Karolinska Institutet, Stockholm, Sweden.

Background and aims: In type 1 and type 2 diabetes mellitus IL-1β is believed to contribute to beta cell failure and destruction. Histone deacetylase (HDAC) inhibitors protect against inflammatory beta cell demise. We recently demonstrated that HDACs regulate beta cell IL-1β production, but it is unknown which inflammasome is responsible for beta cell processing of proIL-1β. Here we wanted to examine the expression levels of the NALP1, NLRP3 and ASC inflammasome components, as well as expression levels of the purinergic p2x7 receptor that senses extracellular ATP as a danger-associated molecular pattern and mediates inflammasome activation via K+ efflux.
Materials and methods: INS-1 cells were preincubated with or without the HDAC inhibitor givinostat for 1h before exposure to 150 pg/mL IL-1β and 0.1 ng/mL IFNγ for 1, 3, 6, 12 or 24 h. Cells were lysed, RNA extracted using Nucleospin II, converted to cDNA using iScript, and mRNA levels were determined by qPCR using the 2ΔΔCt method.
Results: Here we show that cytokines and HDAC inhibition differentially regulated beta cell inflammasome expression. NLRP1 mRNA was induced by cytokines after 3 h ($p<0.001$), peaked at 6 h ($p<0.001$), and was down-regulated after 24 h ($p<0.01$), while NLRP3 and ASC expression was suppressed by cytokines after 6 and 12 h, respectively ($p<0.01$). HDAC inhibition down-regulated basal expressions of NLRP3 at all timepoints ($p<0.001$) and ASC at 12 and 24h ($p<0.001$), while cytokine induction of NLRP1 was attenuated by histone deacetylase inhibition at 3h ($p<0.001$) and 6h ($p<0.001$). P2x7 expression was downregulated after 1 h of HDAC inhibition ($p<0.01$) but was unaffected by cytokines.
Conclusion: We conclude that downregulation of beta cell p2x7 receptor and inflammasome expression may contribute to the protective effects of HDAC inhibition in inflammatory beta cell destruction, suggesting that HDAC inhibitors may be attractive novel antidiabetic drugs.

NLRP3 inflammasome is expressed and regulated in human islets

V.J. Lavallard, G. Parnaud, P. Morel, B. Bédat, D. Bosco, T. Berney;
Surgery, Cell Isolation and Transplantation Center, Geneva, Switzerland.

Background and aims: NRLP3 inflammasome is a protein complex playing an important role in innate immunity. This complex is activated in response to infection, inflammation and autoimmune processes and is involved in the maturation of IL1β by the cleavage of caspase-1. Blood level of IL1β was shown to increase in diabetic patients and NRLP3 inflammasome was suggested to mediate this effect. However, the real contribution of NRLP3 inflammasome in local islet production of IL1β has not been yet demonstrated. The aim of this study was to determine the expression and the regulation of the NRLP3 inflammasome in human islets.
Materials and methods: Human islets were enzymatically isolated from cadaveric donor pancreases. Isolated islets were stimulated or not with 1µg/ml LPS for 4h and successively with 5mM ATP for 30 min. This treatment was performed in the presence or absence of 200µM glyburide, an inflammasome inhibitor. Supernatants were collected and secreted IL1β was quantified by ELISA. The *NRLP3* and *IL1β* genes expressed in islets were studied by real time PCR and caspase-1 by western blot.
Results: *NRLP3* and *IL1β* were found to be expressed in untreated isolated human islets. In response to the LPS plus ATP treatment, *NRLP3* and *IL1β* increased 3.7±0.2 fold (n=4, p=0.02) and 45.5±9.8 fold (n=2), respectively. Glyburide prevented the augmentation of *NLRP3* (2.6±0.2 fold, p=0.03) and *IL1β* (23.4±2.9 fold, n=2). The LPS plus ATP treatment induced the cleavage of caspase-1, an essential enzyme for the maturation and secretion of IL1β. Human islets secreted 38.1±1.8 pg/ml IL1β (n=5, p=0.0097) in response to LPS plus ATP. Glyburide was shown to prevent the cleavage of caspase-1 and decrease IL1β secretion by 97.6% (0.92±0.28 pg/ml IL1β, n=5, p=0.0079).
Conclusion: These results show that the NRLP3 inflammasome is expressed and regulated in human islets in response to LPS plus ATP. The NRLP3 inflammasome could be a potential therapeutic target to prevent local IL1β production and the subsequent islet damages in both diabetes and islet transplantation.

Human serum vs human serum albumin for human islet culture

M. Nacher[1], A. Garcia[2], E. Estil.les[1], B. Nadal[2], M. Pairó[1], C. Garcia[1], J. Busquets[1], A. Novials[2], E. Montanya[1];
[1]Hospital de Bellvitge-IDIBELL-CIBERDEM-Universitat de Barcelona, [2]Hospital Clínic de Barcelona- IDIBAPS-CIBERDEM, Spain.

Background and aims: Human islets are usually incubated for 48 or 72 hours in medium supplemented with human serum albumin (HSA) before clinical transplantation. However, whole serum is preferred for standard tissue culture due to the presence of growth factors improving cell viability. There is conflicting evidence favouring both the use of HSA and of human serum (HS) as best strategy for culture of human islets. The aim of this study was to evaluate the effects of HS versus HSA supplementation of culture media on: a) in vitro beta cell viability and function; b) in vivo islet graft revascularization, beta cell death and metabolic outcome after experimental islet transplantation.
Material and methods: Human islets isolated from the pancreases of 15 cadaveric organ donors were cultured for 3 days in CMRL 1066 medium

supplemented with HSA (HSA group) or human AB serum (HS group) immediately after isolation. Beta cell apoptosis was quantified in islets double stained by TUNEL and insulin, and islet function as glucose-stimulated insulin secretion (GSIS) (basal: 2.8 mM; stimulated: 20 mM). In vivo viability and revascularization was determined in HS and HSA cultured islets transplanted in the anterior chamber of the eye of normoglycemic Balb/c mice (n= 14), using intravenous propidium iodide and rhodamine B isothiocyanate-dextran, respectively. Beta cell apoptosis was quantified in paraffin-embedded eyes double stained by TUNEL and insulin. Function of transplanted islets was determined as fed plasma glucose in streptozotocin (STZ)-diabetic nude mice transplanted with a 2000 IEQs of HS (n= 17) or HAS (n=16) cultured islets.
Results: After 3 days in culture, beta cell apoptosis was lower in HS group (2.45±0.59% vs 5.54±0.68%) (p= 0.008). Insulin content was similar in HS and HSA groups. GSIS was higher in HS group (37.3±13.5 ng/μg DNA vs 26.4±9.3 ng/μg DNA) (p= 0.027). The stimulation index was also higher in HS group (12.0±2.6 vs 5.26±0.50) (p= 0.026), and the ratio stimulated insulin secretion/insulin content tended to be higher in the HS group (4.82±1.59% vs 2.94±0.71%) (p=0.062). However, islets transplanted into the anterior chamber of the eye showed similar viability (intravenous propidium iodide: $5.67.10^{-5}$±$4.51.10^{-5}$ vs $4.00.10^{-5}$±$3.00.10^{-5}$ death cells/μm^2), and beta cell apoptosis (8/903 vs 0/528 apoptotic/total nuclei) (HS vs HSA group), 10-15 days after transplantation. Revascularization was observed in one graft (HS group) on day 10 after transplantation. Metabolic evolution was similar in STZ-diabetic nude mice transplanted with HSA and HS cultured human islets that showed comparable blood glucose levels and percentage of normoglycemic animals over time.
Conclusion: Human islets cultured in medium supplemented with HS showed higher in vitro islet viability and function, but this beneficial effect did not translate into an improved survival and metabolic evolution after transplantation in mice.

Prevention of type 1 diabetes in NOD mice by targeting dipeptidyl peptidase IV is associated to modification of both central and peripheral T-cell subsets
N. Alonso[1], P. Correa[2], A. Teniente[2], R. Colobran[3], M. Julián[1], P. Monge[1], M. Fernández[4], M. Vives-Pi[2], M. Puig-Domingo[1];
[1]Endocrinology and Nutrition Service, Hospital Universitari Germans Trias i Pujol, Badalona, [2]Immunology Service, Hospital Universitari Germans Trias i Pujol, Badalona, [3]Immunology Department, Hospital Universitari Vall d'Hebrón (HUVH), Vall d'Hebrón Institut de Recerca (VHIR), Barcelona, [4]Cytometry Unit, Institut d'Investigació en Ciències de la Salut Germans Trias i Pujol, Badalona, Spain.

Background and aims: CD26 or dipeptidyl peptidase IV (DPPIV) is a multifunctional glycoprotein expressed ubiquitously, with T-lymphocyte costimulatory actions. We aimed to assess the effect of CD26 targeted treatment with a DPPIV inhibitor (MK0626) on the prevention of type 1 diabetes (T1D), the insulitis score and the percentage of T-lymphocyte subsets from both the thymus and the periphery in the *nonobese* diabetic mouse (NOD).
Materials and methods: 15 mice treated with MK0626 administered in the diet, started at 8 weeks of age, and 15 untreated (control group) were followed during 30 weeks. Insulitis score was determined by two blinded evaluators. Lymphocyte subsets were studied in another group of treated and control mice at 2, 4 and 6 weeks of treatment (n=6 at each time-point). Flow cytometry for characterization of lymphocyte subsets was performed using MoAbs (CD3-V450, CD4-APC-Cy7, CD8-V500,CD26-PerCP-Cy5, CD25-PE, FoxP3-FITC, CD44-FITC, CD45RB-PE, CD62L-PerCP-Cy5.5, CCR7-APC) and identified as: double positive (DP) ($CD4^+CD8^+$), double negative (DN) ($CD4^-/CD8^-$), single positive (SP) CD4 ($CD8^-CD4^+$), SP CD8 ($CD4^-/CD8^+$), naïve ($CD3^+CD4^+/CD8^+CD44^-CD62L^+CCR7^-$); central memory (CM)($CD3^+CD4^+$/ $CD8^+CD44^{high}CD62L^{+low}CCR7^+$); effector memory (EM) ($CD3^+CD4^+/CD8^+CD44^{high}CD62L^+CCR7^-$);Tregs($CD4^+CD25^+Foxp3^+$).
Results: MK0626 treatment decreased diabetes incidence by 45% (37.5% *vs* 68% controls, p=0.05). Insulitis score: At week 6, insulitis score significantly decreased in treated vs control mice (0.83±0.27 *vs* 1.52±0.26, p=0.02) with no changes at week 2 and 4. Lymphocyte subsets: at week 4 of treatment, treated mice showed in comparison with the control group: 1) Periphery: decreased percentage of CD4 and CD8 naïve T-cells (p<0.001, respectively), CD4 and CD8 CM T-cells (p<0.001, respectively), and increased percentage of CD4 and CD8 EM T-cells (p<0.001, respectively), 2) Thymocytes: decreased percentage of DN (p=0.002), SP CD4 (p=0.003) and SP CD8 (p=0.004) and increased percentage of DP (p=0.001) thymocytes. No differences were observed at week 2 nor at week 6 of treatment.
Conclusion: Treatment with the DPPIV inhibitor MK0626 in NOD mice decreases the incidence of T1D, reduces insulitis score and modifies the percentage of several T-lymphocyte subsets in the thymus and the periphery. The effect of this drug on both central and peripheral T-cell compartments may be involved in the development of immune tolerance, thereby preventing T1D in NOD mice.

Changes in the circadian rhythmicity of energy metabolism and cerebral cFos expression at diabetes onset in NOD mice
V. Burkart[1], A. Reinbeck[1], M. Ingenwerth[2], G. Sequaris[1], A. Stahr[2], H.-J. Partke[1], C. von Gall[2], M. Roden[1,3];
[1]Institute for Clinical Diabetology, German Diabetes Center, Düsseldorf, [2]Institute for Anatomy II, Heinrich-Heine-University, Düsseldorf, [3]Departments of Endocrinology, Diabetology and Metabolic Diseases, University Clinics Düsseldorf, Germany.

Background and aims: An endogenous rhythm generator located in the hypothalamic suprachiasmatic nucleus (SCN) controls the rhythmicity of metabolic and immunological processes. As the pathogenesis of type 1 diabetes is associated with dysregulated energy metabolism and immune reactivity it may be assumed that disturbances of circadian rhythms of these processes are involved in disease manifestation. We hypothesized that the onset of insulin-deficient diabetes in non-obese diabetic (NOD) mice coincides with alterations of the rhythmicity of metabolic processes and the circadian system.

Materials and methods: Female C57BL6, normoglycemic and newly diabetic (<3 d) NOD mice were kept at a 12-h light/12-h dark cycle. Respiratory quotients (RQ) were determined by indirect calorimetry. Locomotor activity was monitored by interruption of infrared beams ("counts"). Expression of the transcription factor cFos, reflecting neuronal activity, was analyzed in the SCN by immunohistochemistry.
Results: In light cycles all groups of mice show comparable spontaneous locomotor activity, whereas in dark cycles diabetic NOD mice have a lower locomotor activity (575 ± 84 counts) than C57BL6 (1164 ± 478, counts, $p<0.05$) or nondiabetic NOD mice (1169 ± 299 counts, $p<0.05$). Furthermore, diabetic NOD mice have a reduced RQ in light (0.82 ± 0.02) and dark cycles (0.84 ± 0.01) when compared to C57BL6 (light 0.88 ± 0.01, dark 0.94 ± 0.02, $p<0.001$) and nondiabetic NOD mice (light 0.88 ± 0.02, dark 0.95 ± 0.01, $p<0.001$). Cerebral cFos expression was about 40% higher in the SCN area of C57BL6 and nondiabetic NOD mice at ZT02 (2 h after lights-on) than at ZT14 (2 h after lights-off), but the total number of cFos positive cell nuclei was significantly decreased in the SCN of nondiabetic NOD mice at ZT02 (cFos positive cells in SCN: 87 ± 29) when compared to C57BL6 mice (cFos positive cells in the SCN: 196 ± 22). However, diabetic NOD mice showed no light/dark rhythmicity of cFos expression (cFos positive cells in SCN: ZT02: 73 ± 17; ZT14: 78 ± 16).
Conclusion: In conclusion, nondiabetic but diabetes prone NOD mice exhibit a reduced cerebral cFos expression when compared to C57BL6 mice without diabetes predisposition. In newly diabetic NOD mice this abnormality coexists with an altered energy metabolism pointing to a link between the SCN endogenous rhythm generator and the metabolic changes at or even before the onset of insulin-deficient diabetes.

Differential requirement for endogenous IL-15 and IL-21 in activating diabetogenic CD8+ T cells in a virus-induced model of autoimmune type 1 diabetes
S. Ilangumaran, D. Bobbala, S. Ramanathan;
Pediatrics, Immunology division, Université de Sherbrooke, Canada.

Background and aims: We have shown that stimulation of potentially diabetogenic CD8+ T cells with the inflammatory cytokines IL-15 and IL-21 enables them to respond to weak TCR stimuli and induce autoimmune type 1 diabetes (T1D) in a transgenic mouse model. We have also shown that lack of IL-15 or IL-21 protects NOD mice expressing the highly pathogenic 8.3 transgenic TCR on CD8+ T cells from T1D. The aim of this study is to determine the role of endogenous IL-15 and IL-21 in activating potentially diabetogenic CD8+ T cells in a virus-induced T1D model.
Materials and methods: We introduced the null alleles of Il15 or IL21 into RIP-GP mice expressing the lymphocytic choriomeningitis virus (LCMV) glycoprotein in pancreatic beta cells under the rat insulin promoter (RIP). RIP-GP, Il15-/-.RIP-GP and IL21-/-.RIP-GP mice were infected with LCMV and evaluated for T1D development, insulitis and viral load. Lymphocytes from infected mice were characterized phenotypically and tested for the ability to transfer disease to Rag1-/-.RIP-GP mice.
Results: IL-15 deficiency hampered clearance of LCMV in RIP-GP mice, suggesting impaired immune response towards LCMV antigens. Accordingly, the proportion of CD8+ T cells with the CD44hiCD62Llo activated phenotype was significantly lower in Il15-/-.RIP-GP mice than in control mice. Despite this inability to mount protective immune response against LCMV, 50% of Il15-/-.RIP-GP mice developed T1D with marked destruction of pancreatic islets. On the other hand, Il21-/-.RIP-GP mice efficiently cleared LCMV and all mice developed T1D with similar kinetics as wildtype RIP-GP mice.
Conclusion: Our results support the notion that IL-15 is needed for efficient activation of diabetogenic CD8+ T cells. On the other hand, IL-21 is dispensable in LCMV-induced T1D in RIP-GP mice, although a recent study has reported requirement for IL-21 in LCMV-induced T1D in NOD mice expressing LCMV nucleoprotein (NP) in the islets. Our findings suggest that other genetic susceptibility factors may influence the pathogenic role of IL-21.

Alterations of lipid homeostasis and insulin sensitivity in TLR4-deficient non-obese diabetic mice
A. Reinbeck[1], H.-J. Partke[1], H. Al-Hasani[2], V. Burkart[1], M. Roden[1,3];
[1]Institute for Clinical Diabetology, German Diabetes Center, Duesseldorf, [2]Institute for Clinical Biochemistry and Pathobiochemistry, German Diabetes Center, Duesseldorf, [3]Departments of Endocrinology, Diabetology and Metabolic Diseases, University Clinics Duesseldorf, Germany.

Background and aims: Studies in animal models demonstrate that the toll-like receptor 4 (TLR4) is involved in the maintenance of metabolic homeostasis and implicate a role of TLR4 in the development of autoimmunity. In non-obese diabetic (NOD) mice disturbed glucose and lipid homeostasis may promote the development of autoimmune-mediated diabetes. As glucose homeostasis depends on insulin availability and responsiveness we tested the effect of TLR4 expression on insulin release, insulin action and circulating fetuin A, a mediator of free fatty acid (FFA) binding to TLR4 in NOD mice.
Materials and methods: In female TLR4-expressing ($TLR4^{+/+}$) and TLR4-deficient ($TLR4^{-/-}$) prediabetic NOD mice (age 120 d) body weight and food intake were documented and body composition was analyzed by magnetic resonance imaging (MRI). Glucose-stimulated insulin release was determined in isolated pancreatic islets. Serum levels of insulin and of fetuin A were measured by ELISA. Fasted mice also underwent intraperitoneal insulin tolerance tests (ipITT) to assess insulin sensitivity.
Results: When compared to $TLR4^{+/+}$ NOD mice, $TLR4^{-/-}$ animals have a higher body weight ($TLR4^{+/+}$ 25.4 ± 1.3 g, $TLR4^{-/-}$ 28.1 ± 1.7 g, $p<0.01$), but comparable food uptake ($TLR4^{+/+}$ 0.15 ± 0.01, $TLR4^{-/-}$ 0.16 ± 0.01 g/g body weight per day). Furthermore, $TLR4^{-/-}$ animals have a greater total adipose tissue mass (13.0 ± 1.8 %) when compared to $TLR4^{+/+}$ NOD mice (10.9 ± 1.6 %, $p<0.05$) and increased free fatty acid levels ($TLR4^{+/+}$ 0.5 ± 0.1, $TLR4^{-/-}$ 0.7 ± 0.1 mmol/l, $p<0.01$) and triglyceride levels ($TLR4^{+/+}$ 66 ± 5, $TLR4^{-/-}$ 79 ± 9 mg/dl, $p<0.01$), but similar levels of fetuin A ($TLR4^{+/+}$ 110 ± 7, $TLR4^{-/-}$ 96 ± 12 µg/ml). Glucose-stimulated islets of $TLR4^{+/+}$ and $TLR4^{-/-}$ mice released comparable amounts of insulin (at 5.5 mM glucose: $TLR4^{+/+}$ 129 ± 9 pg/ml, $TLR4^{-/-}$ 105 ± 45 pg/ml; at 28 mM glucose: $TLR4^{+/+}$ 239 ± 16 pg/ml, $TLR4^{-/-}$ 314 ± 84 pg/ml). However, the response of blood glucose to insulin injection during ipITT was 56 % lower in $TLR4^{-/-}$ NOD mice than in $TLR4^{+/+}$ mice ($p<0.001$).
Conclusion: Our finding of disturbed glucose and lipid homeostasis in diabetes-prone TLR4-deficient NOD mice indicates that TLR4 deficiency may accelerate the progression of diabetes by impairing insulin sensitivity rather than by affecting the function of beta cells, the primary target of autoimmune reactivity.

CD26/DPPIV inhibition alters the expression of immune related genes in the thymus of NOD mice
M. Julián[1], N. Alonso[1], R. Colobrán[2], C. Paula[3], A. Sanchez[4], A. Teniente[3], I. Pujol-Autonell[3], M. Vives-Pí[3], M. Puig-Domingo[1];
[1]Endocrinology and Nutrition. Department of Medicine., Hospital Germans Trias i Pujol, [2]Immunology Unit, Research Institute Vall d'Hebrón, , [3]Laboratory of Immunobiology for Research and Applications to Diagnosis (LIRAD), Blood and Tissue Ba, Research Institute Germans Trias i Pujol, [4]Statistics Deparment, University of Barcelona, Spain.

Background and aims: It has been described that CD26/dipeptidyl peptidase IV (DPPIV) inhibition delays the onset of type 1 diabetes (T1D), and even, can reverse new-onset TID in *non obese* diabetic (NOD) mice. We recently observed that targeting CD26/DPPIV decreases the incidence of T1D and reduces insulitis in NOD mice, and alters T-lymphocyte subsets in the thymus and periphery, redirecting towards an immunoregulatory phenotype. In the current study, the effects of a DPPIV inhibitor (MK0626) in the transcriptome of the thymus were examined by microarray analysis.
Materials and methods: MK0626 treatment was administered in the diet to 8 wk old female NOD mice during 6 weeks. Microarray experiments were performed to identify differentially expressed genes after DPPIV inhibition in thymic glands of treated mice (n=5) compared to untreated group (n=5). Statistically significance for differential gene expression was considered for adjusted p- value ≤ 0.05 and $\log_2 FC > \pm 0.8$. Results were validated by RT-PCR.
Results: Transcriptome analysis of the thymus showed that 66 genes were significantly up-regulated in treated mice NOD when compared with controls. Immune response-related genes included those involved in 1) Innate immu-

nity *(Plunc, Ear1,Ear2, Ear11, RegIIIγ, Clec7a, Clec9a,Csf1r, Lbp*), 2) Immunoregulation (*Muc-1, Fcgr2b, Lilrb4*), 3) Chemotaxis (*Ccl11, Ccl6, Ccl3, Ccl9, Ccl27, Ccl21, C3ar1, Cxcl16*), 4) Antigen presentation and processing (*Lgmn)* and 5) Inflammation (*Scgb3a1,Sgb1a1, fstl1, Retnla*). Most of these genes are implicated in central tolerance mechanisms through several pathways: enhancing negative selection of autoreactive T cells, modification of thymic architecture, control of T cell activation and response, enhancement of Tregs expansion and function and, finally, stimulation of apoptotic cells clearance. Differential expression was confirmed in all selected genes by RT-PCR.
Conclusion: Treatment with the DPPIV inhibitor MK0626 in NOD mice alters immune response gene expression profile in the thymus, and potentially may enhance the efficiency of immunological central tolerance.

Immunomodulatory effects of efferocytosis: a key role in the suppression of autoimmunity to beta cells
I. Pujol-Autonell[1], R.-M. Ampudia[1], A. Serracant[1], A. Garcia[1], E. Aguilera[1], M. Puig-Domingo[1], J. Verdaguer[2], M. Vives-Pi[1];
[1]Germans Trias i Pujol Research Institute, Badalona, Spain, [2]IRBLleida-University of Lleida, Spain.

Background and aims: Efferocytosis is a crucial process by which apoptotic cells are cleared by phagocytes, maintaining immune tolerance to self in the absence of inflammation. Type 1 diabetes, caused by the loss of tolerance to beta cells, can be prevented by the administration of tolerogenic dendritic cells (DCs) loaded with islet apoptotic cells in NOD mice. Our aim was to determine molecular mechanisms involved in tolerogenic features achieved by DCs after the uptake of apoptotic cells, thus explaining the prevention of autoimmunity.
Materials and methods: DCs from NOD mice, pulsed with apoptotic islet cells, were administered to pre-diabetic NOD mice and observed by in vivo imaging. The ability of these cells to induce autologous T cell proliferation and to suppress mature dendritic cell function was assessed, together with cytokine production. Microarray experiments were performed to identify transcriptome of DCs after efferocytosis. The role of Prostaglandin E2 -one of the differentially expressed genes- in tolerogenic functions of DCs was determined. For paired data, a non-parametric Wilcoxon test was performed. Otherwise, Mann Whitney test was used. A p-value < 0.05 was considered significant.
Results: In vivo imaging revealed the signal of tolerogenic DCs in the pancreatic lymph nodes three days after the injection. Efferocytosis causes significant molecular and functional changes in DCs: 1) Impaired ability to stimulate autologous T cell proliferation. 2) Cytokine profile typical for immature dendritic cells. 2) Suppressive ability of mature dendritic cell function. 3) Downregulation of antigen processing and presentation gene expression. 4) Increased Prostaglandin E2 production, responsible for immunosuppressive mechanisms.
Conclusion: The tolerogenic behaviour of DCs after efferocytosis points to a mechanism of silencing potential autoreactive T cells in the microenvironment of pancreatic islets through prostaglandin E2 production in the context of autoimmunity. Our results suggest that this is a viable strategy for a variety of autoimmune diseases.

Correlation of islet infiltration to gene expression of blood mononuclear cells and pancreas draining lymph nodes in the LEW.1AR1-iddm rat model of autoimmune diabetes
T. Schoeppe[1], H. Weiss[1], D. Wedekind[2], R. Schmidt[3], M. Tiedge[1];
[1]IBIO, University of Rostock, [2]Hannover Medical School, [3]IBIMA, University of Rostock, Germany.

Background and aims: The LEW.1AR1-iddm rat is an animal model of spontaneous autoimmune diabetes. Islet infiltration occurs within a narrow time range resulting in progressive beta cell destruction and overt diabetes. It was the aim of this study to correlate haemograms and expression profiles of inflammatory genes in peripheral blood mononuclear cells (PBMC) to stages of islet infiltration and gene expression profiles in pancreas draining lymph nodes (PLN).
Materials and methods: Normoglycaemic LEW.1AR1-iddm and LEW.1AR1 control rats were killed at the age of 40, 45, 50, 55 and 60 days. Blood, pancreas, PLNs were asservated for histology and gene expression analysis. Differential haemograms were created from peripheral blood by the ADVIA 2120 system. Serial pancreatic sections were stained with Haematoxylin-Eosin (HE) to document the status of infiltration. RNA was isolated from PLNs and PBMCs. Gene expression was quantified for proinflammatory (TNFα, IFNγ, IL1β) and antiinflammatory cytokines (IL4, IL10), T-cell markers (CD25, CTLA4, NRP1), L-Selectin, TGFβ and FoxP3 by RT-PCR.
Results: The LEW.1AR1-iddm strain showed a 40 % lower lymphocyte content in peripheral blood than the diabetes-resistant LEW.1AR1 irrespective of the stages of islet infiltrations (day 40 - day 60). The early islet infiltration process in LEW.1AR1-iddm rats correlated with a significant higher level of monocytes and granulocytes (1.6-fold). At day 60 there was a significant increase of eosinophil granulocytes in rats with severe islet infiltration. The PBMC profile correlated with higher levels of proinflammatory cytokines TNFα, IFNγ, IL1β at the early stage of islet infiltration (day 40) indicating an activation of the innate immune system. At day 40 PLNs from rats with islet infiltration showed significantly higher levels of CD25 (1.9 fold) and L-Selectin (3.1 fold) but not of proinflammatory cytokines. With progression of islet infiltration (day 45) we observed an increase of IFNγ (1.9 fold) and TGFβ (1.3 fold) followed by an intermittent increase of the antiinflammatory cytokine IL4 (2.5 fold) at day 50. From day 55 there was a marked increase of IFNγ (3.1 fold), NRP1 (2.5 fold) and TGFβ (1.9 fold) in PLNs from infiltrated pancreas. At day 60 PLNs from infiltrated pancreata showed a significant increase of IFNγ (3.5 fold), TNFα and IL10 (1.8 fold) as well as the T cell markers CTLA4 (3.0 fold), CD25, FoxP3 and L-Selectin (1.6 fold).
Conclusion: Although the lymphocyte content is lower in diabetes prone LEW.1AR1-iddm rats this trait was not indicative for the process of islet infiltration. At the early stage of islet infiltration there is a clear activation of the innate immune system in PBMCs while PLNs showed no increase of proinflammatory cytokines and markers of T cell activation. With progression of islet infiltration there was a delayed increase of inflammatory markers in PLNs. Our data provide evidence that activation of the innate immune system is a hallmark of early islet infiltration either as trigger or bystander effect of local inflammation. Immune cell activation in PLNs during progression of beta cell destruction is not mirrored by corresponding activation in PBMCs. Only at late stages of islet infiltration there is a good correlation between immune cell activation markers in peripheral blood and PLN.

In depth lipidomic characterisation of the early stages of the type 1 diabetes pathogenesis
A. Overgaard[1], C. Haase[2], P. Meikle[3], F. Pociot[1];
[1]Glostrup Research Institute, 2600, Denmark, [2]Novo Nordisk, Måløv, Denmark, [3]Baker IDI Heart and Diabetes institute, Melbourne, Australia.

Background and aims: The early mechanisms regulating progression towards β cell failure in type 1 diabetes are poorly understood, but it is generally acknowledged that several factors such as genetic and environmental components are involved. The lipidomic phenotype is sensitive to minor variations in both, and may thus reflect changes that lead to the development of type 1 diabetes. We used a novel extraction technique and subsequent liquid chromatography electrospray ionisation tandem mass spectrometry to profile the lipididome in depth in a genetically modified murine model resembling the early stages of type 1 diabetes. We hypothesize that alterations in the lipidomic phenotypes characterize the early pathogenesis of T1D and by profiling of these provide new insight to the development of type 1 diabetes.
Materials and methods: For this study a transgenic non-diabetes prone C57BL/6 mouse expressing CD154 under the control of the rat insulin promoter (RIP) crossed into the immuno-deficient recombination-activating gene (RAG) knockout (-/-) C57BL/6 mice was used. These mice have reduced β-cell mass, but no lymphocytic infiltration is seen and full blown diabetes does not occur. We considered these mice a good model for addressing the lipidomic phenotype of the early stages of type 1 diabetes. We compared plasma and liver samples from age matched (12 weeks) groups of the RIP CD154 x RAG -/- with their background RAG -/- and C57BL/6 mice (n=10, n=11 and n=11, respectively). The lipidome of plasma and livers were assessed using a novel high through-put extracting technique and subsequent liquid chromatography electrospray ionisation tandem mass spectrometry based multiple reaction monitoring capable of detecting >400 different lipids.
Results: Comparison of the lipidome of the RIP CD154 x RAG -/- mouse to RAG -/- mice and C57BL/6 mice revealed alterations of >100 different lipids in plasma and livers, dominated by the lipid classes phosphocholine and

spingomyelin, with lower total levels seen in the RIP CD154 x RAG -/- mice p<0.05 (Bonferonni corrected). These two classes of lipids are considered donors of choline, where a lower level of this previously has been linked to development of type 1 diabetes. The group of plasmalogens that protects cells from oxidative damage was also significantly lower in the RIP CD154 x RAG -/- mice, p<0.05 (Bonferonni corrected).
Conclusion: These observations provide evidence that lipid disturbances precede the onset of type 1 diabetes, and could by closer examinations lead to earlier diagnosis of patients and identification of new pharmaceutical drug targets.

Carbon monoxide-releasing molecule CORM-A1 ameliorates islet-directed autoimmunity in mice
I. Nikolic[1], T. Saksida[1], M. Vujicic[1], I. Stojanovic[1], F. Nicoletti[2], S. Stosic-Grujicic[1];
[1]Immunology, Institute for Biological Research "Sinisa Stankovic", University of Belgrade, Serbia, [2]Biomedical Sciences, School of Medicine, University of Catania, Italy.

Background and aims: The inflammatory lesions within islets of those with type 1 diabetes (T1D) are characterized by a decrease (or absence) of insulin-producing β cells along with a pancreatic islet cell infiltrates composed of T lymphocytes, B lymphocytes, macrophages, and lesser numbers of other immune cells. Recent studies identified carbon monoxide (CO) as a potential therapeutic molecule due to its anti-inflammatory and anti-apoptotic abilities. CORM-A1 is a pharmacologically designed molecule that is capable of modulating physiological functions via liberating CO. However, its biological activity in T1D has not been examined so far. Therefore, in the present study we investigated possible therapeutic value of CORM-A1 in the model of diabetes induced in C57BL/6 mice by multiple low doses of streptozotocin.
Materials and methods: T1D was induced in C57BL/6 mice with multiple low doses of steptozotocin (MLDS, 5 x 40 mg/kg). CORM-A1 (2 and 4 mg/kg) was administered as prophylactic, or therapeutic treatment. The disease severity was evaluated by weekly measurement of blood glucose level and by histological analyses of the pancreas. To determine the effect of CORM-A1 within the local environment of the endocrine pancreas, infiltrated mononuclear cells were isolated from pancreata at day 8-10 of disease induction and phenotype of cell infiltrates was determined by flow cytometric analysis and real time PCR.
Results: Administration of CORM-A1 during diabetes induction, or even after the induction of the disease, improved clinical and histological signs of the disease. Flow cytometric analyses revealed reduction of percentage of CD4+, CD8+, B220+ (B cells) and pro-inflammatory M1 (F4/80+CD40+) macrophages while anti-inflammatory M2 (F4/80+CD206+) macrophage cell number was unchanged in pancreatic infiltrates of CORM-A1-treated mice compared to diabetic mice. Also, flow cytometric analyses showed reduced proportion of Th1 (CD4+IFN-γ+) infiltrated cells and increased proportion of Th2 (CD4+IL-4+) infiltrated cells in CORM-A1-treated mice compared to control MLDS-treated mice, as well as an expression of these cytokines per cell confirmed by mean fluorescence intensity. However, Th17 cells remained unchanged in both groups. In line with these results, mRNA expression of Th signature cytokines, IFN-γ and IL-4, was inversely regulated, resulting in lower IFN-γ/IL-4 ratio in CORM-A1-treated mice.
Conclusion: Our study suggests that CORM-A1 exerts its protective effect by preventing the infiltration of cells in the pancreas. Furthermore, CORM-A1 suppresses autoimmune response by shifting the balance towards protective Th2 cells. CORM-A1 may thus represent a novel treatment strategy that would operate through interfering with an islet-directed autoimmune response.

Identification of a targetable pathway that controls plasmacytoid dendritic cells and the interferon response
J. Agudo[1], A. Ruzo[1], N. Tung[1], A. Baccarini[1], M. Leboeuf[2], D. Hashimoto[2], C. Becker[2], L.-A. Garrett-Sinha[3,4], C. Kuo[4], B. Brown[1,2];
[1]Genetics and Genomic Sciences, Mount Sinai School of Medicine, New York, [2]Tisch Cancer Institute, Mount Sinai School of Medicine, New York, [3]Department of Biochemistry, New York State University at Buffalo, [4]Department of Medicine, Stanford University, USA.

Background and aims: Plasmacytoid dendritic cells (pDCs) are crucial bridge between the innate and adaptive immune system. pDCs constitutively express TLR7 and TLR9, the toll like receptors that recognize ssRNA and unmethylated DNA, and in response to pathogen associated nucleic acids, pDCs release copious amounts of type I interferon (IFN), which initiates an inflammatory response that recruits and facilitates T cell and B cell immunity. pDCs play a well defined role in the development of autoimmune diseases, such as lupus erythematosus, and recently pDCs were shown to be crucial in the early induction of type 1 diabetes (T1D). Owing to their role T1D pathogenesis, there is a major medical need for strategies that can modulate pDCs and the interferon response.
Materials and methods: Here we set out to delineate the molecular pathways that control pDC's response to nucleic acids and their production of IFN, and to identify genes within these pathways that can be targeted to subdue pDCs during the early stages of T1D development.
Results: We have discovered that the microRNA miR-126 is highly and specifically expressed in mouse and human pDCs, but not other immune cells. Phenotypic analysis revealed that in the absence of miR-126, pDCs undergo early apoptosis and have a diminished capacity to become activated and produce IFN in response to ssRNA and CpG DNA, and miR-126-/- mice injected with TLR7 or TLR9 agonists have a major impairment in their IFN response. Unexpectedly, we found that vascular endothelial growth factor receptor 2 (VEGFR2) is downregulated on pDCs in the absence of miR-126. VEGFR2 is the main receptor for the angiogenic factor VEGF and has, until now, considered to be expressed only in endothelial cells. However, we found that VEGFR2 is highly expressed on mouse and human pDCs, but not other hematopoietic cells, and that knockout of VEGFR2 specifically in DCs impairs their ability to produce IFN similar to the loss of miR-126. While the VEGF pathway has long been known to be key in angiogenesis, these studies uncover a previously unappreciated role for the miR-126/VEGFR2 axis in the innate response to nucleic acids through multiscale control of pDC development and function.
Conclusion: These results link the VEGFR2/miR-126 axis to control of the innate immune response, and, since anti-VEGF and anti-VEGFR2 drugs are already in the clinic, our findings also provide a potential therapeutic means of modulating the response. Elevated VEGF levels and IFN have been associated with early myeloid infiltration in islets during the stages of pre-diabetes. We are now investigating if anti-VEGF drugs can decrease pDC infiltration and IFN production both in NOD mice and *db/db* mice to control T1D and T2D development.

Insulin resistance, beta cell function and the effect of non-HLA genetic variants in Finnish DIPP study children with HLA-conferred risk for type 1 diabetes

M.K. Koskinen[1], R. Hermann[1], J. Matomäki[1], J. Mykkänen[1], M. Vähä-Mäkilä[1], T. Simell[1], S. Simell[1], M. Mäkinen[1], V. Simell[1], M. Saarinen[2], J. Ilonen[3,4], M. Knip[5,6], O. Simell[1];
[1]Department of Pediatrics, University of Turku, [2]Research Centre of Applied and Preventive Cardiovascular Medicine, University of Turku, [3]Department of Clinical Microbiology, University of Eastern Finland, Kuopio, [4]Immunogenetics Laboratory, University of Turku, [5]Department of Pediatrics, Tampere University Hospital, [6]Children's Hospital, University of Helsinki, Finland.

Background and aims: Like in type 2 diabetes (T2D), insulin resistance (IR) has been hypothesised to play a role in the pathogenesis of type 1 diabetes (T1D). The association of different beta cell-specific autoantibodies with various HLA haplotypes and non-HLA polymorphisms is characteristic for the immune mechanisms leading to T1D. The aims of this study were to characterize in a longitudinal manner: 1. Whether markers of insulin resistance show association with diabetes-associated autoantibodies; 2. How different genetic variants known to be associated with insulin resistance and T2D or T1D affect insulin secretory capacity and development of insulin resistance in children at increased genetic risk for T1D; 3. How these factors are related to emergence of various autoantibody patterns.
Materials and methods: Type 1 Diabetes Prediction and Prevention Project in Finland (DIPP) is a population-based follow-up study of genetically susceptible children to T1D. To date, a total of 1101 intravenous glucose tolerance tests (IVGTTs) have been performed to 492 children in the Turku DIPP center. 92 of these children have been diagnosed with T1D. Insulin resistance values were measured using HOMA-IR (homeostasis model assessment) and beta cell function was evaluated by first phase insulin response (FPIR). As part of regular follow-up visits, diabetes-associated autoantibodies were analysed. Autoantibody measurements were carried out using techniques standardized according to DASP recommendations. Selected non-HLA genetic variants (n=23) were analysed in a subcohort of study children. Statistical analyses were performed using RM ANOVA for log-transformed values. The models included the child's progression to diabetes, autoantibody level, genetic variants and their interaction. In case of positive interaction the progression groups were analysed separately.
Results: The relationship between IAA and fasting insulin and HOMA-IR levels differed between progressors and non-progressors (p=0.002 for fasting insulin and p=0.003 for HOMA-IR).Progressors' fasting insulin had a strong positive correlation with IAA (β(se)=0.11(0.032), p<0.001). This association of fasting insulin and IAA can also be seen in HOMA-IR (β(se)=0.12(0.036); p=0.002). The non-progressors showed no correlation between IAA levels and fasting glucose or HOMA-IR. Other antibodies (IA2, GAD) showed no association with fasting insulin. Fasting glucose did not associate with any of the antibodies. Analyses of genetic variants are ongoing and results will be reported in the meeting.
Conclusion: Our preliminary findings imply that there is a relationship between insulin resistance and serum IAA levels in children who later progress to T1D.

Better glycaemic control but similar diabetes associated complications in LADA compared to type 2 diabetes in the DPV cohort in Germany and Austria

N.C. Schloot[1], K. Badenhoop[2], W. Kerner[3], H.-R. Engels[4], A. Dapp[5], J. Bayer[6], G. Goetz[7], A. Zimmermann[8], I. Schuetz-Fuhrmann[9], R. Holl[10], for the DPV initiative and BMBF competence net Diabetes mellitus;
[1]Heinrich-Heine University, German Diabetes Center, Institute for Clinical Diabetology, Düsseldorf, Germany, [2]University Hospital, Goethe-University Frankfurt, Germany, [3]Klinikum Karlsburg, Germany, [4]Internal Medicine, Berlin-Hellersdorf, Germany, [5]Internal Medicine, Spaichingen, Germany, [6]Diabetes Center, Forchheim, Germany, [7]Internal Medicine, Kirchheim-Nuertingen, Germany, [8]Diabetes Center, Bad Aibling, Germany, [9]Krankenhaus Hietzing, Vienna, Austria, [10]Institute of Epidemiology and Medical Biometry, Ulm University, Germany.

Background and aims: We characterized German/ Austrian LADA (latent autoimmune diabetes of adult) in comparison to type 1 (T1D) and type 2 diabetes (T2D) for anthropometry, HbA1c, associated complications, insulin therapy.
Materials and methods: Data were analyzed from anonymized longitudinal electronic records of 190,703 people with diabetes manifestation > age of 35 yrs from the German/Austrian multicenter Diab Pat Verlaufsdokumentation (DPV) database. Patients were categorized "LADA" if islet antibodies were present and without insulin therapy for at least 6 months after diabetes onset. T2D patients were islet antibody negative, while T1D patients were islet antibodies positive and received insulin at diabetes onset. Anthropometric data, diabetes duration, diabetes associated complications and insulin dose per kg body weight were compared for the most recent year of follow-up. Analyses were adjusted for age, sex, BMI and diabetes duration.
Results: LADA patients (n=238) were significantly older (median age 59.05yrs) than T1D (n= 1128, age 53.65 yrs) and slightly younger than T2D (n=2744, age 60.75yrs) (p<0.000001). Diabetes duration in LADA (6.6 yrs) was longer compared to T1D (2.80yrs) and similar to T2D (6.50 yrs) (p<0.000001), BMI of LADA (29.38 kg/m2) was higher than in T1D (25.48 kg/m2) and similar to T2D (30.10kg/m2) (p<0.000001). Upon adjustment for age, sex, BMI and diabetes duration, HbA1c was significantly lower in LADA (8.0%) compared to T1D (8.4%) and also to T2D (8.2%) (p<0.05). 72% of LADA and 63% of T2D were treated with insulin. Insulin dosage did not differ between LADA (0.61U/kg body weight), T1D (0.62) and T2D (0.66) (p>0.05). Severe hypoglycaemia was more frequent in T1D (0.38 events/ patient-year) versus LADA (0.12; p< 0.0001) or T2D(0.038; p < 0.0001). Prevalence of hypertension was similar in LADA (73 %) and T2D (73%), significantly more frequent compared to T1D (57%, (p<0.0001). Dyslipidemia occurred more often in T2D (78%) or LADA (78%) compared to T1D (64%, p<0.0001). Microalbuminuria was less frequent in T1D (26%) compared to LADA (37%) and T2D (37%, p<0.003)) , similar to macroalbuminuria (T1D: 1.6%, T2D: 3.9%, LADA 4.5% (p<0.02/p<0.001). Non-proliferative (NPR) and proliferative retinopathy (PR) was diagnosed with comparable frequencies in T1D (NPR 15%; PR 3.9%) , LADA (15% /2.3%) and T2D (15%/4.3%).
Conclusion: LADA patients showed better glycemic control with more severe hypoglycemic events compared to patients with T2D. LADA and T2D did not differ for hypertension, dyslipidemia, albuminuria and retinopathy. Type 1 diabetes patients showed HbA1c similar to T2D and were diagnosed less frequently with hypertension, dyslipidemia or albuminuria, but similar rates of retinopathy.

Incidence of autoimmune antibodies in diabetes type 1 patients with long diabetes duration: the JEVIN-Trial

T. Heller[1], C. Kloos[1], R. Schiel[2], G. Wolf[1], U.A. Müller[1];
[1]Internal Medicine III, University Hospital Jena, [2]Clinic for Diabetes und Metabolic diseases, MEDIGREIF Inselklinik Heringsdorf, Germany.

Background and aims: The JEVIN-Trial started as a cross-sectional survey in 1989/90 on the quality of diabetes care of insulin treated patients with diabetes (DM) type 1 and 2 (n=190; age 16-60y), registered in Jena. Since then, the population with DM1 was followed up every 5 years until 2009/10. The aim of the present investigation was to detect the incidence of autoimmune antibodies like insulin auto-antibodies (IAA), thyreoperoxidase (TPO)

antibodies, glutamate decarboxylase (GADII) auto-antibodies and parietal cell antibodies (PCA) in patients with DM1 and long diabetes duration. We detected the prevalence of clinical autoimmunethyreoiditis and vitamin B12 deficiency.
Materials and methods: 131 patients with DM1 were analyzed in 1989/90. Of the living population in 2009/10 (n=104) 83 (79,8%) patients were identified and 76 (92%) patients were screened regarding the IAA; pathologically with a titre of >0,4U/ml, TPO antibodies with >60U/ml, GADII antibodies with >0.9U/ml and positive PCA antibodies with >160. Mean age of the population was 58.1y; women 34%, diabetes duration 35,1y (20-68), BMI 26,56kg/m2, blood pressure 144/83mmHg, A1c 6.9% (DCCT adj.).
Results: Of all patients 71% (n=54) had at least one increased antibody titre. Patients with increased antibodies had significant shorter DM-duration (33y vs 42y;p=0.03) and higher A1c (7% vs 6.5%;p=0.015). Most patients had pathologically elevated IAA with 52.6% (n=40), mean titre 9.9U/ml ±10.51 (min: 0.6; max: 36.5U/ml). These patients were by trend younger (56y vs 61y;p=0.052) and had by trend shorter DM-duration (33y vs 38y;p=0.087). GAD II antibodies were elevated in 30.3% (n=23), mean titre 33.2U/ml ±51.78 (min: 1.0; max: 166.2U/ml). These patients had significant shorter DM-duration (30y vs 38y;p=0.001) and by trend higher A1c (7.2% vs 6.7%;p=0.07). Elevated TPO antibodies were detected in 24% (n=18), mean titre 1306.7 U/ml ± 1999.22 (min: 65; max: 8283.4U/ml) and 7 patients had clinical autoimmunethyreoiditis. No difference between patients with pathologically and patients with normal TPO antibody titre were found regarding age, DM duration, BMI, blood pressure and A1c. PCA antibodies were present in 5.3% (n=4) with a mean of 880.0 ±1120.0 (min: 320.0; max: 2560.0). These patients had by trend a higher A1c as patients without increased PCA-antibodies (7.1% vs 6.4%:p=0.062). No one had clinical vitamin B12 deficiency.
Conclusion: About two third of patients with long term diabetes type 1 had at least one positive autoantibody. Only 1/3 of all patients had still pathologically increased GADII antibodies. Of patients with elevated TPO antibodies, less of half had clinically autoimmunethyreoiditis.

559

Subgroup analysis of DIA-AID 1, an immune intervention phase 3 study in newly diagnosed type 1 diabetes patients
P. Pozzilli[1], I. Raz[2], T. Linn[3], F. Bonnici[4], D. Elias[5], A. Avron[5], M. Tamir[5], R. Eren[5], S. Dagan[5];
[1]Endocrinology & Metabolic Diseases, University Campus Biomedico, Rome, Italy, [2]Diabetes Unit, Department of Medicine, Hadassah University Hospital, Jerusalem, Israel, [3]University Hospital Giessen, Germany, [4]New Groote Schuur Hospital, Cape Town, South Africa, [5]Andromeda Biotech Ltd., Yavne, Israel.

Background and aims: DIA-AID 1, a phase 3 clinical trial in newly diagnosed type 1 diabetes (T1D) adult patients demonstrated preservation of endogenous insulin secretion and clinical benefits after 2 years of treatment with DiaPep277®. Analysis of the modified intent-to-treat (mITT) population data revealed that DiaPep277® significantly preserved C-peptide levels compared to placebo (treatment effect of 23.4%, p=0.037). This preservation was supported by clinical outcomes such as a significantly higher percentage of patients who maintained HbA1c levels ≤ 7% at study end. In addition, a significantly higher proportion of treated patients were in partial remission at study end. DiaPep277® treated patients experienced fewer hypoglycemic events with a significant decrease in the rate of hypoglycaemia. The aim of this analysis was to define the profile of patients who better responded to treatment.
Materials and methods: We conducted analyses of 10 subgroups looking for a treatment effect higher than that observed in the entire mITT population. These included baseline insulin dose, fasting C-peptide, HbA1c, age, gender, BMI and body weight, seasonality, HLA genotype and Northern European phenotype.
Results: The baseline characteristics that mostly impacted the treatment effect of DiaPep277® were the insulin dose, age, Northern European phenotype and HLA genotype. In 164 patients who were randomized with baseline insulin ≤ 0.35 IU/kg/day, the treatment effect was 34.5% (p=0.009) compared to 7.6% in patients randomized with baseline insulin > 0.35 IU/kg/day (144 patients). Among 152 patients older than 27 years, the treatment effect was 44.4% (p=0.009). In 99 patients from Northern European countries with high prevalence of T1D, the treatment effect was 34% (p=0.046). In 142 patients with moderate and high risk HLA genotype, the treatment effect was 35.4% (p=0.017). There were too few patients to establish an effect in the low risk HLA genotype group. Analysis of subgroups according to their baseline fasting C-peptide or their baseline HbA1c, gender, BMI, body weight and seasonality did not show a difference in treatment effect from the entire mITT population.
Conclusion: Adult patients requiring lower insulin doses at diagnosis could potentially benefit the most from DiaPep277®. The geographical and HLA analyses indicate that patients with a higher genetic predisposition to T1D responded well to treatment.
Supported by: NCT006 15 264

Long term safety and efficacy of DiaPep277® - initial results of an extension study to DIA-AID 1
O. Mosenzon[1], I. Raz[1], Z. Landau[2], L. de Vries[3], R. Eren[4], D. Elias[4], A. Avron[4], M. Tamir[4], S. Dagan[4], J. Wainstein[2];
[1]Diabetes Unit, Department of Internal Medicine, Hadassah University Hospital, Jerusalem, [2]Diabetes Unit, Wolfson Medical Center, Holon, [3]Institute for Endocrinology and Diabetes, Schneider Children's Medical Center, Petach Tikva, [4]Andromeda Biotech Ltd., Yavne, Israel.

Background and aims: DIA-AID 1, a phase 3 clinical trial in newly diagnosed type 1 diabetes (T1D) adult patients demonstrated preservation of endogenous insulin secretion and clinical benefits after 2 years of treatment with DiaPep277®. An open-label, active-treatment extension study to DIA-AID 1, to evaluate long-term safety and efficacy of DiaPep277® is ongoing in 3 medical centers in Israel.
Materials and methods: Patients eligible for the extension study were those who completed the DIA-AID 1 study and had stimulated C-peptide levels ≥0.2 nmol/l regardless of their original allocation, DiaPep277® or Placebo. Patients are being treated with 1 mg of the drug administered for 2 years at 3 month intervals in addition to insulin. Forty-three patients were enrolled in the extension study, of which 28 were originally treated with DiaPep277® (DiaPep277® - DiaPep277® treated) and 15 with Placebo (Placebo -DiaPep277® treated).
Results: Preliminary results from 32 patients (17 DiaPep277® - DiaPep277® treated and 15 Placebo - DiaPep277® treated) who completed the 2 year extension study indicate that there are no safety concerns. Out of 81 adverse events reported by 31 subjects, only two were related to the study drug, both of which were resolved. Only one severe adverse event was reported which was not considered related to the study medication. The most common non-related adverse events were infections and infestations (35/81, 43%) followed by gastrointestinal disorders (9/81, 11%). A higher proportion of patients who were treated for 4 years with DiaPep277® maintained fasting C-peptide ≥ 0.2 nmol/l at the end of the 2-year extension study, 42% compared to only 17% of the Placebo -DiaPep277® treated patients. Similarly, a higher proportion of patients who were treated for 4 years with DiaPep277® maintained target HbA1c ≤ 7% at the end of the extension study, 59% vs 27% of the Placebo - DiaPep277® treated patients.
Conclusion: These results suggest that 4 years treatment with DiaPep277® is safe and well tolerated. The extended treatment maintains patients in better glycemic control and preserves beta cell function. The full results of this study will be available by the end of 2013.

Serum vitamin D may modulate fetuin-A, cytokines and insulin resistance across the spectrum of glycaemia
D. Dutta[1], S.A. Mondal[2], A.H.H. Reza[2], A. Sinha[3], S. Chakraborty[2], S. Mukhopadhyay[1];
[1]Department of Endocrinology & Metabolism, IPGMER & SSKM Hospital, [2]Department of Biochemistry, IPGMER & SSKM Hospital, [3]Department of Endocrinology & Metabolism, Medical College & Hospitals, Calcutta, India.

Background and aims: Vitamin-D is believed to modulate glucose homeostasis and cytokines. Fetuin-A (FetA) is believed to modulate insulin resistance (IR) and inflammation, by being the principle ligand for free fatty acid induced activation of toll like receptor-4 and NF-κB. TNFα, IL1β and IL6 are the principle cytokines implicated in IR. IL1ra is a predominantly anti-inflammatory cytokine. This study aimed to evaluate the relation between vitamin-D, FetA, cytokines and IR in normal individuals (NI), individuals with prediabetes (IPD) and newly diagnosed treatment naïve type-2 diabetes (T2DM).

Material and methods: 30 NI (Group-I), 57 IPD (Group-II) and 37 T2DM (Group-III) who had persistent normoglycaemia, IFG and/or IGT and blood glucose in diabetes range respectively, over 2 OGTTs over a week, without any co-morbidities underwent estimation of insulin, 25-hydroxyvitamin-D (25OHD) (CLIA, Architect, USA), IL6, TNFα, IL1ra, IL-1β and FetA (ELISA, Ray Biotech, USA).
Results: 75% and 41.1% individuals (M:F=57:67) had 25OHD ≤30 and ≤20ng/ml respectively. Mean age of NI, IPD and T2DM was 39.7±7.7, 42.4±8.8, 42.2±6.7 years respectively. Significantly increased FetA (489.2±103.7 vs 443.8±116.6ng/ml; P=0.02), hsCRP (3.2±1.9 vs. 2.3±1.8mg/L; P=0.005), IL1β (7.9±7.7 vs. 6.1±2.9pg/ml; P=0.03), fasting glucose (112.4±22.4 vs. 105.5±22.8mg/dl; P=0.04) and IR (HOMA2IR; 1.5±0.99 vs. 1.1±0.8; P=0.01) was observed in individuals with metabolic syndrome (MetS; IDF criteria; n=46) compared to those without (n=78). In NI, HOMA2-IR had positive correlation with BMI (r=0.57; P=0.02), IL1β (r=0.52; P=0.02), hsCRP (r=0.48; P=0.06) and FetA (r=0.49; P=0.04). Serum 25OHD had inverse correlation with IL6 (r=-0.47; P=0.006), IL1β (r=-0.56; P=0.01), hsCRP (r=-0.46; P=0.01) and positive with IL1ra (r=0.42; P=0.02). BMI positively correlated with IL1ra (r=0.45; P=0.01). Among IPD, HOMA2-IR had positive correlation with BMI (r=0.39; P<0.001), hsCRP (r=0.23; P=0.06) and TNFα (r=0.23; P=0.03). Serum 25OHD had inverse correlation with HOMA2-IR (r=-0.31; P=0.001), TNFα (r=-0.28; P=0.003), IL6 (r=-0.26; P=0.006), IL1β (r=-0.27; P=0.02), FetA (r=-0.31; P=0.01) and positive correlation with IL1ra (r=0.33; P=0.006). IL1ra was negatively correlated with TNFα (r=-0.3; P=0.01) and IL6 (r=-0.28; P=0.03). In T2DM, 25OHD had positive correlation with IL1ra (r=0.36; P=0.02) and negative with FetA (r=-0.35;P=0.03).
Conclusion: The inverse correlation of 25OHD with inflammatory cytokines along with positive correlation with IL1ra supports anti-inflammatory role of vitamin-D. It may be hypothesized that vitamin-D may exert its beneficial effects on IR through decreased inflammation and modulation of FetA, as evidenced by significant inverse correlation of 25OHD with FetA in IPD and T2DM.

Comparison of clinical, anthropometric, glycemic, insulin resistance, inflammatory cytokines, fetuin

Parameter	Group-I (Normoglycaemia) (n=30)	Group-II (Prediabetes) (n=57)	Group-III (Diabetes) (n=37)	P-value
BMI (kg/m2)	24.69±2.79	26.4±4.92	26.21±4.97	0.18

25-hydroxy vitamin D and thyroid autoimmunity in patients with type 2 diabetes mellitus and controls

K.A. Toulis, X. Tsekmekidou, M. Yavropoulou, E. Papanastassiou, A. Papazisi, A. Gotzamani-Psarakou, J. Yovos, K. Kotsa;
Aristotle University of Thessaloniki, Greece.

Background and aims: Although the association between type 1 Diabetes Mellitus and thyroid autoimmunity (TAI) is established, relevant evidence is inconclusive in the setting of type 2 Diabetes Mellitus (T2DM). Several lines of evidence suggest the role of vitamin D in the regulation of the immune system. Thus, we aimed to explore the putative association between T2DM and TAI focusing on the role of 25-hydroxy Vitamin D [25(OH)D].
Materials and methods: Subjects with an established diagnosis of T2DM were consecutively recruited from the outpatient diabetes clinic of a tertiary reference hospital during 2012. Community-dwelling individuals from the same region were also recruited as controls. Medical history were retrieved and blood samples were drawn for the measurement of 25(OH)D levels and titers of autoantibodies against thyroid peroxidase (TPOab) and thyroglobulin (TGab). A subject was designated as TAI positive if either TPOab or TGab was above 100 U/mL. To explore the potential association between 25(OH)D and thyroid autoimmunity while controlling for potential confounders - namely age, gender, body mass index (BMI), and presence of T2DM, multivariate logistic regression analyses were undertaken. Standardized values (z-scores) of the natural logarithms for all continuous variables were used. All analyses were undertaken within Stata 10.0.
Results: A total of 498 participants (264 patients with T2DM and 234 healthy controls) constituted the study population. Patients with T2DM were younger (mean age: 67.6 versus 72.2, Mann-Whitney $p < 0.001$), had significantly lower 25(OH)D levels (Mann-Whitney $p < 0.001$) and higher anti-TPO titers (Mann-Whitney p: 0.005) compared to controls. TAI positivity was detected in 18.8% patients with T2DM and 14.3% controls. Multivariable logistic regression analyses adjusting for age, gender, body mass index and presence of T2DM suggested that 25(OH)D levels were significantly associated with the presence of thyroid autoimmunity [Odds ratio = 1.49, 95% Confidence Interval (CI) = 1.06 - 2.1, $p = 0.023$]. Presence of T2DM and female gender were also significant predictors.
Conclusion: In an unselected general elderly population, 25(OH)D levels are independently associated with the presence of thyroid autoimmunity. Each unit (expressed in standard deviations, corresponding to approximately 12 ng/mL) increase in 25(OH)D levels is associated with a 50% increase (in odds) for thyroid autoimmunity.

Expression of circulating CD4+CD5+FOXP3+ regulatory T cells in obese patients

T.T. Che, Y. Ren, S.F. Liu;
Endocrinolory and Metabolism, West China Hospital of Sichuan University, Chengdu, China.

Background and aims: $CD4^+CD25^+Foxp3^+$ regulatory T cells (Treg) are natural T cells, which play an important role in immunopathogenesis and maintenance of immunologic balance. Recently, a few studies found $CD4^+CD25^+Foxp3^+$Treg and it's highly expressed molecule cytotoxic T-lymphocyte-associated antigen-4 (CTLA-4) were associated with insulin resistance. We carried this study to further investigate the expression of circulating $CD4^+CD25^+Foxp3^+$ Treg in obese patients and its association with obesity and insulin resistance.
Materials and methods: 20 obese patients without diabetes and 20 obese patients with newly diagnosed diabetes whose body mass index (BMI) were higher than or equal to 28kg/m^2 were enrolled. 20 non-obese healthy subjects were also enrolled in control group. The frequencies of circulating $CD4^+CD25^+Foxp3^+$Treg and the expression levels of CTLA-4 on these cells were analyzed by flow cytometry. The relationship between $CD4^+CD25^+Foxp3^+$Treg and insulin resistance were analyzed by correlation analysis and stepwise multiple regression. Insulin resistance was measured by HOMA-IR.
Results: $CD4^+CD25^+Foxp3^+$Treg in obese patients without/with diabetes were(3.86±0.27)% and(3.76±0.25)% respectively, which were both significantly lower than that in healthy control group(6.36±0.21)% (P<0.05). No statistic difference was found between obese diabetic patients and obese non-diabetic patients. The expression levels of CTLA-4 in $CD4^+CD25^+Foxp3^+$ regulatory T cells in obese patients without/with diabetes were (77.27±2.81)% and (60.32±2.48)% respectively, which were all significantly lower than that in controls(80.09±1.69)% (P<0.05). And obese patients with diabetes was lower than that in non diabetes (P<0.05). In addition, BMI, WC and HOMA-IR were all significantly affecting expression numbers of $CD4^+CD25^+Foxp3^+$Treg (Beta= -0.322, -0.344, -0.331, F = 78.519, P<0.001).
Conclusion: $CD4^+CD25^+Foxp3^+$Treg and expression of CTLA-4 were significantly decreased in obese patients, especially in obese diabetic patients. It may play a role in obesity and insulin resistance.

PS 035 Islet transplantation

564

Acute hypoxia impacts similarly on encapsulated and non-encapsulated human pancreatic islets

I. Hals[1], A. Rokstad[1], B.L. Strand[1], V. Grill[1,2];
[1]Inst of Cancer Researsch and Molecular Medicine, NTNU, Faculty of Medicine, Trondheim, Norway, [2]Dept Internal Medicine, University Hospital of Trondheim, Norway.

Background and aims: Human islet transplantation as a treatment for type 1 diabetes is hampered by the need of life-long immunosuppression to avoid islet graft rejection. Microencapsulation could provide immunoprotection to transplanted islets but also represents an extra barrier between islets and the blood oxygen supply. This could possibly increase the risk of islet damage caused by the hypoxic environment that encounter the islet graft during the early post-transplantation period. Here we compared the impact of hypoxia on microencapsulated vs. non-encapsulated islets to hypoxia.
Materials and methods: Human islets (University of Illinois, Chicago), alginate microencapsulated or non-encapsulated, were exposed to experimental hypoxia (0.1-0.3 % O_2) for 8 h followed by 14-18 h of re-oxygenation. Islet viability was then tested by the MTT assay and by O_2 consumption measurements (O-2k, Oroboros), and islet function was assessed by insulin secretion.
Results: Hypoxia reduced viability as measured by MTT by 33.8 ± 3.5 % in encapsulated islets and by 42.9 ± 5.2 % in non-encapsulated islets ($p < 0.2$ for difference, n = 12). Basal oxygen consumption (at 5.5 mM glucose) was reduced by 22.0 ± 6.1 % in encapsulated islets and by 24.8 ± 5.7 % in non-encapsulated islets ($p < 0.8$ for difference, n = 5-6). FCCP-induced oxygen uptake (reflecting total oxidative capacity) was for encapsulated islets 20.4 ± 4.4 pmol/s/mill cells and for non-encapsulated islets 15.0 ± 3.7 pmol/s/mill cells ($p < 0.4$ for difference, n = 5-6). Previous hypoxia did not affect these values. The stimulation index, i.e. the ratio of stimulated (by 16.7 mM glucose) over basal secretion was decreased less by hypoxia in encapsulated islets (by 29.0 ± 9.7 % vs. 66.0 ± 7.5 % in non-encapsulated islets, $p < 0.02$, n = 8).
Conclusion: Microencapsulation of human islets does not increase susceptibility to negative effects by acute hypoxia. This is a positive finding in relation to potential use of encapsulation for islet transplantation.

Improved siRNA delivery to pancreatic islets using R3V6 peptide carrier

S.-H. Ihm[1], M.-G. Choi[1], H.-J. Yoo[1], M. Lee[2], J. Ihm[3];
[1]Internal Medicine, Hallym University, Anyang, [2]Bioengineering, Hanyang University, Seoul, [3]Chemistry, Kyonggi University, Suwon, Republic of Korea.

Background and aims: Transplantation of isolated pancreatic islets is a promising approach to the treatment of type 1 diabetes mellitus. To enhance survival rate of the transplanted islets, target gene silencing and cytoprotective drug treatment of islet cells have been attempted. However, the efficient delivery of siRNA and hydrophobic drugs into intact islets is a bottleneck. R3V6 peptides, composed of 3 arginines and 6 valines, form self-assembled micelles with hydrophobic cores in an aqueous solution, and have potential as an efficient carrier of siRNA and hydrophobic drug combination delivery. The aim of this study is to improve transplanted islet cell viability through iNOS gene silencing and beta-estradiol (E2) delivery using novel R3V6 peptide carrier.
Materials and methods: Isolated mouse islets were transfected with siRNA-5'FITC using E2-loaded R3V6 carrier or lipofectamine 2000, and transfection efficiency and cytotoxicity were analyzed by confocal microscope and flow cytometry. After transfection of mouse islets with E2-loaded R3V6 peptides carrying siRNA for iNOS (R3V6-E2-iNOS siRNA), iNOS gene expression was assessed by real time RT-PCR. The effect of gene silencing was assessed with inflammatory cytokine-induced cell death (AV-PI flowcytometry) and marginal mass islet transplantation into renal subcapsular space of diabetic syngeneic mice.
Results: The E2-loaded R3V6 carrier delivered siRNA-5'FITC to mouse islets more efficiently than lipofectamine 2000 without cytotoxicity. Transfection of mouse islets with R3V6-E2-iNOS siRNA silenced iNOS gene expression by >60% and significantly reduced apoptotic cell death from cytokine-induced damage *in vitro*. Six weeks after TPL of 160 IEQs, diabetes cure rate with islets transfected R3V6-E2-iNOS siRNA was significantly higher than that with mock-transfected islets (77% *vs*. 36%).
Conclusion: This study suggests that the R3V6 peptides delivered siRNA for iNOS and beta-estradiol with high efficiency into isolated mouse islets leading to islet cell protection from cytokine-induced damage *in vitro* and improved diabetes cure rates after transplantation. Therefore, from a therapeutic viewpoint, target gene silencing of pancreatic islets combined with hydrophobic cytoprotective drug delivery using R3V6 peptide carrier may be a promising method of safe and effective *ex vivo* gene therapy in advance of islet transplantation.

Zinc oxide nanoparticles for the protection of human beta cells

F. Syed[1], M. Bugliani[1], C. Riggio[2], M. Masini[1], P. Masiello[1], M. Suleiman[1], L. Marselli[1], U. Boggi[3], F. Filipponi[4], D. Focosi[1], F. Scatena[1], V. Raffa[2], P. Marchetti[1];
[1]Department of Clinical and Experimental Medicine, Islet Cell Laboratory, University of Pisa, [2]Life Science Institute, Scuola Superiore di Studi Universitari e Perfezionamento Sant'Anna, [3]Division of General and Transplant Surgery, University of Pisa, [4]Transplantation, Hepatology and Infectious Diseases, University of Pisa, Pisa, Italy.

Background and aims: Beta cell inflammation may contribute to the onset and progression of diabetes as well as to graft failure after islet transplantation. Whereas several approaches have been proposed to tackle this problem, here we describe the use of anti-inflammatory zinc oxide nanoparticles for human beta cell protection in-vitro.
Materials and methods: INS-1E beta cells, human pancreatic islets [isolated from 5 non-diabetic cadaveric organ donors (age: 68 ± 11 years, BMI: 24.1 ± 2.7 kg/m2)], and peripheral blood mononuclear cells (PBMCs, prepared from buffy coats of healthy blood donors) were used. Dose (up to 50 μg/ml zinc oxide) and time (up to 7 days) response curves were perfomed and cells were studied in terms of survival, morphology, ultrastructure, insulin secretion and cytokine release.
Results: Light and electron microscopy demonstrated well maintained INS-1E and human beta cells up to 7 days of incubation with zinc oxide, with no evidence of changes in survival and preserved beta cell ultrastructure; electron microscopy also showed the presence of zinc oxide nanoparticles within the cytoplasm. Glucose-stimulated insulin secretion, expressed as stimulation index, was 3.5±2.4 in control human islets and 3.2±2.7 in zinc oxide treated samples. Incubation with zinc oxide dose dependently decreased the viability of PBMCs, with significant reduction (from 808±38 to 416±132 pg/ml; $p<0.01$) of MCP-1 release.
Conclusion: These results show that zinc oxide nanoparticles could represent a novel tool to influence inflammation phenomena in beta cell microenvironment, potentially useful in experimental and preclinical islet cell studies.

Role of oxidative stress in the pro-angiogenic effect of liraglutide on rat pancreatic islets

A. Langlois[1], S. Dal-Ros[1], W. Bietiger[1], C. Mura[1], E. Seyfritz[1], C. Dollinger[1], M. Pinget[1,2], N. Jeandidier[2], S. Sigrist[1];
[1]Centre européen d'étude du Diabète, Strasbourg, [2]Service d'endocrinologie, diabète, maladies métaboliques, Pôle NUDE, Hôpitaux Universitaires de Strasbourg, Université de Strasbourg, France.

Background and aims: The formation of microvascularization by capillary sprouting at site of pancreatic islet implantation is crucial for survival of the graft. Vascular Endothelial Growth Factor (VEGF), a major angiogenic factor, may be a key protein in modulating the angiogenesis of islets after transplantation. Increased of VEGF by Deferoxamine *via* HIF-1α pathway has been shown to be beneficial for islet survival. Previous *in vitro* study realized in the laboratory showed that liraglutide stimulated VEGF secretion significantly in islets and improved their function. Thus, this angiogenic property could explain the benefic effect of liraglutide on the graft. The aim of this work was to determine mechanisms which could explain the pro-angiogenic effect of liraglutide on Rat islets model focusing on hypoxia and oxidative stress pathways.
Materials and methods: Rat islets were incubated in presence of 10 μmol/L of liraglutide during 0, 12, 24 and 48h. HIF-1α translocation and mTOR ex-

pression were assessed using western blotting. mTOR activation was evaluated with the ratio between the expression of phosphorylated mTOR and mTOR. Total antioxidant capacity of liraglutide was performed by a trolox equivalent antioxidant capacity method (ABTS) test from islets supernatant. Finally, the level of intracellular reactive oxygen species (ROS) was measured by immunofluorescence using dihydroethidium (DHE) on frozen sections of islets.
Results: 10 µmol/L of liraglutide did not induce a stimulation of nuclear HIF-1α expression in comparison with control with respectively 0.285±0.049 and 0.322±0.048 of protein/β-actin after 24h of culture (n=4). However, mTOR activation was significantly increased after 24h of treatment with liraglutide (0.962±0.233 vs 0.423±0.037, n=6; p<0.05). Concerning oxidative stress, the level of intracellular ROS was transiently and significantly enhanced in the presence of liraglutide after 12h of culture. Finally, these results were correlated with the ABTS test with a significant increase of the total antioxidant capacity at 12h with liraglutide (control: 4.624±0.11, n=4; lira glutide: 5.537±0.27, n=6; p<0.05).
Conclusion: The mechanism involved in the pro-angiogenic effect of liraglutide seems to be related to oxidative stress inducing overexpression of VEGF and the increase of mTOR activation. Finally, this study showed that it is possible to improve islets vascularization and graft survival using oxidative stress. In that purpose, strategies need to be developed to control oxidative stress.

568

Islet survival and function following intramuscular vs intraportal autotransplantation in the minipig

T. Hubert, L. Quintane, A. Sterkers, V. Gmyr, M.-C. Vantyghem, J. Kerr-Conte, R. Caiazzo, F. Pattou;
Inserm U859, University Hospital of Lille, France.

Background and aims: Islet transplantation is an efficient therapy of diabetes mellitus. The classic intraportal way may not be optimal due to an instant blood-mediated inflammatory response (IBMIR), and low revascularization of islets. Therefore, intramuscular islet transplantation (IMIT) offers an attractive alternative, based on its simplicity, easier access for graft imaging and cell explantation. The aim of our work was to compare survival and function of intramuscular and intraportal autotransplanted islets in the minipig.
Materials and methods: Using the intramuscular injection technique in the minipig (n=30), we demonstrated, by histological evidence, the rapid revascularization of islets autotransplanted into the gracilius muscle. Islet survival assessment was performed using immunohistochemistry staining for insulin and glucagon up to a period of 6 months. Furthermore, we showed the crucial role of minimizing technical trauma to the myofibers and limiting exocrine contamination.
Results: Graft function was confirmed by documenting the acute insulin response (AIR) to intravenous glucose in 5/11 totally pancreatectomized animals. Graft function after IMIT remained however significantly lower than the function measured in 12/18 minipigs who received a similar islet volume in the liver. The mean AIR observed after IMIT was significantly inferior to the level observed after intraportal islet transplantation (2.8 +/- 1.7 mU/L vs 6.2 +/- 1.3 mU/L, p=0.02). As expected, AIR was lowered in both groups when compared to the levels observed in healthy controls (35.9 +/- 9.1 mUI/L, p<0.01 vs intramuscular and intraportal islet recipients).
Conclusion: Collectively, these results suggest, in a clinically relevant preclinical model, that IMIT can become a promising alternative to intraportal infusion.

Coronary artery disease in diabetic patients long-term after simultaneous pancreas and kidney transplantation compared with kidney transplantation alone

J.P. Lindahl[1], K. Endresen[2], A. Günther[3], A. Hartmann[1], T. Jenssen[1];
[1]Department of Transplant Medicine, Section of Nephrology, [2]Department of Cardiology, [3]Department of Radiology, Oslo University Hospital, Norway.

Background and aims: Improved long-term glycaemic control protects against development of cardiovascular disease and death in type 1 diabetic patients. We aimed to determine whether long-term normoglycaemia (>8 years), as achieved by successful pancreas and kidney transplantation, would delay development of coronary artery disease (CAD) as compared with successful kidney transplantation alone (KTA).
Materials and methods: Twenty-eight type 1 diabetic patients who had received simultaneous pancreas and kidney (SPK) grafts were compared with eighteen single live donor kidney (LDK) recipients. Unlike KTA recipients from deceased donors, recipients from live donors are younger and more comparable in comorbidity with SPK recipients. At follow-up 8-12 years later, the patients underwent coronary angiography (SPK; *n*=23, LDK; *n*=18) and computed tomography (CT) examination (SPK; *n*=25, LDK; *n*=14) to obtain coronary artery calcium scoring (CACS). The Mann-Whitney *U* (Wilcoxon) and χ^2 tests were used to compare continuous and categorical variables, respectively. Binary logistic regression was used to correlate CACS with coronary artery stenosis (>50% diameter stenosis).
Results: Age (mean±SD) at transplantation was 41.3±6.7 and 40.5±10.0 years in the SPK and LDK groups, respectively (*p*=0.59). Duration of diabetes at engraftment was 29.1±7.2 and 28.1±10.0 years for the SPK and LDK recipients, respectively (*p*=0.26). Follow-up after transplantation was 12.1±4.3 years in the SPK group and 10.6±2.5 years in the LDK group (*p*=0.39), and HbA1c was 5.7±0.5% vs 8.5±1.8%, respectively (*p*<0.001*)*. At follow-up there was no difference in coronary artery lumen narrowing between the groups. Twenty-two out of twenty-three (96%) SPK recipients and sixteen out of eighteen (89%) LDK recipients had coronary irregularities (*p*=0.57). Among those, fifteen (65%) SPK and eight (44%) LDK recipients (*p*=0.18) had significant coronary artery stenosis (>50% diameter stenosis). Agatston score (mean±SD) **o**f coronary arteries with CT scan was 2335±2133 and 1701±1657 for the SPK and LDK groups, respectively (*p*=0.33). There was no significant correlation (OR 1.000, CI 1.000, 1.001; *p*=0.054) between high CACS and coronary lumen narrowing (>50% diameter stenosis).
Conclusion: The appearance of CAD as judged by coronary angiography as well as CACS was similar in SPK recipients compared with LDK recipients in spite of more than 8 years with normoglycaemia in the SPK group. This pilot study may suggest that hyperglycaemia is not the main reason for progression of stable CAD in diabetic patients.

570

Long-term effects of pancreas transplantation in type 1 diabetes

M. Occhipinti[1], F. Vistoli[2], M. Barsotti[2], G. Amorese[2], U. Boggi[2], P. Marchetti[1];
[1]Dept. Clinical and Experimental Medicine, [2]Dept. Oncology and Transplant Surgery, University of Pisa, Italy.

Background and aims: Long-term efficacy and safety results of pancreas transplantation (PTx) in the treatment of type 1 diabetic (T1D) patients are matter of debate. We report the outcomes of a single centre whole PTx programme from April 1996 to March 2013.
Materials and methods: Data were analyzed retrospectively taking into account the following milestones: 1996, first simultaneous cadaveric pancreas-kidney transplantation (SPKTx); 2000, first pancreas transplantation alone (PTA); 2001, first simultaneous cadaveric pancreas-living kidney transplantation (SPLKTx); 2002, first pancreas after kidney transplantation (PAK); 2010, first laparoscopic, robotic-assisted PTx.
Results: Overall, 348 PTx were performed in 331 patients (mean age 39.5 yrs; range 22-60) according to established recommendations; of them, 198 were SPKTx, 28 SPLKTx, 91 PTA and 31 PAK. In the group of 226 combined transplantations, 78 (34.5%) were performed on T1D uremic patients preemptively. PTx were systemic-bladder drained in 39 cases, systemic-enteric drained in 139 cases and portal-enteric drained in 170 cases. Immunosuppressive regimen was quadruple for each procedure: induction (ATG=130; Basiliximab=218) + calcineurin inhibitor (CSA=66; TAC=282) + antimetabolite (AZA=2; MMF=346) + low dose steroids. Relaparotomy rate was 14.1% (49/348). Overall, 1, 3, 5 and 10 yr patient actuarial survival rate was 96, 95, 94 and 92%. The respective insulin-independence rate was 88, 85, 83 and 81% in SPKTx and 87, 79, 76 and 75% in PTA. At the same times, grafted kidney survival rate was 92, 90, 88 and 85%. Twelve pancreases were lost due to vascular thrombosis, and the remaining for acute or chronic rejection. Successful PTA was also associated with improved blood pressure and lipid parameter values, and better echocardiographic measures. Seven SPKTx and 2 PTA recipients developed tumors during the follow-up.
Conclusion: PTx, including PTA, associates with favourable long-term clinical outcomes in T1D patients.

571

Alpha-1 antitrypsin is associated with long term graft function markers after clinical islet transplantation

M.-C. Vantyghem[1], A.-S. Balavoine[1], M. Costeur[2], M. Balduyck[3], F. Zerimech[3], V. Desforges[4], C. Noel[5], J. Kerr-Conte[6], F. Pattou[6];
[1]Endocrinology and Metabolism, Lille University Hospital, [2]Faculté de Pharmacie, Lille University Hospital, [3]Center of biology-pathology, Lille University Hospital, [4]Endocrinology, Versailles Hospital, [5]Nephrology and Transplantation, Lille University Hospital, [6]INSERM U859, Lille University Hospital, France.

Background and aims: Gluco and lipotoxicity induce oxidative stress and up-regulate inflammatory cytokines, leading to neutophil activation and ß cell damage. Oxidative stress results in disruption of the balance between 1) pro-oxidant (malondialdehyde (MDA) issued from free fatty acid (FFA) peroxidation) and antioxidant (superoxide dismutase (SOD)) on the one hand, 2) neutrophil activation producing proteases, and protease inhibitors such as alpha-1-anti-trypsine (A1AT) and anti-elastase activity (PAE), on the other-hand. Beneficial effects of A1T1 are suggested in islet transplantation (PNAS 2012). Nevertheless, no assessment has been performed in clinical islet transplantation. This work describes the evolution of oxidative markers after islet transplantation.
Materials and methods: SOD, MDA, FFA, total antioxidant status (TAS)), A1AT, PAE, tacrolimus and sirolimus blood levels, metabolic parameters, kidney markers, and ß score, an index of graft function ranging from 0 (no function) to 8 (excellent function) were measured before and yearly over a 10-year period in 31 islet transplanted patients either alone (ITA: n=18) or after kidney (IAK: n=13).
Results: A1AT and PAE significantly differed according to the level of ßscore (groups 0, 1-2, 3-4, 5-6, 7-8) (p< 0.0001), at the difference with other oxidative markers. A1AT and PAE differed between group 0 and all other ßscore groups including 1-2 (p<0.01). A1AT and PAE, strongly correlated (r=0.936, p<0.0001), and both correlated with graft duration (only A1AT given: r=0.325, p=0.001), BMI (r=-0.207, p<0.04), fasting blood glucose (FBG) (r=-0.188, p=0.0074), C-peptide (r=0.176, p= 0.011), and sirolimus (r= 0.280, p<0.0001), but not tacrolimus. From the 6 oxidative markers, only TAS differed between ITA and IAK groups (p=0.003), the 2 groups also differing by creatinine, MDRD and microalbuminuria levels (p<0.0001).
Conclusion: Neutrophil activation markers (A1AT, PAE) are the only oxidative markers consistently influenced by graft function: a higher level of protease inhibitors is associated with lower FBG, higher C-peptide and ßscore, but also with sirolimus, suggesting a specific role of mTOR inhibitors on oxidative stress. These results confirm the association between high level of A1AT and successful graft function in clinical islet transplantation. Nevertheless, it does not foresee the efficiency of exogenous A1AT administration after islet transplantation.

Improvement of sensory nerve conduction correlates with CGMS mean glucose and variability reduction five years after islet transplantation for type 1 diabetes

D. Quintin[1], V. Raverdy[2,3], R. Caiazzo[2,4], C. Noel[5], J. Kerr-Conte[1], F. Pattou[2,4], M.-C. Vantyghem[2];
[1]Enodcrinologyand Metabolism, Lille University Hospital, [2]INSERM, U859 Diabetes Cell Therapy, Lille University Hospital, [3]Lille University, European Genomic Institute for Diabetes, [4]Endocrine Surgery, Lille University Hospital, [5]Nephrology and Transplantation, Lille University Hospital, France.

Background and aims: Long-term benefit-risk ratio of islet transplantation remains unclear.
Materials and methods: This study describes the evolution of peripheral and autonomic neuropathy 5 years after islet transplantation with the Edmonton protocol in type 1 diabetic patients. Twenty-one consecutive patients (13 islet-alone, 8 islet-after-kidney), transplanted for at least 5 years, underwent biological evaluation, continuous blood pressure and glucose monitoring (CGM), lower-limb electrophysiological and cardiovascular autonomic testing (R-R variation with paced breathing, Valsalva ratio, postural heart rate and blood pressure changes) before transplantation and yearly during 5 years.
Results: Ten/21 patients were insulin-independent 5 years post-transplantation with a median (IQR) A1c at 6.0 (5.8-6.7) vs. 7.8 (6.9-8.3)% in the insulin-requiring group p<0.001). Three lost their islet graft, but were analyzed in intention-to-treat. The medians of sensory action potential (p<0.05) and both sensory and motor nerve conduction velocities (p<0.01) improved between 0 and 5 years. All 4 parameters significantly correlated negatively with CGM mean glucose and all except sensory nerve conduction velocity negatively with triglycerides (p≤0.01). Sensory conduction velocity correlated negatively with glucose variability (SD) on CGM (p<0.01). Tacrolimus levels negatively correlated with motor conduction parameters (p≤0.02). All 4 parameters correlated positively with ß score or post-prandial C-peptide level (p<0.05). Cardiovascular reflex testing did not change over the 5-year follow-up.
Conclusion: Islet-alone or after-kidney transplantation improved significantly sensory nerve conduction parameters. As previously demonstrated, mean glucose was the main factor influencing this improvement.

Reduction of fat mass and leptin with the mTOR inhibitor, sirolimus, in humans: From transplantation to lipodystrophies?

E. Parent[1], F. Defrance[1], S. Boury[1], G. Lion[1], R. Caiazzo[1], I. Wolowczuk[2], P. Mathurin[1], J. Kerr-Conte[3], F. Pattou[1,3], M.-C. Vantyghem[1,3];
[1]regional university hospital of Lille, [2]CNRS UMR 8199, [3]INSERM UMR 859, Lille, France.

Background and aims: Sirolimus inhibits adipocyte differentiation. This study compares weight and fat markers in two groups of patients treated or not with sirolimus, before and after transplantation.
Materials and methods: 19 islet-alone transplanted patients treated with sirolimus and 7 islet-alone or liver-transplanted patients NOT treated with sirolimus were compared 1 year after transplantation in terms of weight, fat mass (equation of Body Fat and percentage of fat mass by DEXA), and metabolic parameters. 14/19 islet-alone transplanted patients treated with sirolimus were reassessed 5 years post-transplantation.
Results: Before transplantation, the metabolic and weight/fat parameters were similar in the 2 groups except for C-peptide. One year post-transplantation, Body Fat and leptin reduction was more important in the sirolimus than in the NON-sirolimus group (p<0.05). Leptin levels were lower in the sirolimus group (p=0.01). Compared to pre-transplant values, one year post-transplantation, weight, fat mass and metabolic parameters did not change in the NON-sirolimus group while the sirolimus group showed a significant reduction in weight (p<0.001), BMI (p<0.001), Body Fat (p<0.001), percentage of body (p<0.05) and truncal (p<0.05) fat mass, HbA_{1c} levels (p<0.001) and ßscore (p<0.01). Compared to pre-transplant values, the sirolimus group showed a significant reduction of leptin level one (p=0.004) and five years (p=0.01) post-transplantation, as well as a persistent reduction of HbA_{1c} (before: 8.4 (1.5); 1-year: 5.8 (1.7) ; 5-years 6.7 (1.7)% and ß score (before: 0.0; 1-year: 7.0 (3.5) ; 5-years 4.0 (4.0)) (p< 0.05). Sirolimus correlated with leptin (r=-0.22, p=0.018) and body fat mass (r=-0.18, p=0.03).
Conclusion: These results suggest that sirolimus modulates the amount and/or the quality of adipose tissue and innate immunity, opening new perspectives both in the choice of immuno-suppressant, and the treatment of nucleopathies, especially lipodystrophies.

Specific measurement of the proglucagon-derived peptide glicentin in human samples

E. Ludvigsen, C. Gäredal, L. Grufman, R. Boman, H. Ritzén, M. Simonsson, A. Carlsson, R. Gunnarsson;
Mercodia AB, Uppsala, Sweden.

Background and aims: Preproglucagon is processed into glucagon like protein-1, glucagon like protein-2, oxyntomodulin and glicentin in endocrine L-cells in the intestine. The biological actions of glicentin are similar to those of glucagon, including stimulation of insulin secretion, inhibition of gastric acid secretion and regulation of gut motility. Until today it has been difficult to measure plasma concentrations of glicentin alone because of its shared sequence with glucagon and oxyntomodulin. In vitro studies have suggested that glicentin may be cleaved by peptidase DPP-4. Our aim was to develop a specific ELISA for measurement of glicentin in human samples. Different methods of sample preservation were also investigated.
Materials and methods: Monoclonal antibodies against human glicentin were generated in mice. A solid phase two-site enzyme immunoassay was developed, using a C-terminal anti-glicentin clone for capture and a peroxidase-conjugated N-terminal clone for detection. Calibrators were prepared by synthetic glicentin. Specificity was evaluated against oxyntomodulin and glucagon. Selectivity and linearity was evaluated by recovery upon dilution and addition. Glicentin preservation in 4 different sample types was examined: 1 = serum, 2 = EDTA, 3 = EDTA + aprotinin, 4 = EDTA + protease + esterase + DPP-4 inhibitor.
Results: There was no detectable cross-reactivity to oxyntomodulin or glucagon at concentrations up to 3000 pM of each tested peptide. The recovery upon dilution was 88 - 132% (mean 107%). The recovery upon addition was 83 - 100% (mean 90%). The glicentin concentration in 20 apparently healthy donors was in the range 8.8 pM - 75 pM. Stability studies indicates that EDTA + protease + esterase + DPP-4 inhibitor is the best method of sample preservation ($p < 0.05$, sample type 4 vs. samples types 1, 2 and 3, ANOVA).
Conclusion: ELISA can be used as a method for specific determination of glicentin in human samples. Sample preservation must to be considered when collecting blood for glicentin determination. Specific measurement of glicentin is needed to further understand the physiological function of this proglucagon-derived peptide.

A novel glucagon receptor antagonist improves hyperglycaemia in both hyperinsulinaemic and relatively insulin-deficient db/db mice

K. Sasaki, E. Ohki, M. Shiraishi, Y. Watanabe, N. Abe, S. Nomura;
Mitsubishi Tanabe Pharma Corporation, Toda-shi, Japan.

Background and aims: In patients with type 2 diabetes, an imbalance of insulin/glucagon levels leads to hyperglycemia *via* the excessive production of glucose in the liver. Many agents for type 2 diabetes improve insulin secretion or insulin sensitivity; i.e., those are insulin dependent agents. A Diabetes Outcome Progression Trial (ADOPT) revealed that the effect of treatment with the insulin-dependent agent sulfonylurea or thiazolidinedione was attenuated with a reduction of pancreatic beta cell function in some years. Several clinical trials revealed that glucagon receptor (GCGR) antagonists lowered blood glucose levels in diabetic patients. However, it remains unclear whether GCGR antagonists improve hyperglycemia in diabetes with advanced reduction of beta cell function. The glucose-lowering effects by the suppression of glucagon action were insulin-independent; therefore, GCGR antagonists would be effective for various diabetic patients, including those with advanced reduction of beta cell function. To confirm this hypothesis, we examined the difference in the anti-hyperglycemic effects of GCGR-A, our novel GCGR antagonist, between hyperinsulinemic and relatively insulin-deficient db/db mice.
Materials and methods: GCGR-A was synthesized at our laboratories. For the GCGR binding assay or cyclic AMP assay, we used 293 cells overexpressing the human or mouse glucagon receptor. To examine glucose-lowering effects, GCGR-A was orally administered as a single dose to ob/ob mice and orally administered to young (6 weeks) or old (12 weeks) db/db mice once a day for 2 weeks.
Results: GCGR-A inhibited glucagon binding to human GCGR with a Ki value of 170.2 nmol/l (95% CI, 100.9-286.9 nmol/l), and inhibited glucagon-induced cyclic AMP production with an IC_{50} value of 82.5 nmol/l (59.4-114.6) for human GCGR and 15.7 nmol/l (5.3-46.5) for mouse. Single treatment with GCGR-A lowered plasma glucose levels ($AUC_{0\text{-}6\ h}$: vehicle, 2476.5 ± 228.6; 0.1 mg/kg, 2089.8 ± 118.6, NS; 0.3 mg/kg, 1705.8 ± 135.6, $p < 0.01$; 1 mg/kg, 1740.3 ± 139.9 mg·h/dl, $p < 0.01$) without a change in plasma insulin levels in ob/ob mice. In the next study, we examined the antihyperglycemic effect of GCGR-A using hyperinsulinemic young db/db mice and relatively insulin-deficient old db/db mice (plasma insulin levels in the fed state were 15.4 ± 1.4 and 4.3 ± 0.3 ng/ml, respectively). Chronic treatment with 1 mg/kg GCGR-A improved hyperglycemia not only in young db/db mice but also in old db/db mice ($AUC_{0\text{-}8\ h}$: young, 6007.6 ± 372.9 *vs* 6962.0 ± 182.6 (vehicle), $p < 0.05$; old, 6280.0 ± 215.1 *vs* 7246.2 ± 100.3 mg·h/dl, $p < 0.01$; mean difference *vs* vehicle: young, 954.4 ± 372.9; old, 966.2 ± 215.1 mg·h/dl). On the other hand, the chronic effect of 10 mg/kg pioglitazone in old db/db mice was attenuated compared with that in young db/db mice (young, 5294.5 ± 319.0 *vs* 6962.0 ± 182.6, $p < 0.01$; old, 6759.9 ± 167.7 *vs* 7246.2 ± 100.3 mg·h/dl, $p < 0.05$; mean difference *vs* vehicle: young, 1667 ± 319.0; old, 486.3 ± 167.7 mg·h/dl). These results show that GCGR-A is effective for hyperglycemia independent of beta cell function.
Conclusion: GCGR-A is a novel oral GCGR antagonist and will be beneficial in various diabetic patients, including those with advanced beta cell dysfunction.

A euglycaemic clamp pilot study assessing the effects of the glucagon receptor antagonist LY2409021 on 24-hour insulin requirement in patients with type 1 diabetes mellitus

C. Kapitza[1], P. Garhyan[2], Y. Ding[2], R.P. Kelly[3], T.A. Hardy[2], C.M. Kazda[4];
[1]Profil, Neuss, Germany, [2]Eli Lilly and Company, Indianapolis, USA, [3]Eli Lilly, Singapore, [4]Lilly France, Neuilly-sur-Seine, France.

Background and aims: Recent research has shown that blocking glucagon action prevents lethal metabolic effects seen in mice with type 1 diabetes mellitus (T1DM). LY2409021 (LY), a potent, selective antagonist of the human glucagon receptor, is being investigated as a treatment for type 2 diabetes mellitus. To test its effects in T1DM, we assessed whether single oral doses of LY could result in clinically meaningful reductions of the 24-hour insulin requirement in patients with T1DM.
Materials and methods: Twenty T1DM patients had euglycemia (5.6 mmol/L) maintained overnight by a glucose-controlled insulin infusion system (Biostator) after their usual insulin regimens were discontinued. On Day 1, euglycemia was maintained using regimens of variable intravenous insulin and standardized meals. These regimens were readministered on Day 2, but patients, randomized 1:2:2, also received a placebo or a 100-mg or 300-mg single dose of LY before breakfast.
Results: Patients had a mean age of 43.0 years (SD, 10.3 years), a mean diabetes duration of 19.0 years (SD, 13.8 years) and a mean baseline HbA1c of 7.6% (SD, 0.7%). The placebo-corrected 24-hour insulin dose needed to maintain euglycemia was reduced by a mean of 17.0% (95% confidence interval [CI], -33.7% to -0.4%; *P*=.046) and a mean of 19.6% (95% CI, -35.0% to -4.3%; *P*=.019) in 100-mg and 300-mg dose groups, respectively. Group mean glucose values were well matched and maintained near euglycemia throughout the clamp procedure. Although LY led to an expected 2- to 3-fold dose-dependent increase in plasma glucagon levels, no significant changes from placebo values were observed for other pharmacodynamic parameters, including levels of glucagon-like peptide-1 (total and active), C-peptide, lipids, and β-hydroxybutyrate. No clinically significant differences between LY and placebo groups were observed in hypoglycemia or adverse event frequency during and after the clamp procedure.
Conclusion: Results of this pilot study suggest that glucagon antagonism can reduce insulin requirements in T1DM.

Mice deficient in glucagon gene exhibit impaired glucose tolerance and the resistance to obesity on high-fat diet feeding

N. Ozaki[1], Y. Takagi[1], K. Kinoshita[1], Y. Seino[2], Y. Oshida[1], Y. Murata[3], Y. Hayashi[3];
[1]Research Center of Health Physical Fitness and Sports, Nagoya University, [2]Department of Metabolic Medicine, Nagoya University School of Medicine, [3]Department of Genetics, Nagoya University, Japan.

Background and aims: Glucagon is produced in pancreatic α-cells from the precursor proglucagon that is encoded by glucagon gene (*Gcg*), and plays critical roles in glucose homeostasis. Blockage of glucagon receptor signaling has been shown to improve glucose metabolism in mice fed high fat diet (HFD). In addition, glucagon receptor knockout mice were resistant to diet-induced obesity. *Gcg*-deficient mice that are homozygous for a *Gcg*-GFP knock-in allele ($Gcg^{gfp/gfp}$) cannot produce proglucagon-derived peptides (PGDPs) such as glucagon, glucagon-like peptide-1 (GLP-1) and GLP-2. We have recently reported that $Gcg^{gfp/gfp}$ mice displayed improved glucose tolerance and enhanced insulin secretion, and that ectopic GIP expression in β-cells maintains insulin secretion. Here we studied glucose and energy metabolism in $Gcg^{gfp/gfp}$ mice with HFD-induced obesity.
Material and methods: $Gcg^{gfp/gfp}$ and $Gcg^{gfp/+}$male mice were fed either a normal chow diet (NCD) or an HFD for 15-18 weeks. We investigated glucose tolerance, insulin secretion, morphometrical analysis of pancreatic islets, energy balance and gene expression.
Results: Fasting glucose levels were increased in both $Gcg^{gfp/gfp}$ and $Gcg^{gfp/+}$ mice fed HFD compared to those fed NCD. Intraperitoneal glucose tolerance test (IPGTT) showed that glucose tolerance in HFD-fed mice were impaired compared to NCD-fed mice regardless of the genotype, however, glucose level 120 min after glucose loading was significantly lower in $Gcg^{gfp/gfp}$ mice fed HFD than $Gcg^{gfp/+}$mice fed HFD. Increase in ß-cell mass was observed in $Gcg^{gfp/+}$mice fed HFD, but not in $Gcg^{gfp/gfp}$ mice fed HFD ($Gcg^{gfp/+}$, 1.59 ± 0.35; $Gcg^{gfp/gfp}$, 0.68 ± 0.11 %, p < 0.05). These results indicate that mice deficient in glucagon do develop diet-induced diabetes in the combined deficiency in other PGDPs. HFD feeding increased body weights in both $Gcg^{gfp/gfp}$ and $Gcg^{gfp/+}$ mice during the experimental period. The ratio of weight gain was obviously lower in $Gcg^{gfp/gfp}$ mice than $Gcg^{gfp/+}$mice ($Gcg^{gfp/+}$, 46.9 %; $Gcg^{gfp/gfp}$, 21.3 %). Oxygen consumption was enhanced in $Gcg^{gfp/gfp}$ mice fed HFD compared to $Gcg^{gfp/+}$mice fed HFD in light phase. HFD feeding significantly increased uncoupling protein 1 (UCP1) mRNA expression in brown adipose tissue of $Gcg^{gfp/gfp}$ mice. These findings suggest that PGDPs play some roles in regulation of brown adipose tissue function through regulating the expression of UCP1.
Conclusions: Considering that GLP-1 levels were elevated in animal models depleted in glucagon receptor signaling, our results suggest that deficiency in GLP-1, but not glucagon contributes to glucose intolerance in $Gcg^{gfp/gfp}$ mice fed HFD, and that deficiency in glucagon signaling enhances oxygen consumption in HFD-fed mice, resulting in resistance to diet-induced obesity.

578

Secretion and effects of GLP-1 on pancreatic alpha cell

V. Sancho Bornez, R. Lupi, G. Faro, D. Lucchesi, S. Del Guerra, A. Dardano, S. Del Prato;
Endocrinology and Metabolism, University of Pisa, Italy.

Background and aims: An intra-islet incretin system has been recently suggested most likely through modulation of the expression and activity of proconvertase 2 and 1/3 (PC1/3, PC2) in pancreatic alpha-cell accounting for local release of GLP-1. Little is known, however, whether this alpha-cell activity can be affected by the typical metabolic alteration occurring in type 2 diabetes.
Materials and methods: AlphaTC1/6 (TC1/6) cells from a mice pancreatic cell line were incubated in the presence of different glucose (G) concentration (5.5, 11.1, 16.7 and 22.2 mM) from 0 to 120 h and expression of PC1/3, PC2, and GLP-1R mRNA determined by RT-PCR. GLP-1-receptor protein (GLP1R) was determined by immunofluorescence using specific antibodies, and GLP-1 secretion measured by ELISA. Effect of GLP-1 on alpha cell viability was determined by MTT assay following incubation in the presence of glucose or fatty acid (FA, 2:1 palmitate:oleate, 10^{-5}, $0.5x10^{-4}$, 10^{-4}, $0.5x10^{-3}$ M) with or without 10^{-9} M exendin 4 (Ex-4), a GLP-1 analog resistant to DPP-IV degradation.
Results: Upon 16.7 mM G incubation, PC2 expression increased 3.2±0.6 and 3.2±0.9 times after 16 and 24 hr, respectively, returning to basal values after 48hr; PC1/3 expression also increased at 16hr with no decrease with prolongation of incubation. The 16hr increment in PC1/3 expression was accompanied by increased GLP-1 secretion into the medium(313±67% of basal, $p<0.05$) progressively returning to basal values over the ensuing 5 day incubation. After 16hr incubation at 16.7 mM G, GLP-1R mRNA expression increased 19.6±3.4 folds. GLP-1R expression was also documented by immunofuorescence after 24hr incubation at 16.7 mM G. Ex-4 increased viability in cells incubated for 5days at 11.1 to 16.7 mM G but not at lower G (11.1 mM=168±8%, +Ex-4=187±10% of basal, $p<0.05$; 16.7 mM=203±9%, +Ex-4=236±14% $p<0.02$). No effect was apparent for shorter incubations (24 or 48hr). Cell viability decreased after 4h FA incubation at all concentration tested, which was partially prevented with 2hr pretreatment with Ex-4 (10^{-5}M FA=99±4% *vs* Ex-4=125±8% of basal, $p<0.01$; $0.5x10^{-4}$M=89±3% *vs* +Ex-4=110±9% of basal, $p<0.03$, 10^{-4}M= 72±2% *vs* +Ex-4=85±5% of basal, $p<0.04$).
Conclusion: These data suggest that under hyperglycemic conditions, alpha cells can increase expression PC1/3 and activate GLP-1 secretion, which may contribute protecting both alpha and beta-cells from glucose and partially from lipotoxicity.

579

Exploring the Somatostatin axis in primary murine mixed islet cultures

A.E. Adriaenssens, G. Tolhurst, F. Reimann, F. Gribble;
Clinical Biochemistry, University of Cambridge, UK.

Background and aims: Somatostatin (Sst) is a hormone implicated in paracrine suppression of a number of endocrine cells, including alpha- and beta-cells, secreting insulin and glucagon respectively. In the endocrine pancreas, Sst is secreted from delta-cells, which are not readily distinguishable from other islet cells on morphological grounds. We therefore made a new transgenic mouse model expressing Cre-recombinase under the control of the somatostatin promoter. In this model live Sst-expressing cells can be identified when crossed with fluorescent Cre-reporter strains. As Sst release from pancreatic delta cells is stimulated by increased extracellular glucose, we sought to characterize the mechanisms underlying glucose-stimulated Sst release and also investigated a potential role of GLP-1 in modulating delta cell excitation.
Materials and methods: Trangenic mice carrying a ~200kbp construct derived from a bacterial artificial chromosome in which the Sst-coding region has been replaced by iCre-sequence were crossed with Rosa26-reporter mice, either expressing a red fluorescent protein (tdRFP) or a genetically encoded calcium indicator, GCaMP3, after Cre-mediated recombination. Fluorescently tagged delta cells were purified by fluorescence-activated cell sorting for gene expression analysis. Mixed primary cultures established from pancreatic islets were used to monitor real-time responses in identified delta cells during perfusion with different stimuli on a microscope stage, measuring NAD(P)H auto-, Fura-2 or GCaMP3 fluorescence.
Results: Immunohistochemistry carried out on the tdRFP-crossed mice verified specific expression of the reporter in Sst-positive cells. Gene expression analysis revealed that pancreatic delta cells express the canonical beta-cell glucose-sensing components-glucokinase, Kir6.2, and SUR1-as well as the GLP-1 receptor. Monitoring Ca^{2+} in cultures derived from GCaMP3-reporter mice after loading with Fura2-AM verified similar responsiveness of both reporters in delta cells with 1.14-, 1.20- and 1.27 fold increases compared to baseline Ca^{2+} at 1 mM glucose when glucose was raised to 3, 5 and 10 mM respectively (n>7, p<0.05). Addition of the glucokinase activator GKA50 (3 μM) to 1 mM glucose elicited a 1.62-fold increase in Ca^{2+} (n= 4, p<0.01), which was significantly greater than the effect of raising the glucose concentration to 10 mM (p<0.05). GKA50 also increased the metabolic rate as a 1.16-fold increase in NAD(P)H autofluorescence was observed relative to the baseline at 1 mM glucose (n= 7, p<0.001). Addition of 100 nM GLP-1 increased metabolism and intracellular Ca^{2+}, but the 1.03-fold (n= 5, p<0.01) increase in NAD(P)H and 1.26-fold (n= 3, p<0.05) increase in Ca^{2+}-sensor fluorescence were more modest in comparison to the effects of pharmacological glucokinase activation.
Conclusion: We have established a transgenic mouse model enabling live-cell imaging from pancreatic delta cells. Delta cells respond to changes in ambient glucose using similar molecular machinery to pancreatic beta cells. Metabolic flux seems to be strongly controlled by glucokinase activity and as delta cells express the GLP-1 receptor and exhibit increased metabolism in response to this peptide it seems likely that GLP-1 modulates Sst secretion at least in part through activation of glucokinase in delta cells. As most pancreatic alpha cells

do not express the GLP-1 receptor, this might be an important component of the glucagonostatic effect of GLP-1.

GPR120 is expressed preferentially in the delta cells of murine islets of Langerhans and regulates glucose-induced somatostatin secretion
V.M. Stone[1,2], S. Dhayal[1], K.J. Brocklehurst[3], C. Lenaghan[3], M. Bjursell[4], X. Xu[4], T. Admyre[4], D.M. Smith[4], N.G. Morgan[1];
[1]University of Exeter Medical School, Exeter, UK, [2]Karolinska Institutet (present address), Stockholm, Sweden, [3]AstraZeneca, Alderley Edge, Sweden, [4]AstraZeneca, Mölndal, Sweden.

Background and aims: The expression and functional roles of the lipid-responsive G-protein coupled receptor, GPR120, in the endocrine pancreas remain controversial. Some studies have concluded that GPR120 is not expressed in cells of the islets of Langerhans while others imply that it is present in both human and rodent islets. To clarify this situation, we have employed a novel GPR120 knock-out/β-galactosidase knock-in mouse to establish the localisation of this receptor within islets and to determine its functional role.
Materials and methods: A global GPR120 knock-out (KO)/β-galactosidase (β-gal) knock-in (KI) mouse was generated by replacement of the sequence encoding exon 1 of the GPR120 gene with the lacZ gene. This placed β-gal under the control of the GPR120 promoter, thereby allowing detection of β-galactosidase as a surrogate for GPR120. β-gal expression was then studied in pancreas sections from wild type (WT) and GPR120 KO animals either by reporter gene assays or by direct immunofluorescence with anti-β-gal antibodies. Islet endocrine cells were identified with relevant antibodies. Somatostatin (SSN) secretion was studied using islets isolated from WT and GPR120 KO animals treated with three selective, synthetic, GPR120 agonists (designated as compounds A, B or C).
Results: LacZ reporter assays revealed the expression of β-gal (and, by inference, GPR120) in a population of cells distributed peripherally in the islets of GPR120 KO/β-gal KI mice. Staining was absent from WT islets. Dual immunofluorescence staining revealed that β-gal co-localised predominantly with SSN, whereas it was not detected in insulin-positive cells. Treatment of WT islets with each of 3 selective GPR120 agonists resulted in marked inhibition of glucose (16.6mM) -induced SSN secretion (16.6mM glucose alone: 10.4 ± 1.1 pmol/islet/h; 16.6mM glucose plus either compound A : 5.7 ± 0.6 pmol/islet/h; compound B: 4.5± 0.7 pmol/islet/h; compound C: 5.0 ± 0.7 pmol/islet/h; $p<0.01$ in each case) while the agonists had no effect on glucose-induced insulin secretion. None of the GPR120 agonists altered basal SSN secretion (at 3.3mM glucose). The effects of compounds A, B or C on SSN release were similar to those observed with the cholinergic agonist, carbachol; a known inhibitor of glucose-induced SSN secretion. The inhibitory effects of the GPR120 agonists on SSN secretion were lost in islets from GPR120 KO mice. Pretreatment of islets from WT mice with pertussis toxin (Ptx) antagonised the inhibitory effects of compound A on SSN secretion at 16.6mM glucose (control islets: 16.6mM glucose alone: 13.5 ± 1.1 pmol/islet/h; 16.6mM glucose plus compound A: 6.3± 0.5 pmol/islet/h; Ptx-treated islets: 16.6mM glucose alone: 11.3 ± 1.9 pmol/islet/h; 16.6mM glucose plus compound A, 9.0 ± 0.8 pmol/islet/h; $p<0.05$) suggesting that the receptor may mediate its effects via Gαi.
Conclusion: We conclude that GPR120 is expressed predominantly in the delta-cells of mouse islets and that activation of this receptor leads to inhibition of glucose-induced SSN secretion. This response is mediated, at least in part, by coupling of GPR120 to the G-protein, Gαi.

Human bone marrow- and pancreatic islet- derived mesenchymal stem cells: effects of hyperglycaemia and gastrointestinal peptides
A. Carpanetto, E. Favaro, S. Lamorte, S. Bruno, R. Granata, P. Cavallo Perin, M. Porta, E. Ghigo, G. Camussi, M.M. Zanone;
Department of Medical Sciences, University of Turin, Italy.

Background and aims: In the context of diabetes research, mesenchymal stem cells (MSCs) have been shown to endowed with several possibilities to be exploited. MSCs can generate insulin-producing cells, counteract autoimmunity, enhance islet engraftment, improve metabolic control in animal models for type 2 diabetes and treat chronic diabetic complications. Further, MSC derived from pancreatic islets show different characteristics compared to bone marrow derived counterparts, possibly reflecting spontaneous differentiation and commitment. Glucose toxicity is not solely restricted to beta cells, but affects also survival, proliferation of other cells, such as endothelial cells, contributing to beta cell function impairment and loss. In the present study we aimed to evaluate the effects of high glucose conditions on human MSCs derived from different sources, bone marrow and pancreatic islets. Further, in the light of studies indicating a cytoprotective role for ghrelin gene-derived peptides and obestatin on beta and islet endothelial cells, we evaluated whether these peptides may exert their effects also on MSCs in high glucose conditions.
Materials and methods: Human MSCs were obtained from bone marrow (BM-MSCs) and from pancreatic islets (HI-MSCs), characterized and cultured in normal glucose or in 14 mmol/L and 28 mmol/L glucose concentrations for 3 and 7 days. Gene expression of the ghrelin receptors, GHS-R1a and GPR-39, was assessed by RT-PCR. Cell Proliferation and survival were analysed by BrdU (Roche) and MTT assays, respectively. Apoptosis (assessed as Annexin V expression), cell cycle and cell viability were also evaluated using Muse™ Cell analyzer by flowcytometry. High glucose cultures were also treated with ghrelin and obestatin (10 nM).
Results: The RT-PCR analysis showed that both BM-MSCs and HI-MSCs expressed GHS-R1a and GPR-39 receptors. Under high glucose conditions, from 3 to 7 days, proliferation of BM-MSCs and HI-MSCs progressively decreased (respectively of 35 and 44%) compared to normal glucose culture. Early and late apoptosis, assessed as Annexin-V expression, increased in high glucose conditions in both cell lines (in BM-MSCs from 20% to 24%, and in HI-MSCs from 19% to 32%). Preliminary treatment with ghrelin and obestatin in high glucose, increased proliferation and survival in both cell lines, having obestatin the greatest protective effects (increasing proliferation of approximately 42% comparing to high glucose conditions).
Conclusion: These results suggest that HI-MSCs are more affected by high glucose conditions, compared to their bone marrow-derived counterparts, thus affecting potential reparative effects within pancreatic islets. Moreover, the ghrelin gene-derived peptides and obestatin appear to exert protective effects on both cell lines, rendering these peptides an appealing therapeutic tools to regulate islet fate *in vivo*.

Intravenous injection of valsartan augmented pancreatic blood flow without affecting in vivo insulin secretion in male GK rats
H. Chao, L. Wu, Y. Hu;
Department of Geriatrics, Zhongshan Hospital of Fudan University, Shanghai, China.

Background and aims: Results of NAVIGATOR (The Nateglinide and Valsartan in Impaired Glucose Tolerance) demonstrated that treatment with Valsartan for 5 years reduced the incidence of type 2 diabetes Mellitus (T2DM) by 14% in subjects with impaired glucose tolerance (IGT), but the underlying mechanisms remain elusive. Studies with captopril and irbesartan confirmed that blockade of RAS system regulated islet microcirculation and improved islet β cells function in both normoglycaemic and hyperglycaemic rodents models. Since islet microcirculation is important to preserve islet βcells function, and in vivo insulin secretion can be rapidly tuned by changes in islet microcirculation,it is conceivable that the prevention of newly onset diabetes in IGT patients by valsartan might be related to its regulation of islet microcirculation.In this setting, we chose male diabetic GK rats with elevated islet blood flow (IBF) as subjects and treated them with intravenous injection of large dose of Valsartan,and measured pancreatic blood flow (PBF) and IBF,and in vivo insulin secretion.
Materials and methods: Adult male GK rats were randomly divided into two groups. Either Valsartan dissolved in 1ml sodium bicarbonate (3mg•kg-1) or vehicle alone was injected intravenously. A non-radioactive microsphere technique was adopted to measure the regional tissue blood flow. Blood glucose concentrations were measured with test reagent strips, serum insulin concentrations were measured by ELISA.In intravenous glucose tolerance test, 1ml 30% D-glucose solution was injected 10 minutes after the i.v. injection of valsartan(3mg•kg-1). Blood samples were drawn immediately before and 2, 4, 6, 8 and 10 min after glucose administration. Data was analysed by SPSS16.0,and values were given as means±SEM.A difference was defined as significant when $P< 0.05$.
Results: 1.Intravenous injection of valsartan significantly reduced mean arterial blood pressure of male GK rats($P<0.05$).2.Pancreatic blood flow (PBF) was markedly increased by valsartan ($P<0.05$,Fig.1),while neither islet blood

flow (IBF) nor fraction of IBF out of PBF (fIBF) was affected by valsartan treatment. Kidney blood flow was markedly enhanced by intravenous injection of valsartan(P< 0.05).3.Acute treatment with valsartan changed neither GK rats' blood glucose concentration nor insulin secretion.4.Intravenous injection of valsartan did not change blood glucose concentration in intravenous glucose tolerance tests in GK rats.

Conclusion: In diabetic rats with lower blood pressure, both PBF and KBF was significantly enhanced, while elevated IBF was not further increased, indicating that regulation of islet microcirculation involved in the protection of islet β cell and might contribute to its prevention of diabetes in IGT patients.

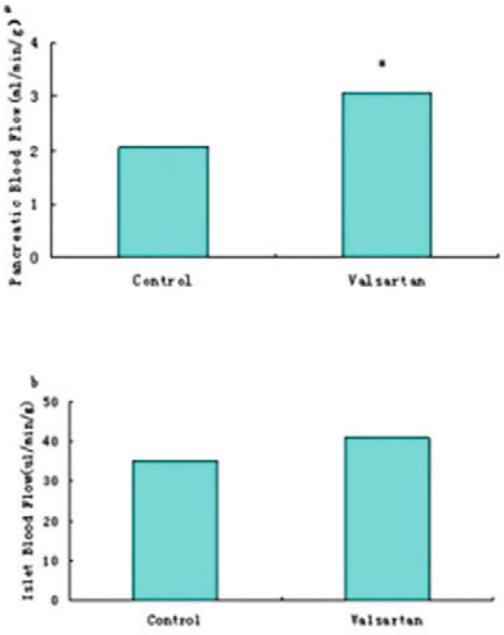

Fig. 1 Pancreatic blood flow was increased by valsartan. *P<0.05 vs control

Human islet amyloid polypeptide improves hepatic insulin signalling

M. Zhou[1,2], A. Cheng[3], G. Xu[1,2];
[1]CUHK Shenzhen Research Insititute, The Chinese University of Hong Kong, Shenzhen, China, [2]Department of Medicine and Therapeutics, The Chinese University of Hong Kong, [3]Institute of Digestive Disease and Li Ka Shing Institute of Health Sciences, The Chinese University of Hong Kong, Hong Kong.

Background and aims: Islet amyloid polypeptide (IAPP) is a pancreatic β cells-derived hormone, which is co-secreted with insulin. IAPP plays a role in glycemic regulation by slowing gastric emptying, lowering body weight, and thereby prevents post-prandial spikes in blood glucose levels. IAPP analog has been used clinically for glycemic control. However, the mechanism underlying the beneficial effects of IAPP is not fully understood. As liver plays a critical role in glucose homeostasis, we investigated whether hepatic insulin sensitivity was regulated by IAPP.

Materials and methods: We used heterozygous IAPP transgenic mice with elevated serum IAPP concentration by 2~3 folds. Huh 7 hepatoma cells were cultured in DMEM with 10% FBS and starved in serum-free medium for 16hours before IAPP treatment.

Results: Compared with wild-type (WT) mice, body weight was decreased by 6% in IAPP transgenic mice. Insulin tolerance test revealed that glycemic regulation in IAPP transgenic mice were more sensitive to insulin. IAPP transgenic mice had higher hepatic glycogen content as shown by PAS staining. Hepatic phosphorylation of AKT and GSK3β in IAPP transgenic mice were much stronger than that in WT mice in response to insulin stimulation through portal vein injection. Moreover, we found that both full length and cleaved active sterol regulatory element-binding protein-1 (SREBP-1) levels were down-regulated in IAPP transgenic mice, while with SREBP-1 changes, insulin receptor substrate-2 (IRS-2) levels were increased. *In vitro* experiments in Huh 7 hepatoma cells also demonstrated that IAPP enhanced insulin-stimulated AKT phosphorylation in a dose-dependent manner. Consistently with *in vivo* experiments, similar changes of SREBP-1 and IRS-2 were observed with IAPP treatment.

Conclusion: Our results demonstrated that IAPP improved hepatic insulin signaling both *in vivo* and *in vitro*. SREBP-1 and IRS-2 signal cascade may be involved in the regulation of IAPP on insulin sensitivity. These results provided novel evidences for clinical usage of IAPP analog for the treatment of diabetes and related hepatic disorder.

PS 037 Clinical hypoglycaemia

584

Nocturnal hypoglycaemia: effect of insulin analogues compared to human insulin in type 1 diabetic patients prone to severe hypoglycaemia

C. Bay[1,2], P. Lommer Kristensen[1,3], U. Pedersen-Bjergaard[1], L. Tarnow[4,5], B. Thorsteinsson[1,2];
[1]Endocrinology Section, Dept. of Cardiology, Nephrology and Endocrinology, Hillerød Hospital, Hillerød, [2]Faculty of Health and Medical Sciences, University of Copenhagen, [3]Department of Endocrinology, Herlev University Hospital, Herlev, [4]Steno Diabetes Center, Gentofte, [5]Health, University of Aarhus, Denmark.

Background and aims: Nocturnal hypoglycaemia is a critical limitation of insulin therapy in type 1 diabetes. Insulin analogues reduce the risk of nocturnal hypoglycaemia in subjects at low risk of severe hypoglycaemia. We tested whether treatment based on insulin analogues compared to human insulin reduces occurrence of documented nocturnal hypoglycaemic episodes in patients with recurrent severe hypoglycaemia (two or more events during the last year).
Materials and methods: 72 participants (46 males, age 54±12 years (mean±SD), HbA1c 8.1±1.1%, duration of diabetes 30±14 years) in a two-year randomised, open-labelled, crossover, multicentre trial of basal-bolus therapy with insulin detemir / insulin aspart or human NPH insulin / human regular insulin stayed overnight at our Diabetes Center for two nights during each treatment arm. Venous blood was drawn hourly from 23:00-07:00 for later plasma glucose measurements. Primary endpoint was occurrence of hypoglycaemia ≤ 3.9 mmol/l (ADA threshold).
Results: Valid data were obtained in 217 nights. One night was excluded due to lack of measurements at bedtime yielding 100 nights in the human insulin arm and 116 in the analogue arm. Kaplan-Meier analysis showed a nocturnal "hypoglycaemia-free survival" of 73%. A higher incidence of nocturnal hypoglycaemia was present in the human insulin arm (40 nights (40%)) than in the insulin analogue arm (19 nights (16%)) (p<0.001) (figure). Cox regression revealed a hazard ratio (HR) of 0.41 (95% CI 0.2-0.6; p<0.001). A possible "carry-over effect" of dinner-time human short-acting insulin was tested by excluding hypoglycaemic events at bedtime (23:00) and midnight (00:00). After exclusion of these events "hypoglycaemia-free survival" was 82%. The incidence rates of hypoglycaemia were still lower in the analogue arm (14 nights (13%)) than in the human insulin arm (21 nights (26%)) (p=0.015) (figure). The number needed to treat with insulin analogues to avoid one episode of nocturnal hypoglycaemia is one patient in approximately 5 nights. No nocturnal peak occurrence of hypoglycaemia was observed in any treatment arm.
Conclusion: Treatment with long-acting insulin analogues significantly reduces the occurrence of nocturnal hypoglycaemia in type 1 diabetic patients prone to severe hypoglycaemia. Dinner-time short-acting human insulin involves a notable "carry-over effect" on the incidence of early nocturnal hypoglycaemia.

Effect of insulin analogues on frequency of mild hypoglycaemia in patients with type 1 diabetes and recurrent severe hypoglycaemia: the prospective, controlled HypoAna trial

R.M. Agesen[1], P.L. Kristensen[1,2], H. Beck-Nielsen[3,4], K. Nørgaard[5], H. Perrild[6], J.S. Christiansen[7,8], T. Jensen[9], P. Hougaard[4], H.-H. Parving[9,8], B. Thorsteinsson[1,10], L. Tarnow[2,8], U. Pedersen-Bjergaard[1,10];
[1]Department of Cardiology, Nephrology and Endocrinology, Hillerød University Hospital, [2]Steno Diabetes Center, Gentofte, [3]Department of Endocrinology M, Odense University Hospital, [4]Faculty of Health Sciences, University of Southern Denmark, Odense, [5]Department of Endocrinology, Hvidovre University Hospital, [6]Department of Internal Medicine, Bispebjerg University Hospital, [7]Department of Endocrinology M, Aarhus University Hospital, [8]Faculty of Health Sciences, University of Aarhus, [9]Department of Medical Endocrinology, Copenhagen University Hospital (Rigshospitalet), [10]Faculty of Health Sciences, University of Copenhagen, Denmark.

Background and aims: Hypoglycaemia is a constant threat for people with type 1 diabetes. Episodes of mild hypoglycaemia (MH) are not always benign because they may impair physiological and behavioural defences against subsequent hypoglycaemia. The HypoAna Trial tested whether insulin analogues in comparison with human insulin are advantageous in reducing the incidence of hypoglycaemia in patients at high risk of severe hypoglycaemia. Here we report the results on MH.
Materials and methods: The study was an investigator-initiated two year, prospective, randomized, open-labelled, blinded endpoint (PROBE) multicenter trial including 159 patients with type I diabetes and two or more episodes of severe hypoglycaemia in the preceding year as the major inclusion criteria. Patients were randomized to treatment with basal-bolus therapy based on analogues (aspart/detemir) or human insulin (regular/NPH) in a balanced cross-over design. Patients were instructed to measure 7-point blood glucose profiles during daytime twice a week and to measure nocturnal blood glucose at 03 a.m. once every month. Episodes of documented MH defined by a measured plasma glucose concentration ≤ 3,9 mmol/L +/- typical symptoms were recorded and compared between the two treatments. Occurrence of MH was evaluated in the last 9 months of each treatment arm.
Results: A total number of 9360 episodes of MH were recorded; 52% in the human insulin arm and 48% in the insulin analogue arm, corresponding to 1,12 and 1,05 episodes per patient-week, respectively (mean). 16% of MH was nocturnal (23-07). The per protocol analysis demonstrated a 6% rate reduction (95% CI: 2-9%; p=0.0077) in the total number of episodes of MH in patients being treated with insulin analogues compared to human insulin. The reduction in MH was solely due to reduction in the rate of nocturnal MH (38%; 95% CI: 31-44%; p=0.0001), whereas daytime occurrence of MH was similar in the two treatment arms (p=0.32). The intention-to-treat analysis demonstrated similar results. The results were obtained during maintenance of baseline glycaemic control (HbA1c: 8.0±1.0% (64±11 mmol/mol) (mean±SD)) throughout both treatment arms.
Conclusion: Insulin aspart/detemir significantly reduces the rate of nocturnal MH in patients with type 1 diabetes and recurrent severe hypoglycaemia compared to regular/NPH insulin. The reduction appears mainly to be due to use of the long-acting insulin analogue.

Patients with type 1 diabetes treated with insulin pumps do not experience a reduced risk of severe hypoglycaemia in a real life setting

C.S.S. Frandsen[1,2], P.L. Kristensen[1,3], H. Beck-Nielsen[4], K. Nørgaard[2], H. Perrild[5], J.S. Christiansen[6], T. Jensen[7], H.-H. Parving[7], B. Thorsteinsson[1], L. Tarnow[3], U. Pedersen-Bjergaard[1];
[1]Department of Cardiology, Nephrology and Endocrinology, Hillerød Hospital, [2]Hvidovre University Hospital, [3]Steno Diabetes Center, Gentofte, [4]Odense University Hospital, [5]Bispebjerg Hospital, Copenhagen, [6]Aarhus University Hospital, [7]Copenhagen University Hospital, Denmark.

Background and aims: The main target in diabetes treatment is adequate lowering of HbA1c to avoid late complications. However, people with type 1 diabetes on intensive insulin treatment are at daily risk of severe hypoglycaemia (SH). SH is feared by patients and relatives and associated with reduced

quality of life. Our aim was to evaluate, in a real life setting, the impact of insulin pump therapy (CSII) on the frequency of SH compared with conventional insulin treatment (CIT).
Materials and methods: A questionnaire on hypoglycaemia and related subjects posted from six Danish diabetes clinics to 6112 unselected adult patients with type 1 diabetes was filled in by 3861 patients (63 %). In a subset of 1728 patients (45%) supplementary clinical and laboratory data was available. Parametric and non-parametric testing was used as appropriate. For multivariate analysis a log-linear negative binomial model was applied with adjustment for age, awareness status, duration of diabetes and sex, and in the subpopulation also for HbA1c and plasma creatinine.
Results: 3813 patients with type 1 diabetes (CSII vs. CIT: 211 vs. 3602 patients (83% on ≥4 injections/day), men 37% vs. 54%, age 45±14 vs. 48±15 years (mean±SD), duration of diabetes 25±13 vs. 23±14 years, awareness status (aware/impaired/unaware) 38/47/15 vs. 46/42/12 %) were eligible. The number of episodes of SH was 1.3±4.3 (range: 0-40) and 1.2±5.0 (range: 0-112) per patient-year in the CSII and CIT groups, respectively (p=0.8). The adjusted multiple regression analysis confirmed that no difference in the frequency of SH existed between the groups while occurrence of SH increased with age (p=0.01) and decreasing hypoglycaemia awareness (p<0.001). In the subpopulation (CSII vs. CIT: 112 vs. 1616 patients (82% on ≥4 injections/day), men 43 vs. 53%, age 48±14 vs.51 ±15 years, duration of diabetes 27±12 vs.26±14 years, awareness status (aware/impaired/unaware) 38/46/16 vs. 44/42/14 %, HbA1c 7.6±0.9 vs. 8.0±1.0 % (p<0.001), p-creatinine 71±16 vs. 80±48 µmol/l (p=0.031)), the frequency of SH was 1.2±4.1 (range: 0-30) and 1.2±5.0 (range: 0-112) episodes per patient-year (p=0.2). This finding was confirmed in the adjusted regression analysis where occurrence of SH was associated with increasing plasma creatinine (p=0.01) and decreasing hypoglycaemia awareness (p<0.001).
Conclusion: In this large questionnaire study occurrence of SH the last year, in a real life setting, was similar in patients treated with CSII and with other, primarily basal-bolus, insulin regimens. Confounding by indication may be involved. However, indications for starting CSII and whether CSII was started during the last year or earlier are not known. To further elucidate these aspects supplementary clinical and laboratory data on a larger proportion of the CSII patients are needed.

Relationship between glycaemic control and hypoglycaemia using insulin glargine versus premixed insulin in type 2 diabetes: a subanalysis of GALAPAGOS

B. Sethi[1], A. Comlekci[2], F. Gomez-Peralta[3], W. Landgraf[4], M.-P. Dain[5], V. Pilorget[5], P. Aschner[6];
[1]CARE Hospital, Hyderabad, India, [2]School of Medicine, Dokuz Eylul University, Izmir, Turkey, [3]Unit of Endocrinology and Nutrition, Hospital General de Segovia, Spain, [4]Sanofi, Frankfurt, Germany, [5]Sanofi, Paris, France, [6]Pontificia Universidad Javeriana, Hospital Universitario San Ignacio, Bogotá, Colombia.

Background and aims: The GALAPAGOS study investigated the efficacy and safety of insulin glargine (GLA) QD ± glulisine (GLU) QD at the main meal compared to premixed insulin (PRE QD or BID) in insulin-naïve type 2 diabetes (T2DM) patients uncontrolled on OADs. A similar percentage of patients in the overall GLA and PRE groups reached the primary endpoint (HbA1c <7% and no symptomatic confirmed hypoglycaemia [PG ≤3.1 mmol/L] at 24 weeks), failing to demonstrate superiority, but demonstrating non-inferiority of GLA-based treatment. Since hypoglycaemia is an important safety factor and may also impact patient adherence to therapy, we performed a *post-hoc* analysis of the relationship between glycaemic control and symptomatic confirmed hypoglycaemia [PG ≤3.1 mmol/L] in the 2 groups.
Materials and methods: GALAPAGOS was a 24-week, open-label, randomised, multinational, superiority trial. Patients were initially randomised to GLA QD or PRE (QD or BID) while continuing OADs (metformin ± insulin secretagogue [IS]). A second PRE injection could be added any time in PRE QD patients; one injection of GLU at main meal could be added in GLA QD patients with HbA1c ≥7% and FPG <7 mmol/L from week 12 onwards. IS was stopped with the addition of a second injection. Insulin titration targeted FPG ≤5.6 mmol/L. The relationship between HbA1c at study end and event rate of hypoglycaemia throughout the study was analysed using negative binomial regression.
Results: There were a total of 256 documented confirmed overall symptomatic hypoglycaemic events [PG ≤3.1 mmol/L] with GLA and 623 events with PRE, and an incidence rate of 22% for GLA and 35% for PRE (p<0.001). The estimated event rate (episodes/patient-yr) of documented confirmed overall hypoglycaemia [PG ≤3.1 mmol/L] was 1.2 for GLA and 2.9 for PRE; rate ratio was 0.41 [95% CI: 0.30, 0.56, p<0.001] and NNT=8 to have one less patient to experience a hypoglycaemia within 6 months with GLA rather than PRE therapy. When the estimated number of events/patient-year was plotted against HbA1c at study end, there was a greater risk of overall hypoglycaemia with PRE vs. GLA treatment at all HbA1c levels (Figure). Similar results were obtained for nocturnal hypoglycaemia [PG ≤3.1 mmol/L] with 79 confirmed events with GLA and 221 events with PRE; incidence rates were 7% and 19%, respectively. Estimated rates were 0.4 and 1.0 episodes/patient-year, respectively; rate ratio: 0.35 [0.22, 0.56; p<0.001] and NNT=9.
Conclusion: In this analysis, the use of insulin glargine or premixed insulin produced a similar HbA1c lowering, but the use of insulin glargine was associated with a lower rate of confirmed symptomatic hypoglycaemia at all levels of HbA1c.

The effect of vildagliptin relative to sulphonylureas in Muslim patients with type 2 diabetes fasting during Ramadan: the VIRTUE study

A. Hassoun[1], M. Al-Arouj[2], R. Medlej[3], M.F. Pathan[4], I. Shaltout[5], M.S. Chawla[6], P. Geransar[7], S. Hristoskova[8], S. DiTommaso[8], M.Y. Kadwa[8];
[1]Dubai Diabetes Center, United Arab Emirates, [2]Dasman Diabetes Institute, Dasman, Kuwait, [3]Chronic Care Center, Saint Joseph University, Beirut, Lebanon, [4]BIRDEM Hospital, Dhaka, Bangladesh, [5]Cairo University, Egypt, [6]Lina Diabetes Care Center, Mumbai, India, [7]Novartis Pharmaceuticals UK Ltd, Frimley, Surrey, UK, [8]Novartis Pharma AG, Basel, Switzerland.

Background and aims: The VIRTUE study was a prospective, observational study that assessed the risk of hypoglycemic events (HE) in patients with type 2 diabetes mellitus (T2DM) who fast during Ramadan.
Materials and methods: The study enrolled Muslim patients with T2DM in two cohorts: vildagliptin (n=684) or sulphonylurea (SU; n=631), both given either as monotherapy or dual therapy with metformin. Patients were recruited from 10 countries in the Middle East and Asia. Mean HbA1c was 7.39% and mean BMI was 28.99kg/m^2. The primary endpoint was the proportion of patients with ≥1 HE during Ramadan. Secondary endpoints included change in HbA1c, change in body weight, treatment adherence and overall safety.
Results: Significantly (p<0.001) fewer patients experienced 1 or more HE with vildagliptin (n=36/669, 5.4%) compared with SU (n=123/621, 19.8%). No patients reported a grade 2 HE (requiring third-party assistance) with vildagliptin compared with four patients receiving SUs (p=0.053). The mean change in HbA1c, pre- to post-Ramadan, was -0.24% in the vildagliptin group compared with +0.02% in the SU group (-0.26% between treatment difference; p<0.001). Greater body weight reductions were observed with vildagliptin compared with SU (-0.76 vs. -0.13 kg; -0.63kg between treatment difference; p<0.001). Treatment adherence was high with a similar number of missed doses between cohorts. A higher proportion of SU-treated patients

experienced adverse events compared with vildagliptin (22.8% vs. 10.2%), with the difference driven by hypoglycemia, which was reported as the most common adverse event.
Conclusion: Vildagliptin therapy was associated with significantly fewer patients experiencing hypoglycemia compared with SU therapy in this large cohort of fasting patients with T2DM. This outcome is particularly meaningful when viewed in the context of good glycemic and weight control accompanied by favorable tolerability observed in vildagliptin-treated patients who fasted in this study.

Hypoglycaemia is associated with retinopathy in French type 2 diabetic patients at inclusion in the Gerodiab cohort
J.-P. Le Floch[1], J. Doucet[2], B. Bauduceau[3], C. Verny[4], the SFD / SFGG Intergroup;
[1]Diabetology, Clinique de Villecresnes, Villecresnes, [2]Internal medicine, geriatrics, therapeuthics, Rouen University Hospital, Villecresnes, [3]Diabetology, Begin Hospital, Saint-Mandé, France, [4]Geriatry, Bicetre University Hospital, Le Kremlin Bicetre, France.

Background and aims: The observational Gerodiab cohort study aimed to describe the mortality and morbidity and associated factors in 987 French type 2 diabetic patients aged 70 years and over, during a five-year period. This study looked for factors associated at baseline with the frequency of hypoglycemia during the previous 6 months.
Materials and methods: Hypoglycemia was assessed on clinical events and self-monitoring. Data (mean±SD) were analyzed using t-test and chi² test; multivariate analyses used the logistic model.
Results: Patients with hypoglycemia (33.6%) had a longer duration of diabetes (21±11 vs.16±10 yr; P<0.001) but a similar age (77±5 vs. 77±5 yr; NS). They had a lower BMI (29±5 vs. 30±5 kg/m²; P<0.05), DBP (73±11 vs. 75±10 mmHg; P<0.05), LDL-cholesterol (2.3±0.8 vs. 2.6±1.0 mmol/L; P<0.001), MDRD (65±22 vs. 69±23 ml/min; P<0.01) and a slightly but not significantly lower HbA1c (58±11 vs. 60±15 mmol/mol [7.5±1.0 vs. 7.6±1.4%]; NS). They had a higher frequency of retinopathy (36 vs. 21%; P<0.001), nephropathy (54 vs. 44%; P<0.05) and peripheral neuropathy (36 vs 24%; P<0.01), whilst the frequency of strokes, heart failure and cerebral involvement was similar in both groups. Scores of geriatric scales (Mini-Mental State Examination, Mini-Nutritional Assessment, Instrumental Activity of Daily Living and Activity of Daily Life) were similar in both groups with the exception of the mini-Geriatric Depression Scale score which was more frequently impaired (42 vs. 31%; P<0.01). Insulin was the only treatment associated with increased frequency of hypoglycemia (75 vs. 48%; P<0.001). Using stepwise logistic regression, hypoglycemia was associated with retinopathy (P<0.01), LDL-cholesterol and the mini-GDS score (P<0.05), successively (concordance 44%; P<0.001).
Conclusion: These results underline the association between hypoglycemia and retinopathy in elderly type 2 diabetic patients and support the importance of individualizing goals in order to prevent hypoglycemic events.

Glucose variability and hypoglycaemic excursions in elderly type 2 diabetic patients treated with insulin
V.V. Klimontov[1,2], A.I. Tsiberkin[1,2], O.N. Fazullina[1], M.A. Prudnikova[1], N.V. Tyan[1], V.I. Konenkov[1];
[1]Institute of Clinical and Experimental Lymphology, [2]Novosibirsk State University, Novosibirsk, Russian Federation.

Background and aims: Continuous glucose monitoring (CGM) systems provide new opportunities for estimation of glucose variability (GV) and detection of hypoglycemia in diabetic patients. It is widely discussed that increased GV and unrecognized hypoglycemia may be associated with cardiovascular complications, particularly in elderly patients. The aim of this study was to estimate determinants of CGM-defined GV and hypoglycemic episodes in elderly insulin-treated type 2 diabetic patients.
Materials and methods: 76 patients ≥65 years of age were observed. Medical history included diabetic retinopathy (87%), peripheral artery disease (83%), coronary artery disease (61%), heart failure (55%), obesity (45%) and chronic kidney disease (CKD, 46%). Use of basal insulin (47%), premixed insulin (16%) or basal-bolus insulin regimen (37%) was followed by metformin (58%), glimepiride (18%) and DPP-IV inhibitors (18%). 3-days CGM was performed in all patients. During CGM, 3 fasting and 3 2-h postprandial finger-prick glucose values were obtained daily with glucometer. Data are presented as median, percentile 25-75.
Results: GV (SD of mean glucose during monitoring) was similar in patients on basal, premixed insulin and basal-bolus regimen (2.3, 1.8-2.8; 2.3, 2.0-2.8; 2.3, 1.7-3.3 mmol/l respectively; Kruskal-Wallis ANOVA: p=0.76) and did not depend from used oral antihyperglycemic agents. GV correlated significantly with mean monitored glucose (r=0.45, p=0.00005), but not with HbA1c (r=0.22, p=0.06). No associations were found between GV and diabetes complications. Hypoglycemic excursions (<3.3 mmol/l) were detected in 43 (57%) patients by CGM system and in 10 (13%) patients by glucometer (p=0.0001). Most of hypoglycemic episodes detected during CGM (72%) were not recognized by patients. Subjects with hypoglycemia as compared to the other patients demonstrated higher GV (2.7, 2.1-3.1 vs 1.9, 1.5-2.2 mmol/l, p=0.0001) and a tendency to lower mean interstitial glucose (7.0, 6.4-8.3 vs 7.9, 6.8-8.5 mmol/l, p=0.06). Hypoglycemia duration correlated positively with GV (r=0.43, p=0.0001). No significant differences were found between patients with and without hypoglycemia in HbA1c (7.7, 6.9-8.2 vs 7.5, 6.6-8.9% respectively, p=0.94) and daily insulin dose (0.52, 0.38-0.71 vs 0.49, 0.28-0.63 IU/kg, p=0.35). We also failed to find any differences between these groups in age, BMI, diabetes duration, treatment modality, prevalence of heart failure and CKD. The duration of insulin therapy tended to be longer in patients with hypoglycemic episodes (p=0.05). In discriminant analysis mean monitored glucose and GV, but not clinical parameters, were predictors for hypoglycemia with a classification accuracy of 81%.
Conclusion: The results indicate that asymptomatic hypoglycemia is a common complication in elderly type 2 diabetic patients treated with insulin. Traditional risk factors are weak predictors for hypoglycemia in this patient cohort. Glucose variability, but not HbA1c, is associated with incidence and duration of hypoglycemic episodes in elderly insulin-treated patients.

591

Hypoglycaemia among 3048 insulin-treated patients in real life: frequency and predictive factors: results from the prospective DIALOG study
B. Cariou[1], M. Lièvre[2], D. Huet[3], B. Charbonnel[1], C. Sert[4], D. Gouet[5];
[1]Nantes University Hospital, [2]Lyon Est Faculty of Medicine, [3]Paris St Joseph Hospital Group, [4]Novo Nordisk A/S, Paris, [5]La Rochelle Hospital, France.

Background and aims: Few data are available on hypoglycaemia rates in real life. The observational, prospective, multicentre, French DIALOG study examined the frequency of hypoglycaemia in patients with type 1 (T1DM) or type 2 (T2DM) diabetes, insulin-treated for >1 year.
Materials and methods: Endocrinologists and general practitioners consecutively enrolled patients and gave them a prospective questionnaire for self-recording hypoglycaemia over 1 month (using the ADA hypoglycaemia definition). The primary endpoint was frequency of total confirmed hypoglycaemia. Predictive factors (PF) were analysed by a multivariate regression model in 1304 T1DM and 1631 T2DM patients.
Results: Characteristics for the 3048 patients with T1DM / T2DM were: age: 49.7±15.9 / 66.8±10.6 years, BMI: 25.4±4.3 / 31.0±5.9 kg/m², HbA_{1c}: 7.8±1.2 / 7.8±1.1%, duration of diabetes: 20.9±13.0 / 17.7±9.3 years. Hypoglycaemia rates are shown in the table. Main PF in T1DM were previous history of hypoglycaemia (odds ratio [OR] 8.16), >2 daily insulin injections (OR 2.75), BMI <30 kg/m² (OR 2.14), insulin therapy duration 10 years (OR 2.00) and age >65 years (OR 1.86). In T2DM, main PF were previous history of hypoglycaemia (OR 3.52), insulin therapy duration >10 years (OR 1.72), >2 daily insulin injections (OR 2.69), use of insulin secretagogues (OR 1.54) and absence of coronary artery disease (OR 1.45).
Conclusion: DIALOG is one of the largest prospective studies of hypoglycaemia in real life which demonstrates a high frequency of confirmed hypoglycaemia in both T1DM and insulin-treated T2DM. Previous history of hypoglycaemia appears to be the main predictive factor for hypoglycaemia.

	Type 1 (N=1317)		Type 2 (N=1731)

Global prevalence of hypoglycaemia: association to treatment factors, self-management education and quality-of-life measurements

N. Hermanns[1], A. Nicolucci[2], M. Comaschi[3], M. Davies[4], M. Escalante[5], A. Forbes[6], R.I.G. Holt[7], S. Kalra[8], A. Kokoszka[9], E. Menéndez-Torre[10], N. Munro[11], F. Pouwer[12], I. Tarkun[13], M. Peyrot[14], DAWN2 Study Group; [1]Research Institute Diabetes (FIDAM), Bad Mergentheim, Germany, [2]Consorzio Mario Negri Sud, Santa Maria Imbaro, Italy, [3]ICLAS, Rapallo, Italy, [4]University of Leicester, UK, [5]University of Guadalajara, Mexico, [6]Kings College London, UK, [7]University of Southampton, UK, [8]Bharti Hospital and BRIDE, Karnal, India, [9]Medical University of Warsaw, Poland, [10]Hospital Central de Asturias, Oviedo, Spain, [11]University of Surrey, Guildford, UK, [12]Tilburg University, Netherlands, [13]Kocaeli University, Kocaeli, Turkey, [14]Loyola University Maryland, Baltimore, USA.

Background and aims: Hypoglycemia is limiting patients achieving optimal glycemic control. The 2nd Diabetes Attitudes, Wishes and Needs (DAWN2) allows a global analysis of the incidence of severe hypoglycemia (SH) and its psychosocial correlates, and the role of diabetes education in the prevention of hypoglycemia.
Materials and methods: In each of the 17 countries across 4 continents, a sample of 500 adults, stratified by diabetes type and treatment, completed a questionnaire asking about the number of SH (defined as requiring assistance of a 3rd party for recovery) over the past 12 months, and about diabetes education received. The 5-Item Problem Areas in Diabetes (PAID-5) and the WHO-5 well-being index were completed. The impact of diabetes education on change in relative risk of SH was analyzed by logistic regression models.
Results: Of the 1368 adults with types 1 (T1DM) and 7228 type 2 diabetes (T2DM), 33% self-reported ≥1 severe SH during the past 12 months. The overall incidence was 1.64 episodes per year (epy). Persons with T1DM were more affected by SH than those with T2DM (54.0% vs 28.9%), and had a higher incidence of events/yr (2.86 vs 1.4). More insulin users than non-insulin users reported SH (42.3% vs 25.0%). Highest SH rates were reported in Turkey (3.71 epy) and lowest in Japan (0.31 epy). Compared to those without SH, individuals with SH reported more diabetes-related distress (PAID-5 score +9.2 and +13.2, respectively; p<0.0001) and lower well-being (WHO-5 score -4.3 and -6.8, respectively; all p<0.0001). When comparing countries, for every 5% more participants having received diabetes education, the risk of SH was reduced by 12% in T1DM (OR 0.88; 95% CI 0.79-0.97) and by 13% in T2DM (OR 0.87; 95% CI 0.77-1.0).
Conclusion: This global study shows a high incidence of hypoglycemia in persons with both T1DM and T2DM. There are expectable differences in the incidence of hypoglycemia between T1DM and T2DM and in T2DM between insulin users and non-users. But since only subsets of PWD report hypoglycemia problems, the existence of risk groups for SH is likely. However, the fact that these incidence data rely solely on self-report must be acknowledged. Interestingly, hypoglycemia is associated with elevated diabetes-related distress and poorer well-being. Large differences in incidence of SH between countries were found. Countries with more participants in diabetes education had a lower incidence of SH. Thus, participating in diabetes education seems to be important for individuals with either T1DM or T2DM to prevent or ameliorate hypoglycemia problems.

PS 038 Hypoglycaemia mechanism and prevention

Hypoglycaemia promotes thrombosis and inflammation for at least one week in patients with type 2 diabetes

E.Y.K. Chow[1], A. Iqbal[1], F. Phoenix[2], S.R. Heller[1], R. Ajjan[2];
[1]University of Sheffield, [2]University of Leeds, UK.

Background and aims: Increased cardiovascular (CV) mortality has been reported in trials of intensive glycaemic control in individuals with type 2 diabetes (T2DM). There is strong evidence that hypoglycaemia confers excess mortality in the weeks subsequent to the event. Altered fibrin structure characteristics and subclinical inflammation have been implicated in the predisposition to these CV events. We hypothesise that low glucose creates a thrombotic/inflammatory environment, contributing to increased mortality following hypoglycaemia. Our aim was to examine the effect of hypoglycaemia on fibrin network structure/fibrinolysis as well as plasma C-reactive protein (CRP) and fibrinogen following an experimental hypoglycaemic episode.
Materials and methods: Ten patients with T2DM with mean (±SD) age of 50±8 years, duration of diabetes 9.5±4.6 years and HbA1c 8.7±2.1% were recruited. All completed paired hyperinsulinaemic clamp studies separated by at least 4 weeks. Glucose was maintained at hypoglycaemia (2.5mmol/L) or euglycaemia (6mmol/L) for two 60 minute periods. Fibrin network properties and fibrinolysis of plasma samples were investigated using a dynamic turbidimetric assay. Clot maximum absorbance (an indicator of fibrin network density) and time from full clot formation to 50% lysis (an indicator of fibrinolysis potential) were analysed. Plasma fibrinogen levels were measured using the Clauss assay, and high sensitivity CRP (hs CRP) was determined via an immunoturbidemetric assay. Four time points were analysed: baseline, end of clamp, day 1 and day 7 post clamp in both arms.
Results: Clot maximum absorbance increased after hypoglycaemic clamps reaching a peak at day 7, whereas a decrease was detected in euglycaemic clamps (Δ 0.040±0.093 and Δ-0.035±0.080 AU, respectively compared with baseline; p = 0.01). Clot lysis time increased after hypoglycaemic clamps, a change that persisted at day 7, in contrast to euglycaemic clamps that were associated with reduced lysis times (Δ64±119 vs Δ-51± 64 s; p = 0.02, see Fig). CRP levels increased significantly comparing baseline with day 7 following hypoglycaemia, whereas a reduction was noted after euglycaemic clamps (Δ 0.80±0.98 vs Δ-0.89±0.80 mg/L, p<0.0001). Fibrinogen levels were higher day 7 after hypoglycaemia compared with euglycaemic control (Δ1.09±2.58 vs Δ 0.17 ±1.25 mg/ml, p = 0.05).
Conclusion: Hypoglycaemia induces prothrombotic changes in the fibrin network and aggravates subclinical inflammation, effects that are sustained for at least 1 week. By contrast, hyperinsulinaemic euglycaemia was associated with anti-thrombotic and anti-inflammatory changes, by unclear mechanisms, that persisted after the intervention. These data provide a possible explanation for the observed increase in CV mortality weeks after a hypoglycaemic event. Moreover, hypoglycaemia may override the benefits of intensive glucose control by creating a thrombotic and inflammatory milieu.

Experimental hypoglycaemia decreases cardiac vagal function for between 7 to 30 days in patients with type 2 diabetes

A. Bernjak[1], E.Y.K. Chow[2], E. Walkinshaw[1], A. Lubina-Solomon[1], P.J. Sheridan[2], S.R. Heller[1];
[1]Human Metabolism, [2]Cardiovascular Sciences, University of Sheffield, UK.

Background and aims: Intensive glycemic therapy is associated with excess cardiovascular (CV) death in type 2 diabetes patients at high CV risk and severe hypoglycaemia predicts increased cardiovascular mortality in the weeks following the event. Since decreased cardiac vagal function predisposes to arrhythmias and sudden cardiac death, we explored the effect of hypoglycaemia on autonomic balance for up to 4 weeks following an experimental hypoglycaemic episode.
Materials and methods: 11 adults with type 2 diabetes and no CVD (mean age 50±8 years, 8 male, duration of diabetes 9.5±4.6 years) underwent paired hyperinsulinaemic clamps at least one month apart. Glucose was maintained at euglycemia (6mmol/l) and hypoglycaemia (2.5mmol/l) for two 60 minute periods in each arm. Heart rate variability (HRV) measures in time and frequency domains were obtained one, seven and 30 days after clamps from 5-minute ECG recordings. Spectral analysis of heart rate variability was performed based on Task Force guidelines. Low frequency (LF: 0.04-0.15Hz) and high frequency (HF: 0.15-0.4Hz) powers were calculated. A value of $p<0.05$ was considered statistically significant.
Results: Mean heart rate at day 7 was significantly higher after hypoglycaemia (HYPO), mean difference 5.4 (95% CI 0.2 to 10.6) bpm, compared with no change after euglycaemia (EU) 0.0 (95% CI -3.9 to 3.9) bpm, $p=0.04$. Mean HF power increased at day 7 after EU clamp 0.10 (95% CI -0.10 to 0.30) ms^2 but decreased after HYPO clamp -0.21 (95% CI -0.46 to 0.05) ms^2, $p=0.02$, indicating reduced vagal tone (see figure). In contrast, the LF/HF ratio at day 7 decreased after EU -2.14 (95% CI -0.49 to -2.79) and increased after HYPO 0.35 (95% CI -1.59 to 2.3), $p=0.02$, suggesting diminished and increased sympathetic contribution respectively. All HRV measures recovered to baseline at day 30 and there were no differences between the two groups.
Conclusion: Hypoglycaemia impaired cardiac vagal function, an effect that persisted beyond the episode for at least 1 week. There were moderate improvements in vagal function following hyperinsulinaemic euglycaemia that may be protective. Our data demonstrate that in type 2 diabetes patients a single moderate hypoglycaemic episode can perturb autonomic function beyond the acute episode for between 7 and 30 days. This work identifies a mechanism which could contribute to increased CV risk following hypoglycaemia.

Insulin prevents counter-regulatory glucagon secretion by stimulation of somatostatin release

P. Rorsman[1], E. Vergari[1], M. Brereton[2], Q. Zhang[1], B. Hastoy[1], R. Ramracheya[1], A. Salehi[3], A. Clark[1], F.M. Ashcroft[2];
[1]OCDEM, Churchill Hospital, University of Oxford, UK, [2]Parks Rd, University of Oxford, UK, [3]Department of Clinical Sciences, Lund University, Malmo, Sweden.

Background and aims: Hypoglycaemia is a major complication of insulin therapy in diabetic patients. This results from impaired counter-regulation

of glucagon secretion. The underlying mechanism is not known but it has been proposed that insulin directly inhibits glucagon secretion. Here we have tested this hypothesis by measurements of insulin-induced effects on pancreatic islet hormone secretion.
Materials and methods: Islet hormone release was measured in static incubations of groups of 10-20 size matched human or mouse pancreatic islets. Effects of insulin on the cytosolic calcium concentration ([Ca2+]i) was measured by confocal microscopy. Insulin receptor distribution was documented by immunocytochemistry.
Results: Insulin (100 nM) inhibited glucagon secretion as strongly as an increase in glucose from 1 to 6 mM. The inhibitory effect of insulin was seen only at 1 mM glucose and at 6 mM glucose, insulin actually stimulated glucagon secretion. Insulin had a weak stimulatory effect on C-peptide release but strongly (>3-fold) stimulated somatostatin release in islets exposed to 1 mM glucose. In mouse islets, insulin also potentiated somatostatin secretion. The inhibitory effect of insulin on glucagon secretion was antagonized by the insulin receptor S961. Interestingly, the SSTR2 antagonist CYN154806 prevented the suppressor effect of insulin on glucagon secretion in mouse islets (in which insulin likewise inhibits glucagon secretion and stimulates somatostatin secretion). The presence of insulin receptors in somatostatin-releasing delta cells was verified by immunocytochemistry. Measurements of [Ca2+]i in human islets revealed that insulin evoked [Ca2+]i oscillations at 1 mM glucose in a small subset of cells. A similar stimulation by insulin was seen in mouse delta cells. Insulin tolerance tests revealed improved insulin tolerance in mice in which insulin was co-administered with CYN154806.
Conclusion: Our data suggest that the suppressor effect of insulin on glucagon secretion, rather than being mediated by a direct effect on the alpha cells, results from stimulation of somatostatin secretion from the delta cells which then inhibits glucagon secretion by a paracrine effect. These findings highlight the significance of paracrine signalling in (human) pancreatic islets and suggest that insulin-induced hypoglycemia in diabetic patients may be possible to control with somatostatin receptor antagonists.

Pharmacokinetics and pharmacodynamics of a chemically stable micro-dosed glucagon in a diabetic swine model of type 1 diabetes
B. Newswanger[1], S. Prestrelski[1], N. Scott[1], E.R. Damiano[2], J. Jiang[2], F.H. El-Khatib[2], K.M. McKeon[2], S.J. Russell[3], P. Sluss[3];
[1]Xeris Pharmaceuticals, Austin, [2]Boston University, [3]Massachusetts General Hospital, Boston, USA.

Background and aims: In order to create a bihormonal bionic endocrine pancreas that provides both insulin and glucagon replacement therapy for type I diabetics, a pumpable glucagon formulation is needed that is bioactive on the liver and chemically stable for up to three days at near body temperatures.
Materials and methods: We analyzed the pharmacokinetics (PK) and pharmacodynamics (PD) of a stable, non-aqueous, concentrated (5 mg/ml), pumpable, liquid glucagon formulation in an animal model of type 1 diabetes. Both fresh and aged (~7-8 days stored in a pig's backpack) doses of the glucagon were administered subcutaneously in separate experiments using an insulin pump connected to an infusion set inserted in Yorkshire swine after streptozoticin (STZ) treatment. Experiments began ~5 hours postprandially and after blood glucose had been regulated to between 60 and 140 mg/dl. Two consecutive glucagon doses (separated by ~60-120 minutes) were administered from the same pump reservoir for each experiment. Venous blood glucose concentration was measured in real time every 10 minutes (GlucoScout, International Biomedical) in order to assess glucagon PD. To assess glucagon PK, plasma samples were drawn every 10 minutes for plasma glucagon concentration, measured by immunoassay (Millipore). Identical experiments were conducted with freshly reconstituted commercially available glucagon formulation (Eli Lilly), which is chemically stable in solution for only a few hours.
Results: The first dose showed less of a PD response due to the higher plasma insulin levels that persisted from the insulin therapy in the pre-experimental period. Consequently, only the second dose response for each experiment (n = 3 experiments) was considered when calculating the increase in blood glucose that accompanied each glucagon dose. On the other hand, every dose response (2 doses per experiment, n = 3 experiments) was considered in the calculation of glucagon Tmax. The average Tmax for fresh and aged non-aqueous glucagon was 9 and 12 minutes, respectively (n = 6 experiments for both) and 10 minutes for freshly reconstituted Lilly glucagon (n = 4 experiments). The average increase in blood glucose during the second dose response for fresh and aged non-aqueous glucagon was 13.7 and 17.6 mg/dL/10g, respectively (n = 3 experiments), compared with 18.5 mg/dl/10g for freshly reconstituted Lilly glucagon (n = 2 experiments).
Conclusion: These preliminary results suggest that non-aqueous glucagon shows comparable efficacy, both aged and fresh, to freshly reconstituted Lilly glucagon in STZ-treated diabetic pigs. This swine model translates well to humans and paves the way for an upcoming first-in-human study using a stable pumpable glucagon in the bihormonal closed-loop artificial pancreas.

Preclinical pharmacology study of stabilised liquid glucagon
S.J. Prestrelski, B.J. Newswanger;
Xeris Pharmaceuticals, Austin, USA.

Background and aims: Severe hypoglycemia remains a significant unmet medical need. Currently approved glucagon rescue products (Lilly, Glucagon™ for Injection; Novo Glucagen®) are based on lyophilized formulations which require reconstitution, complicating ease of administration in emergency situations. A simple, ready-to-use, soluble glucagon formulation has been developed based on biocompatible, non-aqueous solvents that effectively suppress the fibrillation of glucagon typically observed in aqueous solutions. Upon characterization with both RP-HPLC and bioassay, this non-aqueous formulation has demonstrated superior chemical stability after six months of storage at room temperature and accelerated conditions. With a formulation exceeding CMC criteria required for the target product profile, *in vivo* pharmacology of the drug product was established in a rodent model.
Materials and methods: A comparative pharmacology study was comprised of 4 treatment groups of SD male (n=10) and female (n=10) rats. Rats were injected subcutaneously (SC) with 2.5 μg, 5 μg, or 50 μg non-aqueous glucagon, or with 5 μg Lilly Glucagon™ reference drug. Blood was collected from each animal pre-dosing (t=0 min), and 2.5., 5, 10, 15, 30, 45 and 60 min post-dose for determination of blood glucose and plasma glucagon concentrations.
Results: The study demonstrated that at *half the dose*, SC injected non-aqueous glucagon resulted in similar ($p > 0.05$) pharmacokinetic endpoints (AUC, C_{max}, $T_{max,\ and}$ $T_{1/2}$) to 5 μg SC doses of the Lilly Glucagon™ reference drug. Injection of 2.5 μg non-aqueous glucagon showed rapid absorption (T_{max} ~ 5 min), and marked elevation of blood glucose levels in male rats (TBG_{max} ~ 11.5 min). BG_{max} was normally distributed (p=0.2007) between groups. There was a proportional relationship between the non-aqueous glucagon injection dose (2.5 μg, 5 μg, or 50 μg) and the measured plasma glucagon concentrations.
Conclusion: The statistical analyses the study reported herein showed the non-aqueous glucagon formulation for SC injection to have a favorable non-clinical pharmacokinetic and pharmacodynamic profile when compared with the non-clinical *in vivo* behavior of the Lilly Glucagon™ reference drug. In a concurrent 14-day GLP safety/toxicology study, there were no statistically significant histopathological findings indicative of toxicity of the non-aqueous glucagon, again as compared to Lilly Glucagon™. Overall these data support development of the non-aqueous glucagon as a room-temperature stable, ready-to-use rescue drug for severe hypoglycemia, as well as a glucagon formulation suitable for a bi-hormonal (insulin-glucagon) infusion pump.

Effects of RAS blockade on ECG and EEG during hypoglycaemia in patients with type 1 diabetes
L.H. Færch[1], B. Thorsteinsson[1,2], L. Tarnow[3], T.W. Kjær[4], J. Kanters[5], C. Larroude[6], U. Pedersen-Bjergaard[1];
[1]Dept. of Cardiology, Nephrology and Endocrinology, Hypoglycaemia research group, Hillerød, [2]Faculty of Health Sciences, University of Copenhagen, [3]Health, University of Aarhus, [4]Neuroscience Centre, University of Copenhagen, [5]Dept. of biomedical Sciences, University of Copenhagen, [6]Dept. of Biomedical Sciences, University of Copenhagen, Denmark.

Background and aims: Increased heart rate and QT prolongation are associated with hypoglycaemia in type 1 diabetes, potentially leading to sudden death from ventricular tachyarrhythmia. High renin-angiotensin system (RAS) activity increases the risk of severe hypoglycaemia in type 1 diabetes, and RAS is implicated in ventricular tachyarrhythmia. Moreover, high spon-

taneous RAS activity may result in lower cerebral activity at the EEG and a more pronounced cognitive impairment during mild hypoglycaemia in type 1 diabetes, thus conferring an increased risk of severe hypoglycaemia. We therefore studied the effect of RAS blockade on ECG and EEG during hypoglycaemia in patients with type 1 diabetes.
Material and methods: Nine patients with type 1 diabetes and high RAS activity were included in a double-blind, randomised, balanced, cross-over study of the effect of 32 mg candesartan or placebo for one week on ECG (QT interval, heart rate) and EEG during two hyperinsulinaemic hypoglycaemic clamps separated by at least 4 weeks. Heart rate and QT intervals were calculated from five 12-lead ECG recordings of 10 sec duration obtained at the beginning and end of the baseline and hypoglycaemic periods. ECG analysis was done semi-automatically and QT analysis was performed by a trained cardiophysiologist. The QT interval was corrected for differences in heart rate (HR) according to Bazett's (QTcb) and Fridericia's (QTcf) formulas. A 20-lead EEG was obtained during a 5-min resting period at baseline and hypoglycaemia. The mean centroid frequency (5-11 Hz) was used to evaluate the effect of hypoglycaemia on the five brain areas: frontal cortex, cortex of the central sulcus, temporal cortex, parietal cortex, and occipital cortex.
Results: Heart rate increased from baseline to hypoglycaemia on the placebo day (p=0.01) but remained unchanged on the candesartan day (p=0.65). Heart rate on candesartan was 3.3 (0.8-5.8) (mean (95%CI)) beats per min lower than on placebo (p=0.02). QTcb and QTcf were increased by approximately 2.5% during hypoglycaemia (p<0.008) with similar effect during candesartan and placebo treatment. EEG was not affected by candesartan in any of the different brain areas (p=0.2-0.4).
Conclusion: Candesartan possesses a stabilising effect on heart rate during hypoglycaemia but has no effect on length of the QT interval. No effect on centroid frequency was observed in any brain area at candesartan treatment compared to placebo.

Effects of 6 weeks treatment with sitagliptin on counterregulatory and incretin hormones during acute hypoglycaemia in patients with type 1 diabetes

J.E. Schopman[1], J.B.L. Hoekstra[1], B.M. Frier[2], J.J. de Sonnaville[3], A.M. Stades[4], R. Zwertbroek[5], J.J. Holst[6], F.K. Knop[7], F. Holleman[1];
[1]Internal Medicine, Academic Medical Centre, Amsterdam, Netherlands, [2]The Queen's Medical Research Institute, Edinburgh, UK, [3]Internal Medicine, Tergooiziekenhuizen, Hilversum, Netherlands, [4]Internal Medicine, University Medical Center, Utrecht, Netherlands, [5]Internal Medicine, Westfriesgasthuis, Hoorn, Netherlands, [6]Biomedical Sciences, The Panum Institute, Copenhagen, Denmark, [7]Internal Medicine, Gentofte Hospital, Copenhagen, Denmark.

Background and aims: Within a few years of onset of type 1 diabetes the glucagon response to hypoglycaemia is severely diminished. Inhibitors of the enzyme dipeptidyl peptidase 4 (DPP-4), which under normal circumstances inactivates the incretin hormones, enhance glucagon secretion during hypoglycaemia in patients with type 2 diabetes. The aim of this study was to assess whether the DPP-4 inhibitor sitagliptin enhances the glucagon response to hypoglycaemia in patients with type 1 diabetes.
Materials and methods: We conducted a single-centre, randomised, double-blind, placebo-controlled, three-period cross-over study. We studied 16 male patients with type 1 diabetes and intact hypoglycaemia awareness (median [interquartile range] age 32 [27-40] years, diabetes duration 11 [6-15] years and HbA1c 66 (61-71) mmol/mol (8.1 [7.7-8.6] %)). Participants received sitagliptin (100 mg/day) or placebo as outpatients for 6 weeks and attended the hospital for three acute hyperinsulinaemic hypoglycaemia studies (at baseline, after sitagliptin treatment and after placebo). During the experiments arterialized blood glucose was stabilized for 30 minutes at 5.0 mmol/l (initialisation phase). Thereafter glucose infusion was discontinued until the patient developed objective evidence of an autonomic reaction (defined by an increment of 20% or more in heart rate and/or systolic blood pressure) or until blood glucose fell below 2.0 mmol/l. Following autonomic reaction the insulin infusion was terminated and an infusion of 20% glucose was commenced at a rate of 50 ml×h-1. We measured plasma concentrations of glucagon and other hormones during the hypoglycaemia studies at the middle of the initialisation phase, during autonomic reaction, and 10, 20 and 40 minutes after the onset of autonomic reaction.
Results: No significant differences were observed for the glucagon or adrenergic counterregulatory response during the three hypoglycaemia studies, but absolute growth hormone concentration at 40 minutes after occurrence of autonomic reaction was significantly lower after sitagliptin treatment (median [interquartile range] 23.0 [0.2-211.0] mEq/l) when compared to placebo (90.0 [8.8-180] mEq/l) (p=0.008), but not significantly lower when compared to baseline (64.0 [4.0-205.0] mEq/l) (p=0.16). The change in growth hormone concentration from the initialisation phase to 40 minutes after onset of autonomic reaction was also significantly lower after sitagliptin treatment 23.0 [1.5-73.4 mEq/l] than after placebo (82.6 [35.3-137.5] mEq/l) (p=0.001), but not when compared to baseline (37.1 [7.5-95.7 mEq/l]. No differences in growth hormone responses were observed between the three hypoglycaemia studies at other time points.
Conclusion: Sitagliptin does not enhance the glucagon counter-regulatory response in patients with type 1 diabetes.

Risk factor assessment for irreversible brain damage in patients with drug-induced severe hypoglycaemia

T. Iwakura, M. Kondo, S. Sasaki, N. Matsuoka, T. Ishihara;
Diabetes and Endocrinology, Kobe City Medical Center, Japan.

Background and aims: Type 2 diabetes patients who are treated with insulin or sulfonylurea drugs (SU) commonly experience severe hypoglycemia (SH) as a common adverse effect. Recently, many studies have shown a relationship between SH and cardiovascular events, but few have examined the risk factors for irreversible brain damage (IBD) due to SH.
Materials and methods: We retrospectively analyzed the risk factors for IBD in patients with drug-induced SH. We investigated 189 type 2 diabetes patients (age 73.8 ± 10.9 years) who visited our hospital's emergency department because of drug-induced SH between November 2008 and October 2012. The Glasgow Coma Scale (GCS) was used to determine the level of consciousness. IBD was defined as a GCS below 14 at day 14. We examined the following risk factors: age, gender, diabetic medication, plasma glucose level, HbA1c level, and GCS on arrival at the hospital and estimated maximum duration of coma (MAXC duration) before treatment. MAXC duration was defined as the interval between the time the patient last confirmed clear sensorium and the first care given in the hospital; duration of protracted hypoglycemia was defined as the interval between the time care was first given and the first stable capillary glucose level of >100 mg/dL.
Results: The patients' plasma glucose levels (34.4 ± 11.2 mg/dL) correlated with GCS on arrival at the hospital ($p < 0.001$). The mean HbA1c level was 6.70 ± 1.13%. One hundred and fourteen patients had been treated with SU; 50 with insulin; 13 with both SU and Dipeptidyl peptidase 4 (DPP4) inhibitors; 11 with both SU and insulin; and 1 with both insulin and DPP-4 inhibitors. Ten patients had IBD. Logistic analysis revealed that the risk factors for IBD were low plasma glucose levels on arrival (odds ratio [OR]: 0.81; 95% confidence interval [CI]: 0.62-0.94, $p < 0.01$), low GCS score on arrival (OR: 0.58; 95% CI: 0.25-0.95, $p < 0.05$), and MAXC duration (OR: 1.28; 95% CI: 1.13-1.65, $p < 0.001$). MAXC duration of less than 8 hours was likely to be associated with recovery of consciousness, but when the duration was longer than 12 hours, recovery was unlikely. Hypoglycemia due to SU use was associated with a longer duration of protracted hypoglycemia compared with the duration associated with hypoglycemia due to insulin use (7.89 ± 5.31 hours vs. 2.70 ± 3.02 hours, $p < 0.001$).
Conclusion: Our data suggest that MAXC lasting longer than 12 hours before treatment is the most reliable predictor for the development of IBD. Long-acting insulin and SU are likely to be the causes of IBD.

601

Hypoglycaemia related events due to falls in elderly diabetics (H.E.A.L.E.D) study in US veterans

Y. Zhao[1,2], S. Kachroo[3], H. Kawabata[4], S.A. Colilla[4], L. Shi[1], J. Mukherjee[5], U. Iloeje[5], V. Fonseca[6];
[1]Global Health Systems and Development, Tulane University, New Orleans, [2]Southeast Louisiana Veterans Health Care System, New Orleans, [3]Bristol-Myers Squibb, Nassau Park, [4]Bristol-Myers Squibb, Hopewell, [5]Bristol-Myers Squibb, Wallingford, [6]Section of Endocrinology, Tulane University, New Orleans, USA.

Background and aims: Fall-related events in the elderly are associated with increased morbidity and mortality. This retrospective cohort study aimed to examine the association between hypoglycemia and fall-related events among elderly veterans with type 2 diabetes mellitus (T2DM).
Materials and methods: Electronic medical and pharmacy records were obtained for patients (N=149,053) with at least 2 records of T2DM diagnosis (ICD-9-CM codes: 250.x0 and 250.x2) from the Veterans Integrated Service Network (VISN) 16 data warehouse from 01/01/2004 to 06/30/2010. The VISN 16 covers Arkansas, Louisiana, Mississippi, Oklahoma, and parts of Alabama, Florida, Missouri, and Texas. Patients with type 1 diabetes were excluded (ICD-9-CM codes: 250.x1 and 250.x3). Subjects were required to be ≥65 years at cohort entry (01/01/2004) and have continuous enrolment and pharmacy benefits throughout the study period. The date of the first recorded hypoglycemia (ICD-9-CM codes: 250.8, 251.0, 251.1 and 251.2) was defined as the index date for a case. Cases with the index date from 01/01/2005 to 07/01/2009 were included to ensure one-year baseline and one-year follow-up. Controls (no hypoglycemia recorded) were randomly matched with cases by age (+/-5 years), gender, race, and location of the VA medical center. Fall-related events (i.e., fractures and head injuries) were defined as ICD-9-CM codes between 800.x - 995.x, with a fall being the external cause (ICD-9-CM E-codes between E880 - E888), which were recorded within 2 days before and after the fall event. Chi-square tests were used to compare the post-index fall-related events within 30 days, 90 days, 180 days and 365 days between the two cohorts. Generalized estimating equation (GEE) models were fit to compare fall-related events over 365 days in terms of the point estimate of the adjusted odds ratio (aOR) and the 95% confidence interval (95% CI), controlling for baseline characteristics and comorbidities. Two subgroup analyses (ages of <75 years and >=75 years) were also conducted.
Results: A total of 4,274 cases were matched with 4,274 controls. Over one year after the index hypoglycemia, patients with hypoglycemia consistently had higher fall-related events: 30 events (0.70%) among the cases and 2 events (0.05%) among the controls within 30 days; 53 events (1.24%) and 6 events (0.14%) within 90 days; 70 events (1.64%) and 15 events (0.35%) within 180 days; and 98 events (2.29%) and 31 events (0.73%) within 1 year. All cross-cohort differences were statistically significant in elderly veterans and by age group (all p-values <0.05). Correspondingly, the GEE models confirmed the elevated risk of fall-related events over 365 days (aOR=1.93, 95% CI=1.25-2.97) for the elderly veterans, and for the >=75 years group (aOR=1.95, 95% CI=1.15-3.34) and <75 years group (aOR=1.87, 95% CI=0.92-3.83; p=0.085).
Conclusion: Hypoglycemia in elderly diabetic veterans was associated with an almost 2 fold increase in the risk of major fall related events. Physicians treating elderly diabetics need to provide patient education and choose medications that minimize the risk of hypoglycemia and the ensuing complications of falls.

Cocoa flavonoids attenuate high glucose-induced insulin signalling blockade and enhance glucose uptake and production in human HepG2 hepatic cells

S. Ramos[1], I. Cordero-Herrera[1], L. Bravo[1], M.A. Martin[1,2], L. Goya[1];
[1]ICTAN-CSIC, [2]CIBERDEM, Madrid, Spain.

Background and aims: Insulin resistance is the primary characteristic of type 2 diabetes, which results in insulin signalling defects. Flavonoids have been found to possess beneficial effects on health and have drawn attention because of their safety. Cocoa and its main flavanol, (-)-epicatechin (EC), display some antidiabetic effects, but the mechanisms for their preventive activities related to glucose metabolism and insulin signalling in the liver remain largely unknown. In the present work, the effect of EC and a cocoa polyphenolic extract (CPE) on insulin signalling is studied in insulin-responsive human HepG2 cells treated with high glucose.
Material and methods: HepG2 cells treated for 24 h with physiological concentrations of EC (10 μM) and CPE (1 μg/mL) were further exposed to 30 mM glucose for 24 h. Tyrosine phosphorylation of IR and its substrates (IRS-1 and -2) were analysed by Western blot in cellular immunoprecipitates. Total levels of IR, IRS-1 and -2 and key proteins of insulin signalling such as AKT, GSK3, GS, AMPK and PEPCK were assayed by Western blot. Glycogen content and glucose uptake were evaluated by using a commercial fluorometric kit and 2-((7-nitro-2,1,3-benzoxadiazol-4-yl)amino-2-deoxy-D-glucose (2-NBDG) assay, respectively. Glucose production was also determined by evaluating glucose levels after incubating the cells in glucose production buffer.
Results: Pre-treatment of cells with EC or CPE reverted the decreased tyrosine-phosphorylated and total levels of IR, IRS-1 and -2 induced by glucose (30 mM). EC and CPE pre-treatment also prevented the inactivation of the PI3K/AKT pathway induced by glucose, showing a glycogen content similar to those of control cells. Furthermore, glucose induced a diminution of p-AMPK levels, which was avoided by EC and CPE. Pre-treatment of cells with EC and CPE also prevented the increased PEPCK levels and glucose uptake provoked by 30 mM glucose and returned to control values the enhanced levels of glucose production. GLUT-2 expression levels were unaffected by any treatment.
Conclusion: EC and CPE at concentrations that are not toxic to hepatic cells and are reachable through the diet, possess an insulin-like activity. EC and CPE prevented the decrease of the tyrosine phosphorylated and total IR, IRS-1 and IRS-2 levels, as well as the inhibition of PI3K/AKT and AMPK pathways induced by high glucose. Further efforts are needed to define the precise role of EC and cocoa in the regulation of the insulin pathways in liver cells, but it could be suggested that a diet rich in EC and/or cocoa may be a potential chemopreventive tool useful for the management of diabetes.

Can carotid sinus nerve resection be a therapeutic approach for the treatment of insulin resistance?

M.J. Ribeiro, J.F. Sacramento, M.P. Guarino, S.V. Conde;
Farmacologia, CEDOC, Faculdade Ciências Médicas, Universidade Nova de Lisboa, Portugal.

Background and aims: The carotid bodies (CBs) are peripheral chemoreceptors which respond to its classical stimulus, hypoxia, increasing the action potential frequency in their sensorial nerve, the carotid sinus nerve (CSN), leading to an increase in minute ventilation and sympathetic outflow. Recently, our lab demonstrated that CB is involved in aetiology of insulin resistance (IR) and that CSN resection prevents the development of IR in rats fed with hypercaloric diets through sympathoadrenal overactivation. Herein, we tested if blockade of CB activity through CSN resection reverses IR induce by high sucrose (Hsu) diet.
Materials and methods: Four groups of Wistar rats, age 9-12 weeks were used. The control group was fed a sham diet ((7.4% fat+75% carbohydrate (4% sugar) + 17% protein) and the HSu group was fed 35% sucrose in drinking water. CSN bilateral resection in HSu rats was performed after 28 days

of hypercaloric diet under ketamine (30mg/kg)/xylazine (4mg/kg) anaesthesia and brupenorphine (10g/kg) analgesia. These animals were maintained under the hypercaloric diet after CSN denervation. Rats submitted to CSN bilateral resection were compared with animals submitted to the same surgical procedure but in which CSN was left intact (sham). Fasting glycemia and insulin sensitivity were evaluated in conscious rats prior to CSN denervation and once a week after CSN resection, through an insulin tolerance test (ITT). After 3 weeks, rats were anaesthetized with pentobarbital and blood pressure, body weight, visceral and total fat were determined. Also, blood was collected by heart puncture to quantify insulinemia, free fatty acids and triglycerides.
Results: Sham procedure did not modify any of the parameters evaluated. Insulin sensitivity diminished in HSu rats as the constant of the insulin tolerance test (KITT) decreased significantly to 2.46±0, 30 from a control value of 4, 39± 0,29. Basal glycemia was significantly increased in HSu rats (control = 83.33±1.81 mg/dL; HSu = 114.6±12.6 mg/dL). One week after CSN resection, insulin sensitivity increased in HSu rats and hyperglycemia was completely reversed to control values. Two weeks after CSN resection normoglycemia was maintained and insulin sensitivity was completely restored to control values. From the 2nd to 3rd week normoglycemia and insulin sensitivity were maintained, though the animals continued to be submitted to the hypercaloric diet. Weight, total and visceral fat were not modified by CSN resection. HSu diet significantly increased blood pressure and CSN resection reversed this increase.
Conclusion: Our results demonstrate that CSN resection reverses diet-induced HT and IR and may represent a potential therapeutic approach for the treatment of the metabolic syndrome.

Background and aims: The heart is a constitutive energy-demanding organ. Although mitochondrial lipid oxidation is the principal energy source, the maintenance of glucose utilization is necessary for normal cardiac function and alterations in cardiac energy metabolism downstream neurohormonal stimulation play a crucial role in the pathogenesis of heart failure. G protein-coupled receptors (GPCRs) are essential regulators of cardiovascular physiopathology that are under the control of G protein-coupled receptor kinases (GRKs). In particular, the GRK2 isoform is a key regulator of cardiac physiology and increased levels of cardiac GRK2 correlate with cardiac dysfunction and heart failure in humans. Previous works have described the potential role of GRK2 as a modulator of insulin signaling in several tissues, including the heart of young animals. In this work we explore the effect of lowering GRK2 levels in adult mice and under insulin resistance-promoting conditions in order to mimic two different situations in which humans start to develop heart complications.
Materials and methods: We have used GRK2 hemizygous mice ($GRK2^{+/-}$) as a model to assess the effects of a sustained systemic inhibition of GRK2 in heart tissue. Using microarray RNA expression techniques we have compared the transcriptional profile of the cardiac tissue of 9 months old wild-type and $GRK2^{+/-}$ C57BL6 mice, and also characterized the hearts of these animals by echocardiographic and morphometric analysis. We also studied cardiac insulin sensitivity with age and under high fat diet (HFD) by Western Blot.
Results: In 9 month-old $GRK2^{+/-}$ mice we detected changes in the gene expression profile of genes reported to be modulated by insulin or beta-agonists as well as in genes regulated by exercise and physiological heart hypertrophy that were in line with data obtained from the morphometrical studies. We also find that in $GRK2^{+/-}$ mice insulin sensitivity was preserved with age and after a high fat diet feeding. Consequently, we have found that GRK2 levels are increased in the heart of C57BL6 mice fed with HFD as well as in obese (ob/ob) mice.
Conclusion: These results demonstrate the importance of maintaining GRK2 levels under a certain physiological level to preserve insulin sensitivity in cardiac tissue. These data help explain the cardioprotective effects described for the inhibition of this kinase.

Therapeutic properties of the vanadium compound, $VO(dmpp)_2$, by ex vivo and in vivo studies in diabetic GK rats
J. Pelletier[1], N. Domingues[2], C.-G. Ostenson[1], M.M.C. Castro[2];
[1]Dept of Molecular Medicine and Surgery, Karolinska Institutet, Stockholm, Sweden, [2]Dept of Life Sciences, University of Coimbra, Portugal.

Background and aims: Intensive research has been carried out to find compounds to substitute insulin in treatment of diabetes. The bis(1,2-dimethyl-3-hydroxy-4-pyridinonato)oxovanadium (IV), $VO(dmpp)_2$, has shown anti-diabetic effects by *ex vivo* study in Wistar (W) rats and *in vivo* study in obese Zucker rats. We aimed to confirm the therapeutic properties of $VO(dmpp)_2$ in non-obese diabetic Goto-Kakizaki (GK) rats.
Materials and methods: The effects of $VO(dmpp)_2$ on glucose uptake were assessed in W and GK rat adipocytes using [3-^{3}H]-glucose radioactive assay and compared to the effects of insulin and bis(maltolato)oxovanadium (IV), BMOV. W and GK rats were treated daily, during 21 days, with $VO(dmpp)_2$ (44 μg/kg) to show its effects on glycemia, OGTT and insulin signalling pathway using SDS-PAGE.
Results: In adipocytes from both W and GK rats the increase of glucose uptake, relative to basal value, achieved by 100 μmol/l $VO(dmpp)_2$ (193 ± 20% and 254 ± 21%, respectively) and by 500 μmol/l BMOV (152 ± 23% and 219 ± 37%, respectively) were similar to an insulin concentration of 10 ng/ml (176 ± 14% and 201 ± 29%, respectively) considered as the normal blood insulin concentration after a meal. Non-toxic concentrations of 100 and 500 μmol/l of $VO(dmpp)_2$ promoted, respectively, glucose uptake enhancement of 193 ± 20% and 322 ± 16% (1.9 and 3.2 times higher, respectively, $p<0.01$ and $p<0.001$, relative to basal value) in W adipocytes and 254 ± 21% and 424 ± 37% (2.5 and 4.2 times higher, respectively, $p<0.001$ and $p<0.001$, relative to basal value) in GK adipocytes. The same concentrations of BMOV produced a lower glucose uptake effect in both types of adipocytes (100 μmol/l: 111 ± 20%, not significant; 500 μmol/l: 153 ± 23%, $p<0.05$, relative to basal value for W adipocytes, vs 100 μmol/l: 145 ± 26%, $p<0.05$ and 500 μmol/l: 219 ± 37%, $p<0.01$, relative to basal value for GK adipocytes). Thus, $VO(dmpp)_2$ shows in W and GK rat adipocytes a better efficiency on glucose uptake compared to BMOV ($p<0.01$ or less), which is similar or even higher than that of insulin. *In vivo* study shows that after 8 days of treatment, $VO(dmpp)_2$ improved glycemia in GK rats compared to GK rats treated with placebo (8.4 ± 0.3 vs 10.1 ± 0.2 mmol/l, $p<0.001$). After 21 days of treatment, the body weights of W and GK rats were not changed by $VO(dmpp)_2$ but this compound improved glucose tolerance profile in GK rats compared to GK rats treated with placebo (13.1 ± 0.5 vs 20.6 ± 0.7 mmol/l/min, $p<0.001$), despite no increase in plasma insulin levels before and during OGTT. In W rats, OGTT was not changed by $VO(dmpp)_2$ treatment, however, plasma insulin levels were significantly lower in animals treated with this compound when compared to placebo group (0 min: 7.1 ± 1.8 vs 20.6 ± 3.1, $p<0.01$; 30 min: 29.8 ± 3.7 vs 50.9 ± 7.0, $p<0.05$; and 120 min: 7.6 ± 1.0 vs 21.2 ± 5.5 μU/ml, $p<0.05$). In W and GK rats $VO(dmpp)_2$ significantly promoted IRS2 expression ($p<0.05$) and phosphorylated AKT ($p<0.001$ and $p<0.05$, respectively, relative to respective controls) and in GK rats reduced the increase of PTP1B expression ($p<0.001$, relative to GK treated with placebo) which indicates that these proteins are targets of $VO(dmpp)_2$ action.
Conclusion: $VO(dmpp)_2$ shows anti-diabetic properties by improvement on glucose uptake, glycemia and OGTT by interaction with the insulin signalling pathway. These therapeutics properties show that $VO(dmpp)_2$ is a promising molecule for novel therapy of type 2 diabetes.

606

Insulin receptor-sensitising polyaminosterols as a novel therapeutic approach for the treatment of type 2 diabetes

R. Govers[1,2], T. Gonzalez[2], N. Zaarour[2], M. Berenguer[2], Y. Le Marchand-Brustel[3], J.-F. Tanti[3], F. Bost[3], V. Corcelle[3], J. Zhang[4], T. Xu[4], J.M. Brunel[5]; [1]UMR Inserm U1062, INRA 1260, Marseille, France, [2]Inserm U895, Nice, France, [3]Inserm U1065, Nice, France, [4]Institute of Biophysics, Chinese Academy of Sciences, Beijing, China, [5]UMR CNRS U7258, CRCM, Marseille, France.

Background and aims: Insulin governs glucose homeostasis by regulating glucose synthesis by the liver and the uptake of glucose by muscle and fat. A disturbed regulation can lead to type 2 diabetes (T2D), which is characterised by insulin-resistance in muscle, fat, and liver and the production of an amount of insulin that is insufficient to compensate for this resistance. In the present study, we aim to assess the potential therapeutic value of a novel class of polyaminosterols for the treatment of T2D.
Materials and methods: Various polyaminosterols were analyzed for their effect on GLUT4 translocation, glucose uptake, and insulin signalling in 3T3-L1 adipocytes and/or L6 myoblasts. One of the compounds that displayed the highest insulin-sensitizing effect was tested in lean and DIO mice (IP administration) to evaluate its action on glucose tolerance and insulinemia.
Results: In 3T3-L1 adipocytes, certain novel polyaminosterols enhanced insulin action on GLUT4 translocation, glucose uptake, and lipolysis. Moreover, these sterols reduced the half-maximal dose (ED50) of insulin regarding GLUT4 translocation (from 1.6 to 0.3 nM; P<0.0001), while their insulin-enhancing effect was maintained in insulin-resistant adipocytes. In 3T3-L1 adipocytes as well as in L6 myoblasts, these molecules induced an increase in the phosphorylation and activation of the insulin receptor (IR). This sensitization appeared to be a direct action of the sterols on the IR and to be distinct from the mode of action of the well-known aminosterol trodusquemine (MSI-1436). Trodusquemine, described to increase IR activation through inhibition of phosphatase PTP1B, did not sensitize the IR in our cells. Treatment of lean mice as well as insulin-resistant DIO mice with one of our polyaminosterols ameliorated glucose tolerance for all doses tested, without causing hypoglycemia. This amelioration was not accompanied by increased insulin levels suggesting that the sterol acted directly on the insulin-sensitive tissues.
Conclusion: We have identified novel polyaminosterols that increase insulin action in vitro and in vivo, under normal as well as under insulin-resistant conditions. Given the essential role of insulin-resistance in T2D, we speculate that these polyaminosterols could have potential for the development of a novel therapeutic avenue for the treatment of T2D.

Dapagliflozin improves muscle glucose uptake and increases hepatic glucose production in type 2 diabetes mellitus individuals

M. Abdul-Ghani, A. Merovci, C. Solis, R. Eldor, D. Tripathy, D. Giuseppe, R. DeFronzo;
Medicine, University of Texas Health Science Center at San Antonio, San Antonio, USA.

Background and aims: Chronic elevation in plasma glucose concentration increases the risk of microvascular complications and aggravates the core defects of T2DM, i.e. insulin resistance and beta cell dysfunction. Studies in experimental animals have demonstrated that lowering the plasma glucose concentration with phlorizin improves insulin sensitivity in diabetic animals. The aim of the present study was to examine whether lowering the plasma glucose concentration by inhibiting SGLT2 with dapagliflozin improves insulin sensitivity in T2DM individuals.
Materials and methods: 11 males with T2DM (age= 51±3; BMI= 31.1±1.6) received: (i) 75-gram OGTT; and (ii) euglycemic hyperinsulinemic clamp. After completing the baselines studies, subjects were admitted for 3 days to the CRC for the measurement of hepatic glucose production (HGP) rate and starting the dapagliflozin treatment. On day 1, HGP was measured after an overnight fast with ^{3}H-glucose infusion. On day 2, the ^{3}H-glucose infusion was started after an overnight fast and after 3-hour equilibration period, subjects ingested 10 mg dapagliflozin and the ^{3}H-glucose infusion was continued for additional 4 hours. Subjects received dapagliflozin (10 mg/day) for additional 6 days, and at day 3 the HGP was repeated and on days 6 and 7 the OGTT and the euglycemic clamp were repeated.
Results: Dapagliflozin increased urinary glucose excretion by 69±7 gram/24 hours and this glucosuria was accompanied by a 28±6 mg/dl and 72±11 mg/dl decrease in the FPG and 2-hour plasma glucose concentrations, respectively, (p<.001 for both). The decrease in plasma glucose concentration was accompanied by 28% increase (from 4.6±0.6 to 5.9±0.5 mg/kg.min, p<0.001) in the whole body glucose disposal (TGD) rate, and the increase in TGD (19%, p<0.01) remained significant after correcting for urinary glucose loss during the insulin clamp. Surprisingly, the decrease in the plasma glucose concentration was accompanied by 16% (p<0.05) increase in the rate of HGP and 23% increase in plasma glucagon concentration. Dapagliflozin also improved beta cell function. Following dapagliflozin treatment, there was ~2-fold increase in the insulin resistance/insulin sensitivity (disposition) index.
Conclusion: Lowering the plasma glucose concentration with SGLT2 inhibitor, dapagliflozin, improves both core defects of T2DM, insulin resistance and beta cell dysfunction.

ISIS PTP-1B$_{RX}$, a novel protein tyrosine phosphatase antisense inhibitor, improves both insulin and leptin action and increases HMW adiponectin levels in obese subjects

Q. Liu, S. Xia, W. Cheng, R. Geary, S. Bhanot;
Isis Pharmaceuticals Inc., Carlsbad, USA.

Background and aims: PTP-1B is a negative regulator of both insulin and leptin action. Since reduction of PTP-1B activity enhances insulin and leptin sensitivity in preclinical models, PTP-1B inhibitors could be promising therapeutics for T2DM and obesity. However, very few studies have examined the role of PTP-1B in human insulin and leptin resistance due to a lack of specific PTP-1B inhibitors. We developed a specific PTP-1B antisense inhibitor (ISIS PTP-1B$_{Rx}$) and investigated the safety, tolerability and PD of ISIS PTP-1B$_{Rx}$ administered subcutaneously in obese subjects.
Materials and methods: In the present randomized (3:1) double-blind, placebo-controlled Phase 1 study, single or multiple dose levels of a specific PTP-1B antisense inhibitor, ISIS-PTP-1B$_{Rx}$, (50, 100, 200 and 400 mg) were administered subcutaneously to 48 healthy subjects (age=49±11yrs, BMI=30±2.6) over a 4 week treatment period. Primary pharmacodynamic (PD) parameters were analyzed on Day 29 and Day 36.
Results: Treatment with ISIS-PTP-1B$_{Rx}$ for 4 weeks resulted in a dose-dependent increase in HMW adiponectin, with > 4-fold increase in HMW adiponectin in the 400 mg group. As compared to placebo, statistically significant reduction of leptin levels was also observed in ISIS PTP-1B$_{Rx}$ cohorts, with a maximal reduction from baseline of 14% (p=0.0295 vs. placebo). Furthermore, placebo-corrected plasma insulin levels as well as HOMA-IR were significantly reduced with no changes in FPG. ISIS PTP-1B$_{Rx}$ was well tolerated and no SAEs were observed. No clinically significant effects on vital signs, ECG, hepatic or renal function and no hypoglycemia were observed.
Conclusion: These data suggest that PTP-1B may be a novel therapeutic target for T2DM and obese patients and support further development of ISIS-PTP-1B$_{Rx}$ in these populations.

609

The novel myokine YKL-40 is increased by exercise and inhibits TNFalpha-induced inflammation and insulin resistance in human skeletal muscle cells

S.W. Görgens[1], J. Jensen[2], K.B. Holven[3], N. Tennagels[4], K. Eckardt[1], J. Eckel[1]; [1]Paul-Langerhans-Group of Integrative Physiology, German Diabetes Center, Düsseldorf, Germany, [2]Department of Physical Performance, Norwegian School of Sport Sciences, Oslo, Norway, [3]Institute for Basic Medical Sciences, University of Oslo, Norway, [4]Sanofi-Aventis Deutschland GmbH, Frankfurt, Germany.

Background and aims: The glycoprotein YKL-40 is a member of the 18 glycosyl hydrolase family, but has no enzymatic activity. It is known to play a role in tissue remodeling and inflammatory processes and elevated serum levels of YKL-40 are found in patients with e.g. cardiovascular disease, insulin resistance and type 2 diabetes. Based on proteomic profiling of secreted proteins from primary human skeletal muscle cells (hSkMC) we identified YKL-40 as a novel myokine. However, the physiological role of YKL-40 remains largely unknown. The aim of this study was to investigate the effect of muscle

contraction on YKL-40 expression and release *in vitro* and *in vivo*. Furthermore, we investigated potential autocrine effects of YKL-40 in hSkMC.
Materials and methods: HSkMC were *in vitro* differentiated and electrical pulse stimulation (EPS) (1 Hz, 2 ms, 11.5 V) was applied for 24h. RNA, protein and supernatants were obtained, and YKL-40 expression and release was analyzed by quantitative RT-PCR, ELISA and Western Blot. In a human study, blood samples were obtained before and after 60 min of cycling at 70% VO_2max and analysed by ELISA. Furthermore, hSkMC were treated with TNFα in combination with YKL-40, and RNA and supernatants were collected. Effects on IL-6, IL-8 and MCP1 expression and secretion were analyzed by RT-PCR and ELISA. In addition, insulin signaling after acute TNFα treatment +/- YKL-40 was assessed at the level of Akt and GSK3 phosphorylation using Western Blot analysis.
Results: *In vitro* contraction of hSkMC induced by EPS significantly increased YKL-40 mRNA expression (~2fold) as well as secretion (~1.25fold). In addition, we observed a significant increase of YKL-40 serum concentrations after 60 min cycling. The concentrations increased from 15.2±0.8 ng/ml before exercise to 20.1±0.9 ng/ml immediately after exercise. In the post exercise period YKL-40 serum concentrations were significantly reduced after 120 min and normalized close to the basal level at 15.8±0.7 ng/ml. Stimulation of hSkMC with TNFα increased MCP1, IL-6 and IL-8 mRNA expression and secretion. These TNFα-induced effects were prevented by chronic treatment with YKL-40. Moreover, YKL-40 treatment inhibited TNFα-induced insulin resistance at the level of Akt and GSK3 phosphorylation while YKL-40 itself did not impact on Akt or GSK3 activation.
Conclusion: YKL-40 is upregulated by muscle contraction and able to prevent TNFα-induced inflammatory processes by affecting MCP1, IL-8 and IL-6 mRNA expression and secretion. In addition, YKL-40 treatment blocks TNFα-induced insulin resistance. In conclusion, the novel myokine YKL-40 inhibits harmful effects of TNFα and may hence represent an autoprotective factor of skeletal muscle tissue that is upregulated by exercise.

The effects of long-term valsartan treatment on skeletal muscle fatty acid handling in humans with impaired glucose metabolism
G.H. Goossens[1], C.C.M. Moors[1], N.J. van der Zijl[2], M. Diamant[2], E.E. Blaak[1];
[1]Department of Human Biology, NUTRIM School for Nutrition, Toxicology and Metabolism, Maastricht University Medical Centre, Netherlands,
[2]Diabetes Center/Department of Internal Medicine, VU University Medical Center, Amsterdam, Netherlands.

Background and aims: Blockade of the renin-angiotensin system reduces the incidence of type 2 diabetes in humans with impaired glucose metabolism (IGM). Nevertheless, underlying mechanisms remain to be established. The objective of this study was to investigate the effects of the angiotensin II type 1-receptor blocker valsartan (VAL) on skeletal muscle FA handling in subjects with IGM.
Materials and methods: In this randomized, double-blind placebo-controlled trial, fasting and postprandial skeletal muscle FA handling were assessed at baseline and after 26 weeks of treatment with VAL or placebo in 26 subjects with IGM. Fasting and postprandial skeletal muscle FA handling were determined by combining the forearm balance technique with stable isotopes of palmitate. [$^2H_2$]-palmitate was infused intravenously to label endogenous triacylglycerol (TAG) and NEFA in the circulation, and [U-^{13}C]-palmitate was incorporated in a high-fat mixed meal (2.6 MJ, 61% energy from fat) to label chylomicron-TAG. Muscle biopsy samples were taken to determine intramuscular TAG, diacylglycerol (DAG), FFA and phospholipid content, their fractional synthetic rates and degree of saturation, and mRNA expression of oxidative genes.
Results: VAL decreased saturation of intramuscular TAG and DAG fractions but did not affect net muscle uptake of [$^2H_2$]-palmitate, very low-density lipoprotein ([$^2H_2$])-TAG and chylomicron ([U-^{13}C])-TAG, and muscle mRNA expression. VAL decreased FA spillover, as estimated by circulating [U-^{13}C]-palmitate, and FFA rate of appearance, and tended to decrease chylomicron-TAG concentrations.
Conclusion: VAL treatment for 26 weeks decreased saturation of skeletal muscle TAG and DAG stores, suggesting altered intramuscular lipid partitioning of FA. The VAL-induced reduction in postprandial FA spillover, endogenous lipolysis, and chylomicron-TAG concentrations indicate improved adipose tissue lipid buffering capacity.

Low dose pioglitazone-induced reduction in skeletal muscle TACE activity and TNFalpha is associated with an improvement of glycaemic control in type 2 diabetic patients
T.V. Fiorentino[1,2], G. Daniele[1], D. Tripathy[1], Z. Perez-Cadena[1], A. Chavez-Velasquez[1], S. Kamath[1], F. Andreozzi[2], A. Davalli[3], M.L. Hribal[2], G. Sesti[2], M. Federici[4], R.A. DeFronzo[1], F. Folli[1];
[1]Medicine, University of Texas Health Science Center at San Antonio, USA, [2]Internal Medicine, University Magna Graecia of Catanzaro, Italy, [3]Fondazione San Raffaele del Monte Tabor, Milano, Italy, [4]Systems Medicine, University of Rome Tor Vergata, Italy.

Background and aims: Pioglitazone (PIO) is a PPARγ-agonist employed in the treatment of patients with type 2 diabetes mellitus (T2DM) at dosage ranging from 15 to 45 mg/day. PIO treatment has been shown to improve insulin sensitivity, glycemic control and inflammatory state. TNFα is an inflammatory cytokine whose plasma levels are elevated in insulin resistance related disorders. TNFα Converting Enzyme (TACE) is the enzyme producing TNFα from its precursor, and it is physiologically inhibited by Tissue Inhibitor of Metalloproteases 3 (TIMP-3). T2DM is associated with higher TACE activity and lower TIMP-3 levels in skeletal muscle (SKLM). In this study we examined the effect of low-dose PIO (15 mg/day) on TIMP-3/TACE dyad in T2DM.
Materials and methods: Twenty type 2 diabetic patients treated with metformin and/or sulfonylurea were randomized to receive PIO 15 mg/day or placebo (PLC) for 6 months. At baseline and after 6 months of treatment the subjects underwent to: (I) OGTT, (II) euglycemic hyperinsulinemic clamp, (III) SKLM biopsy to evaluate expression levels of insulin signaling cascade proteins, TNFα and TIMP-3/TACE by Western Blot, (IV) TACE activity evaluation on SKLM extracts by an *in vitro* fluorometric assay.
Results: Fasting and 2-hours post-load plasma glucose and HbA1c levels decreased by 10 to 15% ($p<0.05$) after PIO and did not change significantly after PLC. M/I value and insulin secretion/insulin resistance (disposition) index were significantly increased by 25% in PIO ($p<0.05$) but not in PLC group. SKLM TNFα protein levels decreased by 30% (0.26±0.05 to 0.18±0.05 A.U; $p=0.02$) in PIO but not in PLC treated patients. At baseline, TACE and TIMP-3 expression was similar between PLC and PIO group, and did not change in either group after 6 months of treatment. At the end of the study, TACE activity was significantly decreased by 80% as compared to baseline (0.29±0.07 to 0.05±0.01 A.U, $p=0.005$) in PIO whereas in PLC group TACE activity was reduced by ~ 36% in comparison to baseline (0.22±0.1 to 0.14±0.07 A.U, $p=0.07$). In addition, in PIO group the decrease in TACE activity correlated with the changes of HbA1c ($r=0.87$, $p=0.01$) and fasting plasma glucose ($r=0.88$, $p=0.01$). Interestingly, at the end of the study Insulin Receptor β (IRβ) expression was significantly increased by 22% in comparison to baseline in PIO group ($p=0.028$) but not in PLC group. The delta change of IRβ levels was significantly higher in PIO than PLC group (+22% vs. -9%, $p=0.008$ respectively). IRS1, AKT, p-AKT Ser^{473}, Jun N-terminal kinase (JNK), p-JNK Thr^{183}/Tyr^{185}, Extracellular signal-regulated kinase (ERK) and p-ERK Thr^{202}/Tyr^{204} levels were not different at baseline in either group and no changes were observed after 6 months.
Conclusion: The improvements in insulin sensitivity and glycemic control observed in type 2 diabetic patients treated with low-dose PIO (15 mg/day) were paralleled by increased SKLM IRβ expression, reduced TACE enzymatic activity and lower TNF-α protein levels, suggesting an important role of sub-inflammation in regulating insulin sensitivity in humans.

Effect of exercise on fatty acid and glucose metabolism in cultured human myotubes

E.T. Kase[1], J. Lund[1], Y.Z. Feng[1], T.M. Langleite[2], V. Aas[3], J. Jensen[4], K.I. Birkeland[5], H.L. Gulseth[5], C.A. Drevon[2], A.C. Rustan[1], G.H. Thoresen[1,6]; [1]Department of Pharmaceutical Biosciences, University of Oslo, [2]Department of Nutrition, University of Oslo, [3]Oslo and Akershus University College of Applied Sciences, [4]Department of Physical Performance, Norwegian School of Sport Science, [5]Department of Endocrinology, Morbid Obesity and Preventive Medicine, University of Oslo, [6]Department of Pharmacology, University of Oslo and Oslo University Hospital, Norway.

Background and aims: Physical activity has an important place in prevention and treatment of type 2 diabetes. In this study we examined fuel handling in skeletal muscle cells (myotubes) isolated from subjects with normal and abnormal glucose metabolism before and after 12 weeks of extensive endurance and strength training.
Material and methods: Skeletal muscle cells were isolated from m. vastus lateralis of male volunteers before and after an intervention period, including two endurance and two strength training sessions of 6Yuan0 min. per week. Subjects with normal as well as abnormal glucose metabolism were included. The muscle cells were cultured and differentiated into multinucleated myotubes. Lipid and glucose metabolism were studied using radiolabeled 1-[14C] oleic acid and D-[14C(U)]glucose, respectively. In the preintervention experiments the cells were incubated with the PPARδ agonist GW501516 for the last 4 days of the differentiation period. Gene expression was studied using qPCR.
Results: Both groups of subjects showed an increased strength capacity (measured by three different strength tests), increased endurance capacity (measured by VO2 max) and increased insulin sensitivity (measured by clamp GIR). The group with abnormal glucose metabolism had the largest increases, except for in two of the strength tests. Myotubes isolated after a training period of 12 weeks showed an increased oxidation of oleic acid as well as glucose compared to myotubes isolated before the 12 weeks training period. The total uptake of oleic acid in myotubes was also increased after the exercise intervention period. Preliminary data indicated that the expression of some genes important for lipid metabolism and mitochondrial function/biogenesis, such as CD36, PGC1α, Cyc1 and PPARδ, were increased in myotubes after the exercise intervention period.
Conclusion: Exercise have a positive effect on glucose oxidation and fatty acid uptake and oxidation that appears to be conserved in human myotubes.

DNA demethylation enhances myoblasts hypertrophy during the late phase of myogenesis activating the IGF-1 pathway

N. Mazzocchi[1], P. Senesi[2], L. Luzi[2,3], A. Montesano[2], I. Terruzzi[1]; [1]Nutrition-Metabolism Unit, San Raffaele Scientific Institute, [2]Department of Biomedical Sciences for Health, University of Milan, [3]Research Centre, San Donato Hospital and Scientific Institute, Milan, Italy.

Background and aims: Skeletal muscle damage is linked with metabolic syndrome. Cachexia is the dramatic weight loss and muscle atrophy seen in patients with chronic illness including diabetes mellitus. Cachexia causes dramatic loss of skeletal muscle and eventually leads to immobility. During muscle differentiation, myoblasts withdraw from the cell cycle and form myotubes. This process is principally governed by muscle regulatory factors (MRFs) and muscle specific protein such as Myosin Heavy Chain (MyHC). Instead, the end of myogenesis is lead by Myostatin (Mnst). Muscle hypertrophy is an increment of existing muscle fibers size, associated with an enhanced protein accumulation. Insulin Growth Factor 1 (IGF-1) plays an important role in hypertrophy induced by Growth Hormone (GH) treatment or exercise. Also the epigenetic mechanisms of DNA methylation are crucial in transcriptional control of genes involved in myogenesis. However, the specific impact of DNA hypomethylation on late phase of differentiation and on muscle mass regulation is not complete understood. To clarify DNA methylation role in muscle differentiation, we studied the effects of the most common DNA-demethylating agent 5-azacytidine (AZA) on the late phase of muscle differentiation and early stage of hypertrophy.
Materials and methods: The epigenetic process involved in myogenesis was studied with the DNA-demethylating agent 5-azacytidine (AZA). We induced muscle differentiation in C2C12 mouse myoblasts in presence of 5 μM AZA and growth (GM) or differentiation (DM) medium for 48, 72 and 96 hours. To study a potential AZA hypertrophic effect, we stimulated 72h differentiated myotubes with AZA for 24h. Unstimulated cells were used as control. By Western blot and Immunofluorescence analysis, we examined AZA action on myogenic regulatory factors expression, hypertrophic signaling pathway and myotubes morphological features.
Results: During differentiation, protein levels of myogenic markers, Myf6 and Myosin Heavy Chain (MyHC), were higher in AZA stimulated cells compared to control. Myostatin and p21 analysis revealed morphological changes which reflect a tendency to hypertrophy in myotubes. In AZA stimulated neo-formed myotubes, we observed that IGF-1 pathway, kinases p70 S6 and 4E-BP1 were activated. Furthermore, AZA treatment increased MyHC protein content in stimulated neo myotubes. Statistical evaluation was performed using a *t*-test. Data are presented as means ± SD. Results were considered statistically significant if $p \leq 0.05$.
Conclusion: Our work demonstrates that DNA demethylation could play an important role in promoting the late phase of myogenesis, activating endocellular pathways involved in protein increment and stimulating the hypertrophic process. These results constitute a proof of principle of an hypothetical clinical use of this agent in conditions of muscle mass impairment/hypotrophy in chronic disease (diabetes mellitus, metabolic syndrome). Furthermore, the demonstration that AZA-induced DNA demethylation accelerates skeletal muscle differentiation and hypertrophy might constitute a new model to study the regeneration process against atrophy damage in diabetic muscle cachexia.

Knockout of STAT3 in skeletal muscle does not enhance insulin action

A.T. White, S. Schenk;
University of California, San Diego, La Jolla, USA.

Background and aims: Activation of signal transducer and activator of transcription 3 (STAT3) is increased in skeletal muscle from insulin resistant patients. Accordingly, STAT3 activation has been implicated in the development of skeletal muscle insulin resistance, though its precise role, in vivo, remains to be elucidated. Thus, the purpose of this study was to determine whether knockout of STAT3 in skeletal muscle enhances insulin-stimulated glucose uptake, and also, whether it would prevent insulin resistance in a high-fat (HF) diet-induced obesity mouse model.
Materials and methods: Mice with skeletal muscle-specific knockout of STAT3 were generated by crossing mice containing loxP sites flanking exon 22 of STAT3 (a region required for phosphorylation and activation) with mice harboring Cre recombinase under the control of the muscle creatine kinase promoter. Beginning at 10 weeks of age, male mice with muscle-specific knockout of STAT3 (mKO) and their floxed/wildtype (WT) littermates were fed a low-fat (LF; 10% of calories from fat) or HF (60% of calories from fat) diet for 20 days. Body composition and energy expenditure were measured using magnetic resonance imaging and indirect calorimetry, respectively. Basal and insulin-stimulated (0.36nmol/L [60μU/mL]) glucose uptake were measured using a 2-deoxyglucose uptake (2DOGU) assay in isolated soleus and extensor digitorum longus (EDL) muscles.
Results: STAT3 protein abundance was reduced by ~50% in soleus and EDL muscles of mKO vs. WT mice. Body weight and body fat percentage did not differ in WT vs. mKO mice on LF diet, though these parameters were significantly increased by HF diet. Energy expenditure did not differ between WT and mKO mice on either a LF or HF diet. Interestingly, insulin-stimulated 2DOGU (insulin 2DOGU minus basal 2DOGU) in LF-fed mice did not differ between genotypes in soleus (WT = 0.37±0.05; mKO = 0.32±0.05 μmol/20 min/g muscle) or EDL (WT = 0.29±0.02; mKO = 0.30±0.05 μmol/20 min/g muscle). In addition, HF diet significantly decreased insulin-stimulated 2DOGU to the same extent in mKO and WT soleus and EDL muscles (WT = 0.21±0.04; mKO = 0.20±0.04 and WT = 0.16±0.03; mKO = 0.15±0.02 μmol/20 min/g muscle, respectively).
Conclusion: Although activation of STAT3 is increased in skeletal muscle from insulin resistant patients, knockout of STAT3 does not enhance skeletal muscle insulin action. Furthermore, STAT3 knockout does not protect against HF diet-induced insulin resistance in skeletal muscle.

Determination of glucose metabolic fluxes in live myoblasts by microfluidic nanosensing and data analysis

A. Zoso[1,2], A. Zambon[1,2], C. Luni[1,2], W.B. Frommer[3], N. Elvassore[1,2];
[1]Dept. of Industrial Engineering, University of Padova, Italy, [2]Venetian Institute of Molecular Medicine (VIMM), Padova, Italy, [3]Dept. of Plant Biology, Carnegie Institution for Science, Stanford, USA.

Background and aims: Glucose is the main energy source for cells in an organism and its blood concentration is tightly regulated in healthy individuals. However impaired glycemia control has been found in metabolic syndrome and diabetes. Dissecting the dynamics of the different phenomena involved in glucose handling is relevant to identify which mechanisms are disrupted under disease conditions. In this work we performed an integrated quantitative study of glucose processing in living myoblast cultures.
Materials and methods: Murine myoblasts were cultured in a perfused microfluidic chip that allowed dynamic detection with minimal culture perturbation. Medium was continuously collected at the outlet of the culture chamber and its glucose concentration measured via enzymatic assay. Glucose uptake was then determined from the difference of concentration between inlet and outlet. Myoblasts were also transfected with the FRET nanosensor FLIPglu-600μΔ13V for determining cytosolic glucose concentration through live cell imaging. Experiments were carried out at multiple flow rates and inlet glucose concentrations. Mathematical modeling assisted experimental data analysis for the determination of the kinetic constants.
Results: We found a linear relationship between glucose concentration at the inlet (3-13 mM) and at the outlet, where it was reduced due to glucose consumption by the cell population. These measurements were used to derive myoblast glucose uptake rate, which was calculated equal to 34 ± 9.7 fmol/min/cell when the inlet glucose concentration was 5.6 ± 0.3 mM. We estimated that the actual glucose concentration in the immediate vicinity of the cell membrane was about 84% of the inlet one in our experimental conditions. Using an intra-cellular glucose FRET-based nanosensor, we obtained the intracellular glucose concentration. We found that the cytosolic glucose concentration was a linear function of the extracellular one, in the range 0.5-5 mM. In particular, it was approximately 12% of the extracellular concentration in the immediate vicinity of cell membrane. By integrating the results above with a simple mathematical model, we calculated the characteristic times of glucose transport across the membrane, equal to 3.7 s, and of phosphorylation, 0.5 s. From these data we derived the respective kinetic constants of the two processes: 0.27 s^{-1} and 2.01 s^{-1} in living cells. The model was then used to calculate the time a cell needed to reach a new steady state after a change in extracellular glucose conditions, which was about 2 s.
Conclusion: We show a methodology for quantitatively dissecting the contribution of glucose diffusion from the bulk of medium to the cell surface, of single-cell glucose uptake and of glucose phosphorylation kinetics in living cells. Thanks to the minimal perturbation of culture conditions during the measurements and to the precisely controlled microfluidic microenvironment, this system can be suitable to study dynamic alteration in glucose handling also under pathological conditions, i.e. hyperglycemia, hyperinsulinemia or rapid pulses of them.

High fat diet induces selective alterations in microRNA expression profile in rat skeletal muscle

D.K. Andersen[1], J.A. Timmons[2], M.E. Cleasby[1];
[1]Royal Veterinary College, London, [2]Loughborough University, Loughborough, UK.

Background and aims: Skeletal muscle is the major tissue responsible for insulin mediated glucose disposal, and is a principal site for the development of lipid-induced insulin resistance. MicroRNAs (miRNAs) are small non-coding RNAs that bind to the 3'-UTR of specific target mRNAs, resulting in reduced RNA stability or inhibition of translation. MiRNAs have widespread effects to regulate cellular processes and altered expression of specific miRNAs including miR-29, miR-107, miR-143 and miR-126, have been linked to obesity, insulin resistance (IR) and type 2 diabetes (T2D). However, few systematic assessments of miRNA expression in diet-induced IR in muscle have been performed. Here we aimed to identify miRNAs that were dysregulated in muscle from high fat diet (HFD)-fed rats and to predict the effects using bioinformatic tools.
Materials and methods: Six week old male Wistar rats were fed ad lib with HFD or chow for 5 or 20 weeks and following euthanasia, tibialis cranialis (TC) muscles were snap-frozen and total RNA was extracted (n=9-10 per group). Candidate miRNAs for expression screening were identified on the basis of evidence of association with IR, insulin signalling, metabolism or T2D in the literature. Relative quantitation of candidates (20) was performed using a probe based Real-time PCR with normalisation to small nucleolar RNA expression using proprietary kits. Two-way ANOVA was used to test for differences in expression levels between the groups, with factors of diet and study duration. We used TargetScan to predict the effects of the differentially expressed miRNAs on relevant target protein expression.
Results: Expression of miR-126*, miR-22 and miR-187 were all reduced by HFD-feeding (p=0.046, p=0.0011 and p=0.0020 respectively), with the magnitude of each effect tending to be bigger after 20 weeks of diet. There was also a similar trend for miR26a expression (p=0.086). Interestingly, miRs-26a, 185, 21, 29c, 22, 29a, 143 and 451 all showed increases in expression as a result of study duration, implying that relatively small differences in age might have widespread effects on miRNA expression programmes (rats were 15 weeks older in the 20 week-fed than the 5 week-fed groups). In contrast, miR-10b expression was reduced in the older rats. In the case of miR-29a, an age-related up-regulation in expression was reduced by HFD-feeding (interaction p=0.0108). Other miRNAs were not detectably regulated by either factor. TargetScan analysis identified a number of relevant miR-22 predicted targets, including Sirtuin-1 (an energy sensor and a regulator of PPAR-γ and PGC-1 in mitochondria), phosphatase and tensin homologue (PTEN; an AKT phosphatase) and SMAD4 (a key component of the TGF-β signalling pathway). In addition, miR-29a predicted protein targets include insulin receptor substrate-1, PTEN, and PIK3R1 (the p85 regulatory subunit of PI3-kinase).
Conclusion: Our analysis has demonstrated that HFD-induced IR is associated with altered expression of several miRNAs and that these candidates possess putative protein targets with major roles in insulin signalling and metabolism. Using interventional studies, we will now seek to establish whether these miRNAs can determine insulin sensitivity in skeletal muscle through regulation of these or other protein targets.

Debio 0930, a novel direct AMPK activator, improves glycaemic control and lipid profile in metabolic disease models

P. Muzzin, M. Von Holtey, M. Barbier, R. Lysek, A. McAllister;
Debiopharm S.A., Lausanne, Switzerland.

Background and aims: AMP-activated protein kinase (AMPK), a key cellular energy sensor, is a promising target for the treatment of metabolic disorders. This study describes the in vivo metabolic effects of a novel direct AMPK activator, Debio 0930, which is under preclinical development for type 2 diabetes.
Materials and methods: Debio 0930, a small molecule, activated at least two recombinant human AMPK heterotrimers containing the ß1 subunit in a submicromolar rang (5-12 fold stimulation). In human HepG2 hepatocytes, Debio 0930 promoted AMPK activation without any changes in AMP/ATP ratio, supporting a direct mechanism of action. Debio 0930 was also found to have attractive DMPK properties with a favorable in vitro safety profile.
Results: In vivo efficacy of the compound was examined in diet-induced obese (DIO) mice and dyslipidemic hamsters. Following 4-week oral repeat dosing in the DIO mice, Debio 0930 at 60 mg/kg BID reduced fasting plasma glucose and hepatic glucose production, and ameliorated insulin resistance (HOMA-IR). In addition, the treatment demonstrated marked improvement in liver lipid content (TG, Chol, FFA). In dyslipidemic hamsters, oral administration of Debio 0930 at 60 mg/kg for two weeks lowered fasting blood glucose and enhanced the HDL/LDL ratio. Plasma lipoprotein analysis demonstrated that Debio 0930 caused a significant reduction in VLDL and LDL and a substantial rise in HDL compared to vehicle treated animals. Food intake was not affected by Debio 0930 in either study.
Conclusion: In conclusion, Debio 0930 is a novel direct AMPK activator that improves both glycemic control and lipid profile, and potentially could be a new oral agent for the treatment of type 2 diabetes and dyslipidemia.

618

Effects of chronic variable stress on insulin sensitivity, inflammation and plasma hormone levels

S. Müller-Lühlhoff[1], T. Jelenik[2], E. Brandt[1], S. Hartwig[1], S. Lehr[1], P. Nowotny[2], M. Roden[2,3], T.R. Castañeda[1], H. Al-Hasani[1];
[1]Institute for Clinical Biochemistry and Pathobiochemistry, German Diabetes Center, [2]Institute for Clinical Diabetology, German Diabetes Center, [3]Department of Endocrinology and Diabetology, University Clinics Düsseldorf, Heinrich Heine University, Germany.

Background and aims: Stress is a state of threat to homeostasis by intrinsic or extrinsic forces. Studies show that chronic stress and posttraumatic stress disorder contribute to metabolic diseases such as visceral obesity, metabolic syndrome and type 2 diabetes. However, the mechanisms linking stress to metabolic impairment are still unclear. Our aim was to characterize how chronic variable stress (CVS) affects insulin sensitivity in mice. Furthermore, cytokines and hormones, potentially regulating stress-induced changes in insulin sensitivity, were analyzed.
Material and methods: Age- and body weight (BW)-matched male C57BL/6 mice (n=9-11) were exposed to a random series of stressors for 15d (CVS), the unstressed controls (Ctrl) were housed separately. Body composition was analyzed with NMR. After CVS, mice were fasted for 4h and blood was collected (09:00-10:30am) for corticosterone measurements by RIA. Subsequently, insulin sensitivity was analyzed with hyperinsulinemic-euglycemic clamps. At the end of clamps, mice were euthanized and blood and tissues were collected for cytokine (n=8-10) and hormone (n=9-10) analysis by multiplex immunoassay and gene expression (n=7-10) with RT-PCR. Values were analyzed with two-tailed unpaired t-tests, $p<0.05$ was considered significant.
Results: Compared to Ctrl, CVS decreased BW (24.7±0.5, Ctrl: 26.6±0.6 g; $p<0.05$) and lean mass (21.5±0.4, Ctrl: 23.6±0.5 g; $p<0.01$) and increased fat mass (2.6±0.1, 1.9±0.1g; $p<0.0001$). Accordingly, plasma levels of corticosterone were higher in the CVS group (186.2±47.5, Ctrl: 36.6±8.3 ng/ml; $p<0.01$). Basal endogenous glucose production (EGP) was decreased after CVS (19.2±0.9, Ctrl: 23±1 mg/kg/min; $p<0.05$). Whole-body insulin sensitivity was not affected by CVS (glucose infusion rate: 65.4±2.3, Ctrl: 64.3±3.7 mg/kg/min). However, suppression of EGP by insulin was impaired (92±6, Ctrl: 117±7%; $p<0.05$), while insulin stimulation of glucose turnover in peripheral tissues was increased as indicated by the glucose rate of disappearance (Rd) (356±20, Ctrl: 276±9%; $p<0.05$) after CVS. CVS increased IL-10 (300±38, Ctrl: 212±19 pg/ml; $p<0.05$) and decreased RANTES (143±40, Ctrl: 281±32 pg/ml; $p<0.05$) in plasma. Ghrelin (9.85±0.62, Ctrl: 14.13±1.90 ng/ml; $p<0.05$) and glucagon (0.24±0.01, Ctrl: 0.31±0.02 ng/ml; $p<0.05$) plasma levels were decreased after CVS, while leptin was increased (1.72 ±0.22, Ctrl: 1.21±0.10 ng/ml; $p<0.05$). CVS decreased the expression of hepatic *Gck* ($p<0.05$) and *Fasn* ($p<0.05$). In muscle, CVS increased the expression of *Ucp3* ($p<0.05$).
Conclusion: CVS decreases hepatic glucose production and impairs hepatic insulin sensitivity, while glucose turnover in peripheral tissues is improved. As a result of these two opposite effects whole-body insulin sensitivity is not changed by CVS. In addition, CVS decreases in the liver and increases in muscle the expression of glucose and lipid metabolism genes. Furthermore, the changes in IL-10 could also play a role in the regulation of insulin sensitivity by stress.

Glucose as a significant predictor of irisin levels in children

A.-D. Nasser[1], O. Al-Attas[1], K. Alkharfy[1], S. Ur-Rahman[1], O. Amer[1], P. Milan[2], P. McTernan[3], A. Harte[3], M. Alokail[1];
[1]King Saud University, Riyadh, Saudi Arabia, [2]University of Warwick, Coventry, UK, [3]Warwick University, Coventry, UK.

Background and aims: Irisin is a recently identified novel myokine which increases energy expenditure and glucose tolerance and is thus associated with improvements in glucose homeostasis in humans. Coupled with this is that secreted irisin induces white adipocytes into 'beige' or 'brite' adipocytes. Taken together irisin has potential therapeutic applications for weight loss to improve glucose metabolism, insulin resistance in subjects with obesity and type 2 diabetes Mellitus (T2DM). Additionally as a metabolic biomarker studies note, in adults, irisin positively correlates with hyperglycemia, BMI and ghrelin in humans, whilst negatively correlated with insulin, cholesterol as well as adiponectin, with the suggestion of a compensatory role of irisin in metabolic regulation. Although how early irisin in human life irisin may impact as a metabolic biomarker is unknown. Therefore the aim of this study was to establish whether there were (1) significant relationships between serum irisin and metabolic profiles in children as noted in adults; (2) gender differences in association of irisin and metabolic profiles.
Materials and methods: In this cross-sectional study in a cohort of 154 Saudi children (80 Boys age: 12.4(mean±SD) 3.2yr; BMI: 19.5±5.9 and 74 girls: (age: 12.9 (mean±SD) 3.2yr; BMI: 20.6±5.2) fasted bloods, anthropometric and biochemical data was collected. Irisin was assessed by an enzyme-linked immunosorbent assay (ELISA: intra-assay % CV<10% and inter-assay variability <15%) with in house validation and correlated with biochemical and anthropometric data.
Results: There was a significant negative correlation between irisin levels and fasting blood glucose (FBG, r= -0.35, $p<0.001$), sagital abdominal diameter (SAD) (r=0.34, $p<0.001$) and HDL (r=0.17, p=0.04) across the entire cohort studied (n=154). Notably, in girls homeostasis model assessment-estimated insulin resistance (HOMA-IR) was found to be negatively correlated with irisin levels (r=-0.32, p=0.02) as noted in adults. Whilst after a stepwise linear regression analysis it was observed that FBG was the sole predictor of serum irisin levels (R2 =0.16) followed by SAD. Multivariate linear regression analysis after controlling for potential confounders such as age, BMI and gender identified that irisin levels was independently associated with FBG (β=-0.34, p=0.01) particularly in girls.
Conclusion: In the present study, serum irisin level correlated negatively with HOMA-IR, whilst also being independently associated with blood glucose levels, in girls, suggesting that irisin may play a crucial role in glucose intolerance and metabolism, as early as age 12, in females. Irisin levels are raised by modest increases in exercise and, as obesity are increasingly more prevalent in females, improving glucose homeostasis and energy expenditure via increased exercised induced irisin levels, at an early age, may delay onset of obesity and T2DM.

A single mechanism underlies glucose kinetics in euglycaemic and hyperglycaemic clamps and oral glucose tolerance tests

R. Bizzotto[1], A. Natali[2], A. Gastaldelli[3], E. Muscelli[2], E. Ferrannini[2], A. Mari[1];
[1]ISIB-CNR, Padova, [2]University of Pisa, [3]IFC-CNR, Pisa, Italy.

Background and aims: It is known that for a given insulin level glucose clearance (GCL) depends on glucose concentration. This makes GCL assessed in heterogeneous tests such as euglycemic and hyperglycemic clamps and oral glucose tolerance tests (OGTT) not comparable. Currently, no unifying quantitative representation is available to describe these heterogeneous tests. This study aims at modeling glucose kinetics (GK) in all these conditions according to a unique mechanism.
Materials and methods: Data from three studies in nondiabetic subjects were used in the analysis: a three-level hyperglycemic clamp (N=8), a two-level euglycemic hyperinsulinemic clamp (N=8), and paired OGTTs and euglycemic hyperinsulinemic clamps in the same subjects (N=8). In all tests, a glucose tracer was used. Literature data (whole body and forearm) from clamps at various glucose and insulin levels were also included in the analysis. Glucose and insulin ranges in the tests were wide (5-24 mM and 20-10000 pM, respectively). A model was developed based on a circulatory model of GK and basic notions of glucose transport. Glucose utilization was modeled as a Michaelis-Menten function of glucose concentration with constant K_m and insulin-controlled V_{max}. V_{max} was expressed as a Hill function of insulin at the site of action, related to plasma insulin by a first-order delay model. Model parameters were estimated using a population approach, assuming log-normal parameter distributions.
Results: The model was able to fit the tracer data well in all tests. The median K_m of the glucose model was 22.6 mM; the insulin K_m was 630 pM; the insulin delay half-time was 48 min. In a representative subject, GCL at an insulin concentration of 600 pM was reduced from 592 to 458 ml $min^{-1}m^{-2}$ when glucose was raised from 5 to 10 mM. The model reproduced a characteristic feature of GCL calculated with standard tracer methods, i.e., the lack of increase when hyperinsulinemia was accompanied by hyperglycemia, observed both in the hyperglycemic clamp and the OGTT. Insulin sensitivity, defined as GCL at 5 mM glucose and 600 pM insulin, was fully consistent when calculated from the OGTT and the euglycemic clamp (r=0.89, $p<0.002$). In all tests, insulin sensitivity was inversely correlated with BMI, as expected (r=-0.62, $p<0.001$).
Conclusion: We have shown that GK in euglycemic and hyperglycemic clamps and OGTTs can be described with a unifying mechanism, consistent

with the notions of glucose transport. In contrast to classical models ignoring the effects of glucose on GCL, our model reproduces specific features observed with concomitant hyperinsulinemia and hyperglycemia. The model could allow better understanding of glucose metabolism and improved glucose homeostasis simulators, which are relevant e.g. for drug development.

Insulin-mediated suppression of lipolysis in adipose tissue and skeletal muscle of obese type 2 diabetic and normal glucose tolerant men

J.W.E. Jocken[1], G.H. Goossens[1], H. Boon[2], R.R. Mason[3], Y. Essers[1], B. Havekes[4], M.J. Watt[3], L.J. van Loon[2], E.E. Blaak[1];
[1]Department of Human BIology, Maastricht University Medical Center, Netherlands, [2]Department of Human Movement Sciences, Maastricht University Medical Center, Netherlands, [3]Department of Physiology, Monash University, Clayton, Australia, [4]Department of Internal Medicine, University Medical Center, Maastricht, Netherlands.

Background and aims: Impaired regulation of lipolysis and accumulation of lipid intermediates in non-adipose tissues may contribute to obesity-related insulin resistance and type 2 diabetes mellitus (T2D). The aim of the present study was to compare insulin-mediated suppression of lipolysis in abdominal subcutaneous adipose tissue (AT) and skeletal muscle (SM) of obese normal glucose tolerant (NGT) and obese T2D men.
Materials and methods: 11 NGT and 9 long-term diagnosed T2D men (7±1y), matched for age (58±2 vs. 62±2 y), BMI (31.4±0.6 vs. 30.5±0.6 kg/m^2) and $V0_2$ max (28.9±1.5 vs. 29.5±2.4 mL/kg.min) participated in this study. Interstitial glycerol concentrations in AT and SM were assessed using microdialysis during a 1-h basal period and a 6-h step-wise hyperinsulinemic euglycemic clamp (8, 20 and 40 mU.m^{-2}.min^{-1}). AT and SM biopsies were collected to investigate underlying mechanisms.
Results: Hyperinsulinemia suppressed interstitial SM glycerol concentrations by 27±9 and 53±8% in T2D compared with NGT men ($p<0.01$). This was accompanied by increased circulating fatty acid and glycerol concentrations, a lower glucose infusion rate (21.8±3.1 vs. 30.5±2.0 μmol.kg body weight^{-1}.min^{-1}, $p<0.05$), a higher hormone-sensitive lipase (HSL) serine 660 phosphorylation, increased saturated diacylglycerol (DAG) lipid species in the muscle membrane and increased PKC activation in T2D versus NGT men. No significant differences in the insulin-mediated reduction in AT interstitial glycerol were observed between groups.
Conclusion: Our results suggest that a blunted insulin-mediated suppression of SM lipolysis might promote membrane saturated DAG accumulation, which may worsen insulin resistance, at least in part mediated by PKC. This might represent an important mechanism involved in the progression of insulin resistance towards T2D.

Characterisation of PIMT KO mice: a model of deficient protein repair

Y. Brito-Casillas[1,2], J.C. Wiebe[1,3], L. López-Ríos[1,3], R.M. Sánchez-Hernández[1], J.F. Arbelo-Galván[4], M. Monzón-Mayor[4], M.M. Romero-Alemán[4], J. Nóvoa-Mogollón[1,2], A.M. Wägner[1,2];
[1]Servicio de Endocrinología y Nutrición, Complejo Hospitalario Universitario Insular Materno Infantil de Gran Canaria, [2]Ciencias Médicas y Quirúrgicas, Universidad De Las Palmas De Gran Canaria, [3]Bioquímica, Biología Molecular, Fisiología, Genética e Inmunología, Universidad De Las Palmas De Gran Canaria, [4]Morfología, Universidad De Las Palmas De Gran Canaria, Spain.

Background and aims: Post-translational protein modifications may create new antigenic epitopes and elicit autoimmunity. The enzyme PIMT (Protein-L-isoaspartate (D-aspartate) O-methyltransferase), encoded by PCMT1, repairs isomerised Asn and Asp residues and previous data suggest that it could be involved in the pathogenesis of type 1 diabetes (T1D). We have reported that PIMT KO mice show similar glucose responses to an oral glucose tolerance test (OGTT) to their wildtype (Wt) littermates, but a lower nadir and slower recovery from hypoglycaemia during an insulin tolerance test (ITT). Our aim was to assess glucose-stimulated insulinemia and counter-regulatory hormone response to hypoglycaemia, as well as to further characterize PIMT KO mice, with special focus on pancreatic islets and beta-cell mass.
Materials and methods: A total of 12 mice (50% KO/Wt; 50% males) were studied. Relevant clinical features were recorded. At a mean age of 60 days, insulin was measured during an OGTT and glucagon and corticosterone, during an ITT at 0, 15, 30, 60 and 90 min, using commercial ELISA kits. Total and relative organ weights were registered at necropsy. Tissues were collected and frozen/kept in tissue embedding compound. Beta cell mass was estimated assessing islet and beta cell area comparisons, and PIMT expression was evaluated on Wt pancreas by immunohistochemistry (IHC) (antibodies: goat anti-insulin, Santa Cruz; rabbit anti-PIMT, ProteinTech). To assess the effect of age-dependent insulin resistance, OGTT, ITT (120 and 360 days) and HbA1c (120 days) were performed in heterozygous (Het) and Wt mice. KO mice were not assessed at that age, due to short survival. Groups were compared using Mann-Whitney's U or Student's t test ($p<0.05$).
Results: PIMT KO mice showed growth-delay, kyphosis, macrocephaly, cachexia, and abnormal behavioural patterns such as anhedonia, although some heterogeneity was observed. No significant differences were found for corticosterone secretion [AUC Ko vs Wt = 205.85 (±84.57) vs 147.35 (±47.27); $p=0.27$] during the ITT. Insulin and glucagon concentrations fell below the standard curve. Thus, new analyses are ongoing. No differences were found in total body weight [KO vs WT: 19.92 g (±4.17) vs 21.33 (±5.72); $p=0.59$], or relative liver [5.15% (±0.72) vs 4.68 (±0.59); $p=0.46$], pancreas [1.06% (±0.17) vs 1.05 (±0.19)], $p=0.77$] and paragenital fat [1.20% (±0.46) vs 1.08 (±0.19); $p=0.23$)] weights. No significant differences were found at 120 or 360 days between Het and Wt in the OGTT, ITT or HbA1c. IHC revealed colocalisation of PIMT and insulin in the Wt mice.
Conclusion: PIMT KO mice show growth delay and anhedonia, compared to their Wt littermates. Corticosterone response does not explain their slower recovery from hypoglycaemia. Heterozygotes did not show differences from Wt in glucose metabolism or insulin sensitivity. Ongoing analysis may shed additional light on the potential role of PIMT in T1D.

Search for biomarkers that predict the development of type 2 diabetes

N. Yokoi[1], R. Hoshikawa[1], M. Beppu[1], S. Hidaka[1], M. Shinohara[2], S. Seino[1,3];
[1]Division of Molecular and Metabolic Medicine, Kobe University Graduate School of Medicine, [2]Planning and Development Section, CLEA Japan, Inc., Tokyo, [3]Division of Cellular and Molecular Medicine, Kobe University Graduate School of Medicine, Japan.

Background and aims: Metabolomics is a powerful tool to investigate physiological status, diagnose diseases, and identify potential biomarkers. Several metabolites, such as branched chain amino acids (valine, leucine, and isoleucine) and aromatic amino acids (tyrosine and phenylalanine), have been reported to be potential predictors of the development of type 2 diabetes (T2D) in Caucasians. However, the targets of intervention and the mechanisms involved remain to be elucidated. In this study, we performed metabolome analysis of longitudinal plasma changes in an animal model of non-obese T2D, the spontaneously diabetic Torii (SDT) rat.
Materials and methods: The SDT (n=11) and control Sprague-Dawley (SD) (n=11) rats were phenotyped for body weight and blood glucose level from 6 to 25 weeks of age. Fasting plasma samples were collected at 6, 8, 12, 16, 20, and 24 weeks of age. Non-targeted metabolome analysis was performed on the plasma samples using gas chromatography-mass spectrometry (GC-MS). Principal component analysis (PCA) was used as a multivariate analysis method, and fold change analysis and t-test were used as univariate analysis methods.
Results: The SDT rats developed T2D as early as 14 weeks of age, reaching 100% incidence by 20 weeks of age. At 12 weeks of age, before the onset of T2D, the SDT rats exhibited glucose intolerance with impaired insulin secretion upon intravenous glucose tolerance test. On the GC-MS-based metabolomics platform, we obtained about 150 hydrophilic metabolites in plasma samples, including amino acids, carbohydrates, sugars and organic acids. At 12 weeks of age, eight metabolites (adenylosuccinic acid, galacturonic acid, glycine, kynurenine, N-alpha-acetyllysine, palmitoleic acid, taurine, and tryptophan) showed significant differences between SDT and SD rats (nominal p-value at t-test <0.05; fold change <0.67 or 1.5<). In particular, several metabolites in the tryptophan metabolism pathway (e.g., tryptophan and kynurenine) were decreased in SDT rats at 12 weeks of age and later, suggesting that the tryptophan metabolism pathway is involved in the development of T2D in the SDT rat. The lower tryptophan and kynurenine levels were confirmed by an additional longitudinal plasma metabolome analysis on an animal model of obese T2D, the Otsuka Long-Evans Tokushima Fatty (OLETF) rat.
Conclusion: Our data suggest that the longitudinal metabolome analysis of plasma samples of animal models is useful for investigation of the pathophysiology of T2D and for identification of biomarkers of the disease and that the tryptophan metabolism pathway might be a potential target of intervention in T2D.

Elevated ferritin in skeletal muscle and insulin resistance in patients with type 2 diabetes mellitus

T. Kim[1], E. Ha[2], S.-Y. Ahn[2], M. Lee[2], J. Jeon[2], S. Han[2], H. Kim[2], D. Kim[2], S. Choi[2], Y. Kang[3], K.-W. Lee[2];
[1]Division of Endocrinology, Department of Internal Medicine, Kwandong University, College of Medicine, Goyang, [2]Department of Endocrinology and Metabolism, Ajou University School of Medicine, Suwon, [3]Institute of Medical Science, Ajou University School of Medicine, Suwon, Republic of Korea.

Background and aims: Insulin resistance (IR) is a major characteristic of type 2 diabetes mellitus (T2DM). Despite numerous studies, the pathogenesis of IR has not been well established. Ferritin is known to be associated with IR, but little is known about the possible sites (e.g., muscle, liver, adipose tissue) where ferritin may induce IR. It has also been suggested ferritin may be an underlying factor in the development of oxidative stress in skeletal muscle. Thus we hypothesized that ferritin in human skeletal muscle may play a significant role in insulin resistance.
Materials and methods: We recruited 16 T2DM subjects and 12 subjects with normal glucose tolerance (NGT) for this study. Whole-body insulin-mediated glucose uptake was determined using a euglycemic hyperinsulinemic clamp test. We performed biopsies on the vastus lateralis muscle and used immunoblotting to determine levels of 3-nitrotyrosine, ferritin heavy chain, ferritin light chain,transferrin receptor-1(TfR-1), divalent metal transporter-1(DMT-1), and ironregulatory protein-1(IRP-1) in skeletal muscles from both T2DM subjects and NGT subjects.
Results: Tests on T2DM subjects resulted in a higher protein oxidative damage as assessed by detecting 3-nitrotyrosine, when compared with muscles from the NGT group (p-value <0.05). An elevated expression of ferritin, (heavy chain, p-value <0.01; light chain, p-value < 0.001), an important iron storage protein, was associated with T2DM. The iron transport protein, TfR-1, demonstrated a tendency to increase (P =0.07) and the level of DMT-1 protein expression was significantly increased in muscle from the T2DM group (P =0.01). Protein levels of IRP-1 were significantly decreased (P =0.01) in the T2DM group.
Conclusion: In conclusion, altered iron metabolism and iron accumulation in skeletal muscle may be associated with insulin resistance in T2DM patients.

Uric acid is a biomarker of beta cell function in patients with newly diagnosed type 2 diabetes

C. Brangani, L. Boselli, M. Dauriz, R.C. Bonadonna, E. Bonora, M. Trombetta;
Division of Endocrinology and Metabolic Diseases, University Hospital of Verona, Italy.

Background and aims: The relationship between uric acid and insulin resistance has been widely studied, whereas little is known about a potential interaction between uric acid and beta-cell function. Goal of this study was to investigate the relationship, if any, between uricaemia and beta-cell function in patients with newly diagnosed type 2 diabetes.
Materials and methods: In 569 GAD negative, drug naive patients (median [interquartile range]: age 60 [52-66] years, BMI 29.3 [26.6-32.9] kg/m^2, HbA1c 6.6 [6.1-7.4]%, uric acid 0.32 [0.27-0.37] mmol/L) with newly diagnosed type 2 diabetes we assessed insulin sensitivity by the euglycemic insulin clamp (M clamp: 605 [381-845] μmol·min^{-1}·m^{-2} BSA) and beta-cell function by state-of-art modelling of glucose/C-peptide curves during an oral glucose tolerance test (OGTT). There are two main outputs of the model: derivative control (DC: amount of insulin secreted in response to the rate of plasma glucose increase; median [interquartile range]: 444 [66-929] [pmol·m^{-2} BSA]/[mM·min^{-1}]) and proportional control of beta-cell function (PC: stimulus-response curve linking glucose concentration to insulin secretion rate; mean ± SD at the preselected glucose concentrations of 5.5, 8.0, 11.0, 15.0 and 20.0 mM: 158±67, 228±124, 376±229, 602±397, 889±623 pmol·min^{-1}·m^{-2} BSA).
Results: In univariate analysis, serum uric acid concentration was positively related to both DC (p<0.01) and PC (p<0.01) of beta-cell function. In multiple regression analysis, after adjusting for age, gender, BMI, insulin sensitivity and glomerular filtration rate, this positive relationship stayed statistically significant (p<0.01 e p<0.01 for DC and PC respectively). Consistently with this result, uricaemia was inversely correlated to HbA1c (p<0.01), fasting glucose (p<0.01), 1-hour and 2-hour OGTT glucose (p<0.01 and p<0.01 respectively). Patients in the 3rd tertile of uric acid had a 37% increase in DC (p<0.01) and a 21-30% increase in PC (p<0.01) of beta-cell function, when compared to those in the 1st tertile.
Conclusions: In patients with newly diagnosed type 2 diabetes there exists a strong positive correlation between serum uric acid concentration and beta-cell function. This finding might reflect antioxidant activity of uric acid. However, to determine whether uric acid improves beta-cell function per se or through other factors, mechanistic studies will be required.

Plasma soluble leptin receptor levels are associated with beta cell function in patients with type 2 diabetes

T. Morioka, M. Emoto, Y. Yamazaki, H. Urata, S. Imamura, R. Numaguchi, K. Motoyama, K. Mori, S. Fukumoto, T. Shoji, M. Inaba;
Metabolism, Endocrinology and Molecular Medicine, Osaka City University Graduate School of Medicine, Japan.

Background and aims: A soluble form of the leptin receptor (sOb-R) is the main binding protein for leptin in circulation and modulates its bioactivity. Plasma sOb-R levels are positively correlated with leptin sensitivity to body weight and energy expenditure, and inversely with the risk of developing type 2 diabetes (T2D). Hyperinsulinemia observed in a mouse model lacking leptin signaling in β-cells (Pancreas-Ob-R knockout) indicates that leptin acts on β-cell to inhibit insulin secretion. In this study, we investigated the clinical association of plasma sOb-R levels with β-cell function in T2D patients.
Materials and methods: Two hundred and eighty nine T2D patients without renal dysfunction or insulin therapy were included in this study (mean age, 61 years; duration of diabetes, 7.8 years; BMI, 25.4 kg/m^2). Fasting plasma leptin and sOb-R concentrations were measured by ELISA.
Results: The median (interquartile range) of plasma leptin or sOb-R level was 3.5 (1.8 - 6.6) or 23.7 (19.7 - 28.5) ng/ml. Plasma sOb-R was negatively correlated to HOMA-R ($r = -0.232$, $p < 0.0001$), HOMA-β ($r = -0.507$, $p < 0.0001$), and C-peptide index (CPI) ($r = -0.514$, $p < 0.0001$), whereas plasma leptin was positively to each index ($r = 0.615$, $p < 0.0001$, $r = 0.556$, $p < 0.0001$, and $r = 0.425$, $p < 0.0001$, respectively) in simple regression analysis. Multiple regression analyses including age, sex, duration of diabetes, BMI, blood pressure, serum creatinine, glycated hemoglobin, lipid profile, leptin, and sOb-R as independent variables revealed that sOb-R independently and negatively contributed to HOMA-β ($\beta = -0.206$, $p < 0.001$) and CPI ($\beta = -0.341$, $p < 0.0001$), but not to HOMA-R ($\beta = 0.004$, $p = 0.940$), whereas leptin did positively to HOMA-R ($\beta = 0.667$, $p < 0.0001$), HOMA-β ($\beta = 0.531$, $p < 0.0001$), and CPI ($\beta = 0.489$, $p < 0.0001$). These data indicate that plasma sOb-R is associated with decreased β-cell function, whereas plasma leptin is associated with insulin resistance and hyperinsulinemia, independently of obesity and other metabolic parameters, in T2D patients.
Conclusion: Plasma sOb-R levels are associated with β-cell function in T2D.
