[1]Internal Medicine, [2]Clinical Epidemiology and Medical Technology Assessment (KEMTA), Maastricht University Medical Centre, Netherlands.

Background and aims: Methylglyoxal (MGO) is a highly reactive dicarbonyl compound generated by the spontaneous degradation of glycolytic intermediates during glycolysis. MGO is a major precursor for advanced glycation endproducts (AGEs) and can potentially disrupt cellular functions. MGO can be detoxified by the glyoxalase system into D-lactate. Experimental studies have shown that increased levels of MGO are associated with insulin resistance, but this has not yet been confirmed in human studies. Because MGO is difficult to measure, we investigated if plasma D-lactate levels, as a marker of MGO metabolism, are increased in individuals with impaired glucose metabolism (IGM) and type 2 diabetes mellitus (T2DM), and if they are associated with markers of insulin resistance in a large cohort study.
Materials and methods: We investigated 513 of the 574 participants in the baseline assessments of the Cohort on Diabetes and Atherosclerosis Maastricht (CODAM1) study, who were not on insulin treatment and who had complete data on the (co)variables of interest. The study sample consisted of 278 individuals with normal glucose metabolism (NGM, 61% men, 58.6±7.3 years), 118 with IGM (61% men, 59.8±6.5 years) and 117 with T2DM (69% men, 60.7±6.2 years). Plasma D-lactate was measured with ultra-performance liquid chromatography-tandem mass spectrometry and insulin resistance was determined with the Homeostasis Model of Assessment (HOMA2-IR) calculator. Both these variables were $\log_e$ transformed prior to analyses to meet analytical assumptions. We used ANCOVA to first compare the levels of plasma D-lactate (adjusted for age and sex) across categories of glucose metabolism (NGM as referent). With linear regression we analysed the cross-sectional association of plasma D-lactate with HOMA2-IR in the whole study sample. This analysis was first adjusted for age and sex, and further for plasma L-lactate levels, HbA_{1C}, glucose metabolism status, smoking status, prior cardiovascular disease, use of medication (glucose-, lipid-, and blood-pressure-lowering), estimated glomerular filtration rate and waist circumference.
Results: Plasma D-lactate levels (geometric means in μmol/L) were significantly higher in individuals with IGM [8.93 (95%CI: 8.22-9.69)] and T2DM [10.97 (95%CI: 10.09-11.92)] than in individuals with NGM [8.01 (95%CI: 7.60-8.46)], age and sex adjusted: $p=0.03$ and $p<0.001$, respectively. In addition, plasma D-lactate concentrations were positively associated with HOMA2-IR, in both the model adjusted for age and sex [standardized regression coefficient $\beta=0.43$ (95%CI: 0.35-0.51)], as well as in the fully adjusted model [$\beta=0.15$ (95% CI: 0.05-0.24)], $p<0.01$ in both models.
Conclusion: Plasma D-lactate levels, as a marker of MGO metabolism, are increased in patients with IGM and T2DM, and are associated with HOMA2-IR, independently of putative confounders. These results suggest that higher levels of MGO may play a role in the aetiology of insulin resistance. Direct measurement of MGO in cohort studies is necessary to confirm the findings from our current study.

The association between serum prothymosin-α concentrations and insulin resistance in subjects with or without diabetes mellitus

H.-Y. Ou[1], H.-T. Wu[2], F.-H. Lu[3], H.-C. Hung[1], J.-S. Wu[3], Y.-C. Yang[3], C.-J. Chang[3];
[1]Department of Internal Medicine, [2]Research Center of Herbal Medicine, New Drugs, and Nutritional Supplements, [3]Department of Family Medicine, National Cheng-Kung University, Tainan, Taiwan.

Background and aims: Prothymosin-α is a ubiquitous acidic small protein participating in a variety of physiological process including cell proliferation, chromatin remodeling, transcriptional activation, as well as cytokine-like function. One recent study showed that Prothymosin-α exerted immunomodulation actions through binding to Toll-like receptor 4 (TLR-4) to stimulate the production of interferons in cells. In addition, the activation of TLR-4 could impair insulin sensitivity, and disrupt the homeostasis of blood glucose. However, the effects of Prothymosin-α on glucose homeostasis and insulin sensitivity are still unknown.
Materials and methods: A total of 93 age- and sex-matched subjects with normal glucose tolerance (NGT, n=46) and newly diagnosed diabetes (NDD, n=47) were recruited. The anthropometric parameters (body mass index and waist circumference) were recorded. Fasting plasma glucose, serum lipid profiles, biochemistry, insulin, and adiponectin levels were measured. Insulin resistance was estimated by homeostasis model assessment (HOMA-IR). Serum Prothymosin-α concentrations were determined by enzyme-linked immunosorbent assay (ELISA). All subjects received a standard 75-g oral glucose tolerance test and diabetes was diagnosed according to recommendations of American Diabetes Association.
Results: NDD group had higher serum Prothymosin-α concentrations (525 ± 116 vs. 241 ± 46 mg/mL, $p=0.027$) and HOMA-IR (0.90 ± 0.12 vs. 0.53 ± 0.08, $p=0.015$) than subjects with NGT. In addition, subjects with NDD had higher fasting and 2-h postload plasma glucose, A1C, C-reactive protein (CRP), triglyceride, but lower HDL cholesterol than NGT ones. However, there were no significant differences in body mass index, waist circumference, blood pressures, creatinine, total cholesterol, and adiponectin. To explore the effect of Prothymosin-α on insulin resistance, multiple linear regression analysis using HOMA-IR as the dependent variable were performed. Age ($p<0.05$), fasting plasma glucose ($p<0.05$), body mass index ($p<0.05$), and Prothymosin-α ($p<0.05$) were the positively associated factors of HOMA-IR, after adjusting for age, anthropometric indices, lipid profile, systolic blood pressure, creatinine, CRP, and adiponectin.
Conclusion: Prothymosin-α was associated with increased risk of insulin resistance after adjusting for cardiometabolic risk factors. Elevated Prothymosin-α levels might have a clinical implication in the pathophysiology of diabetes and its complications.

ZEBD3 3 is associated with obesity and insulin resistance in humans

Y. Ren[1,2], L. Li[1,2], G. Yang[1];
[1]College of Laboratory Medicine, [2]the Key Laboratory of Laboratory Medical Diagnostics in Ministry of Education, Chongqing Medical University, Chongqing, China.

Background and aims: GWAS have shown that Zbed3 is associated with T2DM. To date, no report has demonstrated the relationship of Zbed3 with insulin resistance and T2DM in humans. To gain insight into the physiological role of circulating Zbed3 in humans, we report here that Zbed3 is a secreted factor detectable in human serum and evaluate whether Zbed3 correlates with obesity and insulin resistance by cross-sectional and interventional studies on anthropometric, metabolic, and hormonal predictors of circulating Zbed3 in humans.
Materials and methods: To determine whether the Zbed3 is a secreted protein in the vitro, we tagged the Flag peptide sequence to the coding region of Zbed3 (Zbed3-F) at the carboxy terminus. 113 healthy subjects, 102 impaired glucose tolerance (IGT) and 109 newly diagnosed T2DM (nT2DM) were studied. We also investigated the Zbed3 mRNA and protein expressions in muscle and adipose tissues in 15 healthy and 15 T2DM subjects. Finally, we examined whether circulating Zbed3 levels were affected by fasting (a low-insulin and low-glucose state) and oral glucose tolerance test (OGTT, a high-glucose state), or euglycemic- hyperinsulinemic clamp (EHC, euglycemic-hyperinsulinemic state).
Results: In vitro, Zbed3 is detected in both conditioned medium and lysates of HEK- 293T cells transfected with overexpressed vector. In the clinical study, there were significantly higher circulating Zbed3 levels in IGT and nT2DM relative to NGT. Zbed3 correlated positively with BMI, WHR, FAT%, blood pressure, FBG, TG, HbA1c, FIns and HOMA-IR, and inversely with HDL-C. Increasing levels of Zbed3 showed a significant linear trend and were independently associated with IGT and T2DM. Zbed3 mRNA and protein in muscle and fat were significantly increased in T2DM patients. Moreover, there was a concentration-dependent effect of glucose on Zbed3 release, whereas insulin exhibited an inhibitory effect on Zbed3 levels.
Conclusion: We identified, for the first time, Zbed3 as a novel secreted protein. More important, we present novel data of increased circulating Zbed3 levels in both IGT and T2DM subjects, increased expressions of Zbed3 mRNA and protein levels in muscle and adipose tissues of T2DM patients, and in vivo regulation of Zbed3 by glucose and insulin. However, the physiologic and pathologic significance of our findings remain to be elucidated.

TIMP3 regulates metabolism acting on different pathways: studies with a metabolomics approach

M. Mavilio, M. Cavalera, V. Marchetti, V. Casagrande, M. Fabrizi, R. Menghini, M. Federici;
University of Tor Vergata, Rome, Italy.

Background and aims: Timp3 down-regulation is associated to insulin resistance, glucose intolerance and atherosclerosis in human subjects and experimental models via up-regulation of inflammatory pathways in WAT, liver and vasculature. We used metabolomics to identify pathways associated to metabolic inflammation in the TIMP3KO mice.
Materials and methods: TIMP3KO and WT mice were subjected to diet induced obesity for 16 weeks. IPGTT, IPITT, LC-MS/GC-MS metabolomics, olecular biology and immuno-fluorescence techniques were used to phenotype mice.
Results: TIMP3KO mice after 16 weeks of HFD were glucose intolerant and insulin resistant compared to WT ($P<0.01$, n=16 per group). TIMP3 deletion exerted negative defects compared to WT mice independently from body weight since both 40 g were comparable in terms of glucose intolerance. We performed metablomics studies to gain insight the effect of TIMP3. Random Forest classification of metabolomics results in wild-type and TIMP3KO serum from animals either on a chow diet or on a high fat diet gave a predictive accuracy of 100 %. TIMP3 had an effect on glycolysis intermediates and Pentose Phosphate Pathway with increased Ribulose and Ribulose-5P and intermediates of the tricarboxylic acid cycle such as alpha-ketoglutarate and malate ($P<0.05$ for all, n=6 per group) independent of the diet. Upon a HFD TIMP3KO exhibited increased alpha-hydroxyisovalerate, alpha-hydroxyisocaproate and 2-hydroxy-3-methyòvalerate ($p<0.05$, n=6 per group), generally associated with a deficiency in branched-chain keto-acid dehydrogenase (BCKDH). On the other hand, levels of isovalerylglycine and isovalerylcarnitine ($P<0.05$ for all, n=6 per group), which are produced distal to BCKDH, were decreased in TIMP3KO serum. Together, this pattern of changes strongly suggests that loss of Timp3 function leads to changed BCKDH activity, expression, or regulation. A number of metabolites derived from the aromatic amino acids tryptophan and tyrosine appeared in the RF Importance Plot as factors separating HFD-fed WT and T3-KO; in fact TIMP3KO exhibited significant increased amounts of indolelactate, 3-hydroxysulfate, p-cresol-sulfate, phenolsulphate and 3-(4-hydroxyphenyl)lactate. Since these compounds are of gut microbiome metabolic origin or contribution we analyzed intestinal inflammation which revealed a significant increased expression of the inflammatory cytokine such as Interleukin 1 beta (IL-1β), Tumor Necrosis Factor alpha (TNFα), CD11b and CD11c ($p\leq 0.05$) and a trend for increased Interleukin 6 (IL-6), F4/80, MHC and CD3.
Conclusion: Metabolomics studies in TIMP3 KO mouse revealed alterations in multiple pathways in association with insulin resistance and low-grade inflammation and particularly related to restricted branched-chain keto-acid dehydrogenase activity suggested by changes in branched-chain AA intermediates and to compounds with gut microbiome metabolic origin or contribution in association to increased intestinal inflammation.

Improvement of metabolite risk profile for type 2 diabetes and cardiovascular disease by weight loss and weight maintenance

A.P.H. Danielsson[1], M. Magnusson[2], N. Geidenstam[1], L.E. Reinius[3], H. Mulder[4], O. Melander[5], M. Ridderstråle[1,6];
[1]Clinical Obesity, Department of Clinical Sciences, Lund University, Malmö, Sweden, [2]Emergency Medicine/Medicine/Surgery, Department of Clinical Sciences, Lund University, Malmö, Sweden, [3]Department of Biosciences and Nutrition (BioNut), Karolinska Institutet (KI), Stockholm, Sweden, [4]Molecular Metabolism, Department of Clinical Sciences, Lund University, Malmö, Sweden, [5]Hypertension and Cardiovascular Disease, Department of Clinical Sciences, Lund University, Malmö, Sweden, [6]Steno Diabetes Center, Gentofte, Denmark.

Background and aims: Branched-chain amino acids (BCAA) and aromatic amino acids are associated with obesity, type 2 diabetes (T2D), and cardiovascular disease (CVD). Recently, we showed that a signature composed of three of these amino acids, the DM-AA score, strongly predicted future T2D and CVD. Here, we investigated if this risk-score could be modified in the long-term by weight loss induced by a low-calorie diet (LCD) followed by a six month weight maintenance period in human adult obese subjects.
Materials and methods: The DM-AA score is composed of the sum of the blood plasma concentrations of isoleucine, tyrosine and phenylalanine and is based on results from a subset with matched controls from the Malmö diet and cancer (MDC) cohort (n=805). Metabolite profiling data from the weight loss program (n=12; 59 metabolites) and additional measurements of HDL, LDL, cholesterol, glucose, triacylglycerols, insulin and adiponectin were obtained at three sampling occasions: Before (BMI 43±1.7kg/m^2) and after (BMI 36±2.0kg/m^2) weight loss (101±26days) as well as after a six month (167±37days) period with maintained weight (BMI 36±1.9 kg/m^2). The profile of each metabolite during the course of the weight loss program was calculated using orthogonal projections to latent structures discriminant analysis (OPLS-DA).
Results: The DM-AA score showed a significant association to both waist circumference and BMI even when adjusting for sex, age, hypertensive treatment, systolic blood pressure, homeostasis model of assessment of insulin resistance, smoking status and diabetes status. During the weight loss study, 85% of the metabolite levels were altered at some point during the program. Moreover, 58% of the metabolites were altered in the long-term, i.e. after weight maintenance. Many of the metabolites followed the profiles of clinical markers. The amino acids in the DM-AA score decreased during the weight loss program but the levels of the BCAA and aromatic amino acids were differentially regulated during the weight loss program: The levels of isoleucine and leucine decreased during weight loss and retained their levels during weight maintenance, while valine returned to baseline level during weight maintenance. Phenylalanine, tryptophan and tyrosine decreased during weight loss and increased slightly during weight maintenance, but remained below baseline concentrations.
Conclusion: Our results illustrate that the obesity-associated risk for future T2D and/or CVD indicated by the DM-AA score is modifiable by weight loss

and remains decreased after weight maintenance. Meanwhile, the effect of weight loss and weight maintenance on metabolites seems to be differential as illustrated by the return to baseline of the third BCAA valine. This information can likely be used for evaluation of the potential benefit of weight loss programs.

Gene-metabolite networks reveal the regulation of clock genes by insulin
N.N. Rudovich[1,2], O. Pivovarova[1,2], J. Mazuch[3], S. Wendt[3], V. Murahovschi[1,2], A. Erban[4], V.J. Nikiforova[5], C. Sticht[6], M. Kruse[1,2], F. Keyhani Nejad[1,2], A.-C. Seltmann[1,2], Ö. Gögebakan[1], L. Willmitzer[5], A. Kramer[3], A.F.H. Pfeiffer[1,2];
[1]Clinical Nutrition, DIFE Potsdam-Rehbrücke, Nuthetal, [2]Endocrinology, Diabetes and Nutrition, Charité University Medicine, Berlin, [3]Laboratory of Chronobiology, Charité University Medicine, Berlin, [4]Department of Applied Metabolome Analysis, Max Planck Institute of Molecular Plant Physiology, Potsdam-Golm, [5]Department of Molecular Physiology, Max Planck Institute of Molecular Plant Physiology, Potsdam-Golm, [6]Medical Research Center Klinikum Mannheim, Germany.

Background and aims: Recently genetic studies suggested that the circadian system is tightly coupled with mechanisms controlling metabolism. This regulation consists of complexly integrated regulatory loops, as circadian regulators of metabolic pathways are themselves regulated by different nutritional and metabolic signals. Secretion of insulin and insulin sensitivity are on circadian control. Here we tested hypothesis, that insulin directly or via metabolic-induced changes may regulate circadian clocks.
Materials and methods: In the randomized single-blind cross-over study on male moderate overweight subjects (n=14) effect of insulin on clock genes were tested in two conditions: in the saline infusion (NaCl-INF) and in the euglycemic-hyperinsulinemic clamp (EC). Adipose tissue biopsies and plasma samples were taken before and after start of saline/insulin-infusions (t = -40, 240 min). Subcutaneous adipose tissue biopsies were analysed by microarray (Agilent 60-mer Whole Human Genome (4x44K) single-color DNA microarrays) and genes of interest were additionally studied by quantitative RT-PCR. To address the great complexity of hypothesized regulatory loops, we used results from gene expression analyse and metabolic profiling (GC-TOF/MS technique) for the reconstruction of integrated gene-metabolites networks of both experiments. For the human adipocyte culture, mesenchymal stem cells were differentiated in vitro into adipocytes and treated with 100nM insulin for 4 hours. The real-time bioluminescence detection was used for monitoring rhythms of clock gene expression in cell/tissue cultures received from PER2::LUC knockin mice.
Results: Five of eighteen core clock genes were significantly changed in experiments. Circadian genes were closely and direct connected to insulin in the NaCL-INF network and to insulin and glycerol in the EC network. Period circadian protein homolog 2 (PER2) was included in the NaCL-INF network but it was disintegrated from the molecular information exchange in the EC-network. In addition, the PER2 gene expression was significantly changed in the subcutaneous adipose tissue samples of NaCL-INF but not in the EC experiments, suggesting that insulin regulates its expression. In the next step, we observed the upregulation of PER2 gene expression by insulin in the human adipocytes in vitro. Using bioluminescence assays of cell/tissue cultures received from PER2::LUC knockin mice we confirmed insulin effects on clock gene expression in adipose tissue and hepatocytes but not in macrophages and lungs.
Conclusion: Our results demonstrate that insulin directly regulates circadian clock machinery in the insulin-dependent tissues in vivo and in vitro. This data contribute to the further understanding the complexity of the interplay between circadian clock and metabolism.

Effect of an isocaloric reduced protein intake on glucose metabolism and fatty liver in ovariectomised rat
C.L. Fournier[1], S. Sacco[2], M.-N. Horcajada[2], K. Bouzakri[3], L.G. Karagounis[2], E. Offord[2], P. Ammann[1];
[1]Department of Rehabilitation and Geriatrics, Division of Bone Diseases, Geneva, [2]Nestlé Research Center, Lausanne, [3]Department of Genetic Medicine and Development, Geneva, Switzerland.

Background and aims: Moderate protein undernutrition (MPU) is frequently observed in postmenopausal women. Moreover, estrogen withdrawal favours fatty liver that is strongly linked with insulin resistance. Therefore to explore the impact of MPU on hepatic and glucose metabolism in a stage of estrogen deficiency, we fed a moderate decreased protein intake to ovariectomized rats.
Materials and methods: Seven-month-old female rats were ovariectomized (OVX) and fed an isocaloric moderate 5% casein diet (MCD; N=10) or an adequate 14% casein diet (ACD; N=10) for 13 weeks. At the end of the study, fasting blood glucose, triglycerides (TG), insulin, IGF-1 and glucagon were measured by enzymatic assays, ELISA or RIA. Hepatic mRNA gene expressions of IGF-1, Peroxisome Proliferator-Activated Receptor alpha (PPARα), PPARγ coactivator 1-alpha (PGC1α) and myostatin receptor Activin receptor type-2B (Acvr2b) were assessed by real-time RT-PCR. Hepatic steatosis was observed by Oil Red O staining of cryostat sections. Just before sacrifice, body composition was evaluated by EchoMRI. Soleus and gastrocnemius muscles as well as tibia were collected.
Results: While MCD didn't induce any changes in body weight and composition, it induced an increase in fasting glycemia (+53% vs. OVX-ACD $p<0.001$) and triglyceridemia (+23% vs. OVX-ACD $p=0.04$) which was associated with hepatic steatosis confirmed by macrovesicular Oil Red O staining. These results were accompanied by reduced hepatic gene expression of PPARα (-40% vs. OVX-ACD $p=0.04$) and PGC1α (-43% vs. OVX-ACD $p=0.007$), two key transcription factors involved in lipid oxidation and mitochondrial biogenesis. While fasting insulinemia didn't change, fasting glucagonemia was markedly increased in the OVX-MCD group (+78% vs. OVX-ACD $p=0.0002$). MCD also decreased hepatic IGF-1 gene expression (-20% vs. OVX-ACD $p=0.004$) while circulating IGF-1 was not changed. Interestingly, a strong correlation ($r=0.74$ $p=0.0002$) was observed between the hepatic gene expression of IGF-1 and that of the hepatic myostatin receptor Acvr2b.
Conclusion: Collectively, these results suggest that MPU impairs glucose and TG metabolism in the first instance by increasing the fasting glucagon, a stimulator of the hepatic glucose production, and secondly by exacerbating the hepatic steatosis in association with a decreased gene expression of PPARα and PGC1α. Moreover, the correlation between IGF-1 and myostatin receptor gene expressions suggests that MPU may interfere with the muscle-liver axis. This tissue interrelationship is under investigation. Finally this study is the first to point out the deleterious impact of MPU on glucose and hepatic metabolisms in an animal model mimicking the postmenopausal phenotype.

Middle-aged overweight male south Asians exhibit a different metabolic adaptation to short-term caloric restriction compared to Caucasians
L.E.H. Bakker[1], B. Guigas[2], T.C.M. Streefland[1], G.C.M. van der Zon[3], H. Pijl[1], A.E. Meinders[1], I.M. Jazet[1];
[1]Endocrinology, [2]Parasitology & Molecular Cell Biology, [3]Molecular Cell Biology, LUMC, Leiden, Netherlands.

Background and aims: South Asians (SA) develop type 2 diabetes at a younger age and lower BMI than Caucasians (C). The underlying cause is still poorly understood but might be related to differences in energy/nutrient-sensing signaling pathways leading to insulin resistance (IR). The present study aimed to compare the metabolic adaptation to short-term caloric restriction (CR) in SA and C.
Materials and methods: 12 middle-aged overweight male SA and 12 matched C (age 44.6±0.8 years, BMI 28.3±0.3 kg/m^2) were studied before and after an 8-day very-low-calorie-diet (VLCD, ~450 kcal/day). Endogenous glucose

production (EGP), glucose disposal rate (R_d), substrate oxidation (ventilated hood) and non-oxidative glucose disposal (NOGD) were determined basal and during a 2-step hyperinsulinemic euglycemic clamp (insulin infusion rates 10 and 40 mU/m²/min). In addition, skeletal muscle biopsies were obtained basal and after 30 min of clamp step 2.
Results: Basal and clamp EGP rates were comparable between groups before the VLCD, despite higher insulin levels in SA, indicating greater hepatic IR. In both ethnicities, hepatic insulin sensitivity (IS) significantly improved after the VLCD. Insulin-stimulated R_d and NOGD (step 2) were lower in SA compared to C before the VLCD (p=0.001) in spite of higher insulin levels in SA, indicating lower peripheral IS. After the diet, R_d improved in SA (p=0.039) despite lowered insulin levels, whereas R_d was not affected in C (p=0.198; between groups p=0.019). This beneficial effect in SA was entirely due to enhanced NOGD (p<0.001). Furthermore, SA mostly relied on glucose oxidation whereas C switched to lipid oxidation after the diet. At the molecular level, no obvious differences were observed in insulin signaling between groups. However, phosphorylation of AMPK and of key proteins involved in the mTOR-pathway was significantly increased after the VLCD only in SA. Furthermore, while protein expression of mitochondrial respiratory-chain complex 2 was not affected by the VLCD in SA, it significantly increased in C.
Conclusion: Middle-aged overweight male SA had lower hepatic and peripheral IS before CR than matched C. After an 8-day VLCD, R_d improved in SA, but not in C. However, SA relied on glucose oxidation, whereas C switched to lipid oxidation. This was reflected in a differential diet effect on the phosphorylation state of AMPK and the mTOR-pathway and on protein expression of respiratory-chain complex 2. We conclude that SA exhibit a different metabolic adaptation to short-term CR.

Obesogenic effect of hypercaloric diet on early undernourished rats: changes in central and peripheral insulin sensitivity
E. Lizárraga-Mollinedo[1,2], J. De Toro-Martín[1], E. Fernández-Millán[1,2], M. García-San Futos[3], T. Fernández-Agulló[3], M. Ros[3], C. Álvarez[1,2], F. Escrivá[1,2];
[1]Bioq. y Biol. Mol II.Facultad de Farmacia, UCM, Madrid, [2]Ciberdem, ISCIII, Madrid, [3]Ciencias de la Salud, Universidad Rey Juan Carlos, Alcorcón, Spain.

Background and aims: Nutritional imbalances during growth stages have an impact on immature tissues and lead to increased risk of several diseases later in life. A correlation between low birth weight and higher risk of obesity has been documented by several studies. However, there are divergences in the published results probably due to disparities in the definition of: onset, severity and duration of the food restriction. Many people all over the world were poorly nourished from immaturity and have experienced a shift toward Western eating habits in adult life. Animal models are helpful to understand this open enquiry replete with important social and health implications. We used a model of early undernutrition followed by nutritional rehabilitation with "cafeteria" diet to study some of those harmful effects.
Materials and methods: Wistar rats were fed *ad libitum* with a commercial chow (3% lipid/w; 2.9 Kcal/g) and a model of severe undernutrition was developed from intrauterine period until 70 days of life. From this adult stage, we started the rehabilitation during 200 days with a "cafeteria" diet (13% lipid/w; 4.6 Kcal/g) prepared by adding complementary ingredients to chow and supplied *ad libitum*. Four animal groups were established: control rats continuing with the normal chow (C), controls given a "cafeteria" diet (CC), undernourished rats kept under restriction (U) and undernourished transferred to "cafeteria"(UC). We measured weekly intakes and food efficiency. Visceral (VAT) and subcutaneous (SAT) adipose tissue were assessed by RMI. Plasma levels of insulin, leptin, triglycerides and cholesterol were determined by RIA, ELISA and enzymatic reaction, respectively. Triglycerides and cholesterol contents were also analyzed in liver and muscle. Hyperinsulinemic-euglycemic clamp was applied to evaluate whole insulin sensitivity. After direct icv injections of insulin and leptin, we analyzed both signalling pathways.
Results: Transfer to "cafeteria" formula elicited 17% and 160% increases of VAT in CC and UC rats, respectively, although the final proportions of this type of fat were similar in both groups. Liver triglycerides were: 12.0 and 19.0 μg/ g protein in CC and UC rats, respectively (p<0.01); as regards skeletal muscle, triglyceride contents were also lower in CC (5.3 μg/g protein) than in UC (20.0 μg/g protein). Insulin hypersensitivity associated with undernutrition was abolished after moving to "cafeteria" diet. Plasma leptin reached a peak at 10 days in control rats, not found in the age-matched undernourished animals. At 70 days, undernourished rats showed hypothalamic resistance to both insulin and leptin.
Conclusion: Our results show that feeding on a "cafeteria" diet leads to a large increase in the whole fat mass, irrespective of the previous nutritional condition. However, the increase in visceral fat is proportionally higher in the UC group. Some deleterious consequences of "cafeteria" diet, such as hyperlipemia and ectopic lipid accumulation, are also more markedly pronounced in UC than in CC. This situation is linked to hyperphagia associated, in turn, with hypothalamic resistance to anorexigenic factors (e.g. insulin and leptin).

Effects of a hypercaloric snacking diet on liver fat and insulin sensitivity in lean men
M.J. Serlie[1], K.E. Koopman[1], A.J. Nederveen[2], M.T. Ackermans[3], E. Fliers[1], S.E. la Fleur[1];
[1]Endocrinology & Metabolism, [2]Radiology, [3]Clinical Chemistry, AMC, Amsterdam, Netherlands.

Background and aims: Hepatic steatosis predisposes to fatty liver disease and is associated with visceral obesity. Also, fat accumulation in the liver reduces hepatic insulin sensitivity which increases plasma glucose concentrations. In addition to ectopic fat accumulation, excessive intake of dietary sugars and fat has been suggested to stimulate triglyceride storage in the liver. In the present study we evaluated the effect of increasing meal size (S) or meal frequency (F) while on a hypercaloric high sugar (HS) or hypercaloric high fat high sugar (HFHS) diet on liver fat, hepatic- and peripheral insulin sensitivity in lean men.
Materials and methods: We included 36 lean healthy men (age: 22.1±2.5yrs; BMI: 22.3± 1.4 kg/m2) and randomised them into 1 of the 4 hypercaloric diet interventions groups or a control group (N=5). Subjects followed the diet for 6 weeks. The caloric intake was 40% above a weight maintaining diet based on energy expenditure assessed with indirect calorimetry. Before and after the diet intervention, we performed a two-step hyperinsulinemic euglycemic clamp with a stable glucose isotope tracer to assess both hepatic- and peripheral insulin sensitivity. We performed MRSpectroscopy (1H-MRS) to measure liver fat.
Results: Weight was significantly increased in all 4 diet groups with no difference between the four diet groups, yet almost all subjects remained within the normal BMI range (20-25 kg/m2). Liver lipid volume was significantly increased in the HFHS- and the HS group randomised to an increase in meal frequency, but not in the groups randomised to increased meal size. A trend towards a decrease in hepatic insulin sensitivity was observed in the HFHS group with increased meal frequency (p=0.08), but not in the HS group. Peripheral insulin sensitivity was unchanged in all groups. None of the measurements were changed in the control group.
Conclusion: Thus, 6 weeks of hypercaloric snacking results in an increase in liver fat and high-fat high-sugar snacking affects hepatic insulin sensitivity. This suggests that a constant nutrient flow to the liver perturbs hepatic glucose metabolism independent of an increase in body weight.

Forced catch-up growth after early food-restriction alters the entero-insular axis programme leading to glucose intolerance in adult female rats
J. De Toro-Martín[1], E. Fernández-Millán[1,2], E. Lizárraga-Mollinedo[1,2], P. Serradas[3], F. Escrivá[1,2], C. Álvarez[1,2];
[1]Bioq. y Biol. Mol. II. Facultad de Farmacia, UCM, Madrid, Spain, [2]Ciberdem, ISCIII, Madrid, Spain, [3]INSERM, U872, Team 9, Paris, France.

Background and aims: Obesity and related diseases have become a major health issue in modern society and the trend is mirrored in developing nations that are transitioning to first world economies and lifestyles. The recent rate at which these diseases have increased suggests that environmental and behavioural influences, rather than genetic causes, are triggering the present epidemic. A relationship has been established between adverse fetal and early-infant phases of life and the subsequent development of adult obesity and type 2 diabetes. Under this scenario, we have performed a study focused on

the relevance of the diet on early stages of life, on the development of obesity and related metabolic disorders in adulthood.
Materials and methods: The experiments were carried out in female Wistar rats aged of six months, belonging to four diet groups: control (C), fed *ad libitum* with a standard chow diet, undernourished (U), fed 35% of the daily control food intake, control high-fat (CHF) and undernourished high-fat (UHF), both fed *ad libitum* with a high-fat diet (HFD) from weaning onwards. To evaluate the impact of the diet, body weight and food intake were assessed weekly, pancreatic and gut histology were studied and visceral fat pad was analysed. Oral glucose tolerance tests (OGTT) were performed to evaluate insulin, GLP-1 and GIP secretion and HOMA-IR values were calculated. Functionality of pancreatic islets was evaluated *in vitro* and gut incretin content was determined.
Results: After weaning, all rats gained weight when fed the HFD, being UHF rats significantly more hyperphagic than CHF animals. Adiposity measures showed that HFD increased visceral fat accumulation and adipocyte size, which were more marked in the UHF population. Although both populations under HFD developed glucose intolerance, UHF rats displayed increased GIP and GLP-1 secretion during OGTT as compared to CHF, showing enhanced glucose-stimulated insulin secretion *in vivo*. Nevertheless, glucose intolerance was more severe and not compensated in UHF rats, suggesting insulin resistance, as shown by HOMA-IR values. Surprisingly, following HFD, the *in vitro* response of beta cells was impaired not only in C rats but also in the U group. Moreover, although islet size and beta-cell volume increased in both HFD-fed rats, UHF rats showed fewer islets compared with their C counterparts. When addressing the effects of HFD on the enteroendocrine K and L cells, we observed a greater impact in U rats. Thus, whereas UHF rats showed a significant hyperplasia in both cell types as compared with U rats, gut histology did not revealed significant differences between C and CHF rats. This result was corroborated by measuring gut GIP and GLP-1 content, which were significantly increased in the UHF population.
Conclusion: The results of this study stress the importance of the nutrition during early life and its relevance in the development of long-term metabolic disorders. Thus, the greatest effects occur in offspring of food-restricted dams submitted to long-term HF feeding, which developed a metabolic syndrome-like phenotype, characterised by increased adiposity, glucose intolerance and an insulin resistance state, highlighting the adverse consequences associated with catch-up growth.

Effects of phentermine and topiramate extended-release (PHEN/TPM ER) on weight loss (WL) and glycaemic parameters by gender, race, and baseline body mass index (BMI)
H. Toplak[1], S. Rössner[2], R. Dvorak[3];
[1]Medical University, Graz, Austria, [2]Karolinska Institutet, Stockholm, Sweden, [3]VIVUS, Inc., Mountain View, USA.

Background and aims: In obese individuals, gender, race, and baseline BMI can affect WL and the risk of developing type 2 diabetes mellitus (T2DM). PHEN/TPM ER has previously demonstrated significant WL in the EQUIP study of obese subjects and in the CONQUER study of obese/overweight subjects with ≥2 weight-related comorbidities. The aim of this post-hoc analysis was to evaluate changes in percent WL, fasting glucose (FG), and annualized incidence of T2DM in subjects based on gender, race, and baseline BMI.
Materials and methods: Data from 2 double-blind, placebo-controlled Phase 3 studies (EQUIP: BMI ≥35 kg/m^2; CONQUER: BMI ≥27 to ≤45 kg/m^2 with ≥2 weight-related comorbidities, including T2DM) were pooled and subjects were stratified by gender (male vs female), race (white vs nonwhite), and baseline BMI (<35 vs ≥35 kg/m^2). Subjects in the intent-to-treat population were randomized to placebo (n=1477), PHEN 3.75 mg/TPM ER 23 mg (3.75/23; n=234), PHEN 7.5 mg/TPM ER 46 mg (7.5/46; n=488), or PHEN 15 mg/TPM ER 92 mg (15/92; n=1479). All subjects received lifestyle modification counseling based on the LEARN program.
Results: In the overall population at baseline, 74.3% (n=2731) of subjects were female, 84.3% (n=3099) were white, mean weight was 107.4±20.1 kg, BMI was 38.4±5.8 kg/m^2, and FG was 5.6±1.1 mmol/L; these values were comparable among subjects across race categories. Mean weight was slightly higher in male subjects than in female subjects. At week 56, subjects receiving PHEN/TPM ER experienced significantly greater least-squares (LS) mean percent WL, regardless of gender, race, or baseline BMI (*P*<.0001 vs placebo for 15/92, all comparisons; Table). FG was decreased in PHEN/TPM ER-treated subjects versus those receiving placebo across race, gender, and BMI categories (Table). In the CONQUER study, the annualized incidence rate of T2DM decreased in female subjects (34% to 64% reduction compared with placebo), in male subjects (4% to 51% reduction compared with placebo), in both race categories (white: 37% to 52%; nonwhite: 42% to 52% reduction compared with placebo), and in both BMI categories (BMI <35: 26% to 70%; BMI ≥35: 39% to 45% reduction compared with placebo). Common adverse events were constipation, dry mouth, and paraesthesia.
Conclusion: PHEN/TPM ER produced significant dose-related WL vs placebo regardless of gender, race, or baseline BMI ≥35. This WL was accompanied by improvements in FG and a lower annualized incidence rate of T2DM, regardless of race and baseline BMI. Whereas glycemic benefits were seen in both genders, this was only significant in female subjects vs placebo. These findings suggest that PHEN/TPM ER, as an adjunct to lifestyle modifications, may be an effective WL treatment for obese and overweight patients, regardless of gender, race, or baseline BMI.

Lorcaserin HCl phase 3 trials in obese and overweight patients: week 52 outcomes for those achieving at least 5% weight loss at week 12: a per prescribing information analysis
N. Finer[1], S. Smith[2], M. Sanchez[3], K. Fraher[3], S. Stubbe[3], C. Turner[3], B. Raether[3], D. Halliday[3], J. Krolikowski[3], R. Fain[4], W.R. Shanahan[3];
[1]UCLH Centre for Weight Loss, Metabolic and Endocrine Surgery, London, UK, [2]Translational Research Institute for Metabolism and Diabetes, Florida Hospital Sanford Burnham Medical Research Institute, Orlando, USA, [3]Arena Pharmaceuticals, San Diego, USA, [4]Eisai, Woodcliff Lake, USA.

Background and aims: Lorcaserin, a selective 5-HT2C agonist, was recently approved by the US FDA for chronic weight management in conjunction with lifestyle modification in obese patients (BMI ≥30), and overweight patients (BMI ≥27) with at least one co-morbidity.
Materials and methods: Three randomized, double-blind, placebo-controlled trials of lorcaserin HCl as an adjunct to lifestyle modification were conducted in patients with diabetes (BLOOM-DM) and without diabetes (BLOOM and BLOSSOM). BLOOM (N=3182) and BLOSSOM (N=4008) enrolled non-diabetic patients, ages18-65 years with BMI 30-45 kg/m^2, or 27 -29.9 kg/m^2 with at least one obesity-related co-morbidity. BLOOM-DM (n=604) enrolled patients without type 2 diabetes (T2DM) with inadequate glycemic control (HbA1c 7-10%) and BMI 27 - 45 kg/m^2.
Results: In those without diabetes, 47% of patients randomized to lorcaserin HCl lost ≥5% of initial body weight at Week 52, compared to 23% of patients randomized to placebo; the values for absolute weight loss were 5.8 kg and 2.5 kg, respectively (MITT-LOCF). In those with type 2 diabetes mellitus (T2DM), results were 38 vs.16% and 4.7 vs. 1.6 kg, respectively. Using AUC for ROC analysis, at least 5% weight loss by Week 12 was identified as the optimal early criterion for predicting at least 5% weight loss at Week 52; patients meeting this criterion at Week 12 were called Responders. In those without diabetes, 49.3% of patients randomized to lorcaserin HCl and 22.6% of those randomized to placebo were Responders. At Week 52, lorcaserin patients without diabetes who were Responders lost on average 10.6 kg, with 85.5% achieving at least 5% weight loss and 49.8% achieving at least 10% weight loss. In those with diabetes, 35.9% of patients randomized to lorcaserin HCl and 11.5% of those randomized to placebo were Responders. At Week 52, lorcaserin patients with diabetes who were Responders lost on average 9.3 kg, with 70.5% achieving at least 5% weight loss and 35.9% achieving at least 10% weight loss. At Week 52, lorcaserin Responders with diabetes showed reduc-

tions in fasting plasma glucose (29.3 mg/dL) and HbA1c (1.2%). At Week 52, lorcaserin Responders without diabetes showed reductions in systolic and diastolic BP and heart rate of 3.4 mmHg, 2.5 mmHg, and 2.5 bpm, respectively and lorcaserin Responders with diabetes had reductions of 2.6 mmHg, 1.9 mmHg, and 3.2 bpm, respectively.
Conclusion: In patients with and without diabetes, Week 12 weight loss was highly predictive of a robust response to lorcaserin in weight loss and improvements in cardiovascular and glycemic parameters at Week 52. At least 5% weight loss by Week 12 provides an early criterion for identifying those who will respond very favorably to lorcaserin.

Beneficial oxytocin effects in adipose tissue of obese/diabetic leptin-deficient mice

J. Altirriba Gutiérrez[1], A. Caillon[1], A. Poher[1], C. Veyrat-Durebex[1], D. Arsenijevic[2], A. Dulloo[2], F. Rohner-Jeanreaud[1];
[1]Laboratory of Metabolism, Department of Internal Medicine Specialties, Faculty of Medicine, University of Geneva, [2]Department of Medicine, Division of Physiology, University of Fribourg, Switzerland.

Background and aims: Oxytocin has been demonstrated to be effective in the treatment of obesity, glucose intolerance and insulin resistance present in diet-induced obese rats and mice. The aim of this study was to examine its effectiveness in a more marked model of obesity and diabetes (leptin-deficient *ob/ob* mice).
Materials and methods: *ob/ob* (O) and lean (L) control mice were treated with oxytocin (T) or vehicle (Unt) subcutaneously for 2 weeks. Pair-fed animal groups were included when the treatment decreased food intake (pair-fed animals received the same daily amount of food than the oxytocin-treated mice). Food, water, body weight and glycemia were measured daily; body composition was determined by magnetic resonance imaging before and after the treatment, and glucose tolerance was assessed at the end of the treatment. Gene, protein and enzyme activities were measured in the adipose tissue and the hypothalamus. At last, adipose tissue inflammation was studied through the quantification of macrophage infiltration by immunofluorescence and gene expression measurements.
Results: In lean mice, the treatment (LT) decreased body weight in comparison with the untreated group (LUnt) only during the first day, the difference being maintained thereafter (overall delta body weight gain: LUnt=3.1g, LT=2.3g, $p<0.05$). In the obese group, the treatment prevented the animals from gaining weight (overall delta body weight gain: OUnt=5.6g, OT=1.4g, $p<0.05$) and fat mass (delta fat mass: OUnt=3.9g, OT=1g, $p<0.0001$) throughout the treatment. The effects in obese mice were partially due to a decrease in food intake (cumulative food intake: OUnt=83.2g, OT=68.5g, $p<0.0001$) and also related to a decreased expression of key genes involved in lipid uptake (*Lpl*) and lipogenesis (*Fas*) and to an increase in lipolysis (*Hsl*). The enzyme activity of Fas was also found to be decreased. Adipose tissue inflammation was reduced (decrease in Mac-2 positive macrophage population OUnt=21.9%, OT=13.6% Mac2+/total cells, $p<0.05$) through a decrease in the M1 pro-inflammatory macrophage population (reduction in *Emr1a*, *Itgam* and *Cd11c* gene expression), without any modification of the M2 anti-inflammatory population (no change in *Mgl1* and *Cd206* gene expression). All these changes were "obesity-dependent", but "food intake-independent", as they were neither present in lean-treated mice, nor in the obese pair-fed group. Although oxytocin treatment decreased food intake in obese mice, no change was observed in the gene expression level of the hypothalamic neuropeptides synthetized within the first-order neurons (*Pomc*/*Cart* and *Npy*/*Agrp*). Surprisingly, although obese-treated mice were leaner, with less fat mass and lower adipose tissue inflammation than untreated mice, their glucose tolerance failed to be improved by the treatment.
Conclusion: Oxytocin effects in lean mice are limited to the first day of the treatment, whereas in leptin-deficient mice, they include prevention of body weight and fat mass gain throughout the treatment. Such oxytocin effects in obese mice are leptin-independent and they are partially due to a decrease in food intake and partially to direct effects on adipose tissue.

A long-acting oxyntomodulin derivative exerts superior body weight lowering to GLP1R agonism in monkeys

A. Pocai[1], B. Hansen[2], R. DiMarchi[3], J. Lao[1];
[1]Diabetes & Endocrinology, Merck, Kenilworth, [2]USF, Tampa, [3]Chemistry, Indiana University, Bloomington, USA.

Background and aims: Analogs of the incretin hormone glucagon-like peptide 1 (GLP-1) stimulate insulin secretion and suppress glucagon levels. Such therapy improves the management of T2D and is often accompanied by modest weight loss. This has prompted the search for alternative approaches to enhance such efficacy. Oxyntomodulin (OXM) is a peptide hormone secreted by the gut following nutrient ingestion that is a dual agonist at the GLP1R and glucagon receptor (GCGR) *in vivo*. OXM causes weight loss in obese man and improves glucose metabolism in T2D patients. We have previously reported that simultaneous activation of the GLP-1 receptor and GCGR can improve glucose metabolism and exhibit superior weight loss when compared to GLP1R agonism in obese rodents. We now report the translation of these observations to spontaneously obese rhesus monkeys, which were treated with a protease-resistant long-acting OXM derivative.
Materials and methods: Body weight and food intake were monitored in twenty-four male and female obese rhesus monkeys randomized for body weight, age and sex and treated daily for 21 days with a long-acting OXM derivative (3 μg/kg s.c., n=8), liraglutide (20 μg/kg s.c., n=8) or placebo (n=8). A meal tolerance test (MTT) was performed in a sequential study in six diabetic rhesus monkeys treated with placebo, liraglutide (10 μg/kg s.c.), placebo and the long-acting OXM derivative (1 μg/kg s.c.).
Results: Daily administration of OXM at a nearly sevenfold lower dose and exposures to the GLP1R agonist liraglutide resulted in superior weight loss (-8% vs -2.5% placebo-corrected). The impact on glycemic control and the potential hyperglycemic risk of GCGR activation was assessed in diabetic rhesus monkeys. Long-acting OXM improved fasting plasma glucose (152 ± 5 vs 122 ± 3 mg/dL, OXM vs. placebo, $P < 0.05$) and glucose tolerance during the MTT in the absence of changes in body weight and food intake.
Conclusion: These results are the first report of the superior pharmacology of a long acting OXM derivative (GLP1R/GCGR dual agonist) in a translational model, deepening our belief that this approach may offer a promising new mechanism in the treatment of T2DM.

Differences in the metabolic response to an oral glucose tolerance test between adult lean and obese individuals

N. Geidenstam[1], P. Spégel[2], H. Mulder[2], K. Filipsson[2], M. Ridderstråle[1,3], A.P.H. Danielsson[1];
[1]Clinical Obesity, Department of Clinical Sciences, Lund University, Malmö, Sweden, [2]Molecular Metabolism, Department of Clinical Sciences, Lund University, Malmö, Sweden, [3]Steno Diabetes Center, Gentofte, Denmark.

Background and aims: Obese individuals often display impaired glucose tolerance during an oral glucose tolerance test (OGTT). Consequently obesity is one of the strongest risk factors for developing type 2 diabetes (T2D). Both obesity and diabetes are conditions associated with a malfunctioning metabolism and it may be of importance to gain a better understanding of the dynamic changes occurring in the metabolome during an OGTT. Currently little is known about difference in metabolic response to an OGTT between obese and healthy lean people. By using a metabolomics approach, we aimed to detect such potential differences to distinguish between metabolites with a disturbed profile that could be used either as markers for future risk or benefit of weight loss to prevent future T2D.
Materials and methods: Serum samples were collected from 14 non-diabetic obese volunteers (body mass index [BMI] 44±1.5 kg/m^2, mean±SEM) at time-points 0, 30, 120 min during a 75 g OGTT. Targeted metabolite profiling was performed by gas chromatography connected to a mass spectrometry (GC/MS). The dataset was compared with data previously obtained from lean volunteers (BMI 22.4±2.4 kg/m^2, mean±SEM) by principal component analysis (PCA) and orthogonal projections to latent structures discriminant analysis (OPLS-DA) to find metabolite patterns discriminating between the OGTT time-points.
Results: As expected, the obese participants displayed impaired glucose tolerance due to lower insulin secretion and thereby unable to suppress blood glucose levels at 120 min during the OGTT compared to lean participants. More than 50 metabolites were identified in the obese and lean group respec-

tively, 35 of these metabolites were found in both groups and could therefore be compared. There was a distinct and significant separation between the patterns of metabolite concentrations from the different OGTT time-points between obese and lean participants. Several of the amino acids that were identified (asparagine, glutamate, taurine, tyrosine and isoleucine/leucine) showed an increased level in the obese compared to the lean during the first 30 min. At 120 min, these amino acids levels were decreased compared to baseline in the blood in both obese and lean individuals. The normal rapid insulin-mediated fatty acid suppression seen in the lean people was partially defect in the obese: The fatty acids identified (palmitic acid, lauric acid, oleic acid, pentadecanoic acid and stearic acid) showed a delayed response in obese individuals and suppressed only after 120 min.
Conclusion: In addition to the expected differences in glucose and insulin levels between lean and obese participants the OGTT is also characterized by other marked differences in the metabolic profiles. The altered OGTT-induced response for amino acids may be an example of an early pre-diabetic change in obese individuals. In addition, the delayed fatty acid response in the obese might serve as a helpful tool to identify the degree of a failing insulin sensitivity response. By finding metabolites with a differential response during an OGTT, it may be possible to distinguish obese people at risk for developing T2D and/or evaluate the effect of preventive measures such as weight loss and thereby become useful in clinical practice.

PS 043 Beta cell function in man

643

In patients with newly-diagnosed type 2 diabetes beta cell function is an independent predictor of glucose control evolution over 18 months
G. Fainelli, R.C. Bonadonna, M. Trombetta, L. Boselli, S. Bonetti, V. Stoico, C. Negri, M. Dauriz, E. Bonora;
AOUI VERONA, Verona, Italy.

Background and aims: We asked the question whether the metabolic phenotype at baseline and/or a number of type 2 diabetes mellitus (T2DM) risk genes may predict the evolution of glucose control (GC) within the first 18 months after diagnosis of the disease.
Materials and methods: 593 GAD-antibodies negative patients with newly diagnosed T2DM (age: 59±0.4 yrs; BMI: 30.0±0.2 kg/m^2) were studied with: 1. Prolonged (5-hours) frequently sampled OGTT to assess beta cell function (BCF) by state of art mathematical modelling of glucose and C-peptide; 2. Standard euglycemic insulin clamp to assess insulin sensitivity (SI); 3. Genotyping the common T2DM risk variants of the following genes: ADAMTS9, CDKAL1, FTO, G6PC2, GCK, GCKR, GNPDA2, HHEX, HNF1B, IGF2BP2, IRS1, JAZF1, KCNJ11, MTNR1B, NOTCH2, PPARG, SCL30A8, TCFL2, THADA, TMEM18, TSPAN and WFS1. GC evolution was defined as the difference between HbA_{1c} at diagnosis (7.0±0.1%) and HbA1c at 18 months (6.5±0.1%).
Results: 141 patients were lost to follow-up, thereby leaving 452 patients for evaluation. In all multivariate regression models, basal HbA1c (standardized beta [stBETA]: 0.92, p<0.0001) was the strongest positive predictor of favourable GC evolution (i.e. the higher HbA_{1c} at diagnosis, the greater its fall within 18 months). No role for T2DM risk gene variants, either as a single SNP or as a genetic score derived from all SNPs, could be detected. BCF (stBETA: 0.26) and eGFR (stBETA: 0.08), but not age nor BMI nor SI nor pharmacological therapy, were positive independent predictors of favourable GC evolution (p<0.001 e p<0.01, respectively).
Conclusion: Thus, better BCF at diagnosis, but not SI nor the T2DM genotype assessed in this study, is an independent predictor and a putative determinant of more desirable short-term (18 months) GC evolution.
Clinical Trial Registration Number: NCT01526720

Cross-sectional and longitudinal analyses of factors contributing to the progressive loss of beta cell function in type 2 diabetes
H. Nakayama, T. Kato, S. Nakayama, H. Kaku, K. Muraishi, I. Tokubuchi, K. Hara, S. Shigemoto, J. Kameo, M. Oho, Y. Tajiri, K. Yamada;
Division of Endocrinology and Metabolism, Kurume University School of Medicine, Japan.

Background and aims: Type 2 diabetes is a progressive disease characterized by insulin resistance and impaired insulin secretion. A gradual decline in insulin secretory capacity is a major obstacle to prevent the development of chronic vascular complications. In this study we assessed factors contributing to the insulin secretory defect in patients with type 2 diabetes by cross-sectional and longitudinal analyses.
Materials and methods: Subjects of this study were 327 inpatients with type 2 diabetes, consisted of 173 males and 154 females, aged 58 ± 13 years, with BMI of 24.3 ± 5.2. The duration of type 2 diabetes was 10.2 ± 8.5 years. The diagnosis of type 2 diabetes was established based on the EASD and ADA criteria for diabetes and the absence of pancreatic autoimmune markers including GAD antibodies and IA-2 antibodies. We excluded patients with renal failure, severe liver disease, or chronic pancreatitis. The lucagon stimulation test (GST) was performed to assess pancreatic β-cell function. None of the subjects were administered with incretin-related drugs. Among the subjects, 22 male and 28 female patients, aged 55.8 ± 9.7 years with BMI of 24.2 ± 4.5, underwent GST again after 4-9 years.
Results: A simple liner regression analysis of the cross-sectional data showed that ΔCPR (6-min postglucagon increment in CPR) decreases at the rate of 0.019 nmol/L/year. In a multiple regression model with gender, age, the duration of diabetes, BMI, the family history of diabetes, habitual alcohol intake, the presence of retinopathy, serum creatinine, basal plasma glucose, HbA1c, total cholesterol, HDL cholesterol, and log transformed triglyceride levels as independent variables, BMI and log(TG) were positively, and the duration of diabetes, the family history of diabetes, and the presence of retinopathy were inversely correlated with ΔCPR. In the 50 patients who underwent GST

twice, ΔCPR decreased from 0.755 ± 0.490 nmol/L to 0.573 ± 0.361 nmol/L over a period of 6.5 ± 0.9 years (p<0.0001). Thus ΔCPR declined at the ratio of 0.028 ± 0.045 nmol/L/year. Baseline BMI was positively associated with the declining rate of ΔCPR during the period between two GSTs. However, in a multiple regression analysis including baseline ΔCPR as an independent variable, baseline ΔCPR and the average of monthly HbA1c levels during the period were positively, and BMI was inversely associated with the declining rate of ΔCPR. Administration of sulfonylurea, biganide, alpha-GI, or insulin was not significantly correlated with the declining rate.
Conclusion: The progressive loss of insulin secretory capacity was demonstrated by both cross-sectional and sequential analyses of patients with type 2 diabetes. Thus the β-cell failure may be attributable to long-term metabolic disturbances. Furthermore, the presence of retinopathy was an independent predictor of insulin secretory defect, suggesting that intra-islet hypoperfusion could be involved in the β-cell dysfunction in patients with advanced microangiopathy. The longitudinal analysis showed that adequate glycemic control is a critical factor in preserving residual insulin secretory capacity in type 2 diabetes.

Predictors of beta cell dysfunction in type 2 diabetes: the Beta Decline study

G.T. Russo[1], A. Arcangeli[2], S. Cercone[3], A. Corda[4], D. Cucinotta[1], S. De Cosmo[5], L. Gentile[6], S. Leotta[7], A. Nicolucci[8], M. Pellegrini[9], G. Vespasiani[10], C.B. Giorda[11];
[1]Clinic and Experimental Medicine, University of Messina, [2]Unità operativa complessa di diabetologia, Ospedale di Prato, [3]MSD Italy, Roma, [4]Ospedale Civile Santa Barbara, Iglesias, [5]Istituto Scientifico Casa Sollievo della Sofferenza, San Giovanni Rotondo, [6]S.O.C. Diabetologia, Azienda Sanitaria Locale di Asti, [7]U.O.C Diabetologia, Ospedale Sandro Pertini, Roma, [8]Department of Clinical Pharmacology and Epidemiology, Consorzio Mario Negri Sud, Santa Maria Imbaro, [9]Ospedale S.M. della Misericordia, Udine, [10]ASUR Marche Zona Territoriale 12, San Benedetto del Tronto, [11]S.C. Diabetologia e Malattie Metaboliche, Ospedale Maggiore di Chieri ASL TO 5, Chieri, Italy.

Background and aims: Beta-cell dysfunction is an early step in the natural history of type 2 diabetes. However, its progression rate is variable and potentially influenced by several factors, including hypoglycaemic drugs. *BetaDecline* is an Italian multi-center prospective study, which has the aim to evaluate the association of beta-cell dysfunction with several clinical variables in a large cohort of type 2 diabetic subjects on stable treatment with oral hypoglycaemic drugs (OHAs) or diet only for more than one year.
Materials and methods: Clinical and lifestyle data were collected in all participants**.** Beta-cell dysfunction has been evaluated by the proinsulin/insulin ratio (P/I) and HOMA-B index; the degree of insulin resistance by $HOMA_{IR}$ model; common metabolic parameters, as well as fasting serum levels of NEFA, IL-6 and hsCRP were also measured.
Results: Overall, type 2 diabetic subjects participating to our study (n=508, 58.7% men and 41.3% women; mean age 63 years) were overweight (mean BMI 29.2 kg/m^2, mean waist circumference 102 cm) with an acceptable metabolic control (mean HbA_{1c} 7.2 %), and a mean diabetes duration of 8.8 years. Of these, 84% was currently treated with metformin, alone (39%) or in combination with other OHAs (45%); 35% was on sulphonylureas (SU), 10% on glytazones, 16% on glinides, 2% on acarbose and 5,5% of them was on diet only. At baseline, the PI/I ratio showed an inverse linear association with male gender, BMI, total cholesterol (T-C), LDL-C, HDL-C and hsCRP serum levels, and a positive linear association with HbA_{1c}, FBG and triglycerides levels (P trend<0.05 for all comparisons); whereas no significant differences were noted in IL-6 and NEFA concentrations, as well as in systolic and diastolic blood pressure values across quartiles of P/I ratio. Both HOMA-B and $HOMA_{IR}$ values progressively decreased across the increasing P/I ratio quartiles (P<0.0001, both). Secretagogues (SU e glinides) use was significantly greater in the highest P/I ratio quartile (P<0.0001), whereas no differences in the distribution of other hypoglycaemic, ipolipidemic and/or anti-hypertensive drugs according to the degree of beta-cell dysfunction were noted. At multivariate analysis, the risk for having a P/I ratio in the top quartile was four- times higher in diabetic subjects on secretagogues drugs (OR=4.2; IC95% 2.6-6.9), and greater in men (OR=1.8; IC95% 1.1-2.9).
Conclusion: In conclusion, in this large cohort of type 2 diabetic outpatients, secretagogues use is independently associated with a decrease of beta-cell secretion, which is also more frequent in diabetic men.

CSII therapy should be stopped for accurate evaluation of beta cell function in type 2 diabetic patients

Y. Tan, W. Xu, S. Luo, J. Yan, B. Yao, J. Weng;
Department of Endocrinology and Metabolism,the Third Affiliated Hospital of Sun Yat-Sen University, Key lab of Diabetology of Guangdong, GuangZhou, China.

Background and aims: It is well accepted that insulin secretagogues should be stopped before evaluation of β-cell function, because their stimulation of insulin secretion may lead to inaccurate assessment. Unlike insulin secretagogues, insulin therapy, especially continuous subcutaneous insulin injection (CSII),has been proved to have effect on "β-cell rest", which means endogenous insulin secretion may decrease during insulin therapy. No study investigates whether insulin should be stopped for evaluation of β-cell function in type 2 diabetic patients during CSII treatment. This study was designed to evaluate the impact of CSII on β-cell function assessment.
Materials and methods: Patients with type 2 diabetes (T2DM) admitted to our University Hospital treated with CSII were enrolled between September 2012 and April 2013. When patients achieved the target of fasting capillary glucose lower than 7.0mmol/L,serum samples were obtained 0min,30mins and 120mins after a fixed meal to measure C-peptide level. Then CSII were stopped at 10pm on the same day. The same tests were repeated on the next day.
Results: 49 patients with mean age of 52.7±12.4years,BMI 25.0±4.0Kg/m^2,HbA1c 10.8±2.8%,achieved the glycaemic target in 8.7±3.1days on 0.67±0.25 insulin(U/d/kg).C-peptide levels measured before stopping CSII were 0.21±0.10 nmol/L at 0min,0.33±0.18 nmol/L at 30mins, and 0.64±0.49 nmol/L at 120mins after the fixed meal. After CSII was stopped, C-peptide levels significantly increased (0min:0.38±0.11nmol/L;30mins:0.67±0.25nmol/L;120mins:1.36±0.65)(p<0.05). The percentages of C-peptide improvement [(C-peptide after CSII stopping - C-peptide before CSII stopping)/C-peptide before CSII stopping] were 133%, 147% and 208% at 0min,30mins and 120mins,respectively.The AUC of C-peptide increased from 103.66±61.33 noml/L×min before CSII stopping to 214.65±82.09noml/L×min after CSII stopping (p<0.05).
Conclusion: Effect of "β-cell rest" induced by intensive insulin therapy may bias β-cell function assessment in type 2 diabetic patients. Therefore, CSII therapy should be stopped for accurate evaluation of β-cell function in type 2 diabetic patients.

Liver transplantation improves both beta cell function and insulin sensitivity and may induce reversal of type 2 diabetes mellitus in cirrhotic patients

V. Grancini[1], M.E. Lunati[1], L. Boselli[2], D. Zimbalatti[1], P. Beck-Peccoz[1], R.C. Bonadonna[2], E. Orsi[1];
[1]Endocrinology and Metabolism, Fondazione IRCCS Ca' Granda - Policlinico di Milano, [2]Endocrinology and Metabolism, University of Verona and Azienda Ospedaliera Universitaria Integrata, Verona, Italy.

Background and aims: Diabetes mellitus develops in a variable proportion of patients undergoing orthotopic liver transplantation (OLT). The roles played by insulin secretion and action in determining changes in glucose tolerance after OLT are imperfectly known. Aim of this study was to monitor glucose tolerance, beta cell function and insulin sensitivity in a cohort of patients undergoing OLT in an effort to unveil the determinant(s) of changes in glucose homeostasis.
Materials and methods: 48 patients patients with liver cirrhosis, 33M/15F, age 52 ± 16 years, were studied before and 3, 6, 12 months after OLT with a frequently sampled oral glucose tolerance test (fsOGTT). Indication to, and treatments before and after OLT were as per ongoing protocols in our Institution, and are strictly adherent to international guidelines. Patients were planned to be classified as NonConverters (NC), i.e. patients who would maintain either nondiabetic or diabetic glucose regulation, or Converters to diabetes mellitus (C), or Regressors to nondiabetic glucose regulation (R). Beta cell function was assessed by state-of-art modelling of glucose/C-peptide curves during the fsOGTT. There are two key outputs of the model: derivative control (DC: amount of insulin secreted in response to the rate of plasma glucose increase; units: [pmol·m^{-2} BSA]/[mM·min^{-1}]) and proportional control of beta-cell function (PC). response to glucose concentration per se, presented as the stimulus-response curve linking glucose to insulin secretion rate at the

preselected glucose concentrations of 5.5, 8.0, 11.0, 15.0 and 20.0 mM; units: pmol·min^{-1}·m^{-2} BSA). The OGIS index, a robust estimate of insulin sensitivity, was computed with the glucose/insulin data of the fsOGTT.
Results: 45% of patients were found to be diabetic before OLT. After transplantation, glucose tolerance improved progressively (p<0.0001), and diabetes prevalence decreased to 40.3%, 30.2% and 24.3% at 3, 6, 12 months, respectively. No C were found. In multivariate analysis, shorter duration of liver disease and higher HDL-cholesterol levels at baseline were significant predictors (p<0.05 for both) of being R. R (p<0.02), but neither NC group (p=0.29-086), showed a significant improvement in the DC of beta cell function. Both in nondiabetic NC and in R, but not in diabetic NC, there were progressive improvements in the DC of beta cell function (p=0.02-0.03, p=0.001-0.02, and p=0.46-0.97 in nondiabetic NC, R and diabetic NC, respectively) and in the OGIS index (p=0.02, p=0.0001 and p=0.74 in nondiabetic NC, R and diabetic NC, respectively). Influences of pre- and post-OLT treatments were found to be minor.
Conclusion: In cirrhotic patients, OLT most often is associated with progressive, remarkable improvements in both beta cell function and insulin sensitivity, which in a number of diabetic patients result into reversal of diabetes. Diabetic patients with a long story of liver disease and low HDL-cholesterol levels are resistant to the beneficial effects of OLT on glucose metabolism.

Modelled response to a meal is useful method to characterise beta cell function (BCF) across the glucose tolerance (GT) spectrum: correlation with FSIGT
D. Chen[1], C. Dalla Man[2], C. Cobelli[2], D.A. Fryburg[3], R.H. Raymond[4], D.S. Lee[1], R.N. Bergman[5], D. Stefanovski[5], for the Beta Cell Project Team of the FNIH Biomarkers Consortium;
[1]Pfizer Worldwide Research and Development, Cambridge, USA, [2]University of Padova, Italy, [3]ROI BioPharma Consulting, East Lyme, USA, [4]R-Squared Solutions, Skillman, USA, [5]Cedars-Sinai Diabetes and Obesity Research Institute, Los Angeles, USA.

Background and aims: It is important to easily measure BCF and IS in longitudinal clinical trials and show similar responses with methodology like the FSIGT. Mixed meal tolerance tests (MMTT) are appealing due to simplicity and relevance to enteric physiology, yet complex due to variable absorption. The goal of this study is to measure BCF and IS to a standard, commercially available 450 kCal meal across the spectrum from normal GT (NGT) to prediabetes (PDM) to type 2 DM (T2DM) and to compare the BCF and IS responses to those from the FSIGT.
Materials and methods: All subjects were tested after an overnight fast on 3 separate days. Each subject had 2 MMTTs and 1 FSIGT. Parameters for BCF were estimated using published methods. The table summarizes sample size, BMI, and respective MMTT/FSIGT measures for: IS (Si); insulin release (Φtot and AIRg); and disposition index (DItot and DI) by group. MMTT parameters and FSIGT Si summarized as geometric means (95% CI); all others as arithmetic means (95% CI).
Results: The table below summarizes the results of the study. For MMTT and FSIGT, Si, Φtot and AIRg, and DI, values decline from NGT to T2DM (all P<0.001). Correlation analysis for each MTT/FSIGT parameter pair ACROSS ALL 3 GROUPS: Si (r=0.69); Φtot/AIRg (r=0.73); and DItot and DI (r=0.74), suggesting that values from the tests tracked similarly across GT states.
Conclusion: Modeled results from the MMTT correspond to FSIGT-derived parameters across range of responses of GT spectrum.

Pramlintide improves insulin action and worsens beta cell responsivity in healthy adults: a minimal model study
A. Mallad[1], M. Schiavon[2], L. Hinshaw[1], C. Dalla Man[2], R. Basu[1], A. Basu[1], C. Cobelli[2], Y. Kudva[1];
[1]Department of Endocrinology, Diabetes, Metabolism and Nutrition, Mayo College of Medicine, Rochester, USA, [2]Department of Information Engineering, University of Padova, Italy.

Background and aims: Use of Pramlintide to treat type 1 diabetes (T1DM) within closed loop artificial pancreas systems is currently being explored. However, its effects on postprandial insulin sensitivity and glucose kinetics are relatively unknown.
Materials and methods: We studied healthy individuals (n=7; 2 males; age 36±4 years; BMI 24±1 kg/m^2; %body fat 29±4%; HbA1c 5±0.2%) with scintigraphically measured normal gastric emptying on two occasions in random order with or without 30mcg Pramlintide administered at start of a mixed meal. The oral glucose and C-peptide minimal models were used to measure insulin action and secretion, respectively.
Results: Although peak plasma glucose concentration was delayed with pramlintide (40.7±2.8 vs. 100.7±5.4 min; p<0.05) postprandial glucose excursions over six hours did not differ. In contrast, postprandial insulin excursion was lower (4904.3±464.6 vs. 3603.2±322.0 μU/ml/6 h; p<0.05) with pramlintide. Insulin sensitivity (S_I) was higher (16.9±3.0 vs. 24.9±2.5 10^{-4} dL/kg/min per μU/mL; p<0.05), β-cell responsivity lower (16.1±1.3 vs. 13.4±0.8 10^{-9} min^{-1}; p<0.05) and disposition index higher (428.0±42.4 vs. 541.9±35.4 10^{-14} dL/kg/min^2 per pmol/L; p<0.05) with pramlintide.
Conclusion: Pramlintide improves insulin sensitivity in healthy adults. In contrast, beta cell responsivity was reduced with disposition index higher with pramlintide. Triple tracer studies were also done in the same subjects and will be reported later. Similar studies are necessary in T1DM before application of pramlintide into future informed closed loop control systems.

Adaptive insulin response to increasing caloric load in healthy subjects
W. Alsalim[1], L. Ohlsson[1], G. Pacini[2], B. Ahrén[1];
[1]Dept of Clinical Sciences, Lund, Sweden, [2]CNR, Metabolic Unit ISIB, Padova, Italy.

Background and aims: The dynamic interaction between insulin demand and insulin levels is a key factor for glycemic control and of importance for the fine-tuned insulin response to ingestion of meals. However, little is known

on the insulin adaptation to different caloric loads in meals of more regular daily life size and at other times of the day than in the morning after an overnight fast. We therefore examined the insulin adaptation to demands created by ingestion of increasing caloric loads in identical meals at lunch time after a standard breakfast in healthy subjects.
Materials and methods: Twenty-four healthy lean subjects (12 M, 12F, mean age 25 yrs, BMI 22.2 kg/m2) ingested a standard 500 kcal meal as breakfast after an overnight fast followed by a standardized lunch exactly four hours later. The caloric content of the lunch was 511, 743 or 1034 kcal and had identical nutrient composition (protein 18E%, fat 32E% and carbohydrate E50%). Blood samples for analysis of glucose, insulin and C-peptide were taken. Insulin secretion was evaluated by an insulinogenic index, calculated as the 120 min area under the curve (AUC) for C-peptide divided by 120 min AUCglucose (IGIC-peptide, pmolC-peptide/mmolglucose), insulin sensitivity with the composite insulin sensitivity index (ISIcomp) and insulin clearance by hepatic insulin extraction (HE) from insulin and C-peptide data.
Results: Plasma glucose rose rapidly after all three meals to a peak at 30 min. The small meal had a post-peak reduction below baseline to a nadir of 3.8±0.1mmol/l after 75min ($p<0.001$). For the two larger meals, glucose levels slowly declined after the peaks to reach baseline after 90 min. Plasma insulin concentrations increased after all three meals with 30 min peak levels being significantly higher with 743 and 1034 kcal meals than with 511kcal meal (both $P<0.02$) but with no significant difference between the two larger meals. IGIC-peptide increased by increasing caloric load and was 0.17±0.01, 0.19±0.01 and 0.21±0.01 after the meals, respectively ($P<0.001$). HE was reduced by increasing caloric load (62±2% with 511 kcal, 58±3% with 743 kcal and 50±3% with 1034 kcal $p\leq0.032$ between meals). There was no significant difference in ISIcomp between the three meals (58±7, 58±8 and 58±7, respectively).
Conclusion: Lunch meals elicit a caloric dependent adaptation in beta cell secretion and reduction in insulin clearance, whereas dynamic insulin sensitivity does not depend on caloric intake. The increased insulinemia at the two larger meals perfectly adapts to the caloric demand, resulting in identical glucose excursions, whereas after a lower caloric lunch (511 kcal) the insulin response is inappropriately high resulting in post peak suppression of glucose below baseline. We suggest that the insulin adaptation to caloric demands after lunch meals in healthy humans involves both beta cell secretion and insulin clearance and is perfect after meals of medium or large size, whereas lower caloric intake results in an overshoot of insulin, which may elicit post-lunch hypoglycemia.

CART is expressed in L-cells and K-cells in humans, regulates GIP and GLP-1 expression in vitro, and potentiates glucose stimulated GIP secretion in vivo in mice
L. Shcherbina[1], A.-H. Thoren Fischer[1], S.E. Falkmer[2], N. Wierup[1];
[1]Lund University Diabetes Centre, Lund University, Malmo, [2]Department of Clinical Pathology, Ryhov Hospital, Jönköping, Sweden.

Background and aims: Cocaine- and amphetamine-regulated transcript (CART) is a regulatory peptide expressed in the nervous system, adrenal medulla, pancreatic islets, adipose tissue, and neuroendocrine tumors. CART stimulates insulin secretion and inhibits glucagon secretion and CART-/- mice have blunted insulin secretion in vitro and in vivo. We have recently shown that CART is expressed in human enteroendocrine cells, including L- and K-cells in the human duodenum and jejunum. Furthermore, we have shown that CART plasma levels increase after a meal in humans. The main objective of the present study was to assess the relationship between CART and the incretins glucagon like peptide 1 (GLP-1) and glucose dependent insulinotropic peptide (GIP) using in vitro and in vivo model systems.
Materials and methods: Human specimens of duodenum and jejunum (n=10) were double-stained for CART and GIP or GLP-1 to quantify the co-expression of CART with incretin hormones. GLUTag and STC-1 enteroendocrine cell lines were used as L- and K-cell models respectively to study regulation of CART gene expression in vitro. Adenoviral overexpression of human CART in GLUTag and STC-1 cells was used in order to study the effect of CART on incretin gene expression. To test the effect of CART on GIP secretion in vivo in mice CART was administered i.v. during an oral glucose-tolerance test (OGTT).
Results: The majority of CART expressing endocrine cells in human duodenum and jejunum were identical to GIP-producing K-cells (75±8 % and 54±17% respectively). CART was also expressed in minor proportions of GLP-1-producing L-cells in both duodenum and jejunum. Expression of CART was also evident in GLUTag and STC-1 cell lines; therefore these cell lines were used to study CART gene regulation. In both STC-1 and GLUTag cells CART mRNA levels were positively regulated by GIP ($P<0.05$), but not by GLP-1. However, adenoviral overexpression of CART increased GLP-1 and GIP mRNA levels ($P<0.05$) in STC-1, but not in GLUTag cells. In addition, intravenous administration of CART 54-102 during an OGTT provoked elevated GIP secretion at 10 and 20 min ($P<0.01$ and $P<0.001$) and AUC for GIP at 0-30 min ($P<0.01$).
Conclusion: CART is co-expressed with GIP and GLP-1 in the human duodenum and jejunum. CART mRNA is regulated by GIP in enteroendocrine cell lines. CART regulates transcription of GLP-1 and GIP in STC-1 cells. CART potentiates glucose-stimulated GIP secretion in vivo in mice. Thus, our data suggest that CART is a regulator of incretin synthesis and secretion. Whether CART is co-secreted with the incretins needs further investigation.

Identification of novel GPR39 agonists that stimulate insulin and GLP-1 secretion in vitro using StaR® technology
O.J. Mace, S. Andrews, A.J.H. Brown, S. Brown, M. Congreve, A. Jazayeri, J. Patel, R. Prihandoko, B. Tehan, F. Marshall;
Heptares Therapeutics, Welwyn Garden City, UK.

Background and aims: Activation of GPR39, a GPCR expressed in the gastrointestinal tract, adipose tissue, liver and pancreas, by zinc couples to Gαs and Gαq to increase intracellular cAMP and(or) Ca^{2+} levels. Genetic studies have implicated a key role for GPR39 in metabolic regulation and pancreatic islet function. Using proprietary stabilised receptor (StaR®) technology and a homology modelling based approach, agonists for GPR39 have been identified and used to examine the role of GPR39 in insulin and incretin secretion *in vitro*.
Materials and methods: cAMP (Gαs) and IP_1 (Gαq) accumulation in response to agonist stimulation was assayed in HEK293 cells transiently expressing hGPR39. The secretion of insulin or GLP-1 in response to GPR39 agonism was evaluated using the pancreatic β-cell line, NIT-1, or primary

mouse intestinal epithelial cells (mIECs). Endpoints were assayed using HTRF cAMP, IP_1, insulin or active GLP-1 detection kits (Cisbio).
Results: Zn^{2+} and compounds (G#01, G#07, G#50 and G#89) stimulated Gαs and Gαq activity in HEK293 cells expressing hGPR39 (table 1). Mock transfected HEK293 cells were unresponsive to Zn^{2+} or compound. G#01, G#50 and G#89 acted as positive allosteric modulators of Zn^{2+}, significantly improving the $EC_{50(cAMP)}$ of Zn^{2+} from 245.3 ± 13.4 nM to 59.6 ± 6.1, 56.1 ± 5.2 and 37.9 ± 3.7 nM, respectively (all $P < 0.001$). Compounds stimulated GLP-1 secretion from mIECs and glucose-dependently stimulated insulin secretion from NIT-1 cells above the E_{max} for Zn^{2+} (table 1; $P < 0.001$). siRNA knockdown of GPR39 inhibited the insulin secretory activity of Zn^{2+} and all compounds, and inhibited basal insulin release from NIT-1 cells by 34 ± 8.7 % ($P < 0.001$). The insulinotropic activity of G#01, G#07, G#50 and G#89 (100 μM) was driven by a combination of Gαs and Gαq since it was partially inhibited by 5 μM H-89 (a PKA inhibitor) and also partially inhibited by both 5 μM nitrendipine (a voltage-gated Ca^{2+} channel inhibitor) and 50 nM LY333531 (a PKC inhibitor). GLP-1 secretion mediated by these compounds (100 μM) was inhibited by both 5 μM nitrendipine and 50 nM LY333531 indicating a Gαq-mediated component, and secretion by G#01 and G#89 was also inhibited by 5 μM H-89, showing that Gαs contributes towards the GLP-1 response raised by these compounds.
Conclusion: In summary, GPR39 agonists identified using StaR® technology can stimulate insulin and GLP-1 secretion from native/primary cell systems *in vitro*. GPR39 agonists which can stimulate Gαs and Gαq signalling pathways to elicit gut hormone responses and increase glucose-dependent insulin secretion positions GPR39 agonists as potential efficacious agents for metabolic disease and may have therapeutic benefits.

Peptide sensing by glucagon-like peptide-1 secreting L cells
E. Diakogiannaki[1], R. Pais[1], H. Parker[1], G. Tolhurst[1], A. Ramzan[1], J. Horscroft[1], H. Daniel[2], F. Gribble[1], F. Reimann[1];
[1]Clinical Biochemistry, University of Cambridge, Cambridge, UK, [2]Nutritional Physiology, Technische Universität München, Munich, Germany.

Background and aims: L-cells are enteroendocrine cells scattered along the length of the intestinal tract. They secrete several metabolically active peptides, most notably glucagon-like peptide-1 (GLP-1) which enhances postprandial insulin secretion, reduces appetite and promotes β-cell survival and proliferation. GLP-1 is secreted physiologically in response to ingestion of a variety of macronutrients, including carbohydrates, protein and lipids. It remains unclear, however, how protein digestion products trigger GLP-1 secretion, and the aim of this project was to investigate the mechanisms underlying L-cell detection of small peptides.
Materials and methods: A transgenic mouse model in which GLP-1 producing cells were labelled with the yellow fluorescent protein, Venus, was utilised to identify and purify L-cells. Primary murine colonic cultures were stimulated with di/tripeptides and protein hydrolysate, and GLP-1 secretion was measured. Ratiometric [Ca2+]i imaging experiments were carried out on identified L-cells in mixed epithelial cultures loaded with Fura-2AM.
Results: The di- and tripeptides, glycine-phenylalanine (GF), leucine-glycine-glycine (LGG) and the non-hydrolysable dipeptide glycine-sarcosine (GSar) stimulated GLP-1 secretion from primary intestinal cultures (1.5±0.4, 1.5±0.3, 1.5±0.1 fold stimulation respectively, compared to baseline, $p<0.05$) accompanied by reversible rises in L-cell Ca^{2+} levels (measured as 1.3±0.1 fold for GLL and 1.5±0.1 fold for GSar increases of the 340/380 nm fluorescence ratio compared to baseline, $p<0.01$). GSar-triggered GLP-1 secretion was abolished by the Ca^{2+} channel blocker nifedipine. Consistent with the involvement of voltage gated Ca^{2+} channels, GSar did not elicit a Ca^{2+} response in Ca^{2+} free buffer. Dipeptides, including GSar, are established substrates for the proton-coupled transporter PepT1. To investigate the potential involvement of PepT1 in GLP-1 secretion, experiments were performed at pH 6.5, 7.4 or 8. GSar-triggered GLP-1 release was pH dependent, with highest responses evident at pH 6.5 (1.9±0.1 fold above baseline, $p<0.001$) and lowest responses at pH 8 (1.2±0.1 fold above baseline, $p<0.05$). At pH 8, the Ca^{2+} response to GSar was also impaired. The non-translocated PepT1 inhibitor 4-Aminomethylbenzoic acid (AMBA) significantly reduced GSar stimulated GLP-1 release ($p<0.05$ vs GSar alone). Consistent with a role for PepT1 in protein sensing, GSar triggered GLP-1 release was impaired in colonic cultures from PepT1-/- mice ($p<0.01$ vs secretion from $PepT1^{+/+}$ mice). Protein hydrolysate (1, 5 or 50mg/ml), dose dependently enhanced GLP-1 secretion (1.6±0.1, 3.6±0.3, 10.3±0.4 fold vs baseline respectively, $p<0.001$) and these responses were unaffected by AMBA. A selective Ca^{2+}-sensing receptor antagonist (NPS2143) significantly attenuated protein-hydrolysate triggered GLP-1 secretion ($p<0.01$).
Conclusion: Our findings suggest that the stimulation of GLP-1 secretion from primary murine cultures by protein digestion products involves mechanisms employing PeptT1 and the Ca^{2+}-sensing receptor. Although GLP-1-mimetics and DPP4 inhibitors are widely used in the treatment of type 2 diabetes, stimulating pathways involved in endogenous GLP-1 release could offer new therapeutic strategies for diabetes and obesity.

Distribution of fatty acid binding receptors in GIP-secreting K cells in the small intestine
K. Mori, N. Harada, K. Suzuki, S. Yamane, A. Hamasaki, K. Sasaki, D. Nasteska, E. Joo, K. Shibue, T. Harada, N. Inagaki;
Department of Diabetes and Clinical Nutrition, Graduate School of Medicine, Kyoto University, Japan.

Background and aims: Gastric inhibitory polypeptide (GIP) is an incretin secreted from enteroendocrine K-cells after nutrient uptake and has a role in compensatory insulin secretion in obese state and fat storage in adipocytes. GIP secretion is increased under high-fat diet (HFD) feeding. We reported that long-term high-fat diet (HFD) feeding increases GIP mRNA and content in K-cells of GIP-GFP knock-in (GIP-GFP) mice which enable us to visualize K-cells by EGFP (Suzuki K, et al. J Biol Chem 2013). On the other hand, it is unknown how single-dose HFD-administration increases GIP secretion. Several fatty acid binding receptors are reported to be involved in GLP-1 secretion, however their expressions in K-cells remains unclear. In this study, we evaluated expressions of these receptors in K-cells.
Materials and methods: Tissue distribution of K-cells and K-cell number in gastrointestinal (GI) tract were evaluated by flow cytometry analysis and immunohistochemistry using GIP-GFP heterozygous mice. After collecting GFP-positive cells and GFP-negative cells as K-cells and non-K-cells, respectively, from GI tract by flow cytometer, RT-PCR was performed to evaluate expressions of GIP and fatty acid binding receptors (GPR40, GPR41, GPR43, GPR119, and GPR120).
Results: Immunohistochemical and flow cytometry analysis showed that GFP-positive cells were expressed in upper (US) and lower (LS) small intestine, but not in stomach and colon. The number of GFP-positive cells was significantly higher in US than those in LS (0.052% vs. 0.028% of epithelial cells; $P<0.05$). GIP mRNA expression and GIP content was 4-hold and 2-hold higher in K-cells of US than that in LS, respectively. GPR120 mRNA expression was exclusively high in K-cells of US, while GPR40 and GPR43 mRNA expressions were exclusively high in K-cells of LS. GPR41 and GPR119 mRNA expressions tended to be increased in K-cells of LS, but there was no significantly difference between K-cells and non-K-cells. Because GPR40, GPR43, and GPR120 belong to Gq-protein-coupled receptor, we examined inositol trisphosphate receptor (IP3R) expression and found that IP3R isoform 3 was mainly expressed in K-cells of US and LS.

Conclusion: There is a difference in not only K-cell number but also GIP expression in K-cells between upper and lower small intestine of GIP-GFP mice. Furthermore, fatty acid binding Gq-protein-coupled receptors, such as GPR40, GPR43, and GPR120, are highly expressed in K-cells and might be involved in GIP secretion after high-fat diet ingestion.

Temporal profiles of hormone expression in mouse enteroendocrine cells

P. Richards, F. Reimann, F.M. Gribble;
Clinical Biochemistry, University of Cambridge, UK.

Background and aims: Hormones from intestinal endocrine cells coordinate a complex array of metabolic effects including the regulation of intestinal motility, insulin secretion and appetite, with the two incretin hormones glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide-1 (GLP-1) being therapeutic candidates for treating type 2 diabetes. In a recent study using reporter mice in which a yellow fluorescent protein Venus is driven by the promoter for either GIP or GLP-1, we showed that the respectively labelled K and L cell populations have a more plurihormonal nature than previously thought. Cholecystokinin (CCK), for example, traditionally considered a product of I-cells, was co-produced by the majority of small intestinal K and L cells. This study examined whether enteroendocrine cells express different hormones during the course of their lifespan.
Materials and methods: We used mouse models in which cre-recombinase was expressed under the control of promoters for either GIP (GIP-Cre) or proglucagon (GLU-Cre), which when crossed into a floxed tandem red fluorescent protein (tdRFP) reporter strain resulted in permanent labelling of the cells after first expression of either GLP-1 or GIP. Fixed tissue samples from GIP- or GLU-Cre x tdRFP mice were immunostained with antibodies against different hormones. Percentages of cells producing different hormones were assessed by immunostaining of cell suspensions and flow cytometric (FACS) analysis. Confocal microscopy of immunostained fixed tissue was performed to analyse hormonal co-localisation in intracellular compartments.
Results: By immuno-FACS analysis, 94±1% of RFP+ve cells from GIP-Cre x tdRFP mice stained for GIP, and 71±2% of colonic RFP+ve cells from GLU-Cre mice stained for GLP-1. In these same mouse models, 60±3% of GIP positive cells and 72±2% of colonic GLP-1 positive cells contained tdRFP. The high percentage of RFP+ve cells staining for GIP in GIP-Cre x tdRFP mice indicates that once a cell has started expressing GIP in the small intestine, it continues to produce the hormone at the protein level during its entire lifespan. In these mice with labelled K-cells, the percentages of RFP positive cells that were immunostained for GLP-1 (4±0.5%), CCK (94±1%) and somatostatin (8±1%) were similar to the proportions revealed previously using the model in which Venus was driven directly by the GIP promoter. In the small intestine of GLU-Cre x tdRFP mice, 80±6% of RFP+ve cells stained for CCK and 16±2% stained for GIP, proportions similar to our previous observations in GLU-Venus mice (90% and 15%, respectively). By confocal microscopy of triple-stained small intestinal tissue, a subset of cells was found to contain GLP-1, Peptide YY (PYY) and CCK, and the hormones were found located in the same intracellular compartments.
Conclusion: Our data suggest that individual enteroendocrine cells can produce a number of hormones, and that under stable dietary conditions the proportions of co-expressed hormones do not vary markedly throughout the lifetime of a single K or L-cell. Whether the percentage overlaps are altered by diet or metabolic disease will be an interesting area for future studies.

Loss of GIP responsiveness in human adipocytes from an obesity context: potential therapeutic implications

S. Fernandez-Veledo[1,2], V. Ceperuelo-Mallafre[3], X. Duran[2], K. Roche[1,2], N. Vilarasa[4,2], V. Vicente[1], J. Vendrell[1,2];
[1]Hospital Universitari de Tarragona Joan XXIII-IISPV, [2]CIBERDEM-Instituto de Salud Carlos III, Madrid, [3]Hospital Universitario Virgen de la Victoria-CIBERObn, Malaga, [4]Hospital Unveristari de Bellvitge, Barcelona, Spain.

Background and aims: Incretins has emerged as important players in the glucose homeostasis since both glucagon-like peptide 1 (GLP-1) and glucose-dependent insulinotropic peptide (GIP) stimulates glucose-dependent insulin secretion. In fact, new pharmacological agents based on incretin action have emerged as useful tools fighting insulin resistance and type 2 diabetes (T2D). Contrary to GLP-1, GIP has been discarded for diabetes treatment because a low insulin secretory property has been detected in T2D patients. However the extra-pancreatic effects of these molecules deservers further investigations and adipose tissue effect of incretins is far from clear. Interestingly, genome-wide association studies for identifying loci correlated with body mass index (BMI) have shown that GIP receptor (GIPR) is a new loci associated with body BMI.
Materials and methods: GIPR expression was analysed in subcutaneous (SAT) and visceral (VAT) human adipose tissue sample from lean and obese subjects and replicated in three different cohorts. A series of lipogenic, lipolytic and GPCRs signaling gens were also screened in adipose tissue. In vitro studies were performed to evaluate the effect of GIP on insulin sensitivity and inflammation. GIP responsiveness was evaluated in human adipocyte cell lines in normoxic and hypoxic environment, as well as in adipose-derived stem cells obtained from lean and obese patients.
Results: GIPR expression was consistently down-regulated in adipose tissue from obese patients, both at mRNA and protein expression levels. Body mass index, adrenergic receptor kinase 1 (GRK2) and adipose triglyceride lipase (ATGL) genes were the main determinants of the GIP mRNA expression in SAT depot (ß coefficients: -0,199; 0,78 and 0,28; p: 0,03; <0,001 and 0,003 respectively). Study of glucose uptake and insulin signalling in human subcutaneous/visceral adipocytes revealed GIP as an insulin sensitizer incretine. Long-term treatment with GIP not only increases insulin sensitivity on glucose uptake but also attenuated insulin resistance induced by IFN-γ in human subcutaneous adipocytes. Analysis of IL-6 and MCP-1 mRNA expression also revealed an anti-inflammatory effect of GIP. These effects of GIP observed under normoxia were not detected in human fat cells cultured in mild hypoxia environment. In agreement, GIP increases insulin sensitivity in human adipose-derived stem cells from lean but not obese patients.
Conclusion: Beneficial effects of GIP in human adipocytes might be compromised in an obesity context. Normalizing GIP function on insulin sensivitiy and inflammatory state in human adipocytes might represent a potential therapeutic approach in the treatment of obesity-associated metabolic disorders.

Glucose-dependent insulinotropic polypeptide: blood glucose stabilising effects around fasting glycaemia in patients with type 2 diabetes

M. Christensen[1,2], S. Calanna[1,3], J.J. Holst[2], T. Vilsbøll[1], F.K. Knop[1,2];
[1]Diabetes Research Division, Department of medicine, Copenhagen University Hospital Gentofte, Hellerup, Denmark, [2]Department of Biomedical Sciences, Panum Institute, University of Copenhagen, Denmark, [3]Department of Clinical and Molecular Biomedicine, University of Catania, Italy.

Background and aims: We have previously shown in healthy subjects that the gut-derived hormone glucose-dependent insulinotropic polypeptide (GIP) has inverse effects on glucagon and insulin release, highly dependent on the plasma glucose levels. In addition, disturbances in GIP signalling have been causally linked to the inappropriate insulin and glucagon levels characterising patients with type 2 diabetes. Consequently, we aimed to determine the glucose-dependency of GIP effects in patients with type 2 diabetes.
Materials and methods: Twelve male subjects with type 2 diabetes (age: 62±1 years (mean±SEM); BMI: 29±1 kg/m^2; HbA_1c: 6.5±0.1%) were each studied on six different occasions. In a randomised order, the effects of intravenously physiological doses of GIP or placebo (saline) were compared at three glycaemic levels i.e. fasting glycaemia, insulin-induced hypoglycaemia, or hyperglycaemia (1.5×fasting plasma glucose).
Results: During *fasting glycaemia* (plasma glucose ~8 mmol/l), GIP elicited significant increments in both insulin and glucagon levels, resulting in neutral effects on plasma glucose. During insulin-induced *hypoglycaemia* (plasma glucose ~3 mmol/l), GIP elicited a minor first phase insulin response and a significant glucagon response during the initial 30 minutes, resulting in less glucose needed to be infused to maintain the clamp (29±8 vs. 49±12 mg×kg^{-1}, p<0.03). During *hyperglycaemia* (plasma glucose ~12 mmol/l), GIP augmented both first and second phase insulin secretion, with similar or slightly less glucagon suppression compared to saline, resulting in more glucose needed to maintain the clamp during GIP infusions (265±21 vs. 213±13 mg×kg^{-1}, p<0.001).
Conclusion: In patients with type 2 diabetes, GIP counteracts insulin-induced hypoglycaemia conceivably through a predominant effect on glucagon

release and subsequent enhancement in endogenous glucose production. In contrast, during hyperglycaemia, GIP increases glucose disposal through predominant effects on insulin release.

GLP-1 response after oral glucose overload test in patients with a history of gestational diabetes
M.J. Picon Cesar, A. Muñoz Garach, S. Maraver Selfa, A.M. Gomez Perez, I.M. Cornejo Pareja, F. Tinahones Madueño;
Endocrinology, Hospital Universitario Virgen de la Victoria, Malaga, Spain.

Background and aims: Assessing levels of GLP-1 before and after an oral glucose overload a year after the delivery in two groups of women who developed gestational diabetes mellitus (GDM) during pregnancy: healthy and pathological according to oral glucose overload.
Materials and methods: We have studied 41 women with prior GDM at 12.20 ± 1.36 months postpartum with a mean age of 32.88 ± 3.58 years and a BMI of 27.5 ± 5.23 kg/m2. Levels of glucose, insulin, C-peptide and GLP-1 were analysed before and 2 hours after an oral load of 75 g glucose. Women were classified as healthy and unhealthy according to oral glucose load test results.
Results: Levels of glucose (95.52 ± 9.45 mg / dl vs. 11.76 ± 38.72 mg / dl), C-peptide (2.44 ± 0.95 ng / ml vs. 10.41 ± 3.16 ng / ml), insulin (10.83 ± 6.68 mU / ml vs. 72.84 ± 43.2 mU / ml) and GLP-1 (2.27 ± 1.51 vs. 2.43 ± 1.92 ng / ml) were significantly increased after oral glucose overload. After dividing the patients according to healthy and pathological oral glucose tolerance test, we found that baseline levels of insulin (9.55 ± 5.82 mU / ml vs. 13.48 ± 7.66 mU / ml), glucose (91, 79 ± 5.70 mg / dl vs. 103.85 ± 11.0 mg / dl) and C-peptide (2.22 ± 0.82 ng / ml vs. 2.88 ± 1.07 ng / ml) were increased in pathological women compared to healthy ones, whereas GLP-1 levels (2.49 ± 1.72 ng / ml vs. 1.79 ± 0.71 ng / ml) were decreased. After loading, the levels of insulin and C-peptide increased significantly in both groups. Glucose levels increased significantly only in the group of pathological women and by contrast, GLP-1 levels increased significantly in the group of healthy women.
Conclusion: Women with a pathological response to the oral glucose overloading test showed a dysfunction in the production of GLP-1 after oral glucose overloading test compared with healthy women that showed a significant increase.

Time course of the incretin effect across the spectrum of glucose tolerance assessed by modelling analysis
A. Tura[1], E. Muscelli[2], A. Gastaldelli[3], E. Ferrannini[2,3], A. Mari[1];
[1]ISIB-CNR, Padova, [2]University of Pisa, [3]IFC-CNR, Pisa, Italy.

Background and aims: An oral glucose tolerance test (OGTT) determines a higher insulin response than an isoglycemic intravenous glucose infusion (IIGI), due to the incretin effect. The incretin effect is typically evaluated as the relative increase in insulin secretion (ISR) in the OGTT compared to the IIGI test. This integral index does not reveal how the action of incretins develops over time. We aimed at evaluating the time course of the incretin effect and its impairment in glucose intolerant states using paired OGTTs and IIGIs and a mathematical model.
Materials and methods: Modeling analysis was performed in 50 subjects; 23 had normal glucose tolerance (NGT), 17 had impaired glucose tolerance (IGT) and 10 had type 2 diabetes (DM). The subjects underwent a 3-hr OGTT (75 g) and an IIGI test, with measurement of glucose, insulin, C-peptide, GLP-1 and GIP. The model represents ISR during IIGI as the sum of two components. The first term describes the dependence of ISR on glucose concentration through a dose-response function (slope = glucose sensitivity), modulated by a glucose-dependent potentiation factor. In the second term, early ISR is proportional to the glucose rate of change with time; its characteristic parameter is *rate sensitivity*. During the OGTT, ISR is represented in an analogous way, but using an OGTT-specific rate sensitivity and multiplying the IIGI dose-response component by a time varying term representing *incretin potentiation* (P_{INCR}).
Results: During IIGI, β-cell glucose sensitivity was progressively impaired from NGT to DM (85.4±8.6, 58.4±8.4, 36.3±5.7 pmol min^{-1} m^{-2} mM^{-1}; NGT, IGT, DM), as was rate sensitivity (673±158, 571±126, 80±36 pmol m^{-2} mM^{-1}). The incretin effect on rate sensitivity (OGTT: 1733±269, 1410±210, 912±172 pmol m^{-2} mM^{-1}) was clearly present in all glucose tolerance groups (P<0.002), but was impaired in DM compared to NGT (P<0.038). In NGT, incretin potentiation P_{INCR} (Figure) rapidly increased and remained sustained during the whole OGTT (mean P_{INCR}>1 both in the period 30-90 min and 120-180 min, P<0.009). In IGT, the increase was transient (P_{INCR}>1 only in the period 30-90 min, P<0.007), while in DM there was no significant increase (P>0.2). After adjustment for BMI, a factor known to influence the incretin effect, a significant difference in P_{INCR} AUC between NGT and DM was observed (P=0.049). In the whole group, mean P_{INCR} was significantly but loosely correlated with GLP-1 AUC (r=0.49, P<0.006), while the relationship was not significant for GIP. The individual minute-by-minute correlation between P_{INCR} and GLP-1 or GIP were significant only in 20% of the subjects.
Conclusion: We have quantified the time course of the incretin effect by modeling analysis in NGT, IGT and DM. The incretin effect on early ISR is present in all groups, although blunted in DM. The onset of the incretin effect is rapid and sustained in NGT, transient in IGT and virtually absent in DM. The profiles of the incretin effect are poorly related to those of the incretin hormones.

High glycaemic index (GI) diet induced hepatic fat accumulation and insulin resistance is associated with high glucose-dependent insulinotropic polypeptide (GIP) secretion
F. Keyhani-Nejad[1,2], F. Isken[1,2], A.L. Birkenfeld[1,2], M. Irmler[3,4], J. Beckers[3,4], A.F.H. Pfeiffer[1,2];
[1]Department of Clinical Nutrition, German Institute of Human Nutrition, Nuthetal, [2]Department for Endocrinology, Diabetes and Nutrition, Charité - University of Medicine, Berlin, [3]Institute of Experimental Genetics, Helmholtz Zentrum München, German Research Center for Environmental Health (GmbH), Neuherberg, [4]German Center for Diabetes Research (DZD), Munich, Germany.

Background and aims: A high GI diet promotes the development of non-alcoholic fatty liver disease and insulin resistance. Also, high GI diet strongly stimulates GIP secretion. Here, the aim was to investigate GIP secretion in response to diets with different GIs and its contribution to hepatic fat accumulation upon long term intervention and related molecular mechanisms.
Material and methods: Weight matched, male C57Bl/6J mice were fed a high or low GI diet identical in macro and micronutrient composition, 40% Kcal from fat, 40% Kcal from carbohydrate, using sucrose or an identical glucose-fructose dimer which is cleaved slowly but resorbed completely resulting in a bypass of the upper GI tract. Body weight and food intake were assessed weekly. Body composition was measured by nuclear magnetic resonance spectroscopy. GTT was performed by injecting 2mg/g glucose intraperitoneally (IPGTT). Liver triglyceride content (TG) was determined from livers in fasted mice. Studies were repeated in GIP receptor knockout (Gipr-/-) and their Wild Type (WT) littermates. Transcriptome analysis was performed using Illumina Mouse Ref-8 v2.0 microarrays and data was interpreted using the Ingenuity pathway software.
Results: After 22 weeks of consuming isocaloric high fat diets, either containing high or low GI carbohydrates, body weight, body composition and food

intake did not differ between groups. Postprandial plasma GIP level was 2.3 - fold higher compared to the low GI group (AUC 49640 ± 3770 vs. 21730 ± 3380, p<0.001), while GLP-1 level was unchanged. Hepatic TG content was increased 2- fold in the high GI group (3.1 ± 0.4 vs. 1.6 ± 0.3 mg/mg, p<0.01). During an IPGTT, the high GI group showed an increased glucose and insulin excursion (AUC 3787 ± 310 vs. 2873 ± 175 and 113360 ± 18530 vs. 66273 ± 7003, p<0.05; respectively) compared to the low GI diet group, indicative of aggravated insulin resistance in the high GI group. Deletion of GIP receptor in Gipr-/- mice completely abolished the metabolic derangements compared to WT mice on a high GI diet. Microarray analysis of WT animals resulted in 136 probes with fold changes>1.3x, which were significant (p<0.01) differentially expressed between high GI and low GI groups. Of these, 63% were upregulated and 37% were downregulated by high GI diet. Notably, upregulated genes were involved in the NAD biosynthesis, Type I Diabetes Mellitus and Maturity Onset Diabetes of Young (MODY) signaling pathways. Downregulated genes were related to inflammation and immune responses. Suppressor of cytokine signaling-2 (Socs2) was upregulated 2.3-fold in high compared to low GI fed mice and is known to be involved in the JAK2/STAT5 signaling pathway.
Conclusion: Together, these data suggest that high GI feeding leads to increased GIP levels, which contributes to elevated liver fat and insulin resistance even under isocaloric conditions. Our molecular analysis suggests that Socs2 could be a potential biomarker for high GI induced fatty liver without differences in body weight and composition.

The non-hematopoietic erythropoietin analogue, ARA290, improves glucose tolerance by stimulating insulin secretion in spontaneously type 2 diabetic Goto-Kakizaki rats

C. Muller[1], K. Yassin[1], L.-S. Li[2], M. Palmblad[3], P.-O. Berggren[2], A. Cerami[4,5], C.-G. Östenson[1];
[1]Dept of Molecular Medicine and Surgery, Karolinska Institute, Stockholm, Sweden, [2]The Rolft Luft Research Centre for Diabetes and Endocrinology, Stockholm, Sweden, [3]Dept of Parasitology, Leiden University Medical Center, Leiden, Netherlands, [4]Araim Pharmaceuticals, Ossining, USA, [5]Dept of Nephrology, Leiden University Medical Center, Netherlands.

Background and aims: Beside its well-known function in hematopoiesis, erythropoietin (EPO) has been shown to exert tissue protective effects in many animal models including in the diabetic db/db mouse. However, use of EPO as tissue protection is limited due to increased hematopoietic activity and associated adverse effects. We have studied effects of ARA290, a non-hematopoietic EPO analogue, in vivo on glucose homeostasis and in vitro on β-cell function in diabetic Goto-Kakizaki (GK) rats and non-diabetic Wistar (W) rats.
Materials and methods: GK and W rats were treated during 4 weeks with ARA290 (daily s.c. injection, 30μg/kg body weight) or PBS as placebo. Non-fasting plasma glucose (PG) levels were measured every week. Intraperitoneal glucose tolerance test (IPGTT) was performed prior to treatment and after 4 weeks. Insulin release was assessed by radioimmunoassay.
Results: In ARA290-treated GK rats, PG levels were significantly lower after 4 weeks of treatment (8.0±0.2 vs. 9.3±0.2 mmol/l, p<0.05) and the IPGTT was significantly improved compared to placebo-treated GK rats (AUC being 1348±146 vs.1873±156 mmol/l per 240 min), while PG levels and IPGTT were similar in ARA290- and placebo-treated W rats. ARA290 improved β-cell function: 1) in vivo, insulin response during IPGTT (from 0 min to 30 min) after 4 weeks treatment tended to be augmented in ARA290 treated-GK rats compared to placebo (13.8±1.0 to 20.8±3.5 mU/l, p=0.067, and 15.5±3.4 to 18.1±2.5 mU/l, p=0.2, respectively), 2) in isolated islets from ARA290 treated-GK rats, glucose induced-insulin secretion was two-fold higher than control (p<0.05), 3) acute treatment with ARA290 (10ng/ml for 1 h) improved glucose-stimulated insulin release from GK rat islets compared to control GK islets (42.75±4.9 μU/islet/h vs. 12.38±2.4 μU/islet/h, p<0.001). Furthermore, islets from ARA290 treated-GK rats showed significantly higher intracellular Ca^{2+} concentrations in response to several β-cell secretagogues (p<0.02). GK islets treated with ARA290 and a Ca^{2+} channel blocker, nimodipine, showed significantly reduced insulin secretion compared to ARA290-treated islets (6.18±1.76 vs. 29.05±5.06 μU/islet/h, p<0.001). ARA290-induced insulin secretion in GK islets was significantly inhibited by diazoxide (K^+-ATP channel opener) (25.59±5.76 vs. 2.05±0.2, p<0.001) but in islets treated with ARA290 and combination of diazoxide/KCl insulin release is significantly increased compared to diazoxide/KCl alone (157.6±21.4 vs. 89.6±11.35 μU/islet/h, p=0.005), suggesting an effect of ARA290 on insulin secretion amplification pathways. PKA inhibitor H89 significantly inhibited ARA290-induced insulin secretion (17.31±1.76 vs. 35.97±4.74μU/islet/h, p<0.002) but not the PKC inhibitor Calphostin C (31.55±6.5 vs. 30.82±4.23 μU/islet/h).
Conclusion: In summary, our results suggest that ARA290 could improve glucose tolerance in diabetic GK rats, most likely due to stimulating effect on insulin secretion via K^+-ATP channel closure, calcium influx and insulin exocytosis.

Effects of exogenous DLK1-Fc treatment on insulin secretion and insulin sensitivity in an animal model of diet-induced obesity

M.-R. Yun, H. Kim, B. Jeon, I. Kwon, H. Seok, J. Huh, B.-W. Lee, E. Kang, H. Lee, B. Cha;
Department of Endocrinology and Metabolism, Yonsei University College of Medicine, Seoul, Republic of Korea.

Background and aims: Delta-like 1homolog (DLK1) is an imprinted gene encoding a transmembrane protein known to inhibit adipogenesis and to

be associated with muscle hypertrophy in animal models. We wanted to investigate the metabolic effects of exogenous DLK1-Fc treatment on skeletal muscle mass and total fat mass in a diet-induced obesity animal model and if any further protective effect against obesity and insulin resistance exists.
Materials and methods: Male C57BL/6 mice were separated into four groups: (1) fed with chow diet and vehicle treated; (2) fed with chow diet and DLK1-Fc treated;(3) fed with high-fat diet and vehicle treated; (4) fed with high-fat diet and DLK1-Fc treated for a period of 8 weeks. DLK1-Fc (15mg/kg) was injected intraperitoneally twice weekly. Body weight and food intake were measured weekly and fasting glucose was checked every 2 weeks. After 8 weeks, total body composition was checked by nuclear magnetic resonance (NMR) and an oral glucose tolerance test (OGTT) was done.
Results: In mice fed a standard chow diet, body weight, fat weight, muscle weight, and body composition were similar in both groups. However, the pancreas weight/tibia length ratio in DLK1-Fc treated group was higher than that of control group. Moreover, overnight fasting glucose was lower and fasting insulin and HOMA-b were higher in DLK1-Fc treated mice compared to the control group. In mice fed a high-fat diet, DLK1-Fc treated animals showed significantly decrease in body weight, especially in fat weight and fat mass analyzed by NMR, fasting glucose, postprandial glucose, AUC for glucose in OGTT, fasting insulin, and HOMA-IR. HOMA-b was higher in mice treated with DLK1-Fc. There was no difference in pancreas weight and muscle weight between the two groups.
Conclusion: These results show that exogenous DLK1-Fc regulates the insulin secretion positively and can improve insulin sensitivity by decreasing fat mass especially in an animal fed with a high-fat diet. In addition, this effect may be related to therapeutic strategies of anti-obesity and/or anti-diabetic drugs by enhancing both insulin secretion and insulin sensitivity simultaneously.

Figure 1. Effects of 8 weeks exogenous DLK1-Fc treatment or vehicle on (a) body weight, (b) fat mass, (c) overnight fasting glucose, and (d) fasting insulin level. Data are mean±s.e.m. CD, chow diet; HF, high-fat diet.

Background and aims: Autophagy was reported to have a function in maintaining β cell mass and function. Autophagy has a close relation to endoplasmic reticulum (ER) stress and unfolded protein response (UPR). ER stress can activate autophagy,and autophagy can remove dysfunctional ER. In this study, we evaluated the effects of PERK deletion, a constituent of UPR, on the β cell mass and function in β cell-specific autophagy deficient mice.
Materials and methods: β cell-specific *Atg7* knockout mice ($Atg7^{\Delta\beta\text{-cell}}$) were use as autophagy deficient model. They were crossed with $Perk^{+/-}$ mice to generate double knockout (KO) mice. Blood glucose levels and body weight were monitored. Intraperitoneal glucose tolerance test was carried out at 20 weeks of age, and then pancreas tissue was harvested to observe the morphologic changes, to measure the pancreatic hormone contents and to isolate islets for RT-PCR.
Results: Heterozygous deletion of *Perk* improved glucose intolerance and glucose-stimulated serum insulin secretion in $Atg7^{\Delta\beta\text{-cell}}$ mice. Pancreatic proinsulin content and prohormone convertase 1/3 activity in the islets were decreased in the $Atg7^{\Delta\beta\text{-cell}}$ mice, which suggested dysfunctional insulin synthesis. It was not impaired in the double KO mice. Increased pancreatic insulin content and suppressed insulin secretion on glucose stimulation in the $Atg7^{\Delta\beta\text{-cell}}$ mice suggested that there was impairment in insulin exocytosis and resultant insulin accumulation in the islets. This phenomenon was somewhat relieved in the double KO mice. Vacuolated change and accumulation of ubiquitin aggregates and p62 inthe islets of $Atg7^{\Delta\beta\text{-cell}}$ mice on immunohistochemical staining were markers for impaired autophagic activity. As these were less observed in the islets of double KO mice, we could speculate that the favourable effects of PERK reduction might be related to recovery of autophagic activity. RT-PCR with isolated islets revealed that some UPR markers were suppressed in the $Atg7^{\Delta\beta\text{-cell}}$ mice but not in the double KO mice. Accordingly, distended ER was found much more on electron microscopy of β cells from the $Atg7^{\Delta\beta\text{-cell}}$ mice compared to those from the double KO mice.
Conclusion: We demonstrated that partial suppression of *Perk* improved the impairment of structure and function of islets in the $Atg7^{\Delta\beta\text{-cell}}$ mice, leading to a recovery of insulin synthesis and secretion. As a result, glucose intolerance of the β cell-specific autophagy deficient mice was relieved by PERK reduction. The mechanisms could be regaining of autophagic activity and recovery of adequate UPR.

Beta cell CART overexpression in mice increases insulin secretion, enhances beta cell survival and attenuates insulin sensitivity

M. Abels[1], M. Riva[1], E. Banke[2], P. Spégel[1], L. Shcherbina[1], A.-H. Thorén Fischer[1], H. Mulder[1], E. Degerman[2], N. Wierup[1];
[1]Lund University Diabetes Centre, Malmö, [2]Lund University Diabetes Centre, Lund, Sweden.

Background and aims: Cocaine- and amphetamine-regulated transcript (CART) is a regulator of pancreatic islet hormone secretion, enhancing insulin secretion and lowering glucagon secretion, thereby fine-tuning blood glucose levels. CART also protects beta cells against glucotoxicity-induced apoptosis. Furthermore, beta cell CART expression in rat islets is regulated by glucose and CART is up-regulated in beta cells of type 2 diabetes (T2D) patients and rodent models of T2D. The aim of this study was to examine the impact of up-regulated beta cell CART on islet function, beta cell survival and whole body metabolism.
Materials and methods: We generated transgenic mice that express CART under the control of the PDX1 promotor resulting in overexpression of CART in the pancreatic beta cells (CARTtg). Mice fed either standard diet or a high fat diet were subjected to oral glucose tolerance test (OGTT), intravenous glucose tolerance test (IVGTT) and insulin tolerance test (ITT). After 4 months, insulin secretion from isolated islets, as well as islet morphology was assessed. Furthermore, glycerol release from adipocytes and metabolomic plasma profiling using GS/TOF-MS were assessed. In addition, mice were subjected to streptozotocin (STZ)-treatment to induce diabetes, followed by glucose monitoring and beta cell mass quantification.
Results: On a standard diet CARTtg had normal in vitro and in vivo insulin secretion, as well as beta cell mass. However, when fed a high fat diet, CARTtg displayed elevated insulin secretion (insulin AUC: wt 674 vs CARTtg 908, p=0.01), but impaired glucose elimination during OGTT (Kg: wt 1.1 vs CARTtg 0.65, p=0.02), increased glucose levels during IVGTT (glucose 5 min (mM): wt 20.0 vs CARTtg 22.0, p=0.005) and decreased insulin sensitivity during ITT (AUC glucose: wt 703 vs CARTtg 754, p=0.02). Metabolomic profiling of plasma revealed that CARTtg had decreased levels of 5 out of 8 analyzed free fatty acids (FFA) (CARTtg: 16-56% reduction compared to wt, p<0.05). In addition, CARTtg had reduced basal glycerol release from isolated adipocytes on both diets (normal diet: CARTtg 42% reduction compared to wt, p=0.004, high fat diet: CARTtg 68% reduction compared to wt, p=0.004) and visceral fat mass was increased in CARTtg fed a high fat diet (wt 2.35g vs CARTtg 3.23g, p=0.03). Furthermore, after STZ-treatment CARTtg mice displayed improved glucose homeostasis (glucose increase (mM) 1 week after STZ-treatment, wt 3.18 vs CARTtg 1.32, p=0.01), and higher beta cell mass compared to wt.

Conclusion: CARTtg mice display normal insulin secretion capacity, beta cell mass and islet morphology when fed a standard diet. Plasma levels of FFA are reduced in the fasting state and lipolysis is decreased. However, on a high fat diet, CARTtg mice become insulin resistant and have more visceral fat. If this is a consequence of elevated levels of circulating insulin, CART or other islet hormones remains to be elucidated. Beta cells in CARTtg mice are protected against STZ-treatment, resulting in an improved glucose tolerance. In the view of CART being up-regulated in islets of T2D patients, these findings emphasize the importance of beta cell CART during T2D progression.

Impaired islet function and structure in mice with hereditary predisposition to high fat diet-induced glucose intolerance
M. Nagao[1], A. Asai[1], W. Inaba[2], M. Kawahara[1], H. Sugihara[1], S. Yagihashi[2], S. Oikawa[1];
[1]Division of Endocrinology, Diabetes and Metabolism, Graduate School of Medicine, Nippon Medical School, Tokyo, [2]Department of Pathology and Molecular Medicine, Hirosaki University Graduate School of Medicine, Hirosaki, Japan.

Background and aims: Several animal models are currently used in the research field of type 2 diabetes. However, they could not fully explain the hereditary predisposition to diet-induced diabetes. Recently, we established two lines of mice with different susceptibilities (prone and resistant) to high fat diet (HFD)-induced glucose intolerance by selective breeding (designated SDG-P and SDG-R, respectively). After a 5-week HFD feeding, SDG-P mice showed evidently higher blood glucose levels relative to SDG-R mice. Here, we analyzed islet function and structure in these new polygenic model mice.
Materials and methods: Male mice of each strain fed a HFD (32% energy as fat) for 5 weeks (from 5 to 10 weeks of age). Blood glucose levels (0, 15, 30, 60, 120 min) and serum insulin levels (0, 15, 30 min) were measured in OGTT. Histological examination of pancreas and morphometric analysis of islet cells were performed under a microscope. Glucose-induced insulin secretion (GSIS) was assessed by batch incubation of isolated islets in medium containing 2.8 or 16.7 mmol/l glucose. Gene expression levels in the isolated islets were measured by real-time quantitative PCR.
Results: Before the HFD feeding (at 5 week-old under normal chow feeding), SDG-P mice showed slightly higher postchallenge blood glucose levels in OGTT as compared with SDG-R mice. Although serum insulin levels were higher in SDG-P mice under fasting condition (p=0.0042), no significant differences were observed in postchallenge insulin levels between the two lines. The in vivo indices of β-cell function (insulin secretion ratio and insulinogenic index; 15 min/0 min in OGTT) were significantly lower in SDG-P mice as compared with SDG-R mice (p=0.0026 and p=0.018, respectively). Correspondingly, isolated islets of SDG-P mice showed significantly lower GSIS than those of SDG-R mice (p=0.024). Gene expression levels of GLUT-2 (p=0.024), SNAP25 (p=0.014), and PDX-1 (p=0.023) were significantly lower, whereas FAT/CD36 was significantly higher (p=0.0064), in SDG-P islets relative to SDG-R ones. Although no significant differences were seen in islet mass and structure before the HFD feeding, SDG-P mice showed two-fold greater β-cell mass (p=0.024) as compared to SDG-R mice after the 5-week HFD feeding. Meanwhile, GSIS in SDG-P islets was still impaired after the HFD feeding (p=0.0010 vs SDG-R).
Conclusion: SDG-P mice showed spontaneous impairments in insulin response to glucose in vivo and lower GSIS in isolated islets. Reduced gene expressions of glucose sensing, exocytosis and transcriptional factors may contribute to the impaired insulin secretion and insufficient β-cell morphological adaptation in SDG-P islets. In addition, increased expression of FAT/CD36, a transmembrane fatty acid transporter, in SDG-P mice may participate in the acceleration of hyperglycemia by HFD feeding. Taken together, these hereditary impairments in pancreatic islets may determine the susceptibility to HFD-induced glucose intolerance.

Evaluation of the effect of liraglutide on beta cell fate in alloxan diabetic mice by tamoxifen-inducible Cre/loxP system
K. Tamura, K. Minami, H. Takahashi, M. Kudo, H. Kitanoya, S. Seino;
Kobe University Graduate School of Medicine, Japan.

Background and aims: Although GLP-1 receptor agonists have been shown to exhibit beneficial effects on not only beta-cell function but also beta-cell mass, the precise mechanism of the effect of the drugs on beta-cell mass is still unclear. The objective of this study is to determine whether liraglutide, a long-acting GLP-1 analog, would favor regeneration of beta cell mass in alloxan-induced diabetic mice. By using tamoxifen-inducible Cre/loxP system, in which beta-cell neogenesis can be distinguished from self-replication, we evaluate the effect of liraglutide on beta-cell fate.
Materials and methods: We crossbred Ins2-CreER knock-in mice with R26R-YFP mice to generate Ins2-CreER/R26R-YFP double knock-in mice, in which pancreatic beta-cells can be labeled specifically and permanently upon injection of tamoxifen, and traced the beta-cells by pulse and chase experiment. Pancreatic beta-cells were labeled by 5 consecutive injection of tamoxifen (4 mg/head/injection) to the male mice at 6 weeks of age. Ten days after the last injection, diabetes was induced by a single dose of alloxan (60 mg/kg, i.p.). On the next day, mice with blood glucose concentration above 300 mg/dL were used for the study. Liraglutide (200 μg/kg s.c.) or vehicle (saline) was administered once daily from the next day (day 0) of alloxan injection to day 30. Food intake and body weight were measured everyday and blood glucose levels were measured twice a week just before administration of drugs. Blood samples were collected to measure serum insulin levels. Beta-cell mass was estimated by immunofluorescent staining of pancreas sections.
Results: By alloxan treatment, pancreatic beta-cell mass was significantly decreased to about 20% of that in normal mice, and blood glucose levels were significantly increased. There was no significant difference in body weight between vehicle- and liraglutide-treated groups after 30 days. Food intake tended to be decreased in the liraglutide-treated group. While blood glucose levels of mice in the vehicle group continued to be increased gradually after alloxan injection, liraglutide treatment significantly suppressed the increment. Serum insulin levels in the liraglutide-treated group were significantly higher than those in the vehicle group. In addition, beta-cell mass in the liraglutide-treated group was two-fold higher than that in the vehicle group, which is correlated with the increment of serum insulin levels. We found that the frequency of insulin-positive cells labeled with YFP was not reduced by treatment of liraglutide for 30 days.
Conclusion: Chronic treatment of liraglutide expands beta-cell mass in alloxan-induced diabetic mice. Our results suggest that contribution of neogenesis is limited, if any, to the increment of beta cell mass by liraglutide treatment.

A role for kisspeptin in islet function during pregnancy
J. Bowe, C. Pilgrim, S. Persaud, P. Jones;
King's College London, UK.

Background and aims: Kisspeptin stimulates insulin release, but the physiological role of endogenous kisspeptin in islets remains unclear. The extremely high levels of kisspeptin released by the placenta suggest a possible role in modulating islet function during pregnancy. This study therefore determined the effects of kisspeptin on islet function in both pregnant and non-pregnant mice.
Materials and methods: Control or pregnant mice were implanted with subcutaneous osmotic minipumps containing either saline, kisspeptin (50nmol/day) or the kisspeptin antagonist kisspeptin-234 (200nmol/day). Intraperitoneal (i.p.) glucose tolerance tests and insulin tolerance tests were performed at mid and late pregnancy (10-12 days, and 16-18 days respectively). Glucose and insulin tolerance tests were performed following a single i.p. administration of glucose (2g/kg body weight) or insulin (0.75U/kg body weight), respectively at mid and late pregnancy (10-12 days, and 16-18 days respectively). Plasma samples were also taken during glucose tolerance tests for the measurement of plasma insulin levels using an ultra-sensitive ELISA.
Results: Chronic administration of kisspeptin-234 in pregnant mice impaired glucose tolerance during both mid-pregnancy (pregnant: 15.5±0.4mmol/L, kisspeptin-234 treated: 18.2±0.7mmol/L plasma glucose 30min post glucose administration, $p<0.05$, n=6) and late-pregnancy (pregnant: 13.1±0.8mmol/L,

kisspeptin-234 treated: 16.4±0.7mmol/L plasma glucose 30min post glucose administration, p<0.05, n=6). Kisspeptin-234 also reduced insulin release in response to glucose (mid-pregnant: 166±18%, kisspeptin-234 treated mid-pregnant: 115±11%; late-pregnant: 199±16%, kisspeptin-234 treated late-pregnant: 142±13% increase in plasma insulin relative to baseline, p<0.05, n=6). Similarly, chronic administration of kisspeptin in non-pregnant mice improved glucose tolerance (control: 17.4±1.2mmol/L, kisspeptin treated: 13.3±0.9mmol/L plasma glucose 15min post glucose administration, p<0.05, n=6) and increased insulin release in response to glucose (control: 157±18%, kisspeptin treated: 202±15% increase in plasma insulin relative to baseline, p<0.05, n=6). Whilst pregnant mice had reduced insulin sensitivity compared to non-pregnant controls in insulin tolerance tests, neither kisspeptin nor kisspeptin-234 had any significant effect on insulin sensitivity in either pregnant mice or non-pregnant controls.
Conclusion: These data support a role for placental kisspeptin in the regulation of islet function during pregnancy, indicating that both endogenous kisspeptin during pregnancy and kisspeptin administration in non-pregnant animals improve glucose tolerance. Furthermore, this effect of kisspeptin is due to increased insulin release in response to glucose rather than an effect on insulin sensitivity.

Maternal high fat diet induced insulin resistance and deterioration of pancreatic beta cell function with a gender difference in mature offspring
H. Yokomizo[1,2], T. Inoguchi[3,2], N. Sonoda[3,2], Y. Sakaki[2], R. Takayanagi[2];
[1]Tagawa Municipal Hospital, [2]Department of Internal Medicine and Bioregulatory Science, Graduate School of Medical Sciences, Kyushu University, [3]Innovation Center for Medical Redox Navigation, Kyushu University, Fukuoka, Japan.

Background and aims: Intrauterine environment may have a significant influence on the health of postnatal offspring. However, the mechanism of developmental origins of health and disease is yet to be clarified. In addition, the role of maternal diet on fetal overnutrition has been less studied than its relationship with fetal undernutrition. Here, we examined whether maternal high fat diet (HFD) may have an effect on glucose metabolism and pancreatic β cell function in mature offspring in mice.
Materials and methods: Female and male C57/BL6J mice were mating and fed either a control diet (CD) or HFD from conception to weaning, and offsprings were fed CD or HFD from 6 to 20 weeks age, resulting in four groups: CD-CD, CD-HFD, HFD-CD and HFD-HFD. Body weight was assessed at birth and once a week for 4 - 20 weeks. At 20 weeks, intraperitoneal glucose tolerance tests (IPGTT) and insulin tolerance test (ITT) were performed, and we evaluated insulin secretion at IPGTT, insulin contents and mRNA levels of *PDX-1*, NADPH oxidase components in isolated islets. In addition, oxidative stress in islets was evaluated by immunostaining of 8-hydroxy-2'-deoxyguansosine (8-OHdG). Liver triacylglycerol content, fat pad weight, average area of adipocyte and mRNA levels of *TNF-α*, *IL-6*, *MCP-1*, *F4/80* and *CD11* in white adipose tissue (WAT) were also evaluated.
Results: Body weight in maternal HFD was greater at birth and from 4 to 6 weeks, while there was a significant difference only between HFD-HFD and CD-HFD in female from 6 to 20 weeks. At 20 weeks, IPGTT and ITT showed that maternal HFD induced glucose intolerance and insulin resistance in offspring. Additionally, WAT mass and mRNA levels of *TNF-α*, *IL-6*, *MCP-1*, *F4/80* and *CD11* in WAT and liver triacylglycerol content were increased in maternal HFD. In contrast, plasma insulin secretion at IPGTT, insulin contents and mRNA levels of *PDX-1* in isolated islets were higher in maternal HFD in female, while they were lower in maternal HFD in male. To investigate the mechanism underlying a gender difference in pancreatic β cell function, oxidative stress in islets was evaluated by immunostaining of 8-OHdG. Staining intensities of 8-OHdG were increased in maternal HFD only in male. In addition, mRNA levels of *gp91phox*, a major source of superoxide production in islets, were increased in maternal HFD only in male.
Conclusion: Maternal HFD during gestation and lactation induced insulin resistance and deterioration of β cell function with a gender difference in mature offspring, accompanied by the progression of adipose tissue inflammation and liver steatosis.

Attenuated hyperinsulinaemia protects female mice with reduced Insulin2 gene dosage from diet-induced obesity
N.M. Templeman, X. Hu, A.E. Mehran, J.D. Johnson;
Cellular and Physiological Sciences, University of British Columbia, Vancouver, Canada.

Background and aims: Hyperinsulinemia can precede obesity, but the causal relationship between these two phenomena has remained controversial. The most widely held paradigm posits that obesity leads to peripheral insulin resistance, which subsequently causes compensatory insulin hypersecretion. We recently demonstrated that prevention of hyperinsulinemia in male mice with reduced *Insulin* (*Ins*) *1* gene dosage ($Ins1^{+/-}$:$Ins2^{-/-}$) was sufficient to prevent diet-induced obesity, which occurred normally in hyperinsulinemic $Ins1^{+/+}$:$Ins2^{-/-}$ control mice. However, *Ins1* is the rodent-specific result of a duplication-transposition event of *Ins2*, and it is unclear whether these genes have distinct functional roles. In the present study, we sought to examine the effect of reduced *Ins2*, which is analogous to the ancestral gene found in humans, on the development of diet-induced hyperinsulinemia, obesity, insulin resistance, and glucose intolerance, in female and male mice.
Materials and methods: Male and female $Ins1^{-/-}$:$Ins2^{+/-}$ mice and $Ins1^{-/-}$:$Ins2^{+/+}$ controls were placed on a high fat diet (HFD) or chow diet (CD) from weaning. Body mass, insulin secretion, and blood glucose response to intraperitoneal injections of glucose or insulin were assessed over a 1-year period.
Results: Female mice with deleted *Ins1* and reduced expression of the ancestral insulin gene ($Ins1^{-/-}$:$Ins2^{+/-}$) had lower basal circulating insulin as early as eight weeks of age, compared to $Ins1^{-/-}$:$Ins2^{+/+}$ controls ($p < 0.05$). Hyperinsulinemia in HFD-fed $Ins1^{-/-}$:$Ins2^{+/-}$ females (at 15 weeks, HFD: 0.6 ± 0.1 ng/mL, CD: 0.4 ± 0.0 ng/mL; $p < 0.05$) preceded the onset of obesity. At 27 weeks, all HFD-fed females had elevated basal and glucose-stimulated insulin levels, but this was reduced by over 50% in $Ins1^{-/-}$:$Ins2^{+/-}$ females ($p < 0.05$). Diminished hyperinsulinemia corresponded with attenuated diet-induced obesity (on HFD at 52 weeks, $Ins1^{-/-}$:$Ins2^{+/+}$: 36.1 ± 1.2 g, $Ins1^{-/-}$:$Ins2^{+/-}$: 31.0 ± 1.5 g; $p < 0.05$). A progressive worsening of glucose tolerance and insulin sensitivity coincided with the development of obesity in all HFD-fed mice, despite the decreased weight gain in $Ins1^{-/-}$:$Ins2^{+/-}$ females. Thus, diet-induced obesity could be selectively attenuated in female mice with reduced *Ins2* gene dosage. Surprisingly, male $Ins1^{-/-}$:$Ins2^{+/-}$ mice did not show the expected reduction in insulin levels with reduced *Ins2* gene dosage, and all HFD-fed males in our study became comparably hyperinsulinemic (*e.g.* basal insulin on HFD at 27 weeks, $Ins1^{-/-}$:$Ins2^{+/+}$: 2.1 ± 0.6 ng/mL, $Ins1^{-/-}$:$Ins2^{+/-}$: 1.9 ± 0.7 ng/mL; $p = 0.9$). Consistent with a role for hyperinsulinemia in weight gain, all HFD-fed male groups also reached a similar degree of diet-induced obesity (at 52 weeks, $Ins1^{-/-}$:$Ins2^{+/+}$: 43.1 ± 1.7 g, $Ins1^{-/-}$:$Ins2^{+/-}$: 43.4 ± 2.0 g; $p = 0.9$). $Ins1^{-/-}$:$Ins2^{+/-}$ males did exhibit minor glucose intolerance as early as six weeks, and unlike $Ins1^{-/-}$:$Ins2^{+/-}$ females, it was not transient. However, $Ins1^{-/-}$:$Ins2^{+/-}$ males did not appear otherwise distinct from $Ins1^{-/-}$:$Ins2^{+/+}$ controls, suggesting that a single allele of *Ins2* is mostly sufficient to meet the insulin secretory demands of male mice under these conditions.
Conclusion: Our results point to sex-specific differences in requirement for two alleles of *Ins2* to sustain hyperinsulinemia and weight gain. Collectively, these experiments strongly support the concept that protection from hyperinsulinemia leads to attenuated obesity in high fat-fed mammals.

Characterisation of glucose homeostasis in a novel rat model of leptin deficiency
A.M. D'souza[1], A. Asadi[1], S.D. Covey[2], T.J. Kieffer[1];
[1]Cellular and Physiological Sciences, University of British Columbia, Vancouver, Canada, [2]Biochemistry and Molecular Biology, University of British Columbia, Vancouver, Canada.

Background and aims: The *ob/ob* mouse has a spontaneous mutation of the gene encoding leptin, resulting in the development of obesity and impaired glucose homeostasis. It has been the only animal model of leptin deficiency to date. However, through the use of zinc finger nuclease technology, a rat model of leptin deficiency was created by deletion of 151 bp of the leptin gene. Here we sought to characterize the metabolic phenotype and glucose handling of leptin deficient rats to determine if they are comparable to *ob/ob* mice.
Material and methods: Rats heterozygous for the mutated leptin gene were bred to produce wildtype (WT) and knockout (KO) littermates. Blood glu-

cose, plasma insulin and insulin sensitivity were compared between WT and KO rats after a 4-hour fast. Glucose tolerance was measured via oral gavage of glucose (1.5 g/kg body weight) after an overnight fast. These measures were then evaluated in the presence of leptin therapy (100 μg/day via mini osmotic pump) to determine if leptin replacement in KO rats would reverse the phenotype. Alpha and beta cell area and pancreas morphology were assessed by immunostaining for insulin, glucagon and GLUT2.
Results: Differences in body weight between WT and KO rats were evident by 6 weeks of age and continued to increase so that by 36 weeks of age male KO rats weighed 1.8-fold more than WT littermates (KO=1048.27±29.67 g *vs*. WT=567.13±28.01 g; p<0.05). A similar trend was observed in females (581.53±28.56 g *vs.* 347.63±20.85 g; p<0.05). Total fat mass was 2-fold and 2.8-fold higher in male and female KO compared to WT rats, respectively. By 6 weeks of age, fasting insulin levels were 22-fold higher in male KO compared to WT (12.59±1.82 ng/ml *vs.* 0.57±0.12 ng/ml, p<0.05) and 54-fold higher in female KO compared to WT (37.38±0.84 ng/ml *vs.* 0.69±0.02 ng/ml, p<0.05). Fasting insulin remained elevated at 36 weeks of age. KO had larger islets and the proportion of beta cell area per pancreas section was 3-fold higher in KO compared to WT (1.7±0.9 % *vs*. 0.5±0.1%; p<0.05). No differences in alpha cell area were evident (p=0.625). Despite larger islet size, KO rats had reduced GLUT2 expression, impaired glucose stimulated insulin secretion, and were glucose intolerant by 7 weeks of age. The same trend of glucose intolerance and impaired glucose stimulated insulin secretion was observed in female KO rats. Leptin therapy (100 μg/day) resulted in an attenuation of weight gain, improved fasting insulin levels (4.83±1.32 ng/ml compared to 12.74±3.05 ng/ml pre-leptin) and glucose tolerance that was comparable to WT (KO AUC=249.5±46.5 *vs*. WT AUC=178.9±41.3; p>0.05).
Conclusion: The absence of functional leptin in rats results in a phenotype similar to the leptin-deficient *ob/ob* mouse, marked by obesity, fasting hyperinsulinemia, and defective *in vivo* glucose stimulated insulin secretion. Furthermore, defects in pancreas morphology and function that have been observed in *ob/ob* mice were also evident in this rat model, including hypersecretion of insulin, increased islet size and reduced GLUT2 expression. These data provide compelling evidence of the conserved effects of leptin on glucose homeostasis across species and indicate that the leptin KO rat will be a useful model to further study the mechanisms of action of leptin as well as therapies for obesity and glucose intolerance.

Hypothalamic nitric oxide regulates peripheral insulin bioavailability
F.O. Martins[1,2], S. Tovar[3], S. Pérez-Sieira[3], D. Gonzalez-Touceda[3], J.G. Jones[1,4], A. Natali[5], C. Diéguez[3], M. Macedo[4,6];
[1]Centre for Neurosciences and Cell Biology, University of Coimbra, Lisbon, Portugal, [2]Institute for Interdisciplinary Research, University of Coimbra (IIIUC), Portugal, [3]Centro de Investigación de Medicina Molecular y Enfermedades Crónicas (CIMUS), Universidad de Santiago de Compostela, Spain, [4]Portuguese Diabetes Association (APDP-ERC), Lisbon, Portugal, [5]Metabolism Unit, Department of Internal Medicine, University of Pisa, Italy, [6]Centro de Estudos de Doenças Crónicas, New University of Lisbon, Portugal.

Background and aims: The bioavailability of insulin for peripheral tissues is defined by the rates of insulin secretion and hepatic insulin clearance. Human studies demonstrated that NO is an important regulator of insulin clearance. Whether the control of insulin clearance is solely dependent on hepatic mechanisms or also relies on hypothalamic regulation is uncertain. Hypothalamus is a critical regulator of energy metabolism and endocrine functions. Therefore, we hypothesized that NO production by central/hypothalamic axis regulates insulin clearance and therefore peripheral insulin bioavailability.
Materials and methods: Male Wistar rats were submitted to brain surgery using a stereotaxic apparatus to the implantation of the simple, for intracerebroventricular (i.c.v.), or the double cannulas, for nucleus specific infusion. After the bregma localization the following coordinates were used: Lat: 1.2mm, AP: 1.0mm for lateral ventricle (i.c.v.), AP: -1.8mm, Lat: +/- 0.4mm, DV: -8.0mm for paraventricular nucleus (PVN) and AP: -2.52mm, Lat: +/- 0.6mm, DV: -9.2mm for ventromedial hypothalamus (VMH). Bolus infusions of 250ug/2uL of L-NAME (or 2uL of saline in the control animals) were performed in each side of the brain. An oral glucose tolerance test (OGTT) (2g/kg) was performed 45min after L-NAME bolus infusion. Glycemia was monitored and blood samples were collected. Insulin and c-peptide levels in the plasma were quantified. Insulin clearance was evaluated by the ratio between plasma c-peptide and insulin areas levels across the OGTT.
Results: Acute L-Name infusion did not affect glycaemia either basal or upon the OGTT (AUC Ctrl vs. LN: i.c.v.: 949.8 ± 36.8 vs. 921.0 ± 18.2, n.s.; PVN: 960.5 ± 30.3 vs. 944.4 ± 11.0, n.s.; VMH: 1015.0 ± 68.9 vs. 994.4 ± 44.2, n.s.). After the glucose bolus, both i.c.v. and PVN L-NAME treated animals demonstrated a decrease in plasma insulin levels (AUC Ctrl vs. LN: i.c.v.: 14.9 ± 0.8 vs. 10.1 ± 1.4, p<0.5; PVN: 14.8 ± 2.3 vs. 10.3 ± 0.9, p<0.5; VMH: 9.3 ± 1.4 vs. 9.6 ± 1.6, n.s.) with no alterations in c-peptide levels (AUC Ctrl vs. LN: i.c.v.: 13155 ± 984 vs. 13482 ± 1445, n.s.; PVN: 10167 ± 756 vs. 10596 ± 922, n.s.; VMH: 9744 ± 1550 vs. 10010 ± 1039, n.s.). Insulin clearance was calculated and both i.c.v. and PVN but not VMH nitric oxide synthesis suppression resulted in an increase in insulin clearance after the glucose bolus (AUC Ctrl vs. LN: i.c.v.: 8574 ± 534 vs. 11510 ± 632, p<0.5; PVN: 6514 ± 338 vs. 8044 ± 498, p<0.5; VMH: 8118 ± 597 vs. 8518 ± 1234, n.s.).
Conclusion: Together these results reveal that after a glucose bolus, and not in the fasting state, increased levels of nitric oxide in the hypothalamic/PVN region lead to decreased insulin clearance supporting the hypothesis that hypothalamic function is a regulator of peripheral insulin bioavailability.

Continuous glucose monitoring (CGM) discloses high glycaemic variability in patients with "late dumping" after RYGB

K. Rett[1], D. Wagenknecht[1], E. Fischer[1], K. Krieger[1], E. Weitz[1], R. Chandra[2], C. Stier[2];
[1]German Obesity Center, conservative branch, [2]German Obesity Center, surgical branch, Krankenhaus Sachsenhausen, Frankfurt/Main, Germany.

Background and aims: Weight loss after Roux-en-Y gastric bypass surgery (RYGB) has been repeatedly associated with at least transient regression of type 2 diabetes in obese persons. The dark side of improved glycaemic control is postbariatric noninsulinoma pancreatogenous hypoglycaemia syndrome (NIPHS). NIPHS prevalence is largely unknown with published rates ranging from 0.2% to more than 30%. Both figures however may not represent real life: The former originates from retrospective data from the SOS-study counting hospitalisation for diagnoses associated with post-gastric bypass hypoglycaemia. The latter results from measuring reactive hypoglycemia after an oral glucose challenge, a procedure which is not validated and may not be reasonable after RYGB. We therefore examined RYGB patients under daily life conditions by combining continuous tissue glucose monitoring (CGM) with simultaneous assessment of nutrition, physical activity and symptoms of hypoglycaemia.
Materials and methods: 27 consecutive patients (22 women, 5men; mean age 43 y) with type 2 diabetes who had undergone RYGB for obesity, were examined 6-14 months after bariatric surgery because they reported symptoms that were compatible with dumping syndrome. During 7 days of continuous measurement of interstitial glucose (IG; Dexcom seven$^+$, lower alert limit: 70 mg/dl), nutrition and physical activity were recorded in detail. In addition, autonomous and neuroglucopenic symptoms of hypoglycaemia were assessed semiquantitatively according to the Edinburgh Hypoglycaemia Scale. Glycaemic variability (mean absolute glucose; MAG) was calculated using EasyGV software.
Results: As a consequence of weight loss (BMI pre-OP 46.9±1.5 kg/m^2 / post-OP 35.6±2.5 kg/m^2) most of the subjects had reduced or stopped their antidiabetic medication. Average HbA1c was 5.9±0.3 % (pre-OP 6.5±0.3%). Average IG was 116 mg/dl, however 25 (93%) of the patients had at least one episode with IG<70 mg/dl. The typical IG-pattern was a steep prandial glucose peak already after small amounts of carbohydrates and consecutive postprandial nadir into the hypoglycaemic range and a high glucose variability likewise (MAG 3.0±0.2 mg/dl/h; normal range 0.5-2.2). Autonomous and neuroglucopenic symptoms showed high interindividual variability and invariably occurred after the sensor alert and thus were not helpful for early recognition of low IG. Percentage of time spent at IG concentrations greater than 180 mg/dl and less than 70 mg/dl was on average 10.4 and 10.5 %, respectively.
Conclusion: Using CGM, both hypo- and hyperglycaemic excursions are detectable more frequently than expected and perceived. Thus 93% of the RYGB-patients had reactive low IG after marked prandial glucose peaks and a high overall glycaemic variability. The popular perception of postbariatric subjects with type 2 diabetes focusing on successful weight loss, improved fasting plasma glucose and normalized glycated hemoglobin obviously does not consider the complex postoperative situation of many patients. In particular, high glucose variability as well as the surprisingly high percentage of time spent above the renal threshold of glucose and below the threshold of neuroglucopenia should give rise to closer glucose monitoring and more intense nutrition counseling.

Mechanisms of diabetes remission after bariatric surgery: role of the gut

M. Nannipieri[1], S. Baldi[1], D. Colligiani[1], A. Mari[2], D. Guarino[1], R. Berta[3], S. Camastra[1], M. Anselmino[3], E. Ferrannini[1];
[1]Clinical and Experimental Medicine, University of Pisa, [2]Biomedical Engeneery, CNR of Padua, [3]Surgery, Azienda Ospedaliera Universitaria Pisana, Italy.

Background and aims: In morbidly obese patients with type 2 diabetes (T2DM), Roux-en-Y-gastric-bypass (RYGB) and sleeve gastrectomy (SLG) similarly restore euglycaemia, but the mechanisms are not completely understood. We investigated the mechanisms of diabetes remission in patients undergoing either surgery.
Materials and methods: 35 T2DM, 23 treated with RYGB and 12 with SLG, received an MTT before, 15 days and 1 year after surgery. An OGTT was performed at 1 year. Insulin sensitivity was assessed by Matsuda index and ß-cell function by modelling analysis of the C-peptide response to meal. Plasma amylin, ghrelin, PYY, pancreatic polypeptide (PP), glucagon, and GLP-1 concentrations were measured during MMT.
Results: Based on fasting and 2-h post-OGTT glycaemia, at 1 year diabetes resolved in 20 of 35 patients (13 RYGB and 7 LSG); in the remaining 15 patients, diabetes was improved but not in remission. Age, BMI and kind of surgery did not differentiate regressors (R) from non-regressors (NR). Diabetes duration (6 ± 4 vs 12 ± 5 years, p<0.0001, R vs NR), baseline HbA1c, (7.5 ± 1.4 vs 9.2 ± 2.4%, p=0.002), and higher baseline mean plasma glucose levels separated R from NR. Before surgery, time to glucose peak during MTT was earlier in R than NR (70 ± 33 vs 97 ± 36 min, p=0.003). At baseline, ß-cell glucose sensitivity was 3 times higher in R than NR (p<0.003). Furthermore, while all metabolic parameters showed the expected improvement post-surgery, the extent of the improvement was significantly less in NR as compared to R for glycaemic control, insulin sensitivity and ß-cell glucose sensitivity (p<0.05 or less for all). Before surgery, fasting amylin concentrations were lower, and fasting GLP-1 levels were higher, in R than NR (both p<0.05). Fasting GLP-1, PYY, PP, ghrelin, glucagon and amylin showed similar changes following surgery in R and NR. Before surgery, R and NR differed only for their GLP-1 response to MTT, which was blunted in R group (p=0.04). After surgery, meal-stimulated GLP-1 concentrations increased in R, but did not change in NR, while postprandial glucagon decreased more in NR than R. The responses of the other hormones to MTT did not differ between R and NR. In a logistic regression analysis, remission of diabetes was independently predicted by diabetes duration, ß-cell glucose sensitivity and MTT-stimulated GLP-1.
Conclusion: In morbidly obese T2DM patients, RYGB and LSG have a similar impact on remission of diabetes. Baseline ß-cell glucose sensitivity, duration of diabetes and GLP-1 concentrations are predictors of diabetes remission.

Intestinal lipogenesis in morbidly obese subjects is higher in those with high insulin resistance

E. Garcia-Escobar[1,2], C. Gutierrez-Repiso[2,1], S. Garcia-Serrano[1,2], F. Soriguer[1,2], J. Garcia-Arnes[2,3], S. Valdes[1,2], M. Gonzalo[1,2], J.L. Gallego-Perales[4], E. Garcia-Fuentes[2,3];
[1]CIBERDEM CB07/08/0019 of the Instituto de Salud Carlos III, [2]Servicio de Endocrinología y Nutrición, Hospital Regional Universitario Carlos Haya, [3]IBIMA, [4]Servicio de Cirugía General, Hospital Regional Universitario Carlos Haya., Malaga, Spain.

Background and aims: Intestine is a significant site of triglyceride production in the body. Both the fructose-fed hamster and the sand rat models of insulin resistance exhibit upregulated *de novo* lipogenesis in the intestine. However, little is known about *de novo* lipogenesis in human intestine. In this study we investigate the association between insulin resistance and lipogenesis in the intestine of morbidly obese subjects with low and high insulin resistance.
Material and methods: The study was undertaken in 30 morbidly obese subjects, 15 with low and 15 with high insulin resistance. The HOMA-IR was calculated to determine insulin resistance. Jejunum samples were obtained during gastric bypass to analyze the mRNA expression of different lipogenic genes.
Results: The morbidly obese persons with high insulin resistance had low mRNA expression of ACC1 (179.9±45.0 vs. 117.5±46.4, p=0.011), and a higher mRNA expression of apolipoprotein AIV (32.2±31.1 vs. 82.1±46.9, p=0.016), PEPCK (26.8±16.2 vs. 47.3±17.1, p=0.049), and SREBP1c (31.6±41.0 vs. 88.5±38.5, p=0.019). No significant differences were found in the mRNA expression of MTP, DGAT and SCD1. The apolipoprotein AIV mRNA expression correlated positively with body weight (r=0.467, P=0.033), insulin (r=0.729, P<0.0001) and HOMA-IR (r=0.653, P=0.001), and negatively with serum adiponectin (r=-0.692, P=0.013). The PEPCK mRNA expression correlated positively with insulin (r=0.494, P=0.017) and HOMA-IR (r=0.465, P=0.025). The SREBP1c mRNA expression correlated positively with insulin (r=0.669, P<0.0001) and HOMA-IR (r=0.616, P=0.008). The DGAT mRNA expression correlated positively with body weight (r=0.587, P=0.005), BMI (r=0.483 P=0.027), insulin (r=0.503, P=0.020) and HOMA-IR (r=0.445, P=0.043).
Conclusion: Increased lipogenesis (PEPCK and SREBP1c) and synthesis of intestinal lipoproteins (apolipoprotein AIV) has been found in human intestine from morbidly obese subjects with high insulin resistance.

Eradication of gut bacteria: effect on postprandial glucose metabolism

K.H. Mikkelsen[1,2], M.F. Nielsen[1,3], U.S. Jensen[4], M. Tvede[4], T. Hansen[2], O.B. Pedersen[2], J.J. Holst[2], T. Vilsbøll[1], F.K. Knop[1,2];
[1]Department of Internal Medicine, Diabetes Research Division, Copenhagen University Hospital Gentofte, Hellerup, [2]The Novo Nordisk Foundation Center for Basic Metabolic Research, University of Copenhagen, [3]Department of Internal Medicine, Kolding Hospital, [4]Department of Clinical Microbiology, Rigshospitalet, University of Copenhagen., Denmark.

Background and aims: Accumulating data suggest that intestinal microbiota contributes to glucose metabolism, but only few human studies have investigated the causality between alterations in gut microbiota and glucose metabolism. We investigated the impact of eradication of intestinal bacteria on postprandial glucose metabolism, gastric emptying and gallbladder emptying in healthy young men.
Materials and methods: Twelve healthy young men (age (mean±SEM): 23±2 years, BMI: 23±1 kg/m2; HbA1c: 5.1±0.1%) received a 4-day oral antibiotic eradication treatment (500 mg vancomycin, 40 mg of gentamicin and 500 mg meropenem once-daily). Eradication was confirmed by culture of faeces. Before, immediately after, and 42 days after eradication, 4-hour meal tests with 1.5 g paracetamol (for evaluation of gastric emptying) with determination of plasma levels of glucose, insulin and paracetamol were made. Postprandial gallbladder emptying was determined using ultrasonography.
Results: We found a significant decrease in both total AUC and incremental AUC for postprandial plasma glucose from before (day 0) to immediately after eradication (day 4) (total AUC: 1314±23 vs. 1290±24 mmol/l×min, p=0.02; incremental AUC: 91±18 vs. 63±20 mmol/l×min, p=0.04). Postprandial insulin and C-peptide responses decreased from day 0 to day 4, although these changes did not reach statistical significance. From day 4 to day 42, postprandial plasma glucose excursions and insulin and C-peptide responses increased to levels not statistically different from baseline. No differences in gallbladder emptying or gastric emptying between day 0, 4 and 42 were observed. Complete gut bacteria eradication (no growth after cultivation of faeces) was obtained after antibiotic treatment (day 4) in six out of the 12 subjects. The remaining six subjects had minimal growth with severely reduced species diversity and bacterial counts. In all 12 subjects yeast could be grown from day 4 faecal samples.
Conclusion: Gut bacteria eradication was associated with a brief, apparently reversible change in postprandial glucose metabolism. These results support the evidence that intestinal bacteria exert important roles in human glucose homeostasis.

Evidence for a leaky gut in type 2 diabetes

J. Wright[1], F. Horton[2], P. Hinton[2], L. Smith[3], M. Robertson[3];
[1]CEDAR Centre, Royal Surrey County Hospital, [2]Medical Physics, Royal Surrey County Hospital, [3]Nutrition, Metabolism and Diabetes Research Group, University of Surrey, Guildford, UK.

Background and aims: There is increasing evidence for a role of the intestine and its microbiota in the pathogenesis of metabolic disease. In animal models of obesity and diabetes, high-fat, high-energy diets alter the composition of the microbiota, favouring the colonisation of gram-negative bacteria with increased concentrations of lipopolysaccharide (LPS). Permeability of the intestine is increased due to impairment of tight junction proteins, with increased absorption of LPS which binds to macrophages in adipose tissue resulting in increased release of proinflammatory cytokines and, ultimately, to insulin resistance.
Materials and methods: Intestinal permeability was measured using urinary recovery of ^{51}Cr-EDTA following an oral dose in twenty well-controlled male subjects with T2DM, and in a control group matched for age, gender, BMI and habitual fat intake.
Results: Urinary recovery of ^{51}Cr-EDTA was significantly increased in T2DM compared to matched controls: 0-6 hour recovery 1.74 ± 0.18 vs 1.01 ± 0.09% (P=0.002); 6-24 hour recovery 2.02 ± 0.29 vs 1.34 ± 0.12% (P=0.043) and total 24h recovery 3.76 ± 0.35 vs 2.35 ± 0.17% (P=0.001) indicative of paracellular permeability of the small intestine, large intestine and total gut respectively. Levels in the subjects with diabetes were similar to those which have been reported in patients with coeliac disease and with some subjects showing levels associated with inflammatory bowel disease. Within the diabetic cohort, measured small intestinal permeability correlated significantly with serum levels of CRP (r=0.694, P=0.001), IL-6 (r=0.548, P=0.012) and TNFα (r=0.564, P=0.01). There was no association with renal function or urine albumin excretion, or with markers of glycaemic control (HOMA-IR, HbA1c, fasting glucose or insulin), BMI or fat intake, but there was a trend towards a relationship between increased permeability and both protein intake (r=0.436, P=0.055) and time since diagnosis (r= -0.442, P=0.051).
Conclusion: Raised levels of inflammatory markers are a key feature of metabolic syndrome. Our findings raise the intriguing possibility that diet-related changes in gut microbiota and intestinal permeability may be key factors in the initiation of inflammation in both visceral and hepatic adipose tissue, and, furthermore, that toxic products of proteolysis such as ammonia, amides, phenols and sulphides may be important mediators of this process.

Postprandial plasma glycine-conjugated deoxycholic acid levels correspond with plasma insulin levels in healthy subjects

S. van Nierop[1], R. Achterbergh[2], L.A. ten Berg-Lammers[3], H.M. Egginк[1], F.M. Vaz[4], R.A.A. Mathot[3], J.A. Romijn[2], M.R. Soeters[1];
[1]Endocrinology and Metabolism, AMC, [2]Internal Medicine, [3]Hospital Pharmacy, AMC, University of Amsterdam, Amsterdam, Netherlands, [4]Laboratory Genetic Metabolic Diseases, AMC, University of Amsterdam, Netherlands.

Background and aims: Bile acids (BAs) are released into the gut after a meal. A fraction escapes reuptake from the portal circulation to enter the systemic

circulation in postprandial peaks. BAs are important in metabolic signalling through their receptors TGR5 and FXR. The physiological role of postprandial BA peaks in the postabsorptive state is not fully known. In this study in healthy volunteers, we investigated postprandial BA levels in relation to insulin levels in different nutritional conditions.
Materials and methods: Seven healthy volunteers underwent a mixed meal test (MMT, Nutridrink, Nutricia; 25% of calculated daily energy requirements) after a 36 hour fast (F), 3 days of hypercaloric feeding (H) or after an overnight fast (control, C). Hypercaloric feeding consisted of 0,5L of cream per day, containing 1680 kcal (fat 88%, carbohydrates 7%, protein 5%) added to the habitual diet. All subjects underwent all interventions in random order, separated by a 4-week period. Serum BA, insulin and glucose levels were measured at 0, 30, 60, 90, 120, 180 and 240 minutes. Individual BAs were measured with HPLC MS; we report on total BA levels and conjugated deocycholic acid (DCA) and chenodeoxycholic acid (CDCA).
Results: Postprandial glucose excursions were not significantly different between interventions. Insulin AUC was higher after fasting (C 28 ± 10 pmol/L vs F 51 ± 19 pmol/L; p = 0.04) but not after hypercaloric feeding (H 26 ± 9 pmol/L; p = 0.82). Total BA as well as individual BA species levels in plasma showed a postprandial rise with postprandial peaks of glycine-conjugated CDCA (gCDCA) and DCA (gDCA) but there were no differences between the interventions. Insulin levels at 0 and 30 minutes after a meal did not correlate to BA levels. However, in groups C and H, there were strong positive correlations between insulin at 60 minutes and gDCA levels at 60 minutes (C r=0.89, p<0.01; H r=0.99, p<0,01), 90 minutes (C r=0.89, p<0.01; H r =0.82, p<0,05), and 120 minutes (C r =0.82, p<0.05; H r =0.82, p<0.05). In contrast, fasting abrogated the correlations between insulin and gDCA levels. gCDCA levels did not correlate with insulin levels.
Conclusion: Postprandial levels of gDCA associate strongly with postprandial insulin levels in healthy humans in control and high fat feeding conditions. Interestingly, our data might imply, if proven in causal studies, that gDCA may sustain the second phase of the biphasic insulin response. There was a strong positive correlation between gDCA levels and insulin levels one hour after a meal. This correlation was not detectable for other BA species, which might suggest that gDCA specifically may modulate the postprandial insulin response. In accordance with this notion, DCA is a strong agonist of the BA transmembrane receptor TGR5, which stimulates insulin release directly through TGR5 on β cells and indirectly via GLP-1 release from enteroendocrine cells. Interestingly, peak postprandial gDCA levels in this study were well above the EC50 for TGR5, supporting a potential physiological, TGR5-mediated effect on insulin secretion.

Activation of renal GLP-1 receptors located in the afferent arteriole causes an increase in renal blood flow
E.P. Jensen[1], C.M. Sorensen[2], C. Deacon[1], H. Kissow[1], S.S. Poulsen[2], N.-H. Holstein-Rathlou[2], J.J. Holst[1];
[1]NNF Center for Basic Metabolic Research, [2]Department of Biomedical Sciences, Faculty of Health and Medical Sciences, University of Copenhagen, Denmark.

Background and aims: It has become evident that glucagon-like peptide-1 (GLP-1) has a range of extra pancreatic effects such as renal effects. It is unknown how these effects are mediated, but the GLP-1 receptor has been identified in numerous tissues outside the pancreas including the kidney. Therefore, it is possible that the extra pancreatic effects are mediated through the GLP-1 receptor. However, the exact cellular localization of the receptor in these extra pancreatic tissues is poorly described. The aim of the present study was to investigate the localization of a renal GLP-1 receptor and to describe possible renal effects of activation of this receptor.
Materials and methods: *In vivo* autoradiography studies in both mice and rats with ^{125}I-GLP-1 were carried out in order to localize specific GLP-1 binding and thereby identify the localization of the GLP-1 receptor. In rats, changes in blood pressure, renal blood flow and diuresis were investigated when GLP-1 was administered through a catheter directly into the renal artery. Furthermore, the dependency of primary endothelial cell mediated smooth muscle cell relaxants nitric oxide synthase (NOS) and cyclooxygenase (COX), was examined by inhibiting these mediators using L-NAME and Indomethacin.
Results: In both mice and rats, binding of ^{125}I-GLP-1 to the smooth muscle cells of the afferent arteriole was observed. Other vascular structures including the glomeruli were negative. This binding could be completely inhibited by simultaneous administration of excess non-radioactive GLP-1. Infusion of GLP-1 in rats mediated an increase in renal blood flow, from a basal level of 9.3±0.5 ml/min to 10.6±0.5 ml/min during GLP-1 infusion (p<0.01). GLP-1 caused a 2.5 fold increase in urine excretion. No changes were observed in blood pressure. The increase in both renal blood flow and diuresis was independent of NOS and COX.
Conclusion: The renal GLP-1 receptor is localized to the smooth muscle cells of the afferent arterioles. GLP-1 infusion mediates an increase in renal blood flow, due to vasodilatation of the renal artery or pre-glomerular vessels, along with an increase in diuresis. The vasodilatation may be caused by specific binding of GLP-1 to GLP-1 receptors on smooth muscle cells in the afferent arterioles.

Up-regulated insulin secretion during insulin resistance involves enhanced GLP-1 response and signalling
L. Ahlkvist[1], G. Pacini[2], B. Ahrén[1];
[1]Medicine, Clinical Sciences, Lund, Sweden, [2]National Research Council, Institute of Biomedical Engineering, Padua, Italy.

Background and aims: Insulin secretion is compensatively up-regulated in insulin resistance to maintain near normal glycemia. The mechanism of this up-regulation has not been fully established. We previously showed in the insulin resistant high-fat diet fed mouse model that the beta-cell expression of the GLP-1 receptor (GLP-1R) is increased which could suggest that GLP-1 signalling contributes to insulin up-regulation in insulin resistance. The validity of this hypothesis depends, however, also on the potential changes in circulating GLP-1 levels in insulin resistance. In particular, it is not known whether insulin resistance is accompanied by a co-increase in GLP-1 levels. Therefore, we have in this study examined whether insulin resistant vs. control mice exhibit differences in mixed meal-induced GLP-1 levels.
Materials and methods: Female C57BL/6J mice were fed a control (CD, 10% fat) or a high-fat (HFD, 60% fat) diet for eight weeks. Then, anesthetized mice were orally given a mixed meal (0.285 kcal; 60/20/20 glucose, protein and fat) with serial blood sampling for determination of glucose (glucose oxidase), insulin and intact GLP-1 (both with ELISA). Areas under the concentration curves (AUC) were calculated for glucose and insulin until 60 min and for intact GLP-1 until 20 min. Baseline (QUICKI) and dynamic (ISI) insulin sensitivity were determined by modelling of glucose and insulin data and beta-cell function was estimated by AUC insulin/AUC glucose until 30 min.
Results: HFD mice (n=8) had lower baseline (0.27±0.01 vs. 0.31±0.01, P<0.001) and dynamic (0.28±0.03 vs. 0.76±0.07, P<0.001) insulin sensitivity than CD mice (n=9), as well as excessive weight (36±1.1 vs. 23±0.3 g, P<0.001). There was no difference in AUC glucose after mixed meal intake between groups in the presence of a significant increase in AUC insulin (109±20 vs. 52±8 pM x min, P=0.026) showing a complete up-regulation of insulin secretion to maintain normal glycemia. Mixed meal-induced GLP-1 responses were significantly increased by three fold in insulin resistant mice. Thus, AUC intact GLP-1 was 66±11 pg/ml x min in high-fat fed mice versus 22±4 pg/ml x min in control mice (P=0.006). This was associated with an improved beta-cell function (257±34 vs. 158±25 pM/mM, P=0.037).
Conclusion: Insulin resistance in mice leads to increased intact GLP-1 levels after mixed meal ingestion in association with a compensatory increase in beta-cell function and insulin secretion. Based on our findings, we suggest that the increased level of intact GLP-1 after meal intake, together with the previously documented increased islet GLP-1R expression, facilitates the beta-cell adaptation to insulin resistance. Sufficient increase in the GLP-1 response after meal intake may therefore be of importance in insulin resistant individuals that do not develop diabetes.

Exendin-4 and rosiglitazone reduced beta cell degeneration and islet inflammation in male Zucker diabetic fatty rats
M. Sörhede Winzell[1], A. Ahnmark[1], H.B. Jones[2], D.M. Smith[1], D. Lindén[1];
[1]AstraZeneca R&D, Mölndal, Sweden, [2]AstraZeneca R&D, Alderley Park, UK.

Background and aims: The Zucker diabetic fatty rat (ZDF) is a well established rodent diabetes model, where the development of hyperglycemia is associated with impaired beta cell function and loss of beta cell mass. The aim of this study was to compare the effects of two different anti-diabetic drugs; the GLP-1 receptor agonist, exendin-4, acting directly on the islets, and the

PPARgamma agonist, rosiglitazone, improving peripheral insulin sensitivity, on blood glucose control and beta cell function.
Materials and methods: Male ZDF rats (7 weeks old) were treated with exendin-4 (70µg/kg/day) or rosiglitazone (1mg/kg/day) for three weeks (n=10/group). Exendin-4 was given subcutaneously twice daily, while rosiglitazone was given orally once daily and control ZDF rats were given vehicle by either route of administration. Lean rats were used as healthy controls. Body weight, food intake and blood glucose and insulin levels were measured regularly. At termination, HbA1c levels were analyzed and pancreases were fixed and embedded in paraffin wax. Sections were stained with hematoxylin and eosin and assessed microscopically.
Results: Random fed blood glucose was reduced by both drugs from 11.8±0.4mM, before start of treatment, to 8.1±0.2mM with exendin-4 and 8.4±0.2mM with rosiglitazone ($p<0.01$), while in vehicle treated ZDF rats, blood glucose was 27.9±0.4 mM ($p<0.001$ compared to treatment groups) at termination. The HbA1c was 5.4±0.1% and 5.2±0.1% in both treatment groups, being similar to lean control rats (4.7±0.04%), while in vehicle groups, HbA1c was 8.2±0.2% ($p<0.001$) at termination. Insulin levels were 10-fold higher in ZDF rats compared to lean controls at the start of the experiment (10.9±0.4 vs. 1.3±0.1 ng/ml, $p<0.001$). During diabetic progression in vehicle treated ZDF rats, insulin levels were reduced, while in exendin-4 and in rosiglitazone treated rats, insulin levels were only marginally reduced. Proinsulin levels were high in ZDF rats (277±27 pmol/l), but significantly reduced with both exendin-4 (125±18 pmol/l;$p<0.001$) and rosiglitazone (27±2pmol/l; $p<0.001$). Rosiglitazone treatment increased food intake and body weight gain. In contrast, food intake was slightly reduced in the rats treated with exendin-4, but with no effect on body weight. Control ZDF islets showed degeneration with associated inflammation/ fibrosis/haemorrhage. Islet morphology was improved in rats treated with either exendin-4 or rosiglitazone. Both drugs showed tangible evidence of increased beta cell hyperplasia and beta cell clustering and reduced beta cell degeneration and islet inflammation.
Conclusion: This study demonstrates that exendin-4 and rosiglitazone were equally potent in maintaining normoglycemia in male ZDF rats. However, the different mechanisms of action were obvious in that the insulin and proinsulin levels were significantly reduced with rosiglitazone compared to exendin-4. However, beta cell function was maintained with both treatments, as demonstrated by a significant reduction in insulin/proinsulin ratio. In summary, both drugs demonstrated protective effects on beta cell function with improved islet morphology in male ZDF rats.

Effects of a training programme at the crossover point on the metabolic abnormalities and cardiovascular risk factors in obese women with metabolic syndrome

J.B. Coquart[1], G. Boitel[2], B. Borel[2], R. Matran[3], C. Mounier-Vehier[4], M. Garcin[2];
[1]CETAPS, EA4488, Université de Rouen, Mont Saint Aignan, [2]UDSL, EA4488, Univ Lille Nord de France, Ronchin, [3]Service d'Explorations Fonctionnelles Respiratoires, EA2689, Centre Hospitalier Régional Universitaire de Lille, [4]Service de Médecine Vasculaire et Hypertension Artérielle, Centre Hospitalier Régional Universitaire de Lille, France.

Background and aims: The crossover point of substrates utilization (COP) is defined as the exercise intensity at which energy from carbohydrate-derived fuels predominates over energy from lipids. COP is considered by some authors as the optimal exercise intensity in patients with metabolic abnormalities. However, to our knowledge, no study has evaluated the effects of training program at COP on the abnormalities (i.e., central obesity, hypertriglyceridemia, reduced high density lipoprotein cholesterol, hyperglycemia, and arterial hypertension) defining the metabolic syndrome (MetS). Thus, the purpose of the present study was to examine the effects of training program at COP on metabolic abnormalities and cardiovascular risk factors in obese women with MetS.
Materials and methods: Eighteen obese women with MetS (age: 54.8 ± 8.4 yrs, height: 160 ± 6 cm) volunteered to take part in this study. MetS was diagnosed according to the criteria proposed by the National Cholesterol Education Program. All participants followed a training program over 12 weeks. This training program consisted of three 45-minute sessions each week on cycle ergometer. The intensity imposed during the training sessions corresponded to COP. Before and after the training program, anthropometrical (i.e., body mass, fat mass, body mass index: BMI, waist circumference), biological (i.e., triglyceridemia, total cholesterol, high and light density lipoprotein cholesterols, glycosylated hemoglobin, fasting plasma glucose, quantitative insulin-sensitivity check index: QUICKI) data and (systolic and diastolic) blood pressures were measured, then compared.
Results: After the training program, body mass (88.4 ± 12.3 vs 85.7 ± 11.1 kg), fat mass (43.2 ± 4.8 vs 41.8 ± 4.8% body mass), BMI (34.3 ± 3.9 vs 33.2 ± 3.6 kg.m-2) and waist circumference (105 ± 10 vs 100 ± 9 cm) were significantly lower (p 0.05). A significant reduction of systolic blood pressure was also noticed (141 ± 15 vs 129 ± 11 mmHg; $p = 0.02$). After the training program, the number of patients with fasting plasma hyperglycemia and with an arterial hypertension were significant decreased of 54.4% and 44.4%, respectively. Moreover, the number of patients with MetS was not significantly reduced of 22.2% ($p = 0.10$).
Conclusion: The present study reveals that a training program at COP has beneficial effects on body mass, fat mass, BMI, and waist circumference, fasting plasma glucose, QUICKI and systolic blood pressure in obese women with MetS. These improvements permit to reduce non-significantly the patients' number with MetS after the training program (decrease of 22.2%), which is probably due to the significant reduction of patients' number with arterial hypertension (reduction of 44.4%) and/or a significant decrease of 54.5% of patients' number with hyperglycemia.

Exercise training improves insulin sensitivity in abdominal adipose tissue but not in brown adipose tissue in healthy, sedentary, middle aged men

K.K. Motiani[1], A. Savolainen[1], J.J. Eskelinen[1], K.A. Virtanen[1], P. Boström[2], J. Jensen[3], R. Parkkola[4], V. Saunavaara[1], J. Knuuti[1], P. Nuutila[5], K.K. Kalliokoski[5], J.C. Hannukainen[1];
[1]Turku PET Center, University of Turku, Finland, [2]Karolinska Institutet, Stockholm, Sweden, [3]Norwegian School of Sport Sciences, Oslo, Norway, [4]Department of Radiology, Univeristy of Turku, Finland, [5]Turku PET Center, University of Turku, Finland.

Background and aims: Recently it has been suggested that exercise stimulates the secretion of a polypeptide hormone irisin. Irisin has been shown to

induce browning of white adipocytes by increasing brown-fat-like development, resulting in an increase in adipose tissue thermogenesis, basal energy expenditure, reduced body fat mass and in rodents enhanced glucose homeostasis. We studied the effects of two different modes of exercise training on insulin-stimulated glucose uptake in white and brown adipose tissue (BAT). We further investigated the effects of exercise on irisin and catecholamine levels and their relation to insulin-stimulated BAT glucose uptake.

Materials and methods: Twenty six healthy, sedentary, middle aged men (age: 48 ± 5 years; BMI: 26.1 ± 2.4 kg·m^{-2}; VO_{2max}: 34.2 ± 4.1 ml·kg^{-1}·min^{-1}) were randomized either to high intensity interval training (HIT) or traditional endurance training (TET) group. The groups were studied before and 48 - 96 hours after two weeks and six sessions of HIT (4-6 x 30 s all out sprints on cycle ergometer with 4 minutes of recovery) or TET training (40-60 min cycling with ergometer at 60 % of VO_{2max}). Insulin-stimulated glucose uptake in BAT, abdominal subcutaneous and visceral fat and skeletal muscle were measured using 18F-FDG and PET-CT. In addition, abdominal MRI, OGTT, plasma irisin and catecholamine levels were determined.

Results: Following intervention, VO_{2max} increased by 4.5 ± 5.9 % (p = 0.001), whole body fat percentage (- 4.0 ± 4.9 %, p = 0.002), abdominal subcutaneous (- 1.6 ± 4.1 %, p = 0.04) and visceral fat (-5.0 ± 8.5 %, p = 0.045) and total cholesterol level (4.9 ± 1.0 to 4.4 ± 0.7 mmol·l^{-1}, p = 0.003) decreased without group differences. As only thirteen out of eighteen subjects (4 HIT/9 TET) showed active BAT, the groups were combined. In the whole study group, no change was observed in insulin-stimulated BAT glucose uptake post exercise (3.1 ± 1.4 vs 2.8 ± 0.7.0 µmol·100 g^{-1}·min^{-1}, p = 0.3). In addition to the exercising skeletal muscles, exercise improved insulin-stimulated glucose uptake in abdominal subcutaneous and visceral fat (p = 0.03 and p = 0.048, respectively). After the intervention, BAT glucose uptake correlated positively with VO_{2max}, HDL cholesterol and inversely with BMI, waist circumference, body fat percentage and abdominal fat masses, all p < 0.05. The results of irisin and catecholamine will be presented in the congress.

Conclusion: Abdominal adipose tissue seems to be more sensitive to exercise-induced changes in insulin-stimulated glucose uptake compared to brown adipose tissue.

Eccentric endurance exercise significantly improves both fasting and postchallenge metabolism in overweight and obese individuals

P. Rein[1], C.H. Saely[1,2], A. Vonbank[1,2], S. Geller-Rhomberg[3], H. Drexel[1,4];
[1]Academic Teaching Hospital Feldkirch, Feldkirch, Austria, [2]Private University of the Principality of Liechtenstein, Triesen, Liechtenstein, [3]Vorarlberg Institute for Vascular Investigation and Treatment, Feldkirch, Austria, [4]Drexel University College of Medicine, Philadelphia, USA.

Background and aims: Eccentric endurance exercise (e.g. hiking downwards) is less strenuous than concentric exercise (e.g. hiking upwards) but data on its potential to reduce cardiovascular risk are scarce.

Materials and methods: We allocated 68 overweight and obese sedentary individuals to an exercise intervention program, consisting of hiking downwards the same route over two months. For the opposite way, a cable car was used where compliance was recorded electronically. The difference in altitude was 540 meters; the distance was covered three to five times a week. A matched group of 12 individuals served as a control group. Fasting and postprandial metabolic profiles were obtained at baseline and after the two months period.

Results: Compared with baseline, eccentric endurance exercise significantly lowered fasting glucose (99±17 vs. 96±13 mg/dl; p=0.036) as well as glucose tolerance following the oral intake of 75g glucose (250±49 vs. 228±54 mg*dl^{-1} h; p<0.001), whereas these parameters remained unchanged in the control group (p=0.495 and p=0.182, respectively). Furthermore, eccentric endurance exercise significantly improved triglyceride tolerance in a standardized oral fat challenge test (2121±1398 vs. 1744±1143 mg*dl^{-1} h; p <0.001), whereas triglyceride tolerance did not change significantly in the control group (p=0.695). Body mass index was slightly but significantly lowered in the eccentric endurance exercise group (29.6±3.1 vs. 29.2±3.3 kg/m^2; p=0.004) but not in the control group (p=0.237).

Conclusion: Eccentric endurance exercise is a promising new exercise modality with favorable effects on both fasting and postchallenge metabolism.

Glucose requirements for prevention of hypoglycaemia during exercise in individuals with type 1 diabetes mellitus

V.B. Shetty[1,2], P.A. Fournier[3], R.J. Davey[4], A.J. Retterath[4], N. Paramalingam[1,4], H.C. Roby[4], E.A. Davis[1,4], T.W. Jones[1,4];
[1]Endocrinology and Diabetes, Princess Margaret Hospital For Children, [2]The University of Western Australia, School of Paediatrics and Child Health, [3]The University of Western Australia, School of Sports Science, Exercise and Health, [4]The University of Western Australia, Telethon Institute for Child Health Research, Centre for Child Health Research, Perth, Australia.

Background and aims: More information is needed to improve guidelines for the prevention of exercise-induced hypoglycaemia in individuals with type 1 diabetes mellitus (T1DM). The aim of our study was to determine the relationship between exercise intensity and the amount of exogenous glucose required to prevent hypoglycaemia during and after exercise at basal insulin levels.

Material and methods: Nine individuals with T1DM (6F, 3M, aged 21.5±4.0 years, BMI of 25.4±5.5 kg/m^2, HbA_{1c} 7.9±0.8%; mean±SD) were subjected to a euglycaemic clamp, whereby stable blood glucose levels between 4.5-6.0 mmol/L were achieved by infusing insulin at a rate that required no glucose infusion (basal insulin infusion rate). Then, while insulin infusion rate remained unchanged, participants performed 40 minutes of exercise at four different exercise intensities (35%, 50%, 65% and 80% VO_2 peak) on four different days. Glucose was infused to maintain euglycaemia during and for two hours after exercise. All 4 treatments were administered following a randomized counterbalanced study design.

Results: The glucose infusion rate (GIR) to maintain euglycaemia during exercise at 35%, 50% and 65% VO_2 peak ranged from 0 to 15g/h. The GIR at each of these three intensities was higher (p<0.05) than at 80% intensity where no glucose was required. The GIR to maintain euglycaemia during recovery ranged from 0 to 8g/h for all exercise intensities.

Conclusions: No glucose is required to maintain euglycaemia during high intensity exercise in individuals with T1DM at basal insulin levels. The amount of glucose needed to maintain euglycaemia during exercise and recovery is less than 15g/h irrespective of the exercise intensity. Glucose requirements to prevent hypoglycaemia during exercise and early recovery vary between individuals and exercise intensities.

Preventing hypoglycaemia by heavily reducing pre- and post-exercise rapid-acting insulin dose may cause hyperglycaemia, but not hyperketonaemia in type 1 diabetes patients

M.D. Campbell[1], M. Walker[2], M.I. Trenell[3], S. Luzio[4], G. Dunseath[4], E.J. Stevenson[1], R.M. Bracken[5], D. Turner[5], S.C. Bain[4], D.J. West[1];
[1]Department of Sport, Exercise and Rehabilitation, Northumbria University, Newcastle upon Tyne, [2]Newcastle University, Newcastle upon Tyne, [3]Institute for Ageing and Health, Newcastle University, Newcastle upon Tyne, [4]Diabetes Research Group, Swansea University, [5]College of Engineering, Swansea University, UK.

Background and aims: Type 1 diabetes patients are encouraged to reduce their pre-exercise, prandially-administered, rapid-acting insulin dose to prevent hypoglycaemia *during* exercise. To combat hypoglycaemia *after* exercise, current opinion advocates a reduction in post-exercise meal-time rapid-acting insulin dose. However, there is little empirical evidence to support this recommendation, and no information pertaining to the glycaemic and metabolic consequences of adopting such a strategy. Therefore, the aim of this study was to examine the glycaemic, metabolic and hormonal effects of large reductions in pre- and post-exercise rapid-acting insulin dose in male type 1 diabetes patients.

Materials and methods: Following written consent, 11 male patients (24±2 years, HbA1c 7.7±0.3% / 61±3 mmol.l^{-1}) attended the laboratory on three mornings in a random and counterbalanced fashion. Firstly, patients self-administered a 25% rapid-acting insulin dose immediately before consuming a standardised breakfast (1g carbohydrate.kg^{-1}BM; 380±10 kcal). After 60 minutes of rest patients performed 45 minutes of treadmill running at 72.5±0.9% VO_{2peak}. At 60 minutes post-exercise, patients ingested a second meal (1g carbohydrate.kg^{-1}BM; 660±21 kcal) administering a Full, 75%, or 50% reduced rapid-acting insulin dose. Blood glucose and lactate, serum insulin, cortisol,

non-esterified-fatty-acid, β-Hydroxybutyrate, and plasma adrenaline and noradrenaline concentrations were measured for 3 h post-meal. Statistical analysis was performed on all data using repeated measures ANOVA, with significance accepted at $p \leq 0.05$.
Results: No conditional differences in glycaemia, or metabolic or hormonal responses were observed before, during or for 60 minutes post-exercise. Following the post-exercise meal, serum insulin concentrations were greatest under Full, and lowest under 50% ($p<0.05$). Declines in blood glucose were evident under Full and 75%, but glycaemia was preserved under 50%. As a result, all patients under 50% were protected from hypoglycaemia (blood glucose ≤3.9 mmol.l^{-1}; 50% n=0, 75% n= 2, Full n=5), but were more exposed to hyperglycaemia (blood glucose ≥8.0 mmol.l^{-1} 50% n=9, 75% n=5, Full n=4). During the post-meal period, β-Hydroxybutyrate concentrations under all conditions were lower than those deemed hyperketonaemic (>1.0 mmol.l^{-1}). All counter-regulatory hormone and other metabolite concentrations were similar between conditions ($p>0.05$), with concentrations similar or lower than resting measures ($p>0.05$).
Conclusion: Heavily reducing rapid-acting insulin dose administered with the meal before and also after running exercise preserves glycaemia and prevents hypoglycaemia in male type 1 diabetes patients. Although some patients may be exposed to periods of hyperglycaemia following the post-exercise meal, this strategy does not augment ketonaemia or cause other metabolic disturbances.

The role of interleukin 6 in regulation of liver metabolism during exercise
J.G. Knudsen[1], R.S. Biensø[1], A.H. Jacobsen[1], H. Adser[2], J. Hidalgo[3], H. Pilegaard[1];
[1]Biology, University of Copenhagen, Denmark, [2]Molecular and Cellular Pharmacology, University of Copenhagen, Denmark, [3]Neuroscience, Universidad de autonoma Barcelona, Spain.

Background and aims: During exercise the skeletal muscle glucose uptake increases creating an increased demand for hepatic glucose production. Gluconeogenesis in the liver has been shown to be regulated both through increases enzyme activity of phophorenolpyruvat carboxy kinase (PEPCK), increased transcription of gluconeogenetic enzymes such as PEPCK, glucose 6 phosphatase (G6Pase) and genes involved in regulating liver substrate choice for example pyruvate dehydrogenase kinase 4 (PDK4). The systemic regulation of such gene expression during exercise is poorly described. Interestingly it has been shown that infusion of the myokine interleukine-6 (IL-6) during low intensity exercise increases the glucose rate of appearance. Liver PEPCK expression has been suggested to be regulated by CCAAT/enhancer binding protein β (C/EBPβ), an IL-6 regulated transcription factor, and a number of studies have reported that injections of IL-6 increased the mRNA content of PEPCK in the liver. However an exercise-induced PEPCK mRNA was absent in both wild type (WT) and IL-6 knockout (KO) mice leaving the role of IL-6 in liver PEPCK regulation unresolved. In addition it has been suggested that liver PDK4 also could be regulated by C/EBPβ, indicating that IL-6 may influence liver substrate choice during exercise through regulation of PDK4. The aim of the present study was to investigate the effect of IL-6 on PDK4 mRNA content in the liver during exercise.
Materials and methods: This was investigated by acute intraperitoneal injection of 3 ng/g IL-6 in C57BL6 WT mice and by a single 1h treadmill exercise bout in C57BL6 WT and IL-6 KO mice. The mice were euthanized by cervical dislocation and liver samples obtained 1 h after the injection and before, immediately after and 4 h after the exercise bout.
Results: The injection of IL-6 increased ($p<0.05$) the PDK4 mRNA content in the liver 2 fold but there was no effect on either PEPCK or G6Pase mRNA content. The exercise bout increased ($p<0.05$) PDK4 mRNA 7 fold in the WT, but this effect was abolished in the IL-6 KO mice. In addition exercise increased PEPCK ($0.5<p<0.1$) and G6Pase ($p<0.05$) mRNA in both WT and IL-6 KO mice.
Conclusion: These data suggest that exercise-induced PDK4 mRNA increases in the liver is dependent on IL-6 signaling, and thus that IL-6 may be involved in the regulation of substrate choice in the liver during exercise.

Resistance exercise induces increases in circulating interleukin-6 in type 1 diabetes individuals
D. Turner[1,2], B.J. Gray[1,2], S. Luzio[2], S.C. Bain[3], G. Dunseath[2], M.D. Campbell[4], D.J. West[4], R.M. Bracken[1,2];
[1]Applied Sports, Technology, Exercise and Medicine Research Centre, College of Engineering, Swansea University, [2]Diabetes Research Group, College of Medicine, Swansea University, [3]Abertawe Bro Morgannwg University Health Board, Singleton Hospital, Swansea, [4]Department of Sport, Exercise and Rehabilitation, Faculty of Health and Life Sciences, Northumbria University, Newcastle-upon-Tyne, UK.

Background and aims: Research has demonstrated a role for interleukin-6 (IL-6) in glucose regulation. Physical exercise has been shown to increase intramuscular release of IL-6 but the magnitude of this rise seems dependent on the degree of hyperglycaemia in individuals with type 1 diabetes (T1DM). 'Weights training' or resistance exercise (RE) can increase IL-6 concentrations in non-diabetic individuals and is recommended for those with T1DM, but can evoke post-exercise hyperglycaemia. Thus, the role of RE in inducing changes in IL-6 and its relationship to blood glucose regulation in T1DM is unclear. The aim of this study was to explore the changes in IL-6 and blood glycaemia during recovery from acute RE sessions of different volume in T1DM.
Materials and methods: After a preliminary session to determine maximal strength, 8 T1DM (7 male: 1 female; age 38±6years, BMI 26.9±1.5kg/m^2, HbA_{1C} 8.7±1% / 71.3±10.6mmol/mol) attended the laboratory fasted having taken their usual basal insulin but omitted rapid-acting insulin, on four separate occasions. Participants completed a **REST** trial, or **1SET (15-min), 2SET (30-min),** or **3SET (45-min)** of RE (8-exercises x 10-repetitions) at 67±3% of 1-RM followed by 60-min recovery. Plasma IL-6 was sampled at rest and for an hour post-exercise. Venous blood pH, HCO_3^-, B_{ecf} (base-extracellular fluid) and blood glucose (BG) were measured before, during and after exercise. Data (mean±SEM) were analysed using repeated-measures ANOVA.
Results: Resting IL-6 concentrations were similar across trials (**1SET** 2.32 ± 1.14, **2SET** 2.16 ± 0.94, **3SET** 2.61 ± 1.11 pg/ml, $p > 0.05$); with 58% of the variance in resting IL-6 accounted for by duration of T1DM ($p < 0.05$). Whereas IL-6 remained similar to rest throughout recovery under **1SET** ($p > 0.05$), IL-6 was greater than rest at 60 min post-exercise under **2SET** (2.94 ± 0.94 pg/ml, $p < 0.05$) and at both 30 (4.01 ± 1.00 pg/ml, $p < 0.05$) and 60 (4.28 ± 1.25 pg/ml, $p = 0.084$) min post-exercise under **3SET**. Under **3SET**, the rise in IL-6 from rest was associated with the magnitude of acid-base disturbance [as reflected in *nadir*; pH r = -0.85, B_{ecf} r= -0.76, HCO_3^- r = -0.81, $p < 0.05$]. Resting BG concentrations were similar between trials (**1SET** 11.7 ± 1.1, **2SET** 11.8 ± 2.0, **3SET** 12.2 ± 1.6 mmol/l, $p > 0.05$). Exercise-induced rises in BG after 30 and 60 min of recovery were similar across exercise trials ($p > 0.05$). Peak BG concentrations during recovery were similar between exercise trials (**1SET** 14.0 ± 1.5, **2SET** 14.9 ± 2.1, **3SET** 13.9 ± 1.9 mmol/l, $p > 0.05$).
Conclusion: The magnitude of rise in IL-6 over an hour after RE was dependent on the number of exercise sets and the corresponding acid-base disturbance in T1DM. In contrast, the number of RE sets did not influence the magnitude of post-exercise hyperglycaemia. The findings demonstrate a link between RE volume and circulating IL-6 in T1DM but its importance in glucose regulation following RE in comparison to other counter-regulatory factors is unclear.

Altered follistatin secretion profile during exercise in type 2 diabetes
J. Hansen[1,2], B. Pedersen[1], P. Plomgaard[1,2];
[1]Centre of Inflammation and Metabolism, Rigshospitalet, [2]Department of Clinical Biochemistry, Rigshospitalet, Copenhagen, Denmark.

Background and aims: Follistatin is known as an endogenous negative regulator of myostatin and activin A. In different animal models, it has been shown to have a large effect on both skeletal muscle mass and glucose homeostasis. It has therefore been proposed as a potential target to improve skeletal muscle regeneration and glucose homeostasis. We have previously demonstrated that plasma follistatin is secreted during an acute bout of exercise in young healthy men and that the origin most likely is the liver. In addition, we have recently demonstrated that plasma follistatin is elevated in patients with type 2 diabetes mellitus (T2DM) and that it correlates with markers of insulin

resistance. The aim of the present study was to investigate plasma follistatin in response to exercise in patients with and without T2DM.
Materials and methods: Subjects with (n=7) and without (n=8) T2DM were recruited to the project matched for age and BMI. They were initially screened with a medical examination, an OGTT, an incremental exercise test (VO_2max test) on a bicycle ergometer, a DXA scan and baseline blood tests. All anti-diabetic treatment was paused one week prior to the experimental day. At the experimental day, after an initial 2 hour rest they performed one hour of bicycle exercise at an intensity of 50% of individual VO_2 max. This was followed by a three hours recovery period of supine rest. Blood samples were obtained during both exercise and recovery.
Results: Subjects with and without T2DM were matched for age 58 vs. 56 years, resp. (p=0.49) and BMI 27.4 vs. 25.1 kg/m^2, resp. (p=0.14). Subjects with T2DM had higher fasting glucose 7.7 vs. 5.1 mM, resp. (p=0.004), HbA_{1c} 6.8 vs. 5.6 %, resp. (p=0.003) and 2h glucose during OGTT 15.7 vs. 5.0 mM, resp. (p<0.001) compared with controls. Subjects with T2DM had lower lean mass 56.0 vs. 65.7 kg, resp. (p=0.009) but no difference in fat mass compared with controls. Subjects with T2DM had similar VO_2max 32.0 vs. 37.0 L/kg/min (p=0.07) compared with controls during the exercise test. At the experimental day, the two groups performed the same relative work 51.3 vs. 54.4% of VO_2max (T2DM vs. controls, resp., p=0.25). During the one hour exercise bout, plasma follistatin was unaffected in both groups. However, two hours into recovery plasma was increased by 45% in controls whereas only by 20% in subjects with T2DM (p=0.002) and three hours into recovery plasma follistatin was increased by 60% in controls but only by 30% in subjects with T2DM (p=0.0007). Subjects with T2DM had elevated plasma follistatin compared to controls (group difference in ANOVA analysis, p<0.05).
Conclusion: In the present study, we demonstrate that exercise-induced follistatin secretion is impaired in subjects with T2DM compared with controls. We also show that plasma follistatin is elevated in subjects with T2DM. These data show that the follistatin secretion profile is altered in T2DM which could indicate an impaired exercise response in these subjects. These findings could have implications for both glucose metabolism and skeletal muscle regeneration in relation to exercise in patients with T2DM.

Physical activity, blood glucose and C-peptide in healthy school children: a substudy of the prospective longitudinal ABIS cohort
J. Ludvigsson[1], K. Huus[2], A. Raustorp[3], L. Åkerman[1];
[1]Dept of Clin Exp Medicine, Linköping university, Linköping, [2]Dept of Nursing, School of Health Sciences, Jönköping, [3]Dept of Nutr Sport Sicences, Linnaeus university and Gothenburg university, Kalmar and Gothenburg, Sweden.

Background and aims: The incidence of type 1 diabetes increased rapidly during the 90-ies and early 2000 parallel to a rapid increase in weight of the general children population. This fits with the beta cell stress hypothesis suggesting that increased insulin demand might contribute to type 1 diabetes. As also physical activity might have decreased we wanted to investigate if lower physical activity further increases beta cell stress already in children.
Materials and methods: A subgroup of school children from the prospective cohort ABIS (All Babies in Southeast Sweden) were asked to participate in some additional tests. 200 children (100 girls, 100 boys) in two communities participated at age 8 and 107 children from one of the communities participated in a follow-up at age 12 (51 girls and 56 boys). Physical activity was **o**bjectively measured as average daily steps (by pedometers), subjectively estimated by questionnaires. We used anthropometric data and measured HbA1c, C-peptide, f-glucose, HOMA-IR and HOMA-B.
Results: Low physical activity was related not only to anthropometric measures (r=.328; p=0.001 for average daily steps *vs* waist circumference at age 12) but also to insulin resistance and beta cell stress (r=-,404; p<0.001 for average daily steps *vs* HOMA-IR at age 12). The connection was especially pronounced in boys, who were more physically active than girls at both time points (p<0.001).
Conclusion: Already in young children low physical activity is related not only to body measures eg increased waist circumference but also to insulin sensitivity, increasing the load on the beta cells. Facilitating physical activity in children might decrease the risk of diabetes, both type 1 and Type 2.

GLP-1-derived nonapeptide GLP-1(28-36)amide represses hepatic gluconeogenesis and improves pyruvate tolerance in high fat diet fed mice
W. Ip[1,2], W. Shao[2], Y.-T. Chiang[1,2], T. Jin[1,2];
[1]University of Toronto, [2]Division of Advanced Diagnostics, University Health Network, Toronto, Canada.

Background and aims: The incretin hormone glucagon-like peptide-1 [GLP-1/GLP-1(7-36)amide] is secreted by intestinal endocrine L cells in response to feeding and exerts beneficial effects on glucose homeostasis. While GLP-1 is quickly degraded in the circulation, it has recently been suggested that certain degradation products of GLP-1 have biological functions. GLP-1 is cleaved by the neutral endopeptidase, NEP 24.11, to produce the nonapeptide GLP-1(28-36)amide. Recently, GLP-1(28-36)amide was shown to improve glucose disposal and attenuate the development of diabetes and hepatic steatosis in high fat diet (HFD) fed mice. However, the mechanisms underlying these effects are unclear. The aim of this study was to examine the biological actions of GLP-1(28-36)amide in the liver and determine whether GLP-1(28-36)amide affects hepatic glucose metabolism.
Materials and methods: C57BL/6 mice (8 weeks old) were subjected to HFD feeding (60% calories from fat) for 13 weeks followed by administration of GLP-1(28-36)amide (18.5 nmol/kg/day) via daily i.p. injection for 6 weeks while maintaining HFD feeding. We measured body weight and food intake, performed i.p. glucose and pyruvate tolerance tests, and examined hepatic gene expression and protein phosphorylation. In addition, we examined the effects of GLP-1(28-36)amide (100 nM) on glucose production, gene expression, and signaling events in isolated mouse primary hepatocytes.
Results: No significant change in body weight gain in response to HFD feeding was observed upon GLP-1(28-36)amide administration. Although GLP-1(28-36)amide intervention slightly improved glucose disposal during i.p. glucose tolerance test, a more profound improvement was observed in the i.p. pyruvate tolerance test, associated with reduced hepatic expression of PEPCK and glucose-6-phosphatase (G6P), two rate-limiting enzymes of gluconeogenesis, suggesting that GLP-1(28-36)amide may reduce hepatic glucose production in vivo. In mouse primary hepatocytes, GLP-1(28-36)amide treatment reduced glucose production and the mRNA levels of PEPCK, G6P, as well as the gluconeogenic transcriptional co-activator PGC-1α, associated with increased CREB Ser133 and β-catenin Ser675 phosphorylation. These effects were partially blocked by the PKA inhibitor H89. Finally, GLP-1(28-36)amide increased cytoplasmic cAMP levels.
Conclusion: Our observations suggest that the beneficial effect of GLP-1(28-36)amide in repressing glucose production in the livers of diet-induced obese animals involves the activation of cAMP/PKA signaling and its downstream targets including CREB and β-catenin. The repression of glucose production along with the activation of CREB by GLP-1(28-36)amide are contradictory to the well-characterized signaling cascade of glucagon involving PKA/CREB in stimulating glucose production in response to starvation. Our observations, however, are analogous to the actions of glucagon and GLP-1 in similarly activating cAMP/PKA signaling, yet resulting in opposite effects in regulating glucose homeostasis. Additional mechanistic study and the identification of the receptor that mediates the effect of GLP-1(28-36)amide in hepatocytes will further the understanding of the therapeutic potential of GLP-1 metabolites in regulating glucose homeostasis and attenuating diabetes.

Reduction of hepatic glucagon receptor expression with an antisense drug (ISIS-GCGR$_{RX}$) increases total GLP-1 levels without affecting cholesterol or BP in normal subjects

E. Morgan[1], C. Bethune[1], L. Watts[1], S. Xia[1], M. McDonnell[2], R. Geary[1], S. Bhanot[1];
[1]Isis Pharmaceuticals Inc., Carlsbad, USA, [2]INC Research Early Stage, Toronto, Canada.

Background and aims: We have previously reported that antisense reduction of hepatic glucagon receptor expression normalized blood glucose levels in rodent T2DM models and produced pharmacological activity in monkeys. In the current double-blind, placebo-controlled dose escalation study, we evaluated the safety and tolerability; and also included plasma biomarkers for PD of ISIS-GCGR$_{Rx}$ after administration of multiple doses to normal subjects.
Materials and methods: This was a randomized, double-blind, placebo-controlled dose escalation study. Subjects were assigned to a dose level (50, 100, 200 or 300 mg/wk) and received 6 doses of the study drug over a 4-week period (3 doses during the first week on Days 1, 3, 5 and once weekly for an additional 3 weeks).
Results: ISIS-GCGR$_{RX}$ treatment was well tolerated and did not cause clinically significant changes in vital signs, triglycerides, total cholesterol, LDL-cholesterol, BP, hepatic or renal function as compared to placebo treated subjects. Also, no hypoglycemia was observed during the treatment period. In addition to demonstrating an acceptable safety profile, ISIS-GCGR$_{RX}$ increased total GLP-1 levels in treated subjects. Total GLP-1 levels increased significantly in all dosing groups starting on Day 15 and continued to increase until Day 36, two weeks post- treatment. By Day 36, mean change from baseline in total GLP-1 levels in the 200 mg and 300 mg dosing groups was 38 ±51 pg/mL (*p=0.0012) and 34 ±15 pg/mL (*p=0.0012) as compared to the placebo treated subjects (0.29 ± 5 pg/mL). Increases in active GLP-1 levels were observed in some groups; however, variability in data precluded a firm conclusion to be made.
Conclusion: Taken together, the safety, tolerability and PD data support further development of ISIS-GCGR$_{RX}$ for T2DM patients who are severely diabetic and uncontrolled with existing therapies.

692

Liver fructokinase: a new target for GLP-1 receptor agonists

F. Francini[1], M.L. Massa[1], M.C. Castro[1], M.P. Polo[2], J.J. Gagliardino[1];
[1]CENEXA Center of Experimental and Applied Endocrinology, [2]INIBIOLP, Institute of Biochemical Research, La Plata, Argentina.

Background and aims: Normal rats fed with a fructose rich diet (FRD) portrait an increase in liver triglyceride (TG) and glycogen content, together with an increase in glucokinase (GK) activity. Since fructose metabolism in the liver starts with its phosphorylation by fructokinase (FK), the aim of this study was to evaluate the effect of co-administration of exendin-4 (GLP-1R agonist) or the DPP-IV inhibitor sitagliptin upon this enzyme as well as on liver TG content and GK activity *in vivo* and *in vitro*.
Materials and methods: Adult male Wistar rats received (3 weeks) a standard commercial diet, without (C) or with 10% fructose (w/v) in the drinking water (F), with or without sitagliptin (115 mg/day per rat) (CS and FS) or exendin-4 (0.35 nmol/kg of bw, ip) (CE and FE). Human HepG2 cells were incubated for 72 with fructose 1.5 mM alone, plus exendin-4 (5 nM), exendin-9 (100 nM) or both. After the treatments, we measured in rats: 1) Serum glucose (G) (enzymatic method), insulin (I) (RIA) and TG (enzymatic method) levels; 2) GK activity in cytosolic (CF) and nuclear (DNF) fractions (enzyme-coupled photometric assay), 3) GK and PFK-2 protein expression (Western blot [Wb]), 4) liver TG content and 5) FK activity. In HepG2 cells we measured TG content, GK and FK activity.
Results: Blood parameters: similar G values were recorded in all groups but F animals evinced a higher level of plasma TG (F: 1.2±0.12 *vs.* C: 0.5±0.01 mM, P <0.05), and I (F: 1.1±0.28 *vs.* C: 0.3±0.02 ng/ml, P<0.05). Co-administration of exendin-4 or sitagliptin prevented the above mentioned changes (TG: FE 0.7±0.09 and 0.7±0.05 P<0.05 vs. F and I: FE 0.3±0.05 and FS 0.29±0.04 P<0.05 vs. F)

Liver results:

	C	CE	CS	F	FE	FS
TG (µg/100 mg tissue)	179±12	181±13	174±12	465±30*	374±30**	301±16**
GK activity (mU/mg protein)	2.7±0.1	2.3±0.1	2.2±0.0	6.8±0.2*	3.3±0.2**	3.7±0.2**
FK activity (mU/mg protein)	3.4±0.1	2.9±0.2	3.7±0.2	5.5±0.1*	3.8±0.1**	3.4±0.1**
PFK-2 protein level (AU)	99.8±2	117±2	76±2	185±8*	72±17**	84±16**

Values are means ± SEM (n =20). * F *vs.* C; ** FE and FS *vs.* F, P <0.05. No changes were observed in GK protein concentration. *In vitro results*: Similar increment in TG content, GK and FK activity were recorded in HepG2 cells incubated with F and again prevented by addition of exendin-4 to the incubation medium. The effect of the later was blunted in the presence of a specific receptor blocker exendin-9.
Conclusions: Sitagliptin and exendin-4 prevented the liver metabolic changes induced by a FRD by blocking the activity of FK, thus preventing fructose metabolism. This effect would be mediated throughout GLP-1 receptor.

Metformin reverses FOXO3-induced hyperactivation of hepatic gluconeogenesis and catabolic pathways

Y. Sunami[1,2], S. Gul[2,3], K.-H. Holzmann[4], F. Leithäuser[5], H. Maier[2], M. Vogel[2,3], T. Luedde[6], B.O. Boehm[7], P. Strnad[6], T. Wirth[2];
[1]General Surgery, Klinikum Rechts der Isar, Munich, [2]Institute of Physiological Chemistry, University of Ulm, [3]International Graduate School of Molecular Medicine, University of Ulm, [4]Microarray Core Facility, University of Ulm, [5]Institute of Pathology, University Medical Center Ulm, [6]Department of Medicine III and IZKF, University Hospital Aachen, [7]Department of Internal Medicine I, Division of Endocrinology, University Medical Center Ulm, Germany.

Members of the FoxO family of Forkhead transcription factors represent the key downstream targets of insulin and growth factors regulating cell survival, energy metabolism, and longevity. Under caloric restriction and cellular stress, FoxOs translocate to the nucleus to activate gene expression, while at postprandial stage, they are inactivated through insulin/PI3K/Akt signalling. Mammals harbor four FoxO family members, i.e. FoxO1, FoxO3, FoxO4, and FoxO6. Evidence that FoxO1 is a critical regulator in insulin signalling for metabolism, the interplay between different FoxO family members is far from being understood. Especially the role of FoxO3 in metabolism has not been well investigated, although the FOXO3 genotype is associated with insulin sensitivity phenotypes and longevity in human. To understand the importance of FoxO3 in the liver in a time- and cell-type-specific manner, we generated transgenic mice that allow the conditional expression of a constitutively active FoxO3 allele. We crossed transgenic mice carrying the tetracycline-regulated transactivator (tTA) under the control of the liver activator protein promotor with transgenic mice constitutively active form of the FoxO3 allele (FoxO3CA) under the control of a tTA-responsive promotor. Double-transgenic mice displayed tetracycline-regulated FoxO3CA expression in hepatocytes. Activation of transgene expression at five weeks of age led to progressive hepatic atrophy in the absence of significant inflammation. In addition, up-regulation of gluconeogenesis-associated genes, complete loss of hepatocyte glycogen and activation of lipid catabolic pathways in the liver were noted. Within two weeks, the animals showed elevated blood glucose and insulin levels as well as impaired insulin sensitivity. The liver phenotype (i.e. hepatic atrophy, increased gluconeogenesis, and hyperglycaemic phenotype) was completely abolished and the global change in metabolic gene expression was normalised after treatment with metformin, an oral antidiabetic drug suppressing the hepatic glucose production. Our findings identify FoxO3 as an essential mediator of hepatic gluconeogenesis and a potential hepatic target of metformin.

Cyclin-dependent kinase 4 inhibits hepatic gluconeogenesis

A. Giralt[1], P.-D. Denechaud[1], S. Lagarrigue[1], I. Lopez[1], S. Huré[1], C. Chavey[2], L. Fajas[1];
[1]Département de Physiologie, Université de Lausanne, Lausanne, Switzerland, [2]Institute Génétique Moléculaire de Montpellier, Montpellier, France.

Background and aims: Cyclin-dependent kinase 4 (Cdk4) is a major cell cycle regulator but is also involved in the regulation of metabolism in non-proliferative conditions. For instance it positively regulates adipogenesis as well as insulin secretion in pancreatic β-cells. Data from our laboratory indicate that Cdk4 activity is increased in response to insulin in liver. Here we study the role of Cdk4 in the control of hepatic gluconeogenesis, a metabolic pathway that is absolutely required for survival during prolonged fasting or starvation, but is inappropriately activated in diabetes mellitus.
Materials and methods: Wild type mice were treated for five days with a 50mg/ kg dose of Cdk4 inhibitor (PD-0332991) or vehicle (DMSO). Gluconeogenesis in vivo was assessed by a pyruvate tolerance test (PTT) after over night fasting. PTT was also performed in fasted R24C mice (constitutively active Cdk4) compared to wild type littermates. Primary hepatocytes were isolated from male mice following portal vein collagenase perfusion. AML12 and HepG2 hepatocytes were cultured and treated for 24 hours with PD-0332991. Hepatocytes were infected with Cdk4 adenovirus for 48 hours. Glucose output in the medium was measured by colorimetric methods. For gene expression analyses, RNA was isolated, reverse transcribed into cDNA and quantitative RT-PCR was performed.
Results: Chemical inhibition of Cdk4 in wild type mice enhances gluconeogenesis in vivo (PTT, AUC 1.23 fold $p = 0.0007$). Cdk4 inhibition increases the expression of gluconeogenic genes (Glucose-6-phosphatase and PEPCK mRNAs) and enhances glucose production in AML12 hepatocytes (2.5 fold, $p < 0.05$). Accordingly, Cdk4 KO primary hepatocytes present increased glucose production compared to wild type hepatocytes (1.5 fold, $p < 0.005$). Inhibition of Cdk4 increases Glucose-6-phosphatase promoter activity in transfected HepG2 hepatocytes under basal conditions (2 fold, $p < 0.05$) and under forskolin stimulation (2.5 fold, $p < 0.05$). In contrast, constitutive activation of Cdk4 (R24C mice) decreases gluconeogenesis in vivo (PTT, AUC 0.8 folds, $p < 0.005$) and impairs glucose production in R24C primary hepatocytes (0.7 fold, $p < 0.05$). Accordingly, Cdk4 adenoviral transduction strongly decreases Glucose-6-phosphatase gene expression (0.2 fold $p < 0.01$) in hepatocytes.
Conclusion: Taken together, our results indicate that Cdk4 inhibits hepatic gluconeogenesis possibly acting as an effector of insulin action in liver metabolism.

695

AICAR regulates G6Pase independently of SRC-2/RORα

A. Madsen[1], J.-I. Bjune[2], G. Mellgren[1], J.V. Sagen[2];
[1]Department of Clinical Science, University of Bergen, The Hormone Laboratory, Haukeland University Hospital, Bergen, Norway, [2]KG Jebsen Diabetes Center for Diabetes Research, The Hormone Laboratory, Haukeland University Hospital, Bergen, Norway.

Background and aims: Hepatic glucose output is important for sustained circulating glucose levels during fasting and this is determined by degradation of glycogen (glycogenolysis) and *de novo* production (gluconeogenesis). The final step in both processes is the conversion of glucose-6-phosphate to glucose by the rate-limiting enzyme glucose-6-phosphatase (G6Pase), which is regulated at transcriptional level. Subjects with type 2 diabetes mellitus (T2DM) exhibit increased hepatic glucose output and thereby elevated fasting glucose levels. Metformin, a synthetic biguanide drug, is the preferred drug for reducing hyperglycaemia in T2DM. Its ability to suppress hepatic gluconeogenesis is attributed to activation of the energy sensing AMP-activated protein kinase (AMPK) pathway, and this has been shown to reduce transcription of G6Pase. Previously, it was demonstrated in mice that the transcriptional coregulator SRC-2 coactivates the nuclear receptor RORα and thus promotes transcription of G6Pase. The aim of this study was to investigate whether AMPK-dependent reduction of G6Pase transcription is partly due to an inhibitory effect on the SRC-2/RORα complex.
Materials and methods: Transactivation assays using either a GAL4-based luciferase system or a reporter construct harbouring the proximal wild type mouse G6Pase promoter (pGL3-G6Pase-Luc -231/+52) were performed in the human hepatoma cell line HepG2. Endogenous expression levels of G6Pase, SRC-2 and RORα in the rat hepatoma cell line FaO were determined by qPCR. Cells were treated with either vehicle (H_2O) or 1mM AICAR.
Results: We employed a GAL4-based luciferase system in which GAL4-RORα (aa 272-523) and SRC-2 were overexpressed in HepG2 cells. Addition of 1mM AICAR significantly reduced luciferase activity ($p<0.001$). We then transfected HepG2 cells with a reporter construct harbouring the proximal wild type mouse G6Pase promoter, and overexpressed full length RORα and SRC-2. In accordance with a previous report, we found that overexpression of SRC-2 and RORα had a strong synergistic effect on reporter activity. Whereas treatment with AICAR reduced the basal activity of the reporter construct, we observed no inhibiting effect when RORα and SRC-2 were overexpressed. Incubation of FaO cells with 1mM AICAR significantly reduced G6Pase expression, whereas mRNA levels of SRC-2 and RORα remained unchanged.
Conclusion: Although it has been shown that SRC-2 co-activates RORα at the proximal G6Pase promoter, upstream regulation of this interaction remains undefined. Our data suggest that treatment with the AMPK-activating agent AICAR reduces cellular G6Pase expression independently of the SRC-2/RORα complex.

Significance of hepatic AMPK in metabolic regulation by sympathetic nervous system

L. Miyamoto[1,2], Y. Tomida[2], A. Kawasaki[2], T. Yamaoka[2], M. Yamane[2], M. Kono[2], K. Tsuchiya[2];
[1]Pharmacology and Physiological Sciences, Frontier Laboratories of Pharmaceutical Sciences,, Inst. of Health Biosciences, The University of Tokushima Graduate School, [2]Medical Pharmacology, Inst. Health Biosciences, Graduate School of the Tokushima University, Japan.

Background and aims: 5'AMP-Activated Protein Kinase (AMPK) is a key metabolic regulator which increases catabolic processes such as lipid oxidation and decreases anabolic processes such as lipogenesis. An anti-obesity adipocytokine, leptin is a potent stimulator of lipid and carbohydrate metabolism. Leptin is reported to activate AMPK in skeletal muscles, which is widely accepted as a major mechanism of its metabolic action. Recently we reported that AMPK activity and its downstream signals are impaired in the fatty liver from A-ZIP/F-1 transgenic mice (A-ZIP), a well-established model of generalized lipodystrophy which lacks adipocytokines. Leptin strikingly ameliorates metabolic disorders including fatty liver in lipodystrophy and is clinically in use. We also found that leptin activates hepatic AMPK via central nervous system and α1-adrenergic effects of sympathetic nervous system, which is followed by reduction of ectopic fat in the liver in vivo. Therefore we hypothesized that hepatic AMPK should play a significant role in metabolic regulation by sympathetic nervous system. The purpose of this study is to elucidate functions of hepatic AMPK in the sympathetic metabolic regulation.
Materials and methods: The effects of AMPK activation were determined in A-ZIP using an AMPK activator, A769662. The effects of an α1-agonist, phenylephrine on AMPK activities, triglyceride (TG) content and glucose production in the liver were studied in isolated primary hepatocytes, normal and high fat diet (HFD)-fed mice.
Results: A769662 activated hepatic AMPK and ameliorated hyperglycemia and fatty liver in A-ZIP analogously to leptin but without affecting body weight or food intake. Phenylephrine also activated AMPK in isolated primary hepatocytes and liver from normal mice in vivo in a dose-dependent manner. In the hepatocytes, AMPK inhibition by a specific inhibitor, BML-275, enhanced glucose production induced by phenylephrine stimulation. AICAR, phenylephrine or a β-agonist, isoproterenol, decreased TG content in the hepatocytes. The AICAR- and phenylephrine-induced TG reduction were completely inhibited by BML-275 while the effect of isoproterenol was not affected by AMPK inhibition. Phenylephrine also activated hepatic AMPK even in the liver from leptin-resistant HFD-fed mice. Continuous administration of phenylephrine for a week ameliorated glucose tolerance, insulin resistance and fatty liver in HFD-fed mice with activating hepatic AMPK.
Conclusion: We found that the α1-adrenoreceptor stimulation causes AMPK activation in hepatocytes. The hepatic AMPK activation mediates reduction of TG content by α-adrenergic stimulation, while it counteracts the hepatic glucose production. In addition, α-adrenergic stimulation as well as the AMPK activator improved fatty liver, insulin resistance and hyperglycemia in diet-induced insulin resistant mice, which is supposed to be mediated by hepatic AMPK activation at least in part. In conclusion, hepatic AMPK plays significant roles in glucose and lipid metabolism regulated by sympathetic nervous system.

697

Redox as a master regulator of liver function

L. Nocito, E. Yoo, B. Corkey;
Medicine, Boston University, USA.

Background and aims: The redox state is the ratio of reduced NAD(P)H or glutathione (GSH) to their oxidized forms $NAD(P)^+$ or GSSG. Redox controls tissue metabolic function by regulating nutrient oxidation, mitochondrial function and handling of reactive oxygen species (ROS). Redox molecules do not pass in and out of the cells, but are in equilibrium with circulating metabolites that freely move across membranes: lactate (L), pyruvate (P), β-hydroxybutyrate (βOHB) and acetoacetate (Acoc). Thus, the ratio of these circulating metabolites is expected to reflect the intracellular redox state and concomitantly, cell metabolism. We hypothesize that all tissues communicate through a master circulating regulatory system that consists of extracellular metabolites that reflect the intracellular redox state: L/P, βOHB/Acoc or cysteine (CyS)/cystine (CySS). The aim of this project was to determine if manipulation of the extracellular redox state affects function of one important metabolic cell type, hepatocytes.
Materials and methods: Primary mouse hepatocytes were treated with extracellular redox metabolites at physiological ratios. The hepatocytes were assessed for production of ROS by fluorescence techniques, glucose production by direct assay and mitochondrial respiration by XF24 Seahorse Analyzer in 3-5 independent experiments and cultures. All of the reported changes were significant at $p \leq 0.05$ (student's t-test).
Results: Endogenous glucose production increased 2.74-fold (± 0.35) after reduction with βOHB, and decreased 0.59-fold (± 0.07) after oxidation with Acoc, compared to the control. In order to understand the mechanism by which these extracellular redox metabolites modulated glucose production, we assessed mitochondrial function by respirometry, as energy is required for gluconeogenesis. Maximal mitochondrial respiratory capacity in primary hepatocytes increased by 0.34-fold (± 0.04) with βOHB and decreased by 0.79-fold (± 0.04) with Acoc. Many reports support a causal relationship between redox changes and ROS production. When primary hepatocytes were treated with ratios of βOHB/Acoc, CyS/CySS and GSH/GSSG that were relatively oxidized in the physiological context, ROS generation was induced by 0.10-fold (± 0.03), 2.0-fold (± 0.5) and 1.75-fold (± 0.15), respectively, thereby corroborating the relationship between redox state and ROS production.
Conclusion: Changes in extracellular ratios of redox metabolites modulated liver gluconeogenesis through a mechanism likely involving changes in ROS levels and mitochondrial respiration. To our knowledge, these experiments show for the first time that the alteration of the extracellular redox environment, which could occur by modulating physiological circulating redox metabolites, can impact liver function. Such changes in circulating redox have been reported in human in response to high fat feeding. Validation of these findings could lead to the establishment of a novel regulatory mechanism constituted by the extracellular redox state acting as a master metabolic regulatory system, which can affect all organs in the body through the bloodstream. Furthermore, future study of extracellular redox pairs in liver and other metabolically-relevant tissues such as adipose tissue or pancreas may provide new approaches for the early detection and/or treatment of metabolic diseases such as diabetes and obesity.

ISIS-$GCCR_{RX}$, a novel glucocorticoid receptor antisense drug reduces CHOL,TG, attenuates dexamethasone induced hepatic IR without systemic GC antagonism in normal subjects

S. Bhanot[1], E. Morgan[1], C. Bethune[1], R. Larouche[2], S. Xia[1], R. Geary[1];
[1]Isis Pharmaceuticals Inc., Carlsbad, USA, [2]PharmaNet/i3, Montreal, Canada.

Background and aims: Reduction of excessive glucocorticoid (GC) action has been reported to alleviate hyperglycemia in rodents and humans. However, systemic GC inhibition results in adrenal insufficiency and stimulation of the HPA axis. We previously demonstrated that liver selective glucocorticoid receptor (CR) antagonism with antisense drugs improved hyperglycemia and hyperlipidemia in preclinical models without systemic GC antagonism. This current Phase 1 study evaluated the safety, tolerability, and PD of ISIS-$GCCR_{Rx}$ after administration of multiple doses in normal subjects.
Materials and methods: This was a randomized, double-blind, placebo-controlled, Phase 1 study in which subjects were assigned to a dose level (60, 120, 210 or 420 mg/wk) and received 8 doses of the study drug over a 6-week period (3 doses during the first week on Days 1, 3, 5 and once weekly for an additional 5 weeks). A dexamethasone (DEXA) challenge (8 mg for 2 days) was administered in the 420 mg MD cohort before and after 6 weeks of treatment.
Results: DEXA induced hepatic insulin resistance and compensatory hyperinsulinemia as well as increased HOMA-IR. ISIS-$GCCR_{Rx}$ attenuated DEXA induced hepatic insulin resistance as reflected by a 10% and 11% reduction in mean fasting insulin levels and HOMA IR, respectively. DEXA induced lymphopenia was not affected with $GCCR_{Rx}$ treatment indicating no systemic CR antagonism. Even in subjects with high-normal cholesterol (mean baseline cholesterol 202 mg/dL and triglycerides 126 mg/dL), reductions in mean total cholesterol (8.4 mg/dL), triglycerides (17%), VLDL (19%) and ApoCIII (16%) were observed. No clinically significant changes in blood pressure (including no orthostatic hypotension), hepatic, renal and standard safety assessments were reported. Importantly, no hypoglycemia or evidence of HPA axis stimulation (no ACTH increases) was observed.
Conclusion: In conclusion, this study demonstrated that liver specific CR antagonism with ISIS-$GCCR_{Rx}$ was well tolerated, improved lipid profiles, and attenuated DEXA induced hepatic changes without affecting the HPA axis, supporting further evaluation in patients with T2DM.

699

Effect of resveratrol in hepatic and renal expression of the glucose transporters GLUT2 and SGLT2 in diabetic rats

H.S. Freitas, E.P. Machado, A. David-Silva, M.M. Okamoto, U.F. Machado;
Physiology and Biophysics, Institute of Biomedical Sciences, São Paulo University, Brazil.

Background and aims: Sirtuins (SIRT) comprise an important family of proteins that possess histone deacetylase activity. Resveratrol, a natural polyphenol, has been reported to be an activator of NAD+-dependent deacetylase sirtuin 1 (SIRT1). Healthful effects of this polyphenol comprises among others, protection against insulin resistance and type 2 diabetes. Increased hepatic output and renal glucose reabsorption contribute to impair glycemic homeostasis in diabetes mellitus. For that, increased expression of Slc2a2 (liver and kidney) and Slc5a2 (kidney) plays a key role. Additionally, increased expression of these glucose transporters in kidney (out cortex tubular cells) has been also related to the development and/or progression of diabetic nephropathy; and increased expression of gluconeogenic enzymes in liver is fundamental to enhance hepatic glucose outflow. Several studies have reported that resveratrol increases insulin sensitivity in muscle and adipose tissue, but the effect of this polyphenol on genes related to glucose production and efflux in liver and kidney and is unknown. The aims of this study are to investigate in diabetic rats treated with saline (DP), insulin (DI) or resveratrol plus insulin (DIP): 1) the expression of glucose-6-phosphatase (G6Ps), phosphoenolpyruvate carboxikinase (Pepck) and Slc2a2 mRNA in liver; and 2) the Slc2a2 and Slc5a2 mRNA expression in kidney.
Materials and methods: Male Wistar rats were rendered diabetic at 75 days of age by single intravenous injection of alloxan (38 mg/kg). After 20 days, diabetic rats were treated during 30 days with saline (DP), insulin NPH (DI) or insulin plus resveratrol (DIR). Insulin was given subcutaneously (4 U/day) and resveratrol intraperitoneally (10 mg/day). In these animals, glycemia, glycosuria, body weight, liver glycogen content, liver Pepck, G6pase and Slc2a2 mRNA content, and renal Slc2a2 and Slc5a2 mRNA content were analyzed.
Results: Plasma glucose concentration and 24-hour urinary glucose decreased with insulin treatment ($p<0.001$ vs DP). Besides, plasma glucose concentration was also further decreased by resveratrol treatment ($p<0.01$ vs DI). The use of the insulin (DI) and insulin+resveratrol (DIR) increased the body weight of rats ($p<0.001$ vs DP), pointing out that resveratrol treatment induced the highest body weight gain ($p<0.01$ vs DI). In liver, insulin treatment increased glycogen content (45%, $p<0.01$ vs DP), and addition of resveratrol induced a further increasing (35%, $p<0.05$ vs DI). Similarly, insulin decreased Pepck mRNA in liver (50%, $p<0.001$ vs DP), and addition of resveratrol induced a further decreasing (33%, $p<0.05$ vs DI). Insulin treatment decreased Slc2a2 mRNA in both liver and kidney (~50%, $p<0.001$, vs DP), as well as the Slc5a2 mRNA in kindey (25%; $p<0.05$ vs DP). Neither the Slc2a2 nor theSlc5a2 expression was altered by addition of resveratrol to the insulin treatment.
Conclusion: The results indicate that addition of resveratrol to insulin treatment increased hepatic insulin sensitivity, which by reducing glucose output, may contributing to improve glycemic control. However, the addition of resveratrol to insulin treatment did not alter the expression of glucose transporters in out cortex renal tubule, suggesting it was not able to alter the nephropathy development.

Cytochrome C oxidase activity in islets and lymphocytes is directly correlated to glucose stimulated insulin secretion in Cohen diabetes rats fed different diets

S.W. Zangen[1], L. Romero-Afrima[1], G. Aharon-Hananel[1], T. Aouizerat[2], A. Saada[2], I. Raz[1];
[1]Diabetes Unit, [2]Monique & Jaques Roboh Department of Genetic Research, Department of Genetic & Metabolic Diseases, Hadassah University Hospital, Jerusalem, Israel.

Background and aims: Pancreatic β-cells couple glucose stimulated insulin secretion with oxidative phosphorylation via cytochrome c oxidase (COX) a copper-dependent, mitochondrial respiratory chain enzyme. The Cohen diabetic sensitive (CDs) rat exhibit hyperglycaemia when fed a high-sucrose-low-copper-diet (HSD) but maintain normoglycaemia on regular-diet. The fact that β-cell dysfunction could be restored in hyperglycaemic-CDs rats when they were fed HSD supplemented with copper lead us to investigate the relation between COX activity and glucose stimulated insulin secretion (GSIS) in isolated pancreatic islets. We also investigated the possibility that COX activity in lymphocytes could serve as an additional biomarker for the prediction of β-cells dysfunction in diabetes.
Materials and methods: CDs-rats were fed 4, 11, 20 and 30 days HSD. Hyperglycaemic-CDs rats were fed 7, 11 and 20 days HSD-copper-supplemented (HSD+Cu). Blood glucose and insulin concentrations were measured before and during oral glucose tolerance test (OGTT) performed at the different periods on HSD or HSD+Cu. COX activity in islets and lymphocytes was determined by spectrophotometry and normalized to citrate-synthase (CS , a mitochondrial matrix control enzyme).
Results: The glucose area under the curve (AUC) of CDs-rats fed HSD increased gradually (1115±47, 1463±85, 1832±76, 1975±37 mmol/l/120min) while GSIS AUC and COX activity decreased (insulin- 61±1.7, 54±2.4, 41±2.4, 26±3.9 ηmol/l/120min and COX/CS- 0.9±0.5, 0.8±0.01, 0.6±0.1, 0.4±0.06) for 4, 11, 20 and 30 days HSD respectively. When fed HSD+Cu, glucose AUC of hyperglycaemic-CDs rats decreased (1583±91, 1026±40, 986±81 mmol/l/120min) while GSIS and islets-COX-activity increased (insulin- 40±4, 56±4, 69±5 ηmol/l/120min and COX/CS- 0.6±0.01, 0.9±0.01 1.4±0.03) for 7, 11 and 20 days HSD+Cu respectively. Reduced COX activity and insulin secretion were detected already after 4 days and partial recovery of COX activity and insulin secretion was initiated after 4 days of HSD+Cu. The insulinogenic index AUC highly correlated with both islets and lymphocytes COX activity (R^2 = 0.9317 and 0.9301 respectively (figure 1).
Conclusion: Our study implies a direct link between dietary low-copper concentrations, reduced COX activity and impaired glucose tolerance in CDs rats. The correlation between COX activity in islets and lymphocytes supports the possibility of lymphocyte COX activity as a biomarker for possible prediction of type 2 diabetes in humans.

Study of key proteins in the newly identified mitochondrial target of thiazolidinediones (mTOT): a new target for insulin sensitisers

W.G. McDonald, S.L. Cole, D.D. Holewa, A.S. Brightwell-Conrad, C.L. Wolfe, J.S. Wheeler, K.R. Coulter, P.M. Kilkuskie, J.R. Colca, R.F. Kletzien;
Research, Metabolic Solutions Development Co., Kalamazoo, USA.

Background and aims: Insulin sensitization is an attractive mode of action to interrupt and prevent the course of diabetes; however, drugs interacting with the only known molecular target to produce this pharmacology, the nuclear receptor PPARγ, have dose-limiting side effects that limit their use. Here we describe the study of key proteins in a newly identified mitochondrial target, mTOT, for compounds shown to be insulin sensitizers in both animal models and in the clinic. Two proteins of this complex, Mpc2 and Mpc1, are involved in the transport of pyruvate into mitochondria. Studies were undertaken to obtain a greater understanding of this target and its potential role in mediating the differentiation of brown adipose cells.
Materials and methods: C-terminal fusions with either a 6xHis-tag or GFP extension on Mpc1 and Mpc2 were expressed in HEK 293 cells in order to study their interaction and to further define the mTOT complex. Mpc2, the protein identified by drug-analog photoaffinity crosslinking was expressed as both the full length and as an N-terminal truncated protein. The activity of mTOT modulators and the complex were examined in primary dedicated progenitor cells from the murine interscapular brown adipose pad.
Results: All fusion proteins were exclusively located in the mitochondrial membrane. Immunoprecipitation of the C-terminal tagged proteins included Mpc2, Mpc1, and the transcription factor prohibitin. Western blots from brown adipose tissue (BAT) cells differentiated in vitro by mTOT modulator compounds also showed an increase in these three components of the mitochondrial membrane complex. Early events in drug action include increased phosphorylation of AKT and changes in acetylation of some lysine residues. Longer term effects include increases in the expression of the mitochondrial deacetylase SIRT3.
Conclusion: In addition to the proteins, Mpc2 and Mpc1, the mTOT complex contains the potential transcription factor prohibitin. Signal transduction may involve connecting changes in mitochondrial metabolism to posttranslational modification of other signaling molecules including transcription factors.

702

In situ detection of mitochondria-endoplasmic reticulum interactions by proximity ligation assay: defective organelle interactions cause hepatic insulin resistance

E.L.P. Tubbs[1], P. Theurey[1], A. Bravard[1], N. Bendridi[1], G. Vial[1], M.-A. Chauvin[1], F. Zoulim[2], M. Ovize[3], H. Vidal[1], J. Rieusset[1];
[1]INSERM U1060- CarMeN, Lyon, [2]Centre de recherche en Cancerologie de Lyon, INSERM UMR-1052, Lyon, [3]Services d'Explorations Fonctionnelles Cardiovasculaires et CIC de Lyon, Hospices Civils de Lyon, France.

Background and aims: Mitochondria and endoplasmic reticulum (ER) are interconnected organelles. Their close contacts, known as mitochondria-associated membranes (MAM), play a pivotal role in Ca^{2+} signalling and energy metabolism. Particularly, Ca^{2+} transfer from the ER to mitochondria involves the VDAC1/Grp75/IP3R1 complex. Recently, we identified cyclophylin D (cypD) as a mitochondrial protein interacting with the VDAC1/Grp75/IP3R1 complex at MAM interface and demonstrated that loss of cypD altered Ca^{2+} transfer from ER to mitochondria and induced hepatic insulin resistance, suggesting a potential role of organelle coupling in the control of hepatic insulin signalling.
Materials and methods: Here we described an approach based on *in situ* proximity ligation assay (PLA) to detect and quantify the proximity between ER and mitochondrial proteins within the VDAC/Grp75/IP3R1 complex in fixed cells, and investigated a general role of defective MAM in hepatic insulin resistance.
Results: We demonstrated that the close proximity of both VDAC1/IP3R1 and Grp75/IP3R1 could be visualized by *in situ* PLA in fixed HuH7 cells, confirming their interaction at MAM interface. Down-regulation of VDAC1 and Grp75 expression using specific siRNA (25Nm, 48h), reduced both VDAC1/IP3R1 (-100% and -50%, respectively, $p<0,05$) and Grp75/IP3R1 interactions (-40% and -60%, respectively, $p<0,05$), whereas transient overexpression of

Grp75 (2µg, 48h) increased them in HuH7 cells (VDAC1/IP3R1 :+63% and Grp75/IP3R1:+77%, p<0,05), as well as with the over-expression of mitofusin 2 (mfn2) (VDAC1/IP3R1 :+58% and Grp75/IP3R1:+65%, p<0,05) validating that *in situ* PLA is useful for monitoring perturbations of ER-mitochondria interactions. Using this technique, we demonstrated that both genetic and pharmacological inhibition of cypD reduced ER-mitochondria interactions and altered insulin signalling in both mouse and human primary hepatocytes (-31%, p<0,05). Furthermore, we observed a severe down-regulation of ER-mitochondria interactions in primary hepatocytes of diet-induced diabetic mice (VDAC1/IP3R1: -40%, p<0,05), in parallel of alterations of insulin signalling. In contrast, improvement of organelle contacts, by overexpressing cypD (VDAC/IP3R1: +12,3% p<0,05) or mfn2 using adenovirus (VDAC/IP3R1: +144% p<0,05), enhanced insulin action in hepatocytes of diet-induced diabetic mice.

Conclusion: Collectively, our data indicate that *in situ* PLA is an efficient method to visualize and quantify ER-mitochondria interactions in fixed cells and reveal a new role of altered organelle juxtaposition in hepatic insulin resistance, providing a new pharmacological target for the modulation of insulin signalling.

An mtDNA mutation in the cytochrome-c oxidase impacts age-related processes in liver, muscle and brain

J. Niemann, C. Johne, L. Wuchert, F. Koch, M. Tiedge, S. Baltrusch;
Institute of Medical Biochemistry and Molecular Biology, University Rostock, Germany.

Background and aims: mtDNA mutations were recently discussed to contribute to the development of type 2 diabetes mellitus. In previous studies we described an age dependent increase of glucose-induced insulin secretion of pancreatic islets in a conplastic mouse strain carrying an mtDNA mutation in the cytochrome-c oxidase of the respiratory chain. Therefore the aim of this study was to investigate the capacity of liver, muscle and brain metabolism in C57BL/6NTac-mtNOD/AtJ mice.

Materials and methods: Liver, brain and muscle tissue, and primary hepatocytes were isolated from C57BL/6NTac-mtNOD/AtJ (mtNOD) and C57BL/6NTac (control) mice. Mitochondrial morphology and membrane potential were determined by MitoTracker and TMRE staining. Dendra2 was used to study mitochondrial dynamics. Reactive oxygen species (ROS) were detected by MitoSOX. A luminescence assay was used for ATP measurements. The mtDNA copy number was determined by a mitochondrial to nuclear DNA ratio kit.

Results: In control mice a continuous loss of the homogeneous mitochondrial network structure in liver was observed with ageing. In mtNOD mice the variation in the mitochondrial network started significantly earlier. Thus, the mitochondrial network structure of 6 months old mtNOD mice showed a fragmentation level comparable to 12 months old control mice. In addition a significantly higher amount of circular structures was detected in hepatocytes of mtNOD mice. Studies of mitochondrial dynamics showed that those structures are not participating in fission-fusion processes. In early lifetime significantly fewer mitochondria in hepatocytes from mtNOD mice had a high membrane potential compared to controls. However, this amount increased stepwise in mtNOD mice between the age of 6 and 12 months, whilst it remained unchanged in controls. Likewise the ATP content in hepatocytes of control mice kept unchanged with ageing. In contrast, the ATP content in mtNOD mice was significantly lower at the age of 3 months. At the age of 6 and 9 months the ATP content was increased in mtNOD mice and comparable to control. However, at the age of 12 month again a lower ATP content was observed. At this lifetime the mtDNA copy number of mtNOD mice was significantly higher than in controls. In addition ROS production was significantly elevated compared to control and to earlier points of life of mtNOD mice. Notably, in brain and muscle of mtNOD mice ROS production was significantly higher compared to control at all investigated time points.

Conclusion: Our results indicated that an mtDNA mutation in the cytochrome-c oxidase significantly affects the mitochondrial network structure in liver. In addition we detected an adaptive process in mitochondrial function between the age of 6 and 9 month. The higher ROS production in liver, brain and muscle suggest cellular dysfuntion. Thus, the C57BL/6NTac-mtNOD/AtJ mouse strain represents an interesting model to study trigger effects of age-dependent mitochondrial phenotypes in the pathogenesis of type 2 diabetes mellitus.

Liver mitochondrial function in Zucker diabetic fatty rats during the early stages of the diabetes disease

G. Vial[1], M. Le Guen[2], F. Lamarche[2], D. Detaille[3], C. Cécile Cottet-Roussel[2], L. Demaison[2], I. Hininger-Favier[2], D. Crouzier[4], J.-C. Debouzy[4], H. Dubouchaud[2];
[1]INSERM UMR 1060 Laboratoire CarMeN, Lyon, [2]Laboratoire de Bioénergétique Fondamentale et Appliquée, INSERM U1055, Université Joseph Fourier, BP 53, Grenoble, [3]CRCTB INSERM U1045 / LIRYC, Bordeaux, [4]Unité de Biophysique Cellulaire et Moléculaire Centre de Recherches du Service de Santé des Armées, Grenoble, France.

Background and aims: Zucker Diabetic Fatty fa/fa (ZDF) rats show signs of diabetes by 8 weeks of age that could be related to impairments of skeletal muscle mitochondrial function. Despite its central role in the whole body metabolism, the liver hasn't been extensively studied. Our purpose was to characterize the early alterations of the liver mitochondrial function in ZDF (fa/fa) rats that develop diabetes compared to that of their lean counter-parts ZDF fa/+.
Materials and methods: Liver mitochondrial function was examined in 11- and 14-week-old ZDF (fa/fa) and fa/+ lean control rats (n=6 per group). Oxygen consumption, H2O2 release, calcium retention capacity (CRC) and membrane potential were measured on isolated mitochondria under various conditions of substrates. Membrane fluidity and fatty acid composition of mitochondria were analyzed by electron paramagnetic resonance and RMN. Moreover oxidative stress parameters were performed on liver.
Results: Results show that state 3 (ADP phosphorylating condition) oxygen consumption with palmitoyl-coA as a substrate increases between 11 and 14 weeks of age in lean but not in diabetic animals. These changes are not seen with other substrates (glutamate/malate (G/M) or succinate) suggesting that the use of fatty acids is impaired by the diabetic rats. Moreover, we report an increase with age of the uncoupled respiration (in presence of DNP) in control but not in diabetic animals suggesting a lack of adaption of the respiratory chain in the latter. Using G/M as a substrate, H2O2 release by the respiratory chain was lower in 14-week-old ZDF (fa/fa) diabetic rats at compared to 11-week-old ZDF (fa/fa) and to lean ZDF (fa/+) controls in the presence of rotenone (inhibitor of complex I) or antimycine A (inhibitor of complex III). These changes were not associated with a different in enzymatic activity of the respiratory complexes suggesting regulatory mechanisms independent of their expression levels. Membrane fluidity and composition analyses shown only slight effect linked to diabetes progression but calcium retention capacity analyses show a decrease of CsA effect suggesting mPTP function deregulation.
Conclusion: Diabetes appears with time in ZDF (fa/fa) rats by about 8 weeks of age for the earlier signs. Our data suggest some mitochondrial alterations. Since the age of 11 weeks liver mitochondria present a decreased effect of CsA on CRC. Other alterations occur between 11 and 14 weeks of age, starting by reduced H2O2 release and absence in of O2 consumption increase as seen in lean control animals, suggesting lack of adaptive mechanisms at the mitochondrial level that need to be further characterized.

Role of peroxiredoxin 6 in the pathogenesis of diabetes mellitus

F. Pacifici[1], R. Arriga[1], G.P. Sorice[2], B. Capuani[1], D. Pastore[1], A. Coppola[1], S. Caratelli[1], A. Bellia[1], G. Donadel[1], M. Federici[1], P. Sbraccia[1], G. Sconocchia[3], A. Giaccari[2], A. Orlandi[1], D. Lauro[1];
[1]University of Rome "Tor Vergata", Rome, [2]Catholic University of Rome, [3]Institute of Translational Pharmacology, National Research Council, Rome, Italy.

Background and aims: High levels of insulin resistance (IR) can lead to increased fasting glucose levels, due to augmented hepatic glucose production and reduced peripheral glucose uptake. Furthermore, Type 2 Diabetes usually develops when IR is associated to a defect of glucose mediated insulin secretion. Previous studies demonstrated the relationship between ROS production and increased levels of IR, highlighting the important role of antioxidants enzymes. Peroxiredoxin 6 (PRDX-6) is a peroxidase belonging to a relatively newly discovered class of antioxidant enzymes; it is capable to neutralize peroxides and phospholipid hydroperoxides. Based on this evidence, we investigated PRDX-6 in the pathophysiology of Diabetes Mellitus (DM), using PRDX6 knock-out (KO) and wild type (WT) mice.
Materials and methods: C57BL6/J mice and PRDX-6 KO on C57BL6/J background were used as experimental model. Intraperitoneal Glucose Tolerance Test (IPGTT), Insulin Tolerance Test (ITT), ELISA and hyperinsulinemic-euglycemic clamp were accomplished to evaluate the IR level of our mice model. Mice were stimulated with an infusion of insulin 1 UI/kg into portal vein. Western blot analysis and immunoprecipitation assay of protein extracts from skeletal muscle and liver were performed to analyzed the insulin signaling pathway. Immunohistological analysis was accomplished on liver and pancreas of untreated mice.
Results: Our data revealed that PRDX-6 KO mice developed DM due to reduce glucose dependent insulin secretion and increased levels of IR. We observed a significant decrease in AKT1/2 signaling (respectively $p<0.001$ and $p<0.005$) with subsequent reduction of glucose uptake ($p<0.005$). However, the same analysis on liver protein extracts didn't show any significant modification in insulin signaling activation. Altered lipid metabolism (increased levels of serum triglycerides $p<0.05$ and serum VLDL $p<0.05$) in PRDX-6 KO mice might be associated to hepatic ultra-structurul changes, as defined by NASH score ($p<0.005$). Moreover, in PRDX-6 KO mice immunohistological analysis highlighted significant changes in islets of Langerhans number and morphology ($p<0.05$).
Conclusion: We demonstrated, for the first time, the potential role of PRDX-6 in the pathophysiology of DM, opening interesting perspectives in finding new therapeutics options for DM care.

Effect of association between insulin and PPAR agonists on renal cortex glucose transporters and gluconeogenic enzymes expression in diabetic rats

M.M. Okamoto[1], A. David-Silva[1], M.F.S. Marques[1], R. Sabino Silva[2], H.S. Freitas[1], U.F. Machado[1];
[1]Physiology, University of São Paulo - Institute of Biomedical Sciences, São Paulo, [2]Federal University of Alagoas, Maceió, Brazil.

Background and aims: GLUT2 and SGLT2 in renal cortex can be markers of nephropathy development. Insulin suppresses gluconeogenesis through the Foxo-1 phosphorylation by Akt which leads to Foxo-1 nuclear exclusion and transcriptional inhibition of Pepck and G6pase genes. Although not equate to liver, kidney is a important gluconeogenic organ and contributes to the excessive glucose release in diabetes. Both PPAR alpha and gamma are expressed in the kidney and studies have demonstrated, in addition to hypolipidaemic and anti-diabetic effects, the healthful effects of PPAR agonists due to their metabolic, anti-inflamatory, anti-fibrotic and anti-proliferative properties. These data strongly suggest a potential benefit of these drugs on diabetic nephropathy. We investigate the effect of association between insulin and PPAR agonists (PPAR gamma and alpha, pioglitazone and fenofibrate, respectively) on glucose transporters and gluconeogenic enzymes expression in renal cortex of diabetic rats.
Materials and methods: Diabetic rats were treated with saline (DS), insulin (DI-4U/day), insulin plus pioglitazone (DIP - 20mg/Kg bw), insulin plus fenofibrate (DIF-100mg/Kg bw) or insulin plus pioglitazone and fenofibrate (DIPF) during 5 weeks. Non diabetic rats (ND) were studied as a control group. We evaluated in these groups after treatment: 1) glycosuria and proteinuria; 2) glycemia; 3) SGLT2 and GLUT2 protein expression; 4) nuclear content of Foxo-1 protein; and 5) mRNA content of Pepck and Glucose-6-phosphatase.
Results: DS showed hyperglycemia, glycosuria, proteinuria, increased expression of renal cortex glucose transporters (GLUT2, ~26%, and SGLT2, ~55%, $P<0.05$), increased expression of nuclear Foxo-1 (~39%, $P<0.01$) and PEPCK mRNA content (~84%, $P<0.001$) in comparison to ND. Glycemia of diabetic rats was reduced in DI, DIP, DIF and DIPF (DI~69%, DIP~82%, DIF~53% and DIPF~29%, $P<0.05$ vs DS) and the most prominent reduction was found in DIP ($P<0,05$ vs. all studied groups). DI, DIP, DIF and DIPF presented lower glycosuria (DI~73%, DIP~80%, DIF 80% and DIPF~88%, $P<0.01$ vs DS) and proteinuria (DI~48%, DIP~49%, DIF~54%, DIPF~61%, $P<0.01$vs DS) than diabetic rats. GLUT2 expression was reduced in DI and DIP (DI~19%, DIP~23%, $P<0.05$ vs DS) but increased in DIF and DIPF (DIF~19%, DIPF~21%, $P<0.05$ vs DS). SGLT2 protein was decreased in DI, DIP and DIF (DI~52%, DIP~63%, DIF~41%, $P<0.01$ vs DS), but in DIPF SGLT2 expression back to DS value. Nuclear Foxo-1 protein was decreased in DI and DIP (DI~39%, DIP~29%, $P<0.05$ vs DS) but increased in DIF and DIPF (~60%$P<0.001$ vs DI). G6pase mRNA content was reduced in DI, DIP and DIF in comparison to DS (~38%, $P<0.05$) but increased in DIPF (~27%, $P<0.01$ vs DS). Pepck mRNA content was decreased in DI and DIP (~49%, $P<0.01$ vs DS), unaltered in DIF but increased in DIPF (~45%, $P<0.01$ vs DS).

Conclusion: Pioglitazone promoted additional improvement to the beneficial effect of insulin treatment on glycemic control. However, pioglitazone had no additional effect on insulin-induced reduction of nuclear Foxo-1 and expression of gluconeogenic enzymes and glucose transporters GLUT2 and SGLT2 expression. Finally, the addition of fenofibrate to the insulin/pioglitazone treatment worsened the effects of this association on glycemic control and expression of the nephropathy markers.

A new mutation in SLC5A2 causing familial renal glycosuria in individuals with impaired glucose control
P. Vikman[1], E. Ottosson-Laaksso[1], M. Gullström[2], P.-H. Groop[2], L. Groop[1];
[1]Diabetes and Endocrinology, Malmö, [2]Närpes Health Care Center, Närpes, Sweden.

Background and aims: Renal glycosuria is a condition of glucose excretion in the urine despite normal blood glucose levels. Familial renal glycosuria is in a majority of cases caused by deleterious mutations in SLC5A2, a gene coding for the SGLT2 transporter responsible for 90% of the glucose reuptake in the kidney. The aim of the present study is to characterize the underlying genetic cause of glycosuria in a family with renal glycosuria and impaired fasting glucose/impaired glucose tolerance (IGT/IGT) or diabetes and to explore whether glycosuria protects from deterioration of glucose tolerance.
Materials and methods: We performed exome sequencing of 23 family members, 8 with renal glycosuria. Of the 8 affected individuals, 5 were diagnosed with IFG/IGT or diabetes. Change in glucose tolerance was tested as change in area under the glucose curve (AUCOGTT). Glucosuria was estimated during the OGTT.
Results: In total, 5 variants were found in the sequenced region of SLC5A2, 4 SNPs and one 6 bp deletion. The snpEff and SIFT programs ranked the deletion as highly detrimental. The 6 bp deletion causes a frame shift and splice site mutation in the third exon with a high probability of functional consequences on the protein. The deletion was seen in 9 individuals (6 with glycosuria and 3 without), and significantly associated with glycosuria (p=0.023). Of the nine carriers of the deletion, five had IFG/IGT/diabetes; 3 of them also had glycosuria. There was no significant difference in change in AUCOGTT over time between carriers and non-carriers of the deletion.
Conclusion: Glycosuria in this family is most likely caused by a deletionin the SLC5A2 gene. The data do not provide any support for the view that increasing glucose excretion in the urine would protect from diabetes.

The impact of reduced kidney mass on adipose tissue metabolism and whole-body glucose homeostasis in mice
S.H. Chin[1,2], F. Item[1], S. Wueest[1], M.S.F. Wiedemann[1,2], E.J. Schoenle[1], D. Konrad[1,2];
[1]Division of Pediatric Endocrinology and Diabetology, University Children's Hospital, Zurich, [2]Zurich Center for Integrative Human Physiology, University of Zurich, Switzerland.

Background and aims: Reduced kidney function deteriorates insulin sensitivity in children and adults. However, the underlying mechanisms are poorly understood. Activation of the renin-angiotensin system (RAS)/angiotensin receptors (ATR) impairs insulin signalling in adipose tissue, skeletal muscle and liver and its prevention by ATR blockade (pharmaceutically or genetically) improves glucose homeostasis. We therefore hypothesise that reduced kidney mass impairs glucose metabolism via activation of the RAS.
Materials and methods: Seven-week-old C57Bl6/J mice underwent uninephrectomy (UniNx) or sham operation. After operation, animals were fed either a chow (standard) or a high fat diet (HFD) and glucose homeostasis was assessed 2, 8, and 20 weeks after surgical intervention.
Results: No significant differences were observed in glucose tolerance in chow-fed animals. However, in HFD-fed animals glucose tolerance was further impaired in UniNx mice after 8 and 20 weeks when compared to sham-operated mice. Moreover, skeletal muscle insulin resistance was significantly deteriorated (IS-GDR 22.4 ± 2.8 mg/kg*min in sham vs. 10.6 ± 1.2 mg/kg*min in UniNx; $p < 0.01$) and adiposity was increased in UniNx mice after 20 weeks of HFD. In contrast, hepatic steatosis was decreased and hepatic insulin sensitivity was improved in UniNx mice (insulin-mediated inhibition of EGP 50.2 ± 7.0 % in sham vs. 99.9 ± 18.9 % in UniNx; $p < 0.01$). Plasma angiotensin I concentration was elevated in UniNx compared to sham-operated mice under both chow and HFD 2, 8 and 20 weeks after surgical intervention. Surprisingly, treatment with the ATR blocker telmisartan improved glucose tolerance in HFD-fed sham-operated but not UniNx mice.
Conclusion: Uninephrectomy further impairs obesity-induced skeletal muscle insulin sensitivity but protects from obesity-induced hepatic insulin resistance and steatosis.

Early insulin treatment preserved beta cell function by alleviating local oxidative stress in db/db mice
Y. Shen[1], X. Lai[1], G. Xu[2], L. Xie[3], X. Xia[4], H. Liang[4], J. Weng[4];
[1]Department of Endocrinology and Metabolism, The Second Affiliated Hospital of Nanchang University, Nanchang, [2]Department of Nephrology, The Second Affiliated Hospital of Nanchang University, Nanchang, [3]Department of Ophthalmology, The Second Affiliated Hospital of Nanchang University, Nanchang, [4]Department of Endocrinology, The Third Affiliated Hospital of Sun Yat-sen University, Guangzhou, China.

Background and aims: It was shown that local oxidative stress was involved in β-cell dysfunction, meanwhile it was demonstrated that early intensive insulin therapy could improve β-cell function in several clinical trials. In this study, we explored the potential pathophysiological mechanisms of early insulin treatment in db/db mice.
Materials and methods: High-fat diet fed diabetic db/db mice were divided to control, early insulin treatment (EI) and late insulin treatment (LI) groups. EI or LI mice were injected subcutaneously with glargine from the onset of diabetes or two weeks later, respectively. Introperitoneal glucose tolerance test was performed, and fasting C-peptide (FCP) were tested. The levels of local superoxide dismutase (SOD), glutathione perioxidase (GPX) and reactive oxygen species (ROS) in pancreas were measured.
Results:Early insulin treatment caused a significant decrease in the AUC of glucose (EI 43.56 ± 5.35 vs LI 54.69 ± 4.72 mmol/L*min, $P<0.01$ and control 67.38 ± 3.14 mmol/L*min, $P<0.001$), and a significant rise in FCP (EI 982.45 ± 107.38 vs LI 571.66 ± 83.45 pM, $P<0.001$ and control 339.63 ± 134.81 pM, $P<0.001$). There was a significant elevation in the activity of SOD in pancreas (EI 103.71 ± 21.35 vs LI 87.48 ± 16.92, $P<0.001$ and control 69.55 ± 24.61, $P<0.001$). So did in the inhibition of ROS (EI 648.37 ± 54.29 vs LI 451.64 ± 71.30, $P<0.001$ and control 316.52 ± 16.92, $P<0.001$). There had no change in the activity of GPX between EI, LI and control.
Conclusion: Early insulin treatment increases the activity of antioxidants SOD, and reduces local ROS that were involved in the amelioration of glucose tolerance and β-cell secretion in high-fat diet fed diabetic db/db mice.

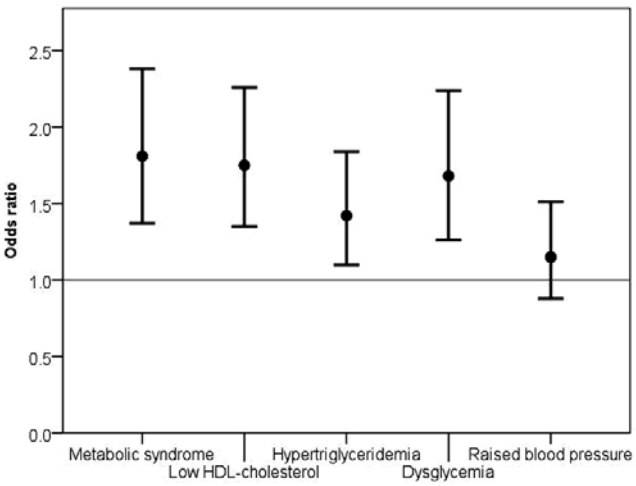
Hyperandrogenaemia in morbidly obese women is associated with increased risk of metabolic syndrome, dysglycaemia and dyslipidaemia

T.G. Valderhaug[1,2], J.K. Hertel[1], N. Norstrand[1], L.K. Johnson[1], P.O. Dale[3], D. Hofsø[1], J. Hjelmesæth[1,4];
[1]Morbid Obesity Centre, Vestfold Hospital Trust, Tønsberg, [2]Department of Endocrinology, Akershus University Hospital, Nordbyhagen, [3]Department of Surgery, Vestfold Hospital Trust, Tønsberg, [4]Department of Endocrinology, Morbid Obesity and Preventive Medicine, University of Oslo, Norway.

Background and aims: Obesity and the polycystic ovarian syndrome (PCOS) are associated with insulin resistance, hyperandrogenemia and metabolic syndrome (MS). Insulin resistance and compensatory hyperinsulinemia may promote hyperandrogenemia, an important component of PCOS. We aimed to test the hypothesis that morbidly obese women with hyperandrogenemia had higher risk of MS and its components than women without hyperandrogenemia (control group).
Methods: A total of 1698 morbidly obese women under 50 years of age consulted our clinic during the period from November 28th 2005 until January 17th 2013 and were consecutively included in the study. We defined MS if waist circumference was ≥ 80 cm combined with minimum two out of four criteria present: 1) low HDL-cholesterol; HDL cholesterol <1.3 mmol/L, 2) hypertriglyceridemia; triglycerides ≥1.7 mmol/L, 3) dysglycemia; fasting serum glucose ≥5.6 mmol/L or diabetes mellitus, and 4) raised blood pressure; systolic blodpressure ≥130 mmHg or diastolic bloodpressure ≥85 mmHg or use of blood pressure lowering medication. We defined PCOS as known PCOS or a free testosterone index (FTI) >0.6 combined with clinical signs of hyperandrogenemia (irregular bleeding or hirsutism). Hyperandrogenemia was defined by free testosterone index (FTI) >0.6. Continuous and categorical variables were compared using student t-test and χ^2 test as appropriate. Backward stepwise logistic regression analysis was used to assess the association between hyperandrogenemia and MS and its components.
Results: A total of 969 (57%), 273 (16%), and 636 (37%) morbidly obese women had MS, PCOS, and hyperandrogenemia, respectively. Compared with the control-group, women with hyperandrogenemia had a significantly higher prevalence of MS (53% vs. 63%, p<0.001), low HDL cholesterol (49% vs. 68%, p<0.001) and hypertriglyceridemia (42% vs. 49%, p=0.004), but a lower prevalence of raised blood pressure (59% vs. 54%, p=0.031). Multivariable adjustments for well known risk factors for MS showed that hyperandrogenemia was independently associated with MS (OR 1.81 [95% CI 1.37-2.38]), low HDL cholesterol (1.75 [1.35-2.26]), hypertriglyceridemia (1.42 [1.10-1.84]), and dysglycemia (1.68 [1.26-2.24]). Conversely, hyperandrogenemia was not associated with increased risk of raised blood pressure (1.15 [0.88-1.51]).
Conclusion: We document a high prevalence of both MS and hyperandrogenemia in a large population of treatments seeking morbidly obese women under 50 years of age. Hyperandrogenemia was associated with 81% increased odds of MS, mainly explained by significant associations between hyperandrogenemia and the lipid and glucose components of the MS.



712

Testosterone replacement in 181 obese, hypogonadal men leads to continuous weight loss and over 5 years and improved glucose homeostasis

F. Saad[1,2], A. Haider[3], G. Doros[4], L. Gooren[5];
[1]Global Medical Affairs Men's Healthcare, Bayer Pharma AG, Berlin, Germany, [2]Research Department, Gulf Medical University School of Medicine, Ajman, United Arab Emirates, [3]Urology Practice, Bremerhaven, Germany, [4]Department of Epidemiology and Statistics, Boston University School of Public Health, Boston, USA, [5]Department of Endocrinology, VUMC Amsterdam, Netherlands.

Background and aims: Obesity can cause testosterone deficiency and vice versa. Weight loss has been shown to increase testosterone levels. This study analysed effects of normalization of testosterone in obese hypogonadal men.
Materials and methods: Open-label, single-center, cumulative, prospective registry study of 181 men (mean age 59.11 ± 6.06 years) with testosterone levels ≤ 12.1 nmol/l were treated with testosterone undecanoate 1000 mg/12 weeks after an initial 6-week interval.
Results: After 5 years the following changes occurred: weight (kg) decreased from 114.71 ± 11.59 to 93.24 ± 8.49. The statistical significance was p<0.0001 vs baseline and vs the previous year over 5 years indicating a continuous weight loss. Waist circumference (cm) declined from 111.2 ± 7.54 to 100.47 ± 7.11 (p<0.0001 vs baseline and vs the previous year over 5 years). Body mass index (BMI, m/kg^2) declined from 36.72 ± 3.72 to 30.22 ± 2.6 (p<0.0001 vs baseline and vs the previous year over 5 years). The mean per cent weight loss after 1 year was 5.2 ± 0.24%, after 2 years 9.11 ± 0.25%, after 3 years 11.58 ± 0.27%, after 4 years 13.78 ± 0.28% and after 5 years 16.41 ± 0.3%. 71 (39%) of our patients had known type 2 diabetes at baseline which was treated by their family physician. In these men, waist circumference decreased by 10.06 cm, weight by 18.29 kg (15.71%). Fasting glucose declined from 6.61 ± 0.77 mmol/L (119.07 ± 13.89 mg/dl) to 5.42 ± 0.16 mmol/L (97.63 ± 2.83 mg/dl), HbA_{1c} from 8.33 ± 0.78 to 5.88 ± 0.4%.
Conclusion: Normalising testosterone produced progressive loss of weight, waist circumference and BMI over the full 5 years of the study. In the diabetic subgroup, both fasting glucose and HbA_{1c} improved progressively over the full 5 years of the study.

Weight loss and beneficial effects on the metabolic syndrome as a result of testosterone treatment for up to 16 years in 381 hypogonadal men

M. Zitzmann[1], F. Saad[2,3], S. Kliesch[1], E. Nieschlag[1];
[1]Centre of Reproductive Medicine and Clinical Andrology, University of Münster, Germany, [2]Bayer Pharma AG, Berlin, Germany, [3]Research Department, Gulf Medical University School of Medicine, Ajman, United Arab Emirates.

Background and aims: Testosterone treatment in men diagnosed with hypogonadism is considered standard therapy, particularly in younger men with congenital forms of hypogonadism. We analysed long-term treatment with

long-acting intramuscular injections of testosterone undecanoate at 3-month intervals after an initial 6-week interval.
Materials and methods: 381 patients (169 with primary, 113 with secondary and 99 with "late-onset hypogonadism") aged 15 to 72 years (mean 42 ± 13 years) received intramuscular injections of 1000 mg of TU during a maximal treatment time of 16 years, corresponding to 8,514 injections. Patients were entered into a registry database once they had received at least 4 injections. Hypogonadism was defined as total testosterone below 12 nmol/L and occurrence of symptoms.
Results: Serum T concentrations rose from 5.3 ± 2.1 to 12.7 ± 2.7 nmol/L within the first year of treatment, 15.6 ± 4.1 nmol/L after the second year, and remained stable thereafter. Body weight decreased from 106.8 ± 16.4 kg at baseline to 86.5 ± 12.7 kg at the end of the observation period. Body mass index declined from 32.6 ± 5.5 to 26.4 ± 3.3 kg/m^2. Waist circumference declined from 117.0 ± 11.1 to 94.2 ± 8.5 cm. Systolic blood pressure decreased from 150.0 ± 14.0 to 131.0 ± 11.06 mmHg, diastolic blood pressure from 99.0 ± 11.0 to 82.0 ± 10.0 mmHg. Heart rate declined from 90.0 ± 9.5 to 76.0 ± 8.1 beats per minute. Total cholesterol improved from 239 ± 35 to 172 ± 22 mg/dl, LDL cholesterol from 161 ± 30 to 111 ± 19 mg/dl, triglycerides from 201 ± 35 to 148 ± 20 mg/dl, and HDL cholesterol from 36.3 ± 9.4 to 52.7 ± 11.6 mg/dl. Fasting glucose decreased from 108.9 ± 29.6 to 94.7 ± 15.3 mg/dl.
Conclusion: Intramuscular injections of testosterone undecanoate lead to improvements in body composition and other features of the metabolic syndrome. These changes are maintained over a long-term follow-up period.

714

Increased free testosterone levels following bariatric surgery are related to weight loss and glycaemic control in men with type 2 diabetes: analysis from a RCT

S.R. Kashyap[1], P. Schauer[2], D.L. Bhatt[3], M. Gupta[4], K. Wolski[5], C. Pothier[5], J. Kirwan[6], S. Brethauer[2], L. Kennedy[1];
[1]Endocrinology, Diabetes and Metabolism, Cleveland Clinic Foundation, Cleveland, [2]Bariatric and Metabolic Institute, Cleveland Clinic Foundation, Cleveland, [3]Cardiology, VA Boston Healthcare System, Brigham and Women's Hospital, and Harvard Medical School, Boston, [4]Pathology, Cleveland Clinic Foundation, Cleveland, [5]Heat and Vascular Institute, Cleveland Clinic Foundation, Cleveland, [6]Lerner Institute, Cleveland Clinic Foundation, USA.

Background and aims: Obesity and type 2 diabetes are commonly associated with male hypogonadism. We hypothesized that bariatric surgery would increase male sex hormones.
Materials and methods: Forty two men (age 49 ± 8y) with moderate obesity (BMI = 37±3 kg/m2) and poorly controlled DM (HbA1c =9.2± 1.4%) were randomized to medical therapy alone (MT; N =14), gastric bypass (RYGB; N =17) or sleeve gastrectomy (SG; N =11) plus medical therapy. Total and free testosterone (ultrafiltration), sex hormone binding globulin (SHBG) and luteinizing hormone (LH) levels were determined at randomization and 12 month follow up and correlated to metabolic parameters and adiposity measures (DXA, leptin in a subset of N=19). No subjects were on testosterone supplementation during this time.
Results: At 12 months, total body weight decreased by 5% in the medical group, 26% in gastric bypass and 27% in SG. HbA1c levels reduced after all interventions; -1.6% in medical, -2.6% in SG and -3.2% in RYGB. Median levels of total testosterone increased similarly in RYGB (468 vs. 243 ng/dL, P < 0.001) and SG (418 vs 287 ng/dL, P < 0.01), but did not change in MT (265 vs 254 ng/dL). Median percent change and absolute change in free testosterone levels were greater in RYGB vs. MT (49% vs. 6%, P = 0.05) and (32.8 vs. 4.2 pg/mL, P = 0.05) respectively, but were not different between SG and RYGB (59% vs. 49%, P = NS). LH levels were similar at baseline and did not change at 12 m among the three groups. The median percent increase in SHBG levels was 71% in SG, 110% in RYGB vs 14% in MT. The increase in free testosterone levels strongly related to the decrease in body weight (r = -0.36, P = 0.02), HBA1c (-0.32, P = 0.04), leptin (r = -0.52, P = 0.02), and truncal fat (-0.57, P = 0.009), but not with CRP levels (r = -0.23, P = 0.3).SHBG rise strongly associated with the decrease in BMI (r = -0.60, P < 0.0001), leptin (r = -0.60, P = 0.006) and insulin resistance measured by HOMA IR (r = -0.58, P = .006).
Conclusion: In summary, surgically induced weight loss improves male hypogonadism in moderately obese males with type 2 diabetes to a greater extent than medical anti-diabetic therapy.The improvment in free testosterone are linked to better glucose control and loss of truncal fat. Mechanistic studies to investigate these linkages are warrented.

Comparison of carotid intima-medium thickness, endothelial function and C-reactive protein in male patients with type 2 diabetes with normal and low testosterone levels

J.M. Farias[1], M. Khoury[2], M. Tinetti[3];
[1]Endocrinology, Hospital Universitario Sanatorio Guemes, [2]Research Department, Hospital Universitario Sanatorio Guemes, [3]Cardiac Imaging, Sanatorio De La Trinidad, Ciudad Autonoma de Buenos Aires, Argentina.

Background and aims: Type 2 Diabetes (T2D) and low serum testosterone are associated with increased risk of atherosclerotic complications. The magnitude of such association; however, in middle-aged patients with T2D has not been determined. We evaluated atherosclerotic markers in patients with T2D with normal and low total testosterone.
Materials and methods: We report preliminary analysis of 115 male patients < 70 years without previous cardiovascular events with normal (≥ 3,5 ng⁄ml, n=79) and low (<3,5 ng⁄ml, n=36) total testosterone (TT). We measured serum C reactive protein (CRP), carotid artery intima-media thickness (IMT), presence carotid atherosclerotic plaque (Plaque) by high-resolution B-mode ultrasound, and endothelial dysfunction (ED) by brachial artery flow meditad dilación. Data were analyzed using simple calculation, Spearman correlation coefficient, Mann Whitney U tests and x2 test. Odds ratio [OR] and 95% confidence intervals (CI) were calculated using simple and multiple logistic regression.
Results: There were no difference in age 56.68±76,7, DM duration: 6.67±3 yrs, BMI 30.1±3.6 kg⁄m2, LDL 119.3±23 mg⁄dl, HDL 39.9±7 mg⁄dl, HbA1c 6.9±0.6%, between normal and low TT groups, p= NS. Frequencies of Low TT was 31.3% (n=36); 53.91% (n=62) and plaque, ED 52.17% (n=60). Mean IMT (0,100±0,014 mm) was significantly correlated with TT, r: -0.39 (p <0.0001) Compared to patients with normal T, those with low T have higher IMT ≥0.100 (80% vs 39%, odds ratio (OR) 6.41(CI95%: 2.5-16.4), p<0,001 and atherosclerotic plaques 68.5% vs. 45%, OR 2.60 (1.12-6.03), p<0.0001; ED (80.5 vs 42.5%, OR 5.77 (2.77-14.77), p <0001, and higher CRP (2.74±582 vs 0.89±0.88 mg⁄L, p<0.0001). Using multiple logistic regression analyses adjusted for age, diabetes duration, HbA1c, lipids, treatment effect, and BMI, we found that TT levels were associated with greater IMT [OR: 8.43 (2.5-25.8)] and ED [OR: 4.98 (1.72-14.37)], but not with the presence of atherosclerotic plaques (p=NS).
Conclusion: Male T2D patients with low total testosterone have greater IMT, ED and CRP compared to diabetic patients with normal TT. Low testosterone in middle age T2D is associated with more advanced atherosclerotic markers (IMT, CRP and endothelial dysfunction).

716

Association of glypican-4 with body fat distribution, insulin resistance and non-alcoholic fatty liver disease

H. Yoo, H. Hong, H. Choi, J. Ryu, Y. Kim, N. Kim, J. Ahn, H. Kim, S. Kim, N. Kim, S. Baik, K. Choi;
Division of Endocrinology and Metabolism, Department of Internal Medicine, Korea University College of Medicine, Seoul, Republic of Korea.

Background and aims: Because visceral adipose tissue is more pathogenic than subcutaneous adipose tissue, the site of fat accumulation plays a pivotal role in metabolic disorders. However, little is known about the factors that determine sites of fat accumulation. Recently, glypican-4 was identified as a novel adipokine capable of enhancing insulin signaling and modulating adipocyte differentiation. Furthermore, glypican-4 is differentially expressed in visceral and subcutaneous adipose tissue, and that its expression in human white adipose tissue is highly correlated with body mass index (BMI) and waist-to-hip ratio (WHR). Therefore, we explored the associations between circulating glypican-4 levels and body fat distribution, insulin resistance, and non-alcoholic fatty liver disease (NAFLD) in non-diabetic Asian subjects.
Materials and methods: We analyzed baseline cross-sectional data from the Korean Sarcopenic Obesity Study (KSOS), an ongoing prospective cohort study. NAFLD was diagnosed by unenhanced computed tomography (CT) using the liver attenuation index. First, we compared circulating glypican-4 levels between subjects with NAFLD and age- and gender-matched control groups. Second, we evaluated the relationships between serum glypican-4 levels and various cardiometabolic risk factors including insulin resistance, arterial stiffness (represented by brachial ankle pulse wave velocity; baPWV), and the ratio of visceral to subcutaneous fat area (VFA/SFA) measured by abdominal CT. Finally, we investigated the effect of a 3-month combined

aerobic and resistance exercise program on changes in circulating glypican-4 levels in obese women.
Results: Circulating glypican-4 levels were higher in men than in women (1.83 [1.19, 2.78] ng/ml vs. 1.17 [0.66, 2.00] ng/ml, P <0.001) and had a significant positive relationship with the waist-to-hip ratio (WHR) (r = 0.20, P = 0.014) and the ratio of visceral to subcutaneous fat area (VFA/SFA) (r = 0.30, P <0.001). Women with NAFLD had significantly higher plasma glypican-4 levels than subjects without NAFLD (1.58 [1.01, 2.62] ng/ml vs. 0.90 [0.59, 1.28] ng/ml, P = 0.001), whereas men did not show any significant difference in glypican-4 levels based on NAFLD (1.97 [1.17, 3.25] ng/ml vs. 1.71 [1.33, 2.71] ng/ml, P = 0.496). Furthermore, glypican-4 levels in women were positively correlated with AST (r = 0.32, P = 0.005), triglyceride (r = 0.27, P = 0.020), glucose (r = 0.31, P = 0.006), and HOMA-IR (r = 0.31, P = 0.006) levels, baPWV (r = 0.23, P = 0.048), and VFA/SFA ratio (r = 0.30, P = 0.009) and were independently associated with NAFLD by multiple logistic regression analysis (P = 0.017, R^2 = 0.33). However, there were no significant correlations between plasma glypican-4 levels and various metabolic risk profiles in men. The 3-month combined exercise training program significantly improved several cardiometabolic parameters. Changes in glypican-4 levels after the exercise program were significantly different between subjects with an increased WHR compared with those with a decreased WHR (P = 0.034).
Conclusion: A gender-based difference in circulating glypican-4 levels was apparent as these were increased in women with NAFLD and related to body fat distribution, insulin resistance, and arterial stiffness.

Gender differences in the HPA axis are abolished in type 2 diabetes
L. Arnetz, N. Rajamand Ekberg, K. Brismar, M. Alvarsson;
Department of Molecular Medicine and Surgery, Karolinska Institute, Stockholm, Sweden.

Background and aims: Dysfunction of the HPA axis has been implicated in the pathogenesis of type 2 diabetes (T2D). The aim of this study was to compare the regulation of the HPA axis between subjects with and without T2D, and secondarily to study the influence of gender.
Materials and methods: 1 μg synthetic ACTH, a low-dose short Synacthen test, was administered to 21 subjects with T2D (median age 62 [range 54-70] years, 11 men/10 women, HbA_{1c} 49 ± 2 mmol/mol, treated with diet or oral antidiabetic agents) and 39 healthy controls (age 58 [41-67] years, 20 men/18 women). Fasting B-glucose, serum cortisol, insulin and C-peptide were measured at baseline and 30, 60 and 90 minutes after ACTH injection. At a later date, patients took 0.25 mg dexamethasone at 10-11 p.m., and returned the next morning for measurement of serum cortisol.
Results: Patients with T2D had higher baseline glucose (p <0.001), insulin (p = 0.012), C-peptide (p = 0.006) and WHR (p = 0.008) but not BMI vs healthy subjects. Despite similar baseline cortisol, T2D subjects had higher peak cortisol after ACTH injection (693 ± 31 vs 624 ± 18 nmol/L, p = 0.043). The men with T2D had higher peak cortisol vs healthy men (691 ± 42 vs 582 ± 21 nmol/L, p=0.024), while peak levels did not differ between healthy women and women with T2D. Among healthy subjects, women had higher peak cortisol vs men (675 ± 26 vs 582 ± 21 nmol/L, p=0.014). This gender difference did not exist among subjects with T2D. Multiple linear regression showed that gender (β = 0.417 ± 0.178, p = 0.023) and BMI (β = -0.277 ± 0.137, p = 0.048) affected peak cortisol, whereas the fasting insulin level and WHR did not. The morning serum cortisol after dexamethasone was similar between the groups (283 ± 25 in T2D, 261 ± 15 in healthy subjects; no gender differences).
Conclusion: In this sample of T2D patients with good metabolic control, adrenal sensitivity to ACTH was increased compared with healthy controls whereas sensitivity to feedback inhibition of the HPA axis remained intact. Increased cortisol production may contribute to insulin resistance and reduced β-cell function in T2D. The absence of gender differences in HPA axis reactivity in T2D, which are present in healthy subjects, suggests that gender differences in cortisol secretion may play a role in the pathogenesis of T2D.

Exenatide improved sperm quality and promoted testosterone metabolism in high-fat-diet induced obese C57BL/6J mice
E. Zhang, F. Xu, Z. Li, J. Yan, X. Xing, Z. Chen, H. Liang, J. Weng;
Department of Endocrinology and Metabolism, the Third Affiliated Hospital of Sun Yat-Sen University; Key lab of Diabetology of Guangdong Province, Guangzhou, China.

Background and aims: Previous study in animal experiments and population showed that obesity impaired male reproductive ability and reduced serum testosterone levels. Weight loss or lipid improving could reverse sperm function and restore serum testosterone levels. Exenatide was reported that it could induce weight loss by suppressing appetite and increasing satiety, and improve lipid metabolism, but few studies have evaluated the effects of this drug on sperm quality and testosterone levels. This study aimed to investigate the effects of exenatide on sperm quality and testosterone metabolism in obese mice fed on high-fat diet.
Materials and methods: Eight-week old male C57BL/6J mice were randomly assigned into two groups for 12 weeks: chow diet (NC, 5% fat w/w) and high-fat-diet (HFD, 37% fat w/w). After the diet induction, the mice on HFD were further randomly allocated to the following interventions for anthoer 8 weeks: HFD+saline (HFD), HFD+Exenatide (HFD+EX). Quantitative parameters of sperm motility were determined by computer assisted sperm analysis. Sperm mitochondrial membrane potential (MMP) were measured on flow cytometer. Sperm DNA damage was assessed by sperm chromatin dispersion test. Serum testosterone levels were measured by ELISA. Testis and liver tissues were collected to test mRNA expression of inflammatory factors and protein expression of the enzymes involved in testosterone metabolism.
Results: Testis and seminal vesicle weight and sperm density had no significant difference among three groups. Sperm motility and viability, percent of sperm positive for high MMP was lower in HFD group than those in NC group. Compared with NC group, percent of sperm with DNA damage in HFD group increased significantly. Exenatide improved sperm motility (63.70±3.32% vs 52.14±3.22%, p<0.05) and percent of sperm positive with high MMP (45.97±2.42% vs 31.16±1.41%, p<0.05), reduced sperm DNA damage (7.17±1.89% vs 13.67±2.14%, p<0.05). The levels of serum testosterone in HFD group were significantly lower than that of NC group (1.02±0.22ng/ml vs 1.83±0.15ng/ml, p<0.05). The levels of serum testosterone in HFD+EX group were comparable with those in HFD group (1.16±0.23 vs 1.02±0.22ng/ml, p>0.05). The mRNA and protein expression of STAR and 17b-HSD were statistically lower in HFD group, which could be reversed by exenatide. In testis tissues of mice, IL-1, TNFa, MCP-1 and F4/80 mRNA expression was significantly higher in HFD group than in NC group. However, these inflammatory cytokines mRNA levels were compared between HFD group and HFD+EX group. The expression of SRD5A1 in liver tissues, an enzyme that reduces testosterone, was significantly higher in HFD+EX group than that in the other two groups.
Conclusion: Our study demonstrated that diet-induced obesity leads to impairment of fertility and leydig cell function in male mice. It also indicated that exenatide treatment improved sperm motility and mitochondrial function of sperm, reduced sperm DNA damage, increased metabolism of testosterone in diet-induced obese C57BL/6J mice.

719

Impaired GLUT4-mediated glucose uptake in skeletal muscle plays a key role in the development of glucose intolerance induced by testosterone deficiency
T. Senmaru, M. Fukui, K. Mitsuhashi, T. Fukuda, H. Okada, M. Tsujikawa, H. Obayashi, M. Tanaka, M. Asano, M. Yamazaki, G. Hasegawa, N. Nakamura;
Department of Endocrinology and Metabolism, Kyoto Prefectural University of Medicine Graduate School of Medical Science, Japan.

Background and aims: Low serum testosterone concentrations are associated with glucose metabolism disorders such as impaired glucose tolerance and type 2 diabetes. However, the precise mechanism of this association is unclear. On the other hand, a high-fat diet (HFD) induces insulin resistance and glucose intolerance in part through impaired insulin signaling and decreased glucose uptake in skeletal muscle. In the present study, we sought to determine whether the mechanism by which testosterone deficiency causes glucose metabolism disorders is through impaired glucose uptake in the skeletal muscle.

Materials and methods: Male C57BL/6J mice aged 7 weeks were either orchiectomized (ORX) or sham-operated (SHAM), and then were fed HFD (507.6 kcal/100 g, fat kcal 56.7%) or standard diet (346.8 kcal/100 g, fat kcal 10%) for 12 weeks starting at 8 weeks of age. Serum testosterone concentrations were analyzed by liquid chromatography-tandem mass spectrometry. Glucose tolerance was assessed by an intraperitoneal glucose tolerance test (IPGTT, 2 g/kg body weight). Gene expression involved in skeletal muscle glucose metabolism was analyzed by quantitative real-time RT-PCR.
Results: Serum testosterone concentrations were not detected in ORX mice. In mice fed standard diet, testosterone deficiency did not affect all metabolic parameters. As expected, HFD increased body weight, subcutaneous and visceral fat mass, fasting blood glucose and serum insulin concentrations in both SHAM and ORX mice. Fasting blood glucose concentrations were higher in ORX mice than SHAM mice (ORX 10.00 ± 1.19 vs SHAM 6.57 ± 0.97 mmol/L, ANOVA $p < 0.0001$, n = 7). In the IPGTT, moreover, blood glucose concentrations at 30, 60 and 120 min after glucose load were significantly higher in ORX mice than SHAM mice (120 min: ORX 30.20 ± 4.54 vs SHAM 25.63 ± 3.95 mmol/L, $p < 0.05$, n =7). Area under the curve for glucose (0 - 120 min) was also higher in ORX mice than SHAM mice ($p < 0.0001$). The expression of GLUT4 was decreased to 1.4-fold by HFD, and further decreased to 2.3-fold by testosterone deficiency. Similarly, the expression of myocyte enhancer factor 2A (MEF2A) and p38 mitogen-activated protein kinase (MAPK) was down-regulated 1.9-fold and 2.2-fold, respectively, both by HFD and by testosterone deficiency. In addition, the expression of TC10, which is a positive regulator of GLUT4 translocation from intracellular site to plasma membrane, was down-regulated in ORX mice fed HFD. These perturbations in ORX mice fed HFD were normalized to the levels of SHAM mice fed HFD by testosterone supplementation. These results suggest that the effect of testosterone is mediated by the p38 MAPK/MEF2 axis, which is a strong inducer of GLUT4 expression.
Conclusion: Decreased GLUT4-mediated glucose uptake in the skeletal muscle due to impaired p38 MAPK signaling pathway may play an important role in the development of glucose intolerance induced by testosterone deficiency. A high-fat diet could be an initiating factor for those changes.

Laparoscopic sleeve gastrectomy ameliorates mRNA expression of inflammation-related genes in subcutaneous adipose tissue but not in peripheral monocytes of obese patients

P. Trachta[1], M. Mraz[1], I. Dostalova[1], Z. Lacinova[1], D. Haluzikova[1], P. Kavalkova[1], M. Kasalicky[2], S. Svacina[1], M. Haluzik[1];
[1]3rd Department of Medicine - Department of Endocrinology and Metabolism, First Faculty of Medicine,, General University Hospital, [2]Surgical Clinic, Military University Hospital, Prague, Czech Republic.

Background and aims: The aim of this two-year prospective interventional study was to determine the effects of laparoscopic sleeve gastrectomy (LSG) on systemic inflammatory markers and the expression profile of genes involved in inflammatory pathways in subcutaneous adipose tissue (SCAT) and peripheral monocytes (PM) in subjects with obesity.
Materials and methods: Thirteen non-diabetic obese females (OB group) and 18 healthy lean sex-matched control subjects (C group) were included into the study. Anthropometric, biochemical and hormonal measurements and adipose tissue sampling were performed at baseline and 6, 12, and 24 months after LSG. mRNA expression of 45 genes involved in inflammatory processes was estimated in SCAT and PM using quantitative real-time PCR.
Results: At baseline, OB group had significantly higher body weight, BMI (22.4 ± 0.5 vs. 42.3 ± 1.1 kg/m^2, p<0.05) and increased serum concentrations of hsCRP (0.42 ± 0.16 vs. 1.45 ± 0.24 mg/l; p<0.05), insulin and proinflammatory cytokines as compared to C group. mRNA expression of macrophage antigen CD68, cytokines (IL-10, IL-18), chemokines (CCL-3, -17, -22) and chemokine receptor CCR1 was increased, whereas the expression of adiponectin receptor 2 (ADIPOR2), JUN proto-oncogene, NFκB2 and vascular endothelial growth factor A (VEGFA) was reduced in SCAT of obese females relative to controls. In PM mRNA expression of CD68, chemokine receptors (CCR-1, CCR-2, CCR-3) and other proinflammatory receptors (TLR-2, TLR-4, TNFRSF1A), macrophage migration inhibitory factor (MIF), ICAM-1, PPARδ and ADIPOR2 were significantly increased in OB relative to C group. After 24 months LSG decreased body weight (BMI 33.0 ± 2.1 vs. 42.3 ± 1.1 kg/m^2; p<0.05) and improved lipid profile (LDL cholesterol 2.37 ± 0.39 vs. 2.76 ± 0.30 mmol/l; p<0.05; TAG 0.95 ± 0.21 vs. 1.71 ± 0.24 mmol/l; p<0.05) without significantly affecting blood glucose (5.18 ± 0.29 vs. 4.99 ± 0.22 mmol/l; p<0.05) or parameters of insulin resistance (HOMA-IR 7.24 ± 1.76 vs. 8.51 ± 1.43; p<0.05). In SCAT, LSG reduced mRNA expression of almost all up-regulated chemokines, chemokine receptors and proinflammatory factors (CCL-3, CCL-17, CCL-22, CCR-1, CCR-4, CD68, IL-1B, IL-18) with maximum changes at month 12 and 24 after the surgery. In contrast, only minimal effect on the proinflammatory expression profile in PM could be seen throughout the whole study period with a persistent increase in mRNA expression of most of the factors including MIF, TLR-2, TLR-4 and other inflammation-related receptors.
Conclusion: In the present study we demonstrate that obese patients have increased mRNA expression of chemotactic and proinflammatory factors in both SCAT and PM. LSG improves this profile in SCAT but not in PM. We suggest that activation of the TLR stress-pathway and increased expression of MIF in PM may contribute to limited effects of LSG on the improvement of insulin resistance. The sustained proinflammatory and chemotactic expression profile in PM even 2 years after LSG may contribute to the persistence and/or possible future re-manifestation of metabolic complications in obese patients after metabolic surgery.

Laparoscopic greater curvature plication improves metabolic control and modulates adipose tissue inflammation in obese type 2 diabetic patients during a 6-month follow-up

J. Drapalova[1], P. Kavalkova[1], K. Dolezalova[2], M. Urbanova[1], P. Trachta[1], Z. Lacinova[1], S. Svacina[1], M. Fried[2], M. Mraz[1], M. Haluzik[1];
[1]3rd Department of Medicine, 1st Faculty of Medicine, [2]OB Klinika a.s., Prague, Czech Republic.

Background and aims: Laparoscopic greater curvature plication (LGCP) is a recently introduced restrictive bariatric procedure reducing gastric volume without the need of resection by invaginating the greater curvature into

the stomach. The aim of our study was to prospectively assess the effects of LGCP on body weight, metabolic parameters and adipose tissue inflammation in obese subjects with type 2 diabetes mellitus (T2DM) during the first 6 months after the operation.
Materials and methods: Eleven T2DM patients undergoing LGCP (T2DM group) and 13 age-matched healthy lean controls (C group) were included into the study. Anthropometric, biochemical and hormonal parameters were measured at baseline, at 1 month and at 6 months after LGCP. Subcutaneous adipose tissue (SCAT) samples were obtained from abdominal region using needle aspiration biopsy. mRNA expression of 44 genes involved in inflammation, immune cell recruitment and tissue remodeling was assessed using quantitative real-time PCR.
Results: After 6 months LGCP substantially decreased body weight (BMI 42.3 ± 2.0 vs. 36.6 ± 2.0 kg/m2, p<0.05), blood glucose (9.88 ± 1.30 vs. 6.96 ± 0.53 mmol/l, p<0.05), HbA1C (63.8 ± 4.7 vs. 56.3 ± 4.2 mmol/mol, p<0.05), lipid profile (total cholesterol 5.48 ± 0.29 vs. 4.61 ± 0.24 mmol/l, p<0.05; triglycerides 3.05 ± 0.72 vs. 1.88 ± 0.28 mmol/l, p<0.05) and low-grade inflammation (hsCRP 4.11 ± 0.76 vs. 2.55 ± 0.90 mg/l, p<0.05). Compared to healthy controls SCAT of T2DM group at baseline showed increased mRNA expression of macrophage markers (CD68, CD11c), proinflammatory cytokines (TNFα), chemokines (CCL-3, -8, -22, CXCL-10), corresponding chemokine receptors (CCR-1,-5, CXCR-3) and tissue remodeling markers (MMP-9, TIMP), whereas the expression of monocyte marker CD14, chemerin and fractalkine (CX3CL1) was decreased. For most factors this expression profile was even more enhanced 1 month after LGCP, while dropping again after 6 months, though only mRNA expression of macrophage antigen CD68, M1 macrophage marker CD11c and M2 marker LYVE1 changed significantly compared to previous values.
Conclusion: During the first 6 months LGCP markedly decreased body weight and improved glucose control, metabolic profile and systemic low-grade inflammation in obese patients with type 2 diabetes mellitus. The increase in SCAT proinflammatory expression profile after 1 month suggests that LGCP-induced weight reduction is initially associated with local adipose tissue stress reaction which is not directly related to systemic parameters and which might be most probably caused by changes in local immune cell content and their phenotype.

Bile acids: key actors of metabolic improvement after gastric bypass?
D. Goncalves, A. Barataud, F. De Vadder, J. Vinera, C. Zitoun, A. Duchampt, G. Mithieux;
Inserm U855, Lyon, France.

Background and aims: Gastric bypass (GBP) makes rapid ameliorations in glucose and energy homeostasis before any weight loss in obese and diabetic patients. The increase in intestinal gluconeogenesis (GNG) has been reported to be a causal factor in these metabolic improvements in a murine model of GBP. Indeed, intestinal GNG causes satiety and potentiates insulin sensitivity. This intestinal glucose production has opposite effects compared to hepatic production, which is associated with deleterious effects such as insulin resistance. Another consequence of GBP is the absence of bile in the alimentary limb, with in parallel an increase in plasma bile acids. The latter are potent inhibitors of GNG. We tested the hypothesis that plasma bile acids might inhibit hepatic GNG, while their absence in the intestinal lumen might lead to an induction of intestinal GNG.
Materials and methods: Bile diversions are performed from bile duct to a mesenteric vein (MV), the mid-jejunum (MJ) or the mid-ileum (MI), in order to mimic different GBP, in standard-diet fed rats. A sham-operated group, which just undergo a laparotomy, is studied in parallel. In order to evaluate the rapid metabolic improvements potentially caused by bile diversions, insulin sensitivity and glucose tolerance tests are performed eight and eleven days after surgeries. The expression of gluconeogenic genes is analysed in both the liver and intestine eight days after surgeries.
Results: All the diversions induce an increase in plasma bile acids (156.5 ± 25.3 µmol/L for MV, 218.8 ± 74.6 µmol/L for MJ, 231.7 ± 69.4 µmol/L for MI vs 19.1 ± 6.5 µmol/L for sham-operated). This high plasma bile acid concentration is associated to a drastic inhibition of hepatic GNG. Indeed, hepatic glucose-6-phosphatase (Glc6Pase) activity is strongly reduced (38.6 ± 3.3 U/g protein for MV, 41.6 ± 4.3 U/g for MJ, 47.5 ± 6.6 U/g pour MI vs 76.2 ± 2.7 U/g for sham), as is its protein expression (about 70% fold decrease for the three diversions). Besides, hepatic mRNA levels of Glc6Pase and phosphoenolpyruvate carboxykinase-c are reduced by about 80 and 50%, respectively, for all diversions. In parallel, the absence of bile in the intestinal lumen leads to an increase in intestinal GNG. For the MV diversion, Glc6Pase activity shows a 1.5 to 2.5-fold increase in the entire intestine. It is induced upstream of the site of bile reinsertion (45.1 ± 6.1 U/g for MJ, 37.9 ± 4.9 U/g for MI vs 24.4 ± 2.2 U/g for sham) and decreased downstream (1.1 ± 0.5 U/g for MJ, 0.1 ± 0.1 U/g for MI vs 4.7 ± 1.7 U/g for sham). Finally, insulin sensitivity and glucose tolerance are markedly improved in mid-jejunum diverted rats.
Conclusion: The only modification of bile routing reproduces the amelioration of glucose metabolism observed after GBP. This improvement is associated with a decrease in hepatic GNG in parallel with an increase in intestinal GNG, in standard-diet fed rats. These results suggest that the regulation of endogenous glucose production by bile acids is a key factor in the metabolic improvements after GBP.

Improvements in insulin sensitivity after gastric bypass is not due to changes in physical fitness
M. Hansen[1], M. T. Lund[1], M. Palsøe[1], A. Floyd[2], J. W. Helge[1], F. Dela[1];
[1]Center of Healthy Aging, University of Copenhagen, [2]Department of Surgery, Koege Hospital, Denmark.

Background and aims: Gastric bypass surgery (GBP) is known to bring 75-80% of type 2 diabetes patients into remission shortly after their operation. We studied insulin sensitivity, body composition and aerobic fitness before and up to 1½ yr after GBP in morbidly obese patients with type 2 diabetes (DM2) and patients with normal glucose tolerance (NGT). The aim was to test if changes in insulin sensitivity were correlated to changes in aerobic fitness. Furthermore, we determined if insulin sensitivity is affected differently by a diet induced or by a GBP induced weight loss.
Materials and methods: 27 subjects (17F/10M, 16NGT/11DM2) were recruited. Subjects were studied 4 times each after a 12h overnight fast: At baseline (A), after 10-12% weight loss (before surgery) obtained by diet induced weight loss (B), 4 months after surgery (C) and 18 months after surgery (D). Each time body composition was measured by Dual X-ray Energy Absorption (DXA) scan followed by measurement of aerobic fitness (maximal oxygen uptake (VO_2max) on a stationary ergometer bike (75W warm-up period, increase 25W/1 min)). On a different test day during the same week, we measured whole-body insulin sensitivity by a hyperinsulinemic (80mU/m²/min) euglycemic clamp.
Results: At baseline body mass index (BMI) and age did not differ between groups. Fasting glucose was significantly (p<0.05) higher (8.6±0.7 vs. 5.4±0.3 mM) and VO_2max (2691±263 vs. 2701±129 ml O_2/min) similar in DM2 vs. NGT, respectively. Baseline (A) Glucose Infusion Rates (GIR) per fat free mass (FFM) were lower in the DM2 vs. NGT (4.2±0.4 vs. 11.1±0.6 mg/min/kg FFM), respectively. Weight loss in NGT vs. DM2 from A-B (6.1±0.6 vs. 5.2±0.8 kg), B-C (22.1±1.1 vs. 26.4±2.6 kg) and C-D (12.6±2.4 vs. 10.0±1.7 kg) was similar in the two groups. In the NGT there was no difference in GIR/FFM from A-B and B-C (p>0.05) - see figure. Remarkably, a weight loss of 28.2±1.3 kg from A to C did not result in increased GIR/FFM in the NGT group. However, after 1½ yr GIR/FFM increased (p<0.05) in NGT. In the patients with DM2 both diet induced weight loss (A-B) and GBP induced weight loss (B-C and C-D) resulted in significantly (p<0.05) increasing GIR/FFM. In contrast to the marked changes in GIR/FFM, aerobic fitness did not differ between the groups at any time (p>0.05) and no significant change was seen at any time A through D (p>0.05).
Conclusion: GBP does not improve GIR/FFM in NGT during the first 4 months postoperatively, even in spite of a marked weight loss. Most likely this is due to an initially relatively well preserved insulin sensitivity. In DM2 the insulin sensitivity improves even by a small weight loss (A-B) and the improvement continues as weight loss continues. However DM2 do not reach same levels of insulin sensitivity as NGT even 18 months after surgery. The improvement in GIR/FFM is not due to increases in peripheral insulin sensitivity resulting from exercise training, as the patients have unchanged VO_2max, indicating that they did not take up exercise after GBP.

GLP-1 Antagonism alters the rate of gastrointestinal transit but not the rate of meal appearance after Roux-en-Y Gastric Bypass in diabetic and non-diabetic subjects

M. Shah[1], J.H. Law[1], F. Piccinini[2], C. Dalla Man[2], M. Sathananthan[1], P.D. Giesler[1], M. Camilleri[3], R.A. Rizza[1], C. Cobelli[2], A. Vella[1];
[1]Endocrinology, Diabetes and Nutrition, Mayo Clinic Rochester, Rochester, USA, [2]University of Padua, Padua, Italy, [3]Gastroenterology, Mayo Clinic Rochester, Rochester, USA.

Background and aims: The contribution of elevated incretin hormones to postprandial glucose metabolism after Roux-en-Y Gastric Bypass (RYGB) has been the subject of some uncertainty. Exendin-9,39, (Exe-9,39) a competitive antagonist of GLP-1 enables examination of its effects on islet hormone secretion and gastrointestinal transit. As part of a study examining the contribution of GLP-1 to the remission of type 2 diabetes after RYGB we studied subjects > 12 months after RYGB together with age and weight-matched controls in the presence or absence of Exe-9,39 infused at 300pmol/kg/min. In addition we studied subjects before and 4 weeks after RYGB randomized to Exe-9,39 or saline.
Materials and methods: Subjects were studied using a standardized triple-tracer mixed meal consisting of 15g of bacon, 1 scrambled egg and 35g of Jell-O labeled with [1-^{13}C]-glucose. [6-^{3}H] glucose was infused intravenously to measure the systemic rate of meal appearance (Meal Ra). Infused [6,6-$^{2}H_2$] glucose enabled measurement of endogenous glucose production (EGP) and glucose disappearance (Rd). The meal was also labeled with ^{111}In-DTPA to enable measurement of gastrointestinal transit. Insulin action (Si) and β-cell responsivity indices (ϕ) were estimated using the oral minimal model.
Results: RYGB resulted in decreased postprandial glucose within 4 weeks of surgery (3.5±0.5 vs. 2.8±0.3 Mol per 6hr, *P*=0.05; 3.0±0.5 vs. 2.5±0.4 Mol per 6hr, *P*=0.02; Exe-9,39 and saline respectively). The net change in glucose concentrations did not differ between groups (*P*=0.39). In contrast, in subjects >1 year after RYGB, Exe-9,39 was associated with increased glycaemic excursion (3.6±0.5 vs. 2.0±0.4 Mol per 6hr, *P*<0.01) due to impaired insulin secretion (13.3±2.5 vs. 19.9±4.2 nmol per 6hr, *P*=0.01). While gastrointestinal transit in controls was unaffected by Exe-9,39, post-RYGB, the % of stomach content emptied at 30 minutes increased (89±4 vs. 79±1%, *P*<0.01) implying accelerated transit by Exe-9,39. Intriguingly, peak MRa was unchanged post-RYGB (157±19 vs. 143±17μmol/kg/min, *P*=0.60) and in control subjects (79±12 vs. 58±12μmol/kg/min, *P*=0.19).
Conclusion: The acceleration of gastrointestinal transit post-RYGB by Exendin-9,39 implies an effect of GLP-1 on gastric emptying even after bypass. However, despite this alteration in transit, together with decreased insulin secretion, no effect on Meal Ra was observed implying differential regulation of meal appearance.

Insulin secretion before and after gastric bypass operation in morbidly obese subjects with and without type 2 diabetes

M.T. Lund[1,2], M. Hansen[1], S. Skaaby[1], S. Dalby[1], A. Floyd[2], J.J. Holst[1], J.W. Helge[1], F. Dela[1];
[1]Department of Biomedical Sciences, University of Copenhagen, [2]Department of Surgery, Koege Hospital, Denmark.

Background and aims: Roux-En-Y gastric bypass (RYGB) may cure 70 % of patients suffering from type 2 diabetes (T2DM) by inducing increased insulin secretion, primarily due to a higher postprandial incretin release, and decreased peripheral insulin resistance due to weight loss. It is likely that the benefit of the operation depend on the remnant β-cell function. Thus patients with little ability to secrete insulin might benefit less than those with a larger secretory capacity. Our aim was to compare insulin secretion after a diet and a RYGB induced weight loss in morbidly obese patients with or without (OB) type 2 diabetes.
Materials and methods: 20 morbidly obese individuals (6M/14F, 10 T2DM/10 OB) were recruited. Subjects reported to the lab thrice: At baseline when assigning for surgery (A), immediately prior to operation after a diet induced weight loss (B) and 4 mo. after RYGB (C). At each visit a 25 g intravenous glucose tolerance test (IVGTT) was performed. Blood samples for determination of insulin were drawn at baseline and frequently for 40 minutes after the injection. First phase insulin response (AIRg) was determined by applying the MINMOD millennium model and total area under the curve (AUC) followed the trapezoidal rule. Two way repeated measures analysis of variance was used to test for significant effect.
Results: Initial body weight (133 ± 6 vs. 123 ± 6 Kg), BMI (44 ± 2 vs. 41 ± 1 Kg/m2) and weight loss (A-B: OB 7 ± 1 and T2DM 6 ± 1 Kg, and B-C: OB 23 ± 1 and T2DM 21 ± 2 Kg) were similar in OB and T2DM, respectively. OB were younger than T2DM (34 ± 3 vs. 44 ± 2 yrs, P < 0.05) had lower fasting insulin at A (P < 0.05) (A: 115 ± 12, B: 94 ± 10, C: 56 ± 6 vs. A: 155 ± 30, B: 115 ± 18, C: 62 ± 8 pM), but similar at test B and C. AIRg decreased significantly postoperatively, but were always higher in in OB, compared to T2DM in whom AIRg did not change throughout the study (A: 4359 ± 861, B: 4029 ± 756, C: 2307 ± 566 vs. A: 774 ± 312, B: 527 ± 166, C: 888 ± 272 pmol/L • 10 min, P < 0.05). Insulin AUC (A: 15350 ± 2251, B: 13670 ± 2397, C: 7641 ± 1553 vs. A: 8774 ± 1205, B: 7078 ± 730, C: 4603 ± 810 pmol/L • 40 min, P < 0.05) was higher in OB than T2DM and decreased postoperatively in both groups.
Conclusion: Insulin secretion patterns prior to and after RYGB were different in OB and T2DM. In OB the markedly decrease in AIRg and AUC clearly is the result of a continuous process starting when weight loss is begun prior to RYGB, i.e. A-B (Figure 1), most likely due to increased peripheral insulin sensitivity. While AUC decreased in T2DM, AIRg was unchanged with weight loss both by diet and by RYGB. Thus in spite of the fact that 8/10 T2DM in the study had remission of their diabetes 4 mo. post-RYGB (e.g. no antidiabetic medicine, normal range fasting glucose and HbA1c) their β-cell dysfunction persisted.

Figure 1. Insulin secretion in morbidly obese subjects with or without type 2 diabetes at baseline (A), after a diet induced weight loss (B) and 4 mo. after gastric bypass surgery.

Implantation of an endoscopically deployed Duodenal-Jejunal Bypass Liner in obese type 2 diabetes subjects: 8 months follow up of ten subjects

Y. Krepak, B. Stratmann, M. Hauber, Y.H. Lee-Barkey, M. Fischer, D. Tschoepe;
Herz- und Diabeteszentrum NRW, Bad Oeynhausen, Germany.

Background and aims: Purpose of this follow up of obese type 2 diabetes mellitus subjects was to evaluate the effect of the duodenal-jejunal bypass liner (DJBL, EndoBarrier®), a 60-cm, impermeable polymer liner anchored in the duodenum to create a duodenal-jejunal bypass, on metabolic parameters in obese subjects with type 2 diabetes.
Materials and methods: Ten subjects with type 2 diabetes (3F, 7M; age 55.5 years (IQR 44.0-59.5); diabetes duration 8.0 years (IQR 6.5-11.3)) and a mean body mass index of 47.1 kg/m2 (IQR 40.6-53.8) were enrolled in a 14 months, prospective, open label study and followed regularly. Endoscopic device implantation was performed under general anesthesia, and the subjects are examined periodically during the next 14 months. This data evaluation presents data from the first eight months follow up.
Results: Implantation procedures were without complications, abdominal pain and nausea were commonly described side effects on the day of implantation. Antidiabetic medication was reduced upon implantation (IM), HbA1c level remained constant during the follow up of 8 months (8M) (IM: 7.65% IQR 6.80-9.15; 8M: 7.70% IQR 6.43-8.87). BMI was lowered significantly (-2.6 kg/m2) (8M: 44.5 kg/m2 IQR 38.4-51.9), body composition changed (fat loss: 3.5%, gain of lean mass: 3.5% (p=ns)). Laboratory values of cholesterol did not change significantly, but liver parameters improved significantly during the follow up: ASAT: IM: 25.0U/l IQR 21.5-41.0; 8M: 22.5U/l IQR 17.0-25.3; p=0.04; ALAT: IM: 34.5U/l IQR 26.8-48.5; 8M: 21.5U/l IQR 11.8-25.8; p=0.04; γGT: IM: 44.0U/l IQR 27.0-76.0; 8M: 25.0U/l IQR 18.3-41.0; p=0.006. Eight subjects took part in the standardized mixed-meal-tolerance tests (500 kcal) and these data were analyzed with focus on GLP-1, Leptin and Ghrelin levels during the evaluation using appropriate ELISA-tests. MMTT took place before implantation, one week later (1W), after 4 months (4M) and after 8 months. Area under the curve analysis was performed and results were compared by repeated measurement ANOVA. Regarding GLP-1 an increase was detectable in the cohort after implantation which was not statistically significant: IM: 293 pmol/l (IQR 170-326), 1W: 319 pmol/l (IQR 286-426), 4M: 285 pmol/l (IQR 134-451), 8M: 328 pmol/l (IQR 290-568). Leptin levels decreased significantly (p<0.05) after 1 week; IM: 1,914 ng/ml (IQR 1,494-6,318), 1W: 1,165 ng/ml (IQR 723-4,558), 4M: 1,323 ng/ml (IQR 1,114-5,377), 8M: 2,137 ng/ml (IQR 1,416-4,228). Ghrelin levels increased non-significantly after implantation: IM: 59,700 pg/ml (IQR 51,350-91,230), 1W: 65,830 pg/ml (IQR 52,230-124,000), 61,160 pg/ml (IQR 56,630-67,150), 8M: 54,700 pg/ml (IQR 33,080-90,750).
Conclusion: The DJBL improves status in obese subjects with diabetes and therefore represents a non-surgical, reversible alternative to bariatric surgery. However, response to the device with regard to weight loss and improvement in diabetes is highly individual. Information from trials including more patients is needed to evaluate the effects in more detail.

727

Influence of severe obesity on circulating endothelial progenitor cells levels and effects of bariatric surgery

A. Ciccarone[1], D. Lucchesi[1], L. Pucci[2], V. Sancho Bornez[1], E. Russo[1], M. Garofolo[1], R. Bellante[1], R. Russo[2], I. Crisci[1], S.G. Popa[3], L. Giusti[1], M. Mota[3], R. Miccoli[1], G. Penno[1], S. Del Prato[1];
[1]Endocrinology and Metabolism, University of Pisa, Italy, [2]Institute of Agricultural Biology and Biotechnology, CNR, Pisa, Italy, [3]Diabetes, Nutrition, Metabolic Diseases Discipline - University of Medicine and Pharmacy, Craiova, Romania.

Background and aims: Endothelial damage and dysfunction are major mechanisms for cardiovascular (CV) morbidity and mortality risk in morbid obesity. The number of circulating endothelial progenitor cells (EPCs), which play an important role in vascular repair and maintenance of the integrity of the endothelial layer, is reduced in obese subjects. Weight loss is associated with reduced inflammation, improved endothelial function and decreased CV risk. Literature on the effect of weight loss on endothelial function and EPCs, however, is scantier. Therefore, we have determined the number of circulating EPCs in subjects with class II-III obesity undergoing bariatric surgery (BS).
Materials and methods: So far, we have enrolled 62 obese subjects (age 51±13 years, range 23-75; BMI 44.0±7.4 kg/m2; 37% class II and 63% class III obesity; M/F 37/63%; 68% DM+ and 32% DM-). Thirty-one healthy subjects (BMI 24.5±2.5 kg/m2) matched for age and gender were evaluated as controls. All subjects are currently regularly followed up after BS and data at 1 (n=20), 6 (n=17), 12 (n=15), and 18 months (n=10) after BS are reported here. Peripheral blood samples were collected and CD34+/KDR+/CD133+ EPCs measured by fluorescence activated cell sorting (FACS) analysis along with metabolic and inflammatory parameters including plasma glucose, insulin, HbA1c, triglycerides, total cholesterol, HDL-C, LDL-C, hs-CRP, fibrinogen, adiponectin, leptin, PAI-1 and IL-6.
Results: At baseline, EPCs were significantly reduced in obese subjects (250±30 cells/ml, M±SE) as compared to controls (484±56 cells/ml, p<0.0001). In the whole cohort, circulating EPCs levels were inversely related to age (r=-0.334; p=0.011), BMI (r=-302; p=0.022), and HbA1c (r=-0.317; p=0.020). Within the obese group, there was no difference in EPCs between males and females (234±39 vs. 260±41, p=0.682), DM+ and DM- (232±32 vs. 289±83, p=0.372), obesity class II and III (220±54 vs. 253±46, p=0.657). As compared to controls, obese subjects had worse metabolic and inflammatory profile. One month after BS (15 DM+ and 5 DM-) BMI and waist circumference were reduced by -6.0±2.1 kg/m2 (p=0.016) and -7.3±2.7 cm (p=0.054), respectively along with improvement in metabolic and inflammatory parameters. On the contrary, EPCs were reduced, thought not significantly, as compared to baseline (168±35 cells/ml; p=0.092). Such a reduction persisted 6 months after BS (216±40 cells/ml) in spite of further reduction in BMI (-13.5±3.3 kg/m2 from baseline; p<0.001) and waist (-17.2±4.1 cm from baseline; p=0.005). However, after 12 months, EPCs increased (343±86 cells/ml, p=0.067; p=0.024 vs. month 1) and remained steady at 18 months (325±58 cells/ml).
Conclusion: Our data confirm that circulating EPCs levels are reduced in morbidly obese subjects with no differences between class II and class III adiposity, and irrespective of the coexistence of diabetes. Body weight loss following BS causes a dual response with an initial reduction followed by a longer-term increase in the number of circulating EPCs. The mechanisms and, more importantly, the clinical implications of these observations require further analysis.

728

Effects of gastric bypass surgery on glucose homeostasis, pancreatic islet and gut morphology, and metabolite profile in a porcine model

N. Wierup[1], P. Spégel[1], M. Ekelund[2], K. Szwiec[3], S. Pierzynowski[3], H. Mulder[1], J. Hedenbro[2], L. Groop[1], A. Lindqvist[1];
[1]Clinical Sciences, Malmö, [2]Department of Surgery, Lund, [3]Department of Cell and Organism Biology, Lund, Sweden.

Background and aims: Gastric bypass (GBP) is currently the most common surgical treatment of obesity. Interestingly, the majority of Type 2 diabetes (T2D) patients display remission of the disease after GBP. The underlying mechanisms behind this remission are not known. We used a porcine model to study how hormonal and metabolite profiles are affected by GBP. In addition we studied the impact of GBP on endocrine cell populations in the gut and pancreatic islets.
Materials and methods: Swedish Landrace x Yorkshire x Hampshire (26±2.5 kg) were operated through an upper midline incision. The gastric pouch (12-15 ml volume) was constructed with staplers using 3-4 cm of the upper stomach. The pouch was carefully completely separated from the remaining main stomach not to interfere with neuromuscular bundles. The jejunal end of the Roux limb (alimentary limb) was brought up and anastomosed to the lowest part of the gastric pouch. GBP-pigs were subjected to oral (OGTT) and intravenous (IVGTT) glucose tolerance tests before and after surgery. Sham-operated, pair-fed pigs served as controls.
Results: During IVGTT GBP-pigs displayed lower glucose (basal levels 2-fold lower) and 2-fold higher insulin levels compared to controls. During OGTT, GBP-pigs displayed 1.5-fold higher glucose and a more rapid and 2.5-fold higher insulin response than controls. In line with this, GBP-pigs had 2-fold higher beta cell mass and, as a sign of beta cell neogenesis, 2-fold higher density of extra-islet beta cells. In addition, insulin and glucagon mRNA was 3-fold higher in GBP-pigs. Further, during OGTT GBP-pigs displayed 3-fold higher GIP levels, whereas GLP-1 levels were unchanged. Furthermore, GBP-pigs displayed elevated density of GIP-producing K-cells, but reduced density of GLP-1-producing L-cells in the gut. Metabolomic analyses revealed a difference in the metabolite pattern between the two groups, mainly explained by the fact that GBP provoked 3.5-fold lower levels of free fatty acids (FFA) and 1.5-3-fold higher levels of branch-chain amino acids (BCAA).
Conclusion: GBP in pigs provokes 1) enhanced insulin secretion and increased beta cell mass. 2) enhanced GIP, but not GLP-1 secretion. 3) increased number of K-cells, but reduced number of L-cells . 4) reduced FFA- and elevated BCAA plasma levels. These responses are all concomitant with improved glycemia.

Variation in the obesity risk gene FTO determines the postprandial cerebral processing of food stimuli

M. Heni[1,2], S. Kullmann[2,3], R. Veit[4], C. Ketterer[1], F. Machicao[2,5], H. Staiger[5,2], H.-U. Häring[1,2], H. Preissl[2,3], A. Fritsche[1,2];
[1]Department of Internal Medicine IV, Tübingen, [2]German Center for Diabetes Research (DZD e.V.), Neuherberg, [3]fMEG Center, Eberhard Karls University, Tübingen, [4]fMEG center, Eberhard Karls University, Tübingen, [5]Institute for Diabetes Research and Metabolic Diseases of the Helmholtz Center Munich at the University of Tübingen, Germany.

Background and aims: Variation in the FTO locus is the strongest known genetic determinant of body weight. FTO is strongly expressed in the CNS. In humans, there is evidence that FTO influences food intake and nutrient-specific food preference. How this gene affects brains' processing of food-related stimuli is unknown. We recently described specific effects of glucose ingestion on the processing of food stimuli. We now investigated how FTO genotype determines these postprandial responses.
Materials and methods: We studied 24 healthy subjects genotyped for FTO SNP rs8050136. Age, gender and BMI were comparable in risk and non-risk-allele carriers (all p≥0.5). Participants were examined at three time points (0, 30, and 120 minutes) after ingestion of 75g glucose solution or water on two days in a randomized order using functional magnetic resonance imaging (fMRI) during visual food picture presentation.
Results: We detected significant differences between FTO genotypes in the prefrontal cortex 30 minutes post-glucose load to food pictures (p=0.0017), while no differences were detected after water ingestion. Non-risk allele carriers responded with a slight increase to glucose intake, while obesity-risk allele carriers showed a significant reduction. Because we previously found this specific area to be insulin responsive, we analyzed possible interactions between FTO genotype and changes in insulin levels after glucose intake. Interestingly, none such interactions were present (ANCOVA p=0.6). Accordingly, prefrontal response differed between FTO genotypes independent of insulin levels (p=0.0003).
Conclusion: Since the prefrontal cortex plays a central role in the inhibitory control of eating, we propose that reduced post-load activity in risk allele carriers contributes to overeating and their risk for obesity. Our findings help to understand how genetic variation influences body weight via the brain.

Six weeks of hypercaloric high-fat-high-sugar snacking decreases diencephalic serotonin transporters, but not dopamine transporters, in lean men

K.E. Koopman[1], J. Booij[2], E. Fliers[1], M.J. Serlie[1], S.E. la Fleur[1];
[1]Endocrinology & Metabolism, [2]Nuclear Medicine, AMC, Amsterdam, Netherlands.

Background and aims: Brain dopamine and serotonin systems are affected in obese subjects. We recently found a decrease in serotonin transporter (SERT) immunoreactivity in hypothalamic post-mortem tissue of overweight compared to lean subjects which is in line with a previously described negative correlation between cerebral SERT and BMI. We furthermore found a decrease in striatal dopamine D2/3 receptor availability in morbidly obese women, also in line with a previously described negative correlation between brain dopamine and BMI. Both dopamine and serotonin are involved in food intake regulation, but whether changes in serotonin and dopamine in obesity are related to eating behaviour or absolute body weight is unclear. We hypothesized that brain serotonin and dopamine systems are altered by both macronutrient content and eating pattern during a hypercaloric diet.
Materials and methods: Twenty five lean male subjects (age: 22.1yrs±2.5; BMI: 22.5±1.3 kg/m2) followed a hypercaloric diet with 40% caloric surplus on top of their regular diet for 6 weeks. Subjects were randomised into a high-fat-high-sugar (HFHS) diet or a high-sugar (HS) diet group. Within the HFHS- and the HS-group, subjects consumed the caloric surplus with meals (increase in meal size) or in between meals (increase in meal frequency). We also included a control group (N=5) who did not follow a diet. At baseline and after 6 weeks subjects underwent SPECT imaging using the well-validated radiotracer 123I-FP-CIT to measure SERT and dopamine transporter (DAT)

availability in the diencephalon ((hypo)thalamus) and striatum, respectively. Specific-to-nonspecific binding ratios (SNS-BR) were calculated and used as the outcome measure.
Results: Weight gain was significantly increased to the same degree in all diet groups, yet BMI remained within normal ranges (19-25 kg/m2) in almost all subjects. SERT SNS-BR in the diencephalon decreased significantly only in the HFHS-group with increased meal frequency. Striatal DAT SNS-BR was not altered by any of the hypercaloric diets. None of the measurements were changed in the control group.
Conclusion: The reduction in SERT was only found in the HFHS group with increased meal frequency. A low SERT was previously shown to be associated with obesity. Our finding suggests that specifically snacking high-fat-high-sugar products induces changes in the human brain and may predispose to a disturbed food intake resulting in obesity.

Increasing HOMA-IR modulates brain responses to meal ingestion in insulin sensitive men: a continuous arterial spin labelling functional magnetic resonance imaging study
Y.S. Cheah[1], S. Lee[1,2], B.M. Wilson[1], L.J. Reed[3], M.J. Brammer[2], F.O. Zelaya[2], S.A. Amiel[1];
[1]Diabetes Research Group, Division of Diabetes and Nutritional Sciences, King's College London, [2]Centre for Neuroimaging Sciences, Institute of Psychiatry, King's College London, [3]Centre for Mental Health, Division of Brain Sciences, Imperial College London, UK.

Background and aims: Functional neuroimaging has demonstrated altered brain responses to food and food cues in type 2 diabetes and obesity, which may persist despite weight loss. Dysregulation of the neural networks that control appetite may therefore play an aetiological role in these insulin resistant conditions. We explored the impact of early systemic resistance to insulin on brain responses during meal ingestion.
Materials and methods: Twenty healthy right-handed non-obese men (mean age 33.6±7.7 years, BMI 24.5±1.9 kg/m^2), with no family history of diabetes, with normal glucose tolerance and without formal insulin resistance (HOMA-IR<2, median 0.88, range 0.35-1.81) were studied twice in random order. Regional cerebral blood flow (rCBF), a surrogate marker of brain activation, was measured using continuous arterial spin labelling magnetic resonance imaging (cASL MRI) in a 1.5T MRI scanner, immediately before (-14 to -8 minutes) and after (0 to +6, +8 to +14, and +34 to +40 minutes) consuming 50ml water or 630 kcal mixed meal following an overnight fast. Subjective measures of appetite were collected using 100-point visual analogue scale with concurrent blood sampling before and after each cASL scan, and net incremental area under curves (iAUC) calculated. ANOVA and multiple regression analysis to calculate whole brain statistical parametric maps of rCBF were performed using SPM-8.
Results: The meal significantly reduced hunger (mean net iAUC, water vs meal: +296.7±85.6 vs -843.6±188.6 point•min, p<0.001) and increased fullness scores (-17.6±58.6 vs 711.2±159.0 point•min, p<0.001), with no correlation with HOMA-IR. The change in rCBF after the meal was of significantly greater magnitude than that after water ingestion in orbitofrontal cortex (OFC, Brodmann area [BA] 10), right dorsolateral prefrontal cortex (DLPFC, BA9), thalamus, pre-central gyrus and precuneus (main effect of meal, voxel wise p<0.001 uncorrected). Multiple regression analysis, correcting for age and BMI, showed no correlation between HOMA-IR and any change in rCBF after water ingestion. However, HOMA-IR was positively associated with change in rCBF between +34 to +40 minutes after meal ingestion, when insulin concentration was at its peak (mean insulin, water vs meal: 4.1±0.5 vs 20.8±3.3 mU/L, p<0.01 corrected), in the left primary gustatory cortex (operculum), superior frontal gyrus (BA9) and OFC (BA11), supplementary motor area (BA6) and bilateral middle occipital gyrus (BA19) (voxel wise p<0.005 uncorrected).
Conclusion: In healthy men, meal ingestion elicits significant changes in the activity of brain networks that relay somatosensory and taste signals (thalamus) to regions involved in the representation of the hedonic experience of food (OFC) and inhibitory control of eating (DLPFC). Yet minor changes in systemic insulin resistance, short of any pathology, may also independently influence meal-induced activity in brain regions involved in processing taste perception and interoception (primary gustatory cortex) and hedonic experience of food (OFC) in ways that may promote continued eating after a meal and subsequent weight gain.

The brain's response to food ingestion in insulin sensitive and insulin resistant obesity: a [^{18}F]-fluorodeoxyglucose positron emission tomography (FDG-PET) study
K.F. Hunt[1], J.T. Dunn[2], A.M. Pernet[1], L.J. Reed[3], P.K. Marsden[2], S.A. Amiel[1];
[1]Diabetes Research Group, Diabetes and Nutritional Sciences Division, King's College London School of Medicine, [2]Imaging Sciences, King's College London School of Medicine, [3]Neuropsychopharmacology Unit, Imperial College, London, UK.

Background and aims: Insulin resistance is associated with obesity. We hypothesised that differences in the brain's response to food ingestion in obesity might be associated with insulin resistance rather than obesity itself. Aim: To investigate the effects of obesity with and without insulin resistance on the brain's response to food ingestion using FDG-PET functional neuroimaging.
Materials and methods: Three groups have been studied: 12 normal weight insulin sensitive people (NWIS, age 32.3±9.3 years, BMI 22.3±1.4kg/m^2, HOMA2IR 0.54±0.16); 9 obese insulin sensitive (ObIS, age 32.7±10.1 years, BMI 33.8±2.6kg/m^2, HOMA2IR 0.56±0.11) and 12 obese insulin resistant (ObIR, age 29.8±11.2 years, BMI 34.3±2.7kg/m^2, HOMA2IR 2.03±0.59). Individuals underwent FDG-PET brain imaging on 2 occasions in random order after an overnight fast: once FED (400kcal meal 15mins prior to FDG injection) and once FASTED (no calorie intake). Brain FDG uptake, a marker of neuronal activation, was compared using Statistical Parametric Mapping. Satiety was assessed using visual analogue scales and a post-scan *ad-libitum* meal.
Results: Across all groups, the FED state was associated with increased fullness scores at 10mins (p<0.001) and reduced food consumption in the post scan *ad-libitum meal* (-180±37kcal, p<0.001) with no significant difference between groups. In NWIS the FED, compared to FASTED, state was associated with increased (cluster-level corrected p<0.05) FDG uptake in the hypothalamus, regions involved in reward (ventral striatum) and interoception (anterior inferior insula) and the cerebellum and decreased FDG uptake in regions involved in inhibitory control (anterior medial frontal cortex, MFC, and dorsolateral frontal cortex, DLFC), interoception, sensory integration and reward (superior insula and lateral orbitofrontal cortex, OFC) and resting state network (precuneus and angular gyrus). There were differences between the three groups in the brain's response to food ingestion (rmANOVA p<0.015, cluster size>50 voxels) in regions involved in reward (globus pallidus, lateral OFC), interoception (anterior inferior insula/frontal operculum), inhibitory control (anterior MFC, posterior DLFC), and resting state network (precuneus, angular gyrus). Both obese groups, compared to NWIS, showed attenuated deactivation in response to food ingestion in inhibitory control regions (anterior MFC and posterior DLFC) (p<0.005, cluster size>50 voxels). ObIR, compared to NWIS, also showed increased activation in the insula and attenuated deactivation in lateral OFC and resting state network that was not seen in ObIS. ObIR showed increased activation in globus pallidus and insula compared to ObIS.
Conclusion: Obesity is associated with attenuated responses to food ingestion in regions involved inhibitory control. However, only insulin resistant obesity is associated with differences in the brain's response to food ingestion in regions involved in interoception and reward. Insulin resistance-associated differences in appetite control may contribute to the obesity of the metabolic syndrome.

Early Alzheimer-type dementia and type 2 diabetes: analysis using Voxel-based specific regional analysis system for Alzheimer's disease (VSRAD)
M. Yoshida[1], N. Yamamoto[1], E. Ohshima[1], A. Saeki[1], M. Sugino[1], T. Kuzuya[2], N. Ohsawa[2], S. Yoshida[3], T. Hanafusa[4];
[1]Internal Medicine, Aino hospital, Ibaraki City, [2]Aino Aging Institute, Ibaraki, [3]Yoshida Clinic, Otsu, [4]Internal Medicine I, Osaka Medical College, Takatsuki, Japan.

Background and aims: Diabetes is known to be a risk factor for Alzheimer's disease (AD).Hyperglycemia itself and insulin resistance are suggested to be the underlying mechanisms. Voxel-based specific regional analysis system for Alzheimer's disease (VSRAD) is the software of automatic image processing which enables statistical analysis of the degree of parahippocampal cortex atrophy and is widely used for early diagnosis of AD in Japan. The purpose of this study is to assess the factor related with the development of early AD in patients with diabetes using VSRAD.

Materials and methods: We studied 121 out-patients with type 2 diabetes over 60 years old (Age 71.1±8.8 years, male 58/female 63, HbA1c 6.9±1.0 %) before and after 5 years of ordinal diabetic treatment. The patients were divided into four groups according to the degree of atrophy with VSRAD, 0-1: little, 1-2: moderate, 2-3: considerable, 3-: marked atrophy. BMI, insulin resistance, glucose/lipid metabolism, and diabetic complications were also assessed in the patients.
Results: The degree of atrophy advanced from 1.59±1.22 to 1.79±1.29 during a 5-year study period. Compared with patients with little atrophy, 32 patients with more than 0.2 advanced degree showed significantly older age (70.8±8.8 vs 70.0±8.8 years old, p=0.012), higher HbA1c (7.0±0.9 vs 6.6±0.7%, p=0.038), and higher 2-hour-postprandial plasma glucose (224±71 vs 190±53 mg/dl, p=0.018). No significant difference was seen between the two groups in the duration of diabetes, fasting plasma glucose, blood pressure, BMI, LDL, HDL, triglyceride, creatinine, or uric acid. Patients in the groups of more severe atrophy had significantly higher incidence of hypoglycemia (more than three times / month, p=0.033) and higher prevalence of visceral obesity (p=0.013). No significant relation was seen between the atrophy and the presence of diabetic retinopathy / nephropathy / neuropathy, cerebrovascular disease, coronary artery disease, arteriosclerosis obliterans, hypertension, dyslipidemia, or the smoking.
Conclusion: Hypoglycemia and postprandial plasma glucose, and HbA1c were suggested to be related with the development of early AD in patients with type 2 diabetes.

Does sleep loss induce diabetes?
S. Harada[1,2], S. Chikahisa[1], N. Shimizu[1], T. Shiuchi[1], H. Séi[1];
[1]Department of Integrative Physiology, Institute of Health Biosciences,
[2]Student lab, Faculty of Medicine, The University of Tokushima, Japan.

Background and aims: Sleep/wake regulatory system and energy metabolism are intertwined each other. Strong associations of diabetes with sleep impairment have been reported. For example, it has been known that an attenuation of slow-wave activity (SWA, power density of the EEG delta band between 0.5 and 2.0 Hz in human), a parameter of sleep pressure, during non-rapid eye movement (NREM) sleep can decrease insulin sensitivity and glucose tolerance in humans. However, the mechanisms for the interaction of sleep loss with diabetes are still unknown.
Materials and methods: In the present study, we investigated whether sleep loss by rearing on different environment would induce diabetes in mice. Male ICR mice (8-week-old) were randomly assigned to two groups to be reared on either normal sawdust (control) or wire net. After 2 weeks of rearing in a different environment, sleep recording, glucose tolerance test (GTT, 2 g/kg) and insulin tolerance test (ITT, 1 U/kg) were performed.
Results: Mice reared on wire net showed a decreased amount of NREM sleep in the dark period and an attenuated SWA (0.5 - 4.0 Hz) during NREM sleep in the light period compared with that of control mice. These sleep-disrupted mice showed an impaired glucose tolerance measured by GTT, although the response to ITT was similar to that of control mice. Plasma insulin response to glucose (2 g/kg) was also disrupted in mice reared on wire net. There was no significant difference in plasma concentration of corticosterone between the two groups. Interestingly, rearing on wire net for 1 week did not induce an impaired glucose tolerance, while it already attenuated SWA during NREM sleep.
Conclusion: These results suggest that sleep loss may induce diabetes via abnormality of insulin secretion in mice. Our data indicate that sleep quality is important for energy metabolism.

Effect of feeding rhythm on sleep/wake regulation
K. Oura[1,2], T. Shiuchi[1], N. Shimizu[1], S. Chikahisa[1], H. Séi[1];
[1]Department of Integrative Physiology, Institute for Health Biosciences,
[2]Student Lab, Faculty of Medicine, The University of Tokushima, Japan.

Background and aims: Disturbance of feeding rhythm has been understood as a risk factor for development of insulin resistance, however, it is not elucidated the detailed mechanism for the effect on sleep/wake regulation. We thus investigated whether different feeding rhythm only during dark period affects sleep/wake regulation without a significant change in amount of food intake.
Materials and methods: Three groups of C57BL/6J mice were given lab chows freely during dark period (ZT12-24, Control group), first half of dark period (ZT12-18;Morning group), or last half of dark period (ZT18-24, Evening group) for 2 weeks respectively. A telemetric device for recordings of body temperature and locomotor activity was implanted in the peritoneal cavity of mice. Two stainless steel miniature screw electrodes were implanted in the skull to record the electroencephalogram (EEG). Teflon-coated stainless steel wires were implanted in the neck muscles on both sides to record the electromyogram (EMG). Flexible cables connected the mice to a polygraph and computer-assisted data acquisition system. Off-line sleep scoring was done on the computer screen by visual assessment of the EEG and EMG activities, thereby distinguishing phases of wake, rapid eye movement (REM) and non-REM (NREM) sleep. The EEG delta and theta frequency band was set at 0.5-4.0Hz and 4.0-7.8Hz, respectively. In this study, power density of the EEG delta (ratio of delta to theta) during NREM sleep was used as a parameter of sleep pressure (slow-wave activity, SWA).
Results: Mice in Evening group showed lower SWA than that of other 2 groups. On the other hand, an amount of NREM, REM and wake in 3 groups did not change. We observed higher monoamine concentrations (serotonin, dopamine and its metabolites), which activates wake system, in cerebral cortex in Evening group. We also found increased mRNA expression of orexin in hypothalamus in Evening group. Body weight in Evening group increased similar with Control group whereas body weight in Morning group did not change during 2 weeks. There were no differences in food intake, locomotor activity and body temperature during 24 hours among 3 groups.
Conclusion: These results indicate that feeding only in the last half of dark period alters sleep homeostasis. This effect may be partly involved in increase of orexin expression in hypothalamus and elevated monoamine concentration in cerebral cortex.

736

The effects of brain insulin action on hepatic glucose metabolism, glucagon secretion and lipolysis in the absence of somatostatin infusion
D.S. Edgerton[1], G. Kraft[1], M. Smith[1], B. Farmer[1], D.W. Neal[1], P. Williams[1], C.J. Ramnanan[2], A.D. Cherrington[1];
[1]Molecular Physiology and Biophysics, Vanderbilt University Medical Center, Nashville, USA, [2]Department of Cellular and Molecular Medicine, University of Ottawa School of Medicine, Ottawa, Canada.

Background and aims: Previous studies suggest that insulin action in the brain of rodents can acutely inhibit hepatic glucose production, glucagon secretion, and lipolysis. In contrast, increasing brain insulin action in dogs did not inhibit glucose production. In those studies, we used the pancreatic clamp technique, which employs somatostatin infusion, and portal vein hormone replacement to control hormones. This raises the possibility that somatostatin may have impaired the impact of brain insulin action on the liver. In this study we used the dog to examine brain insulin effects in the absence of somatostatin.
Materials and methods: Each animal underwent liver catheterization (femoral artery; portal and hepatic veins) and cannulation of the 3rd ventricle (ICV) two weeks prior to study. After a basal sampling period (-30 to 0 min), artificial cerebrospinal fluid (aCSF; n=5) or the PI3K inhibitor LY294004 (to block brain insulin action; LY; n=6) was infused ICV (0-300 min) in fasted conscious dogs. After 60 min, insulin was infused into the hepatic portal vein (1.8 mU/kg/min; ~6-fold basal), while euglycemia was maintained using glucose infusion.
Results: Intraportal insulin infusion elevated hepatic and non-hepatic (including the brain) insulin levels 6-fold in both groups. The decreases in hepatic sinusoidal plasma glucagon levels did not differ in the presence or absence of increased brain insulin signaling (Δ 79±18 vs 58±11%, p=0.32, aCSF vs LY, respectively). The equal suppression in blood glycerol (Δ 50±9 vs 52±6%; p=0.90) and plasma NEFA (Δ 86±4 vs 88±3%; p=0.64) indicate that brain insulin action did not affect lipolysis or fatty acid reesterification. Likewise, insulin in the brain did not affect the time course or magnitude of insulin's effects on glucose turnover or GIR. The suppression of endogenous glucose Ra (Δ 65±9 vs 57±4%; p=0.50), the increase in whole body Rd (Δ 3.8±0.7 vs 4.7±0.5 fold; p=0.33), and the rate of net hepatic glucose uptake (0.36±0.23 vs 0.49±0.11 mg/kg/min; p=0.60) did not differ whether or not brain-liver insulin action was blocked. At the end of the study there was no difference in insulin signaling at the liver in the two groups (hepatic pAkt / total Akt ratios increased equally; p=0.41). On the other hand, brain-liver insulin signaling was blocked by inhibition of PI3K in the brain as indicated by abolition of the insulin induced increase in the ratios of hypothalamic pAkt

/ total Akt (1.7±0.1 vs 1.0±0.1 fold relative to a basal insulin control group; p<0.01) and hepatic pSTAT3 / total STAT3 (2.0±0.5 vs 0.7±0.5 fold; p<0.01) in the LY group.
Conclusion: A 6-fold rise in brain insulin action had no impact on insulin's ability to inhibit hepatic glucose metabolism, glucagon secretion, or lipolysis. Therefore, the presence of somatostatin does not explain the lack of brain insulin effect on hepatic glucose production seen in our earlier studies. The inability of brain insulin action to acutely modify glucose production in the dog is in contrast to its ability to do so in the rodent. This suggests that neural control of the liver is enhanced in rodents or it may reflect the constraints put on experimental design in the rodent because of its size.

Alx3 deficient mice exhibit hypothalamic dysfunction and altered energy expenditure
A. Fernández-Pérez[1,2], M. Mirasierra[1,2], B. Lizarbe[1], S. Cerdán[1], M. Vallejo[1,2]; [1]Instituto de Investigaciones Biomedicas Alberto Sols, [2]Ciber de Diabetes y Enfermedades Metabólicas Asociadas, Madrid, Spain.

Background and aims: Although glucose-stimulated insulin release from pancreatic islets as well as insulin-induced glucose clearance by the liver, muscles and adipose tissue play a central role in the control of glucose homeostasis, it has long been recognized that glucose- and hormone-sensitive neurons located within hypothalamic nuclei also participate in this process operating as a metabolic hub to coordinate the regulation of glucose homeostasis, feeding and energy expenditure. Despite the functional importance of these neurons, the molecular mechanisms by which they control glucose and energy homeostasis are poorly understood. Previous work in our laboratory demonstrated that the aristaless-type homeodomain transcription factor Alx3 is important for the systemic control of glucose homeostasis. Although many phenotypic features of Alx3 deficient mice can be largely correlated with its absence from pancreatic islets, where it is normally expressed, alterations due to defects in extrapancreatic Alx3-expressing cells cannot be ruled out. In the present study, we investigated whether Alx3-deficient mice show phenotypic features that can be correlated with altered hypothalamic function.
Materials and methods: Alx3 knock out and control mice of similar age and body weight were used. Indirect calorimetry was determined using calorimetric cages (Phenomaster, TSE Systems GmbH, Bad Homburg, Germany). Body mass composition was analyzed by MRI. PET was used to monitor the uptake of 18F-Fludeoxyglucose (~300 μCi/mouse i.p.) in the brain. Hypothalamic activity following fasting or feeding periods was evaluated through changes in the ADC (Apparent Diffusion Coefficient) values by functional diffusion weighted magnetic resonance imaging. Expression of Alx3 in the central nervous system was examined by RT-PCR, western blot and immunohistochemistry. Statistical significance was considered for p<0.05.
Results: We confirmed that fasting glucose levels were significantly higher in mutant than in control mice. Alx3-deficient mice exhibited reduced whole energy expenditure and oxygen consumption, and their respiratory exchange rate was also lower than that of control mice. In addition, food and water intake was reduced in Alx3-null animals. No differences were found in locomotor activity. No differences in the uptake of 18F-Fludeoxyglucose were found in any of the brain regions tested, except in the hypothalamus, where tracer uptake was significantly reduced. ADC values in Alx3-deficient mice were significantly lower that those found in control animals both in the fasting and the feeding state. Fasting (16 h) induced significant ADC changes in the arcuate (ARC) and dorsomedial (DMN) hypothalamic nuclei in wild type animals consistent with neuronal activation. No effects were detected in the ventromedial nucleus (VMN). In contrast, in Alx3-deficient mice, no differences were found in ARC whereas similar changes were observed in DMN.
Conclusion: Our data support the notion that Alx3 expressed in the hypothalamus contributes to the regulation of glucose homeostasis and to the control of energy expenditure.

Insulin action in the brain depends on whole-body insulin sensitivity
T. Sartorius[1,2], M. Heni[2], P. Schöpfer[3,4], A. Peter[2], A. Fritsche[1,2], M. Synofzik[3,4], H.-U. Häring[1,2], W. Maetzler[3,4], A.M. Hennige[2];
[1]Institute for Diabetes Research and Metabolic Diseases (IDM) of the Helmholtz Center Munich at the University of Tübingen, [2]Division of Endocrinology, Diabetology, Vascular Disease, Nephrology and Clinical Chemistry, University of Tübingen, [3]Department of Neurodegenerative Diseases, Hertie Institute for Clinical Brain Research, [4]German Center for Neurodegenerative Diseases (DZNE), Tübingen, Germany.

Background and aims: Insulin action in the brain determines food intake, physical activity and finally glucose homeostasis. In particular, insulin improved brain activity and promoted locomotion in lean humans and mice while obese individuals are characterized by impaired insulin action in the brain and physical inactivity. As insulin enters the brain in a receptor-mediated fashion, we hypothesized that whole body insulin resistance might affect the transport of insulin into the brain with impacts on brain activity and locomotion.
Materials and methods: In mice, insulin was applied for four consecutive days by subcutaneous injection (1 unit/kg body weight), and assessment of cortical activity and locomotion in whole-body insulin-sensitive and -resistant C57BL/6 mice were performed by radiotelemetry recordings. Moreover, twenty-two healthy human subjects participated in an oral glucose tolerance testing (oGTT) to determine whole body insulin sensitivity and underwent lumbar puncture to measure insulin and glucose concentrations in the cerebrospinal fluid (CSF).
Results: Subcutaneous insulin injection on four consecutive days did not affect blood glucose or body weight. In insulin-sensitive mice, brain activity was significantly increased in the theta, alpha and beta frequency bands (theta: by 10.0±2.8%; alpha: by 12.3±2.0%; beta: by 11.7±1.4%; P<0.05; n=10/group) while this was not present in insulin-resistant animals. In addition, locomotor activity was significantly increased by 32.4±3.7% (P<0.001) during the insulin treatment period in insulin-sensitive mice but not in those with insulin resistance. Interestingly, when insulin was intracerebroventricularly applied into insulin-resistant animals it increased brain activity in abovementioned frequency bands (alpha: by 18.9±3.5%; beta: by 11.1±2.0%; P<0.005; n=8/group). In humans, blood and CSF concentrations of glucose and insulin were significantly correlated (glucose: P=0.008; insulin: P=0.021). The CSF/serum ratio for insulin was significantly associated with whole body insulin sensitivity (P=0.01, r2=0.4) with reduced insulin transported into the CSF in insulin-resistant subjects, while this was not true for glucose (P=0.3).
Conclusion: Physiological doses of insulin improve brain activity and locomotion in insulin-sensitive mice. However, impaired transport of insulin across the blood-brain-barrier (BBB) contributes to the absent response in insulin-resistant animals which can be in part overcome by an intracerebroventricular injection. This is well in line with our human data where insulin transport into the CSF was impaired in whole-body insulin-resistant subjects. Together, our data point toward a major contribution of insulin resistance at the BBB in the pathophysiology of brain insulin resistance. This underlines the need for sensitizing measures accompanying insulin therapy in insulin resistant patients.

The interleukin-1 receptor antagonist anakinra improves beta cell function in subjects with impaired glucose tolerance

P.C.M. van Poppel, E.V.A. van Asseldonk, M.G. Netea, C.J. Tack;
Radboud University Medical Centre, Nijmegen, Netherlands.

Background and aims: A defect in insulin secretion underlies type 2 diabetes, and is progressive over the course of the disease. The underlying mechanisms are not completely elucidated, but inflammation at the level of the β-cell seems to be involved. The inflammatory response may be fuelled by lipotoxicity or hyperglycaemia and strong evidence has emerged for the involvement of interleukin (IL)-1 β in this process. Blocking the effects of IL-1 in patients with type 2 diabetes mellitus by anakinra, a recombinant human IL-1 receptor antagonist, has been shown to improve glycaemic control by enhanced β-cell function. However, subsequent studies have not confirmed a beneficial effect of other interventions aiming at blocking IL-1 β. We hypothesised that IL-receptor blockade by anakinra would be capable to improve β-cell function in subjects with impaired glucose tolerance.
Materials and methods: The study population consisted of 16 first-degree relatives of patients with type 2 diabetes mellitus who had abnormal glucose tolerance according to ADA criteria including impaired fasting glucose (IFG), impaired glucose tolerance (IGT) assessed by 75 g oral glucose tolerance test, or HbA1c levels of 5.7-6.4%. In a randomised, double-blind, placebo-controlled crossover study subjects were treated with anakinra 150 mg subcutaneously once daily for 4 consecutive weeks or placebo sc once daily for 4 consecutive weeks. After a wash-out period of 4 weeks subjects crossed over to the other treatment arm. At the end of each treatment period β-cell function was assessed by hyperglycaemic clamp and an oral glucose tolerance test was performed.
Results: Eighteen of the 37 initially screened subjects underwent randomization. Of these 18 one subject withdrew before start of the study medication. One participant withdrew in the first treatment period due to discomfort of injection site reaction during the use of anakinra. A total of 16 participants, 6 females and 10 males, completed the trial. Anakinra treatment siginificantly reduced CRP levels, leukocyte and neutrophil counts. Fasting fasting glucose levels (anakinra 5.48±0.17 vs placebo 5.48±0.25 mmol/l) and HbA1c levels (anakinra 5.60±0.11 % vs placebo 5.74±0.11%, P = 0.068) were not significantly different during anakinra. During the hyperglycaemic clamp the glucose levels were nearly identical in both treatment periods (anakinra 9.98± 0.04 mmol/l vs placebo 10.02±0.04 mmol/l respectively, P = 0.43) and mean CV of the hyperglycaemic clamp was below 4 % in both treatment periods. First phase insulin secretion improved after anakinra treatment compared to placebo, 148±20 vs 123±14 mU/l respectively (P = 0.03). In line with these results, the insulin disposition index derived from the oral glucose tolerance tests was lower during anakinra. Second phase insulin secretion, insulin response after arginine stimulus and maximal insulin secretion, did not differ between the two treatment arms. Anakinra had no effect on insulin sensitivity index.
Conclusion: Four weeks treatment with anakinra improves β-cell function in first degree relatives of patients with type 2 diabetes who have IFG and/or IGT supporting the concept of involvement of IL-1β in the (progressive) decrease of insulin secretion capacity associated with type 2 diabetes.

PS 053 Inflammation in obesity and type 2 diabetes

740

Activation of the inflammasome in glomerular cells aggravates experimental diabetic nephropathy

K. Shahzad[1], F. Bock[1], C. Wacker[1], H. Wang[1], S. Ranjan[1], J. Wolter[1], S. Stoyanov[2], K. Reymann[2], M. Thati[1], B. Isermann[1];
[1]Uniklinikum Magdeburg, Institute for Clinical Chemistry and Pathochemistry, [2]Uniklinikum Magdeburg, Leibniz Institute for Neurobiology, Magdeburg, Germany.

Background and aims: Apoptosis and inflammation are both associated with the progression of diabetic nephropathy (dNP) and both can be triggered by mitochondrial dysfunction or ROS-generation, key culprits diabetic complications. NLRP3-inflammasome-triggered inflammation leads to pyroptosis which can be technically difficult to distinguish from apoptosis, leaving the question open, whether apoptosis or pyroptosis has a prevailing role during dNP. To evaluate this question we inhibited apoptosis or inflammation/pyroptosis and directly compared the functional consequences in vivo. .
Materials and methods: The role of apoptosis and the inflammasome in dNP was analyzed in murine models of type 2 (db/db) and type 1 (streptozotocin [STZ] with or without uninephrectomy) diabetes. Diabetic nephropathy was quantified based on albuminuria, histological changes (fractional mesangial area, FMA), and biochemical markers of dNP. Expression levels and proteolytical processing of caspase-1, IL-18 and IL1b was determined by immunoblotting. A subset of mice was injected with anakinra, an IL-1 receptor antagonist, a caspase inhibitor (Casp-3,6,7,8,9), or minocycline, a tetracycline derivate known to stabilize mitochondria. To determine the role of the inflammasome in bone-marrow derived versus tissue resident cells we transplanted bone marrow from Nlrp3-/- mice into db/db or STZ DM. In addition, diabetic mice deficient for the mitochondrial RedOx-enzyme p66shc were analyzed. In vitro NLRP3-WT and mutated NLRP3 (Q705K), a constitutive active NLRP3 mutant, were retrovirally transduced into human endothelial cells or podocytes, followed by the assessment of IL-1b and IL-18 levels by immunoblotting.
Results: In renal cortex extracts of diabetic mice, but not of control mice, an increase of Nlrp3 expression, caspase-1 activation, and maturation of IL-1b and IL-18 was observed. NLRP3-/- or caspase1-/- mice as well as anakinra and minocycline (but not caspase inhibitor) treated mice were protected against dNP. Double/triple confocal immunofluorescence for podocyte/endothelial markers revealed that inflammasome activation (Nlrp3 expression, caspase-1 / IL-1b maturation) is enhanced in glomerular cells (podocytes and endothelial cells) of diabetic mice. The severity of dNP was unchanged in bone marrow chimeras (Nlrp3-/- à db/db or wt à db/db), demonstrating that inflammasome activation in tissue resident cells is sufficient to promote dNP. In diabetic p66Shc-/- mice ROS-makers and inflammasome activation were reduced and these mice were protected against diabetic nephropathy. In vitro studies demonstrated activation of the Nlrp3 /caspase-1/ pro-IL-1b inflammasome pathway upon glucose stimulation in glomerular cells, which was suppressed by minocycline or a caspase-1 inhibitor. This suppressive effect was abolished in cells transduced with the constitutive active NLRP3 mutant (Q705K).
Conclusion: Taken together, these results strongly support that activation of the NLRP3-inflammasome in residential glomerular cells contributes to inflammation/pyroptosis and that this is sufficient to promote diabetic nephropathy. Therefore, the modulation of the inflammasome is a potential therapeutic target in diabetic nephropathy.

741

Protection of beta cell function by therapy with interleukin-1beta antibody in the Cohen diabetes-sensitive rat

G. Aharon-Hananel[1], S. Lenzen[2], A. Jörns[2], I. Raz[1], S. Weksler-Zangen[1];
[1]Diabetes Unit, Hadassah University Hospital, Jerusalem, Israel, [2]Institute of Clinical Biochemistry, Hannover Medical School, Germany.

Background and aims: Cytokines are mediators of β-cell dysfunction in diabetes. Cohen-diabetes-sensitive-rats (CDs) fed a diabetogenic diet develop blunted glucose-stimulated-insulin-secretion (GSIS) and hyperglycemia associated with peri-islet-infiltration of fat and macrophages expressing IL1 β.

We examined, in vivo, the role of IL-1β in the β-cell dysfunction induced by the diabetogenic-diet, by blockading the IL1-β receptor with Anakinra, or by neutralizing IL1-β using an anti-IL-1-β antibody (IL1-β-Ab) in parallel with the diabetogenic-diet feeding.
Materials and methods: CDs rats fed 15 days a diabetogenic-diet were in parallel injected subcutaneously with Anakinra (50 mg twice daily), rat specific IL1-β Ab (0.5 mg/kg) or vehicle. On day 16, rats were weighed, blood glucose and insulin concentrations were assessed before and during the 120 min of an oral glucose tolerance tests (OGTT). Thereafter, rats were killed and pancreases were dissected, weighed and fixed. Pancreatic morphology, macrophage-infiltration (ED1) and IL1-β expression were evaluated in pancreatic sections using electron-microscopy and immunohistochemistry.
Results: 15-days Anakinra-treated CDs rat fed a diabetogenic-diet exhibited a high glucose area under the curve (AUC) that was comparable to the vehicle-treated CDs-rats (1325±43 vs 1351±53 mmol/l/120 min, respectively). Pancreatic fat, macrophage infiltration and IL1-β expression also remained high in these rats. Thus, Anakinra did not protect the CDs-rats from the deleterious effect of the diabetogenic-diet**.** In contrast, a 15-days treatment with IL1 β-Ab protected the CDs-rats from the harmful outcome of the diabetogenic-diet. IL1-β-Ab treated-CDs-rats exhibited a significant reduction in glucose-AUC compared to saline-treated rats (999±88 vs 1351±53 mmol/l/120min, p<0.01 respectively). Accordingly, peak insulin secretion 30 min after glucose administration increased in IL1 β-Ab-treated CDs-rats compared to controls (361±26 vs 270±22pmol/l p<0.05, respectively) and the value of AUC-insulinogenic-index was significantly higher (12±2 IL1-β-Ab vs 6.5±1 ηmol/l/120min p<0.05, respectively) indicating increased insulin secretory capacity of IL1-β-Ab treated CDs-rats. The pancreatic sections of CDs rats treated with IL-1β Ab demonstrated a 2/3 reduction in the number of infiltrating macrophages (6.6±1.3 for IL1-β-Ab vs 19.5±5.1 for saline per mm^2 pancreas, p<0.05) and the IL-1β expression was markedly reduced in the remaining infiltrating macrophages (3.5±0.9 for IL1-β-Ab vs 16.2±3.7 for saline per mm^2 pancreas, p<0.01). In parallel the adipose tissue in the pancreatic tissue was 50 % reduced. All animal groups had a similar body weight (223±15 g for Anakinra vs 230±8 g for IL1-β-Ab vs 240±7 g saline).
Conclusion: Our study provide proof-of-principle evidence that blocking of the IL-1 β action by a neutralizing anti-IL-1 β Ab could improve β-cell function and glucose tolerance and confirms the major role for IL-1β in the development of diabetes in our rat model.

Pivotal role of TNFalpha in mediating ET-1 vasocostrictive effects in small arteries of obese patients
A. Virdis[1], C. Rossi[1], E. Duranti[1], U. Dell'Agnello[1], E. Santini[1], M. Anselmino[2], M. Chiarugi[3], S. Taddei[1], A. Solini[1];
[1]Dept of Clinical and Experimental Medicine, University of Pisa, [2]Surgery Unit IV, University Hospital, [3]Dept of Surgery, University of Pisa, Italy.

Background and aims: Obesity is characterized by vascular low-grade inflammation which reduces NO availability, with an augmented endogenous endothelin (ET)-1-mediated vasoconstriction (VC) and a blunted tonic nitric oxide (NO)-mediated relaxation (VD). We evaluated how TNFα localized in the vascular wall and in perivascular adipocytes (PVA) contributes to the VC induced by endogenous ET-1 and whether this action is indirectly mediated by an effect on tonic NO release in small resistance arteries from obese patients (Ob) and controls (Ctrl).
Materials and methods: Sample of visceral fat were obtained in 14 Ob and 14 Ctrl, matched for metabolic profile and blood pressure values, undergoing a surgical laparoscopic procedure. Small arteries were investigated on a pressurized micromyograph. Endogenous ET-1 effect was assessed in pre-contracted arteries by vascular response to ET_A receptor blockade BQ-123 (1μM). TNFα and NO responses were tested at baseline and after anti-TNFα antibody Infliximab (IFX, 100 μM), and L-NAME (100 μM), respectively. Results are given as maximal response reached at steady state (30' infusion). Gene and protein expression of TNFα, ET-1, ET_A and ET_B receptors were determined by RT-PCR (gene/reference) and IHC (AU) on arterial wall and in PVA.
Results: Ob showed higher TNFα plasma levels (15.3±4.2 *vs* 8.1±2.5 pg/ml, $p<0.05$). In Ctrl, L-NAME-induced VC (15.5±0.6%) was not affected by IFX (15.1±0.4%). In contrast, Ob showed a blunted L-NAME-induced VC (6.0±0.7; $p<0.01$ vs Ctrl), which was potentiated ($p<0.01$) by IFX (12.5±0.8%). Ob were also characterized by a significantly higher TNFα expression, either at the level of arterial wall (24.9±19.6 *vs* 2.8±2.5 AU, $p<0.001$) or in PVA (2.9±1.8 *vs* 1.2±0.7, $p<0.005$); arterial TNFα receptor 1 was also more represented in Ob than in Ctrl (18.4±8.4 *vs* 5.7±3.4, $p<0.001$). In Ob, the VD to BQ-123 (47.0±1.5%) was attenuated ($p<0.01$ by IFX (29.1±2.4%) but not affected by L-NAME (43,3±0.6%). However, when co-infused with IFX, L-NAME further reduced the VD to BQ-123 (19.4±3.0%; $p<0.01$ vs BQ-123+IFX). In Ctrl, VD to BQ-123 was blunted (26.3±1.3%; $p<0.01$ vs Ob) and not affected by IFX (24.1±0.6%). L-NAME significantly reduced the VD to BQ-123 (12.3±1.1%), independently of IFX co-infusion (12.1±0.9%). These results were paralleled by a higher arterial expression of ET-1 (45.8±10.3 *vs* 24.3±15.0, $p<0.001$), ET_A (69.4±6.0 *vs* 9.6±2.8, $p<0.001$) and ET_B receptors (49.5±27.0 *vs* 9.2±2.4, $p<0.001$) in Ob respect to Ctrl. Looking for the intracellular signaling potentially mediating these responses, both p38 and JNK pathways were involved, with IFX significantly reducing JNK phosphorylation in both groups, and p38 phosphorylation only in Ob.
Conclusion: Resistance small arteries of obese patients show an enhanced ET_A-mediated VC and a blunted NO-mediated VD. An excess of vascular and perivascular TNFα, coupled with an increased expression of ET-1 and ET_A receptor in the vasculature of these patients, contribute to the enhanced ET-1-mediated contracting tone by a mechanism which involves an impairment of tonic NO release.

Plasma levels of N^{ε}-(Carboxymethyl)lysine are inversely associated with BMI and inflammation, and explain a part of the obesity-related increases in inflammation
K.H.J. Gaens[1], I. Ferreira[1,2], M.M. van Greevenbroek[1], C.J.H. van der Kallen[1], M.P.H. van de Waarenburg[1], S.S. Rensen[3], W.A. Buurman[3], J.M. Greve[3], C.D.A. Stehouwer[1], C.G. Schalkwijk[1];
[1]Department of Internal Medicine & CARIM School for Cardiovascular Diseases, [2]Department of Clinical Epidemiology and MTA, [3]Department of General Surgery & NUTRIM School for Nutrition, Toxicology and Metabolism, Maastricht University Medical Center, Netherlands.

Background and aims: Dysregulated production of adipokines is a characteristic of obesity and plays an important role in the development of insulin resistance and type 2 diabetes. We have previously shown that levels of the advanced lipoxidation endproduct, N^{ε}-(Carboxymethyl)lysine(CML) in plasma were decreased in obese subjects due to trapping of CML in adipose tissue, where it may contribute to the dysregulation of inflammatory cytokines. In this study, we investigate the relation between BMI and inflammation, and the role of plasma CML in this association.
Materials and methods: We studied 36 obese and 36 control subjects (case-control study), and 513 participants from a large cohort study (Cohort study of Diabetes and Atherosclerosis Maastricht (CODAM study)) with a wide range of BMI, in whom CML plasma levels and levels of circulating inflammatory markers CRP, SAA, sICAM-1, sVCAM-1, and IL-6 were measured. These markers were compiled into a total inflammation score by averaging the respective z-scores (standard deviations of difference from the population mean). Associations between BMI, inflammation and plasma CML levels were analysed with linear regression models, with adjustments for age, sex, smoking status and other metabolic risk factors. To analyse the role of CML plasma levels in the association between BMI and inflammation, additional adjustment for CML plasma levels was performed.
Results: After adjustment for age, sex, smoking and other risk factors, increasing levels of BMI (per 10 kg/m^2) were associated with higher levels of inflammation score [regression coefficient (β)=0.34SD (95% CI: 0.20; 0.48)] in the case-control study, and [β=0.35SD (95% CI: 0.21; 0.50)] in the cohort study. In addition, BMI is associated with lower plasma levels of CML: [β per 10kg/m^2 increase in BMI=-0.31μmol/L (95%CI: -0.44; -0.17) in the case-control study, and [β=-0.27μmol/L (95% CI: -0.38; -0.16)] in the cohort study. Plasma levels of CML were inversely associated with the inflammation score in both the case-control [β=-0.50SD (95%CI: -0.74; -0.26)] and the cohort [β=-0.21SD (95% CI: -0.32; -0.10)] studies. In addition, further adjustment for CML attenuated the associations between BMI and the inflammation score from [β=0.34SD (95% CI: 0.20; 0.48)] to [β=0.25SD (95% CI: 0.09; 0.41)], in the case-control study, and from [β=0.35SD (95% CI: 0.21; 0.50)] to [β=0.30SD (95% CI: 0.15; 0.44)] in the cohort study, thus explaining a significant portion of the association between BMI and inflammation (26 and 14%, respectively).
Conclusion: Obesity is characterized by higher levels of inflammatory markers but by lower levels of CML in plasma, the latter significantly explaining a portion of the positive association between obesity and inflammation. This attenuation suggests that, in the context of obesity, lower levels of CML in plasma, most likely as a result of CML trapping in the adipose tissue, influence the expression of pro-inflammatory cytokines.

Increased leukotriene production is associated with metabolic syndrome in obese subjects

A. Sultan[1,2], A. Avignon[1,2], F. Stanke-Labesque[3], C. Boegner[1], V. Attalin[1], E. Leprieur[1], M. Back[4];
[1]CHU Lapeyronie, Montpellier, [2]INSERM U1046, Montpellier, [3]INSERM U1042, Grenoble, [4]Karolinska institute, Stockholm, Sweden.

Background and aims: Obesity is a major risk factor for insulin resistance and type-2 diabetes. A wealth of evidence indicates that these metabolic comorbidities are associated with presence of low-grade chronic inflammation. In addition to adipokines, adipose tissue inflammation may also be driven by activation of classical proinflammatory pathways such as arachidonate lipoxygenases, leading to the formation of leukotrienes. Indeed, results from animal's studies are in favor of a role of the leukotriene (LT) pathway in obesity induced-insulin resistance. However, there is a paucity of data regarding this association in human obesity. Therefore, the aim of this study was to investigate whether LT production was associated with insulin resistance and with metabolic syndrome parameters in a cohort of obese subjects.
Materials and methods: Subjects admitted for assessment of obesity (BMI≥30 kg/m2) were included and classified according to the presence or not of a metabolic syndrome. Exclusion criteria were treatment with anti-inflammatory medications, asthma, known diabetes mellitus and hs-CRP above 10 mg/l. Laboratory procedures included FPG, HbA1c, Total cholesterol, triglycerides (TG) high and low-density lipoprotein, Hs-CRP, evaluation of insulinresistance by HOMA-IR. Urinary leukotriens (U-LTE4) was measured using enzyme immune assay kit. Correlations between the urinary-LTE4 and clinical /biological parameters parameters were established by Spearman correlation. A multiple stepwise linear regression was performed to evaluate the impact of the components of the metabolic syndrome on U-LTE4. $p<0.05$ was considered significant.
Results: 46 subjects (70% females) were included, mean age 44 years (16-80) and mean BMI 36,8kg/m2 (30-51). Sixteen subjects fulfilled at least 3 of the criteria for metabolic syndrome. There was a positive association of U-LTE4 with metabolic syndrome in a multivariable analysis adjusted for age and gender (β-coefficient 0.192; P=0.023). To assess what part within the metabolic syndrome U-LTE4 correlated with, a stratified comparison was performed for each factor Whereas the levels of U-LTE4 did not differ in groups with and without hypertension, and not between high and low HDL and TG, U-LTE4 was significantly higher in subjects with a high waist to hip ratio and in subjects with high fasting plasma glucose. An age- and gender-adjusted multivariate analysis including the waist to hip ratio, BMI, LDL level, HDL and TG level, blood pressure, HOMA-IR, and Hb1Ac revealed that the waist to hip ratio remained the only parameter significantly correlated with U-LTE4 (P=0.015).
Conclusion: Taken together, our results confirm the previously established notion of chronic low grade inflammation in obesity and further described a novel inflammatory pathway, i.e. the LT pathway that could be involved during obesity-induced insulin resistance. Since this is an observational study, no definite conclusion of causality can be drawn from the present results. One possible mechanism is that increased LT production from visceral fat may be involved in the development of insulin resistance. This notion has received support from animal models. Further studies are needed to investigate the precise mechanisms involved in LT-induced metabolic effects in human disease.

Dipeptidyl peptidase 4 (DPP4) induces inflammation and proliferation of human smooth muscle cells by activation of the ERK and NF-kB signalling pathway

N. Wronkowitz[1], L.A. Villalobos[2], C.F. Sánchez-Ferrer[2], C. Peiro[2], H. Sell[1], J. Eckel[1];
[1]Paul-Langerhans Group for Integrative Physiology, German Diabetes Center, Düsseldorf, Germany, [2]Departamento de Farmacología, Universidad Autónoma de Madrid, Spain.

Background and aims: DPP4 is a ubiquitously expressed cell-surface protease and a novel adipokine, as shown by us. Due to DPP4-mediated degradation of the incretin hormone glucagon-like peptide (GLP)-1, inhibition of DPP4 is now widely used as a therapeutic approach for type 2 diabetes mellitus treatment. In addition, DPP4 inhibitors display beneficial cardiovascular effects that are not only GLP-1 mediated. However, nothing is known about direct cellular effects of soluble DPP4, the circulating form of this enzyme. The aim of this study was to investigate the effects of DPP4 on primary human smooth muscle cells (hSMC) and to identify responsible signaling pathways.
Materials and methods: Primary human vascular smooth muscle cells (VSMC) from three distinct donors were exposed to DPP4 for 6 and 24h, and examined for the activation of different signaling pathways by Western blot analysis. To investigate the expression of different cytokines VSMC were treated with DPP4 for 24h and mRNA were measured by real-time PCR. Effects on proliferation and secretion were detected by ELISA. The specific DPP4 Inhibitor K579 was used in a concentration of 100nM and was added concomitant with DPP4.
Results: Using supraphysiological and physiological concentrations of DPP4 (2-500ng/ml), we could observe a concentration-dependent activation of ERK1/2 (3-fold) after 6h, which remained stable for up to 24h. Additionally, DPP4 treatment induced a 1.5-fold phosphorylation of the NF-κB subunit p65. The increased ERK1/2 phosphorylation as well as the NF-κB phosphorylation could be totally abrogated by the specific DPP4 inhibitor. In accordance with DPP4-induced stress and inflammatory signaling, DPP4 also stimulates hSMC proliferation, which could be completely inhibited by the specific ERK1/2-Inhibitor PD98059 as well as by the DPP4 inhibitor. Downstream of ERK and NF-κB, DPP4 induces iNOS in a concentration-dependent manner. Furthermore we could observe an increased expression and secretion of proinflammatory cytokines like IL-6, IL-8 and MCP-1 (2.5-, 2.4- and 1.5-fold, respectively) by the DPP4 treatment. Both, expression and secretion of these cytokines could be completely blocked by the DPP4 inhibitor.
Conclusion: In conclusion, we show for the first time that soluble DPP4 activates the MAPK and NF-κB signaling cascade resulting in the induction of inflammation and proliferation of hSMC. Our data might therefore partially explain GLP-1 independent cardiovascular effects of DPP4 inhibitors. Due to increased circulating levels of DPP4 in obesity, DPP4 may play a role in linking obesity to cardiovascular disease.

ITCH deficiency protects from diet induced obesity

A. Marino, M. Fabrizi, V. Casagrande, M. Mavilio, R. Menghini, G. Melino, R. Lauro, M. Federici;
School of Medicine, University Tor Vergata, Rome, Italy.

Background and aims: Obesity is associated to increased CD8+ T cell infiltrations and a defective regulation of M2 macrophage polarization state in the adipose tissue that predispose to a chronic state of low-grade inflammation, and in turn insulin resistance, type 2 diabetes and hepatic steatosis. ITCH Knockout (KO) mice show a Th2 polarization; in T cell, ITCH down regulation causes aberrant expression of JunB, IL-4 overproduction and Th2 differentiation. We tested whether the Th2 bias of ITCH KO mice might counteract the defective Th2 /M2 polarization state in obesity-related inflammation and insulin resistance.
Materials and methods: We compared C57BL/10 WT and ITCH KO mice in a context of diet-induced obesity (High fat diet, HFD). Animals were subjected to metabolic characterization: weight and blood glucose monitoring, glucose tolerance tests and indirect calorimetric measurement. At the end of 12 weeks of treatment, WT and KO mice were sacrificed and metabolically active organs were collected for molecular and histological studies. Fasting and feeding sera were collected for assessment of the amount of insulin.
Results: During HFD treatment, ITCH KO mice compared to WT littermates showed lower weight ($p<0.001$), characterized by reduced adiposity associated with decreased fat pad mass and adipocyte size ($P<0.001$), significantly lower levels of blood glucose and HOMA IR index ($p<0.001$). Calorimetric analysis showed an increased O2 consumption and CO2 production in KO mice compared to WT ($p<0.001$), suggesting an accelerated metabolism. In muscle from ITCH KO mice compared to WT we found increased phosphorylation of Ser473 AKT ($p<0.05$). Gene expression analysis of epididimal adipose tissue of ITCH KO mice revealed significantly reduced level of F4/80 ($p<0.05$), increased levels of IL4, IL13 ($p<0.01$), and M2 markers such as YM1, Arg1 and Mgl2 ($p<0.01$), when compared to WT. This suggested a high presence of alternatively activated macrophages M2. We found also significantly increased expression of genes involved in adipocytes differentiation, fatty acid oxidation and mitochondrial function: PPARs, C/EBPs, SREBP1, PGC1 α/β, ACOX1, Tfam, NRF1, SIRT1 ($p<0.01$). After HFD treatment histological analysis of livers from ITCH KO mice showed no signs of macrovesicular steatosis that instead occurred in WT mice. These results suggested that ITCH

deficiency protect mice from obesity-related NAFLD. Finally improved insulin sensitivity of ITCH KO livers was suggested by increased phosphorylation of AKT (Ser473) ($p<0.01$).
Conclusion: When subjected to HFD ITCH KO mice did not show increase in body weight, insulin resistance and hepatosteatosis. The molecular analysis of metabolically active tissues revealed increased levels of M2 markers and fatty acid oxidation. Taken together, our data indicate that ITCH KO mice are partially protected from the metabolic injury caused by HFD.

Parasitic nematode *Trichinella* infection improves obesity-induced diabetes
H. Okada, K. Kajita, M. Yamauchi, T. Ikeda, Y. Uno, H. Morita, T. Ishizuka;
Department of General Internal Medicine, Gifu University Graduate School of Medicine, Japan.

Background and aims: Insulin resistance associated with obesity, particularly visceral obesity, is involved in the pathogenesis of lifestyle-related diseases such as type 2 diabetes. In addition, inflammation caused by chronic bacterial infection such as periodontal disease is known to deteriorate glucose tolerance and insulin sensitivity. However, the effects of parasite infection on glucose tolerance have remained unknown. In addition, that chronic low grade inflammation in adipose tissue is currently considered as a main cause of insulin resistance associated with obesity. Interestingly, a parasitic helminth is known to secrete an immunosuppressive agent and anti-inflammatory materials to suppress an attack from a host. We investigated the effects of nematode parasite, *Trichinella spiraris*, infection on glucose tolerance and macrophage status in adipose tissue.
Materials and methods: Ob/ob mice and C57/BL mice fed with normal or high fat diet (HF) were divided into two groups (10 mice each), and then infected orally with (infected group) or without (un-infected group) *Trichinella*. Four weeks later, body weight, fat weight, fasting plasma glucose and insulin levels were measured. To evaluate glucose tolerance, intraperitoneal glucose tolerance test (ipGTT, glucose: 2g/kg) was performed. To determine the expression levels of adipocyte specific genes (PPARγ and adiponectin) in adipocytes isolated from epididymal fat, M1 macrophage markers (CD11c Nos and IL6) and M2 macrophage marker (CD206, arginase 1 and IL10) in stromal vascular fraction (SVF) and peritoneal lavage (PT), real time PCR was performed. Immunostaining of paraffin sections of the fat tissues was performed using anti-CD11c antibody and anti-CD206 antibody.
Results: Although *Trichinella* infection for four weeks reduced fasting plasma glucose level, it had no influence on the plasma insulin level in C57 /BL and ob /ob mice. These results implied that *Trichinella* infection improves insulin sensitivity. *Trichinella* infection did not affect body weight and fat weight. *Trichinella* infection suppressed plasma glucose levels during GTT in ob/ob mice and HF fed mice, but not lean C57 /BL mice. The expression of M1 markers were suppressed in PT and SVF isolated from infected mice. In contrast, M2 marker, mRNA levels were elevated in SVF and PT isolated from infected mice. These results indicated that *Trichinella* infection shifted macrophage polarization from M1 to M2 in SVF and PT. On the other hand, *Trichinella* infection did not influence mRNA levels of PPARγ, adiponectin, IL-6, IL-10 and MCP-1 in adipocytes. Double immunostaining for CD11c, and for CD206 revealed that more abundant expression of CD206 in the infected group was detected.
Conclusion: *Trichinella* infection increased the ratio of M2 /M1 macrophage, which results in a pro-inflammatory state in adipose tissue and amelioration of glucose tolerance in obese mice.

Obesity and inflammation: molecular pathways involved in CCL5 chemokine regulation in adipocytes
F. Passaretti, V. D'Esposito, C. Padrone, R. Valentino, M.R. Ambrosio, L. Albano, F. Beguinot, P. Formisano;
DISMET e IEOS/CNR, Università degli Studi di Napoli Federico II, Naples, Italy.

Background and aim: Obesity is a chronic, multifactorial disorder that has reached epidemic proportions globally. Derangement of glucose and lipid metabolism are frequently observed in obese individuals. In obesity, adipose tissue is characterized by a chronic low-grade inflammation with secretion of inflammatory cytokines and chemokines that recruit immune cells. Among chemokines, RANTES/CCL5 participates in mediating leukocyte infiltration of adipose tissue. Moreover circulating CCL5 concentrations are elevated in obesity, impaired glucose tolerance (IGT) and type 2 diabetes. We have investigated the effect of metabolic alterations on the control of CCL5 expression and secretion in adipocytes.
Materials and methods: 3T3-L1 preadipocytes were cultured up to confluence and then differentiated into adipocytes. Thereafter adipocytes were incubated in the presence of different concentrations of glucose (5mM; 15mM; 25mM), fatty acids (Oleate 10uM; Palmitate 100uM) or insulin (100 nM). In order to investigate CCL5 secretion and gene expression, ELISA and real time RT-PCR assays were used, respectively. Activation of specific intracellular pathways was assessed by Western Blot analysis. Chromatin Immunoprecipitation assays were performed to evaluate NFkB binding to CCL5 promoter.
Results: We have obtained evidence that, in differentiated 3T3-L1 adipocytes, both glucose and fatty acids (oleate and palmitate) induced CCL5 secretion in a dose dependent manner. At variance, insulin reduced CCL5 secretion. However, CCL5 mRNA levels did not significantly change when 3T3-L1 adipocytes were cultured in the presence of 5mM or 25 mM glucose, while both oleate and palmitate enhanced CCL5 mRNA levels. Again, insulin exerted an inhibitory effect on CCL5 mRNA and prevented fatty acid-induced stimulation. Fatty acid effect on CCL5 expression was paralleled by increased JNK activity. Interestingly, treatment of the cells with SP600125, a JNK inhibitor, significantly reduced the stimulatory effect of oleate and palmitate on CCL5 mRNA. At the opposite, both LY294002 and PD98059, inhibitors of PI3K and MAPK, respectively, increased CCL5 expression levels and prevented insulin inhibitory effect. Finally, both oleate and palmitate increased NFkB binding to CCL5 promoter. Consistently, insulin exposure reduced NFkB recruitment onto CCL5 promoter, and almost completely prevented fatty acid effect.
Conclusion: Oleate and palmitate, while not glucose, induce CCL5 mRNA, possibly via JNK and NFkB pathways. Fatty acid effect on CCL5 is largely prevented by insulin and may depend on PI3K/Akt and MAPK pathways.

PS 054 Fatty acids and triglyceride storage: impact on inflammation and glucose metabolism

Plasma acylcarnitine levels have limited predictive value for metabolic characteristics as insulin sensitivity and energy expenditure

M.R. Soeters[1], M.G. Schooneman[2], S.M. Houten[3], S.R. Miller[4], S. Virtue[1], A. Vidal-Puig[1], A. Napolitano[4], D.J. Nunez[5];
[1]Institute of Metabolic Science, Cambridge, UK, [2]Endocrinology & Metabolism, Academic Medical Center, Amsterdam, Netherlands, [3]Laboratory Genetic Metabolic Diseases, Academic Medical Center, Amsterdam, Netherlands, [4]GlaxoSmithKline, Cambridge, UK, [5]GlaxoSmithKline, Research Triangle Park, USA.

Background and aims: Acylcarnitines are fatty acid oxidation (FAO) intermediates and have been implicated in diet-induced insulin resistance and type 2 diabetes mellitus. Moreover plasma acylcarnitines have been associated with multiple clinical parameters associated to glucose metabolism such as fasting glucose levels and HbA1c. We investigated plasma acylcarnitines in relation to energy metabolism (including energy expenditure (EE)) and insulin sensitivity measurements in obese subjects before and after weight loss. Since acylcarnitines reflect FAO profiles at the mitochondrial level, we expected plasma acylcarnitines either to be predictive for energy expenditure as measured by indirect calorimetry or the amount of weight loss during a weight loss intervention.
Materials and methods: 60 obese subjects were recruited to take part in an outpatient study and were randomized to one of three 12-week interventions: 1- diet (-600 kcal) alone, 2- diet with moderate exercise, and 3- diet with sibutramine. Subjects visited the clinical unit at 0, 4 and 12 weeks for anthropometry by DXA, indirect calorimetry and blood sampling (e.g. plasma acylcarnitine, glucose, insulin and leptin levels). Plasma acylcarnitine profiles were analyzed by tandem mass spectrometry (MS). Statistical analysis (including multivariate regression analysis and subgroup analyses for diet only, diet and exercise and sibutramine) was performed using SPSS. Here, we report on whole group analyses.
Results: We included 60 obese subjects; average age 40.1 ± 8.6(SD) years; 23 males and 37 females. After 12 weeks there was a significant reduction in body weight (pre 100.9 ± 12.6kg vs. post 96.5 ± 13.1, $p < 0.05$) due to a significant decrease in body fat accompanied by significant reductions in HOMA-IR (pre 3.7 ± 2.9 vs. post 2.9 ± 1.4, $p < 0.05$) as well as EE (pre 5.2 ± 0.83 kJ/min vs. post 4.9 ± 0.8 kJ/min, $p < 0.05$) and plasma leptin levels (pre 33.8 ± 22 ng/ml vs. post 23.3 ± 13.4 ng/ml, $p < 0.05$). In general plasma acylcarnitines were significantly higher after 12 weeks: (e.g. free carnitine (CN) pre 33 ± 7.8 umol/l vs. post 36.1 ± 6.7 umol/L; C2-CN pre 4.9 ± 1.7 umol/L vs. post 5.821 ± 2.4 umol/L; C4-3-OH-CN pre 0.026 ± 0.02 umol/L vs. post 0.037 ± 0.04 umol/L and C18-1-CN pre 0.087 ± 0.03 vs. post 0.104 ± 0.03 umol/L; all $p < 0.05$). Multivariate regression analysis did not attribute significant predictive value to the analysed acylcarnitines in relation to our major outcome parameters such as HOMA-IR or EE. There was no relation between attained weight loss and any of the plasma acylcarnitines at baseline.
Conclusion: Previous studies suggested that elevated plasma acylcarnitines play a role in the induction of insulin resistance or reflect insulin resistance. In contrast, despite the amelioration of HOMA-IR, plasma acylcarnitines levels increased during weight loss. This is most probably attributable to higher lipid oxidation due to the caloric deficit. Also EE, RER and body composition were not related to plasma acylcarnitines. Our data warrant the cautious interpretation of plasma acylcarnitines in human metabolic studies.

Plasma acylcarnitines poorly reflect tissue acylcarnitine metabolism

N. Achterkamp[1], M.G. Schooneman[1], M.R. Soeters[1], S.M. Houten[2];
[1]Endocrinology & Metabolism, [2]Emma Children's Hospital/Lab. Genetic Metabolic Diseases, Academic Medical Center, Amsterdam, Netherlands.

Background and aims: Acylcarnitines (ACs) are fatty acid oxidation (FAO) derived metabolites which have been implicated in the induction of insulin resistance. Several studies, both in animals and humans, relate elevated ACs to obesity and type 2 diabetes mellitus. The majority of these studies focus on plasma measurements of ACs. Since insulin resistance occurs inside tissues, it is relevant to know whether plasma AC profiles accurately reflect AC profiles in any of the tissues implicated in insulin resistance. The aim of this study was to investigate if AC profiles in plasma correlate with AC profiles in specific tissues, in both fed and fasted BALB/cJ- and more insulin resistant C57BL/6N (Bl6) mice.
Materials and methods: Mice were housed under standard conditions and fed a chow diet. Both the BALB/cJ and Bl6 groups were split in two, of which one group was fed ad libitum, whereas the other half was fasted overnight to increase fatty acid oxidation and induce insulin resistance. Then, animals were anesthesized with a pentobarbital solution for venous blood sampling and subsequent dissection and harvesting of organs. AC profiles were analyzed by tandem mass spectrometry in plasma and several tissues (eg. liver, adipose tissue and muscle). Metaboanalyst 2.0 was used to determine correlation patterns followed by individual Spearman's rank correlation coefficients for specific metabolites and compartments.
Results: Fasting significantly induced ketosis in BALB/cJ (fasted β-OH-butyrate 1.77 mmol/l vs fed 0.12 mmol/l, $p < 0.001$) and Bl6 mice (fasted 1.06 mmol/l vs fed 0.07 mmol/l, $p < 0.001$). Fasting ketosis was higher in BALB/cJ compared to Bl6 mice ($p < 0.05$). Fasting free carnitine levels decreased whereas in general all other AC levels increased in both mouse strains ($p < 0.05$). Overall, no correlations were found between plasma AC species and their tissue counterparts in either mouse strain. Plasma free carnitine showed no correlations with free carnitine in tissues in all mice. No other short chain species showed correlations, with the exception of plasma C4-3OH-CN (i.e. a ketone body derived AC), which in fed Bl6 mice only correlated with quadriceps femoris muscle (r^2 0.622, p 0.031). However in fasted BALB/cJ mice, which exhibited higher ketosis compared to Bl6 mice, plasma C4-3OH-CN correlated with muscle (quadriceps femoris muscle (r^2 0.627, p 0.039), gastrocnemius muscle (r^2 0.791, p 0.004) and soleus muscle (r^2 0.624, p 0.040)), heart (r^2 0.673, p 0.023) and negatively with BAT (r^2 -0.664, p 0.026). In general all medium and long chain AC species did not correlate in any metabolic state in both BALB/cJ and Bl6 mice.
Conclusion: These data show that plasma AC levels poorly reflect tissue AC levels with the exception of C4-3OH-CN under fasted conditions. A probable explanation for this lack of correlation is that the plasma pool represents only a small percentage of the total AC pool and that the turnover rates of plasma ACs are larger than that of tissue ACs. Therefore, plasma AC levels should be interpreted with caution and a focus on tissue AC levels is warranted in metabolic studies.

γ-Butyrobetaine impairs glucose tolerance in mice on a high carbohydrate diet

M.G. Schooneman[1], F.M. Vaz[2], C.E.M. Hollak[1], M.R. Soeters[1], S.M. Houten[2];
[1]Endocrinology & Metabolism, [2]Lab. Genetic Metabolic Diseases, Academic Medical Center, Amsterdam, Netherlands.

Background and aims: Acylcarnitines (ACs) are fatty acid oxidation (FAO) intermediates and have been implicated in diet-induced insulin resistance and type 2 diabetes mellitus. Elevated AC levels coincide with lower free carnitine and may reflect impaired FAO. Moreover, carnitine acetyltransferase (CrAT) is suggested to play a pivotal role in substrate switching and glucose tolerance via converting acetyl-CoA into acetylcarnitine and regulating mitochondrial and intracellular carbon trafficking. Modulating carnitine availability may facilitate FAO, thereby improving insulin sensitivity. Since the carnitine precursor γ-butyrobetaine (γBB) is most effective in increasing carnitine levels, we compared the effects of γBB administration on glucose metabolism in C57BL/6N (Bl6) mice on chow versus high fat diet (HFD).
Materials and methods: Mice were fed a high fat or chow diet with or without γBB treatment via the drinking water (n=10/group). After 8 weeks of diet, indirect calorimetry, intra peritoneal glucose tolerance test (IPGTT) and intra peritoneal insulin sensitivity test (IPIST) were performed. Then animals were euthanized for blood sampling and dissection. Plasma AC profiles and carnitine biosynthesis intermediates were analyzed by tandem mass spectrometry (MS) and liquid chromatography (LC) MS MS. Statistical analysis was performed using SPSS.
Results: Treatment with γBB did not effect body weight gain (HFD +/- γBB 48.7g vs 49.4g; chow +/- γBB 25.1g vs 25.6g respectively). Whole blood free carnitine levels were lower after HFD, which was restored to chow diet levels upon γBB treatment ($p < 0.01$). Interestingly γBB treatment did not increase whole blood carnitine in chow-fed mice. Treatment with γBB caused a gen-

eral increase of short- (including acetylcarnitine), medium- and long-chain ACs in HFD and chow mice. Mice fed a HFD showed lower RER compared to chow fed mice (mean RER 0.82 vs 0.97 respectively, $p < 0.001$), indicating higher FAO. RER did not change by γBB treatment in both groups. Glucose tolerance was lower in HFD mice, which was not improved by γBB treatment (AUC HFD +γBB 230.6 vs HFD -γBB 199.1, p 0.38). In contrast, γBB treatment of chow fed mice reduced glucose tolerance (AUC Chow +γBB 354.2 vs Chow -γBB 222.5, $p<0.001$). HFD fed mice were insulin resistant compared to chow fed mice as revealed by IPIST, but there was no effect of γBB treatment (AUC HFD +γBB -12.3 vs HFD -γBB -10.2, p 0.53, AUC Chow +γBB -21.3 vs HFD -γBB -19.9, p 0.55).

Conclusion: Although γBB supplementation restored free carnitine levels in HFD fed mice, insulin resistance was not changed. Unexpectedly, in chow-fed mice, γBB treatment impaired glucose tolerance with an unaffected insulin tolerance. This suggests that elevating intracellular carnitine levels via γBB treatment reduces metabolic flexibility in chow animals with regard to glucose tolerance. This is intriguing since substrate availability (i.e. carbohydrates) and oxidation (RER) were equal in the chow groups. Ongoing tissue analyses may help to elucidate the mechanism at hand. We speculate that γBB treatment increases mitochondrial fatty acid uptake and oxidation leading to increased levels of acetyl-CoA as reflected by higher acetylcarnitine levels. Elevated acetyl-CoA inhibits the pyruvate dehydrogenase complex thereby decreasing glucose oxidation with possible negative effects on glucose tolerance.

Relationship between inflammatory phenotype of human macrophages and the lipid storage in lipid droplets

K. Cho, H. Miyoshi, T. Kondo, T. Atsumi;
Internal medicine 2, Hokkaido University, Sapporo, Japan.

Background and aims: Macrophages play a major role in atherosclerosis growing into foam cells while absorbing lipids in atherosclerotic plaques. Infiltrating macrophage polarity (pro/anti-inflammatory balance) in human atherosclerotic plaques has been reported to be associated with increased vulnerability and clinical incidence of stroke. Plaques in patients with symptomatic stroke were more unstable and had a greater infiltration of pro-inflammatory M1 macrophages compared to plaques found in patients with asymptomatic stroke which contained less macrophages, but most of them anti-inflammatory M2 phenotype. Lipid droplets in macrophages and foam cells are covered with Perilipin2 (PLIN2, ADRP), a lipid droplet protein. In adipose tissue, immature lipid droplets are coated with PLIN2, and replaced by Perilipin1 (PLIN1) during maturation. PLIN1 regulates proteins involved in the storage of triglycerides in lipid droplets and thereby prevents lipotoxicity by sequestering harmful lipids in stable lipid droplets. In macrophages, however, the expression and function of PLIN1 and the connection with the macrophage polarity and the function of PLIN proteins in human specimens are poorly understood.

Materials and methods: Monocytes were isolated from healthy human peripheral blood mononuclear cells and differentiated into macrophages with M-CSF. M2 macrophages were obtained by stimulating with low concentrations of recombinant human IL-4 for 6 days. M1 macrophages were obtained by differentiating in the presence of TNFα. Macrophages were cultured for 24 hours or 7 days in the presence of oxidized low density lipoprotein (oxLDL) or very low density lipoprotein (VLDL), and collected for protein analysis, or fixed in formaldehyde for morphological analysis.

Results: In cultured macrophages, both PLIN1 and PLIN2 appeared on the surface of lipid droplets. Small lipid droplets were covered with PLIN2, while large droplets were coated with PLIN1 and contained mainly triglyceride. oxLDL increased macrophage number and the expression of PLIN2 protein. VLDL dramatically increased the expression of PLIN2 during the first 24 hours followed by enhanced expression of PLIN1 and decreased expression of PLIN2. Cholesterol was added, the expression of CD11c, a pro-inflammatory macrophage marker, was increased and the expression of the anti inflammatory marker CD163 rapidly disappeared in M1 macrophages. PLIN2 was expressed after 24 hours while PLIN1 expression was observed only on day 7th. In M2 macrophages, there was no expression of CD11c in the whole period and the expression of CD163 decreased slowly. PLIN2 was slightly expressed after 24 hours, and there was also PLIN1.

Conclusion: Lipid droplets proteins in human macrophages may keep stability of atherosclerotic lesion by storing lipid efficiently, through PLIN1 switched from PLIN2. On the other hand, large amount of lipids, not fully absorbed in macrophages, have increased pro-inflammatory character. Inflammation has a negative effect on plaque stability, and might leads to lipotoxicity to surrounding environments and to rupture of atherosclerotic plaque, rapidly inhibiting PLIN proteins switching.

Coordinated effects of macrophages and free fatty acids on the inflammatory gene expression in pancreatic islets

H. Inoue, J. Shirakawa, K. Orime, Y. Togashi, Y. Terauchi;
Yokohama-City University, Japan.

Background and aims: The numbers of macrophages in the pancreatic islets of patients with type 2 diabetes were reportedly increased. Yet, the pathophysiological significance of macrophages infiltration into islet is unclear. To address this question, we investigated the interaction of islets with macrophages and free fatty acids.

Materials and methods: Isolated mouse pancreatic islets were co-cultured with unstimulated peritoneal macrophages in the presence of lipopolysaccharide (LPS), palmitate, oleate, or adipocytes derived from epididymal fat, in vitro. The mRNA expressions of co-cultured islets were analyzed by real-time PCR. Glucose-stimulated insulin secretion (GSIS) in the co-cultured islets was analyzed. Effects of glucose concentration (5.6 mM/22.2 mM) and TLR4-inhibitory peptide (IMG-2011A) on the gene expression in the co-cultured islets were also assessed.

Results: In the presence of macrophages, the expressions of IL-1β, TNF-α, IL-6, CCL2, S100A8, and S100A9 in islets were increased (2.3-fold**, 2.9-fold**, 7.3-fold**, 9.6-fold**, 13.3-fold** and 72.7-fold**, respectively). LPS enhanced the macrophages-induced expression of IL-1β, TNF-α, IL-6 and CCL2 in islets (1.5-fold; p=0.12, 1.7-fold*, 2.4-fold** and 2.3-fold**), whereas palmitate augmented the expression of S100A8 and S100A9 under the same conditions (4.8-fold** and 3.6-fold**). Oleate unaffected those gene expression levels in islets. Neither LPS nor palmitate was sufficient to facilitate these cytokine expressions in islets in the absence of macrophage. When islets were co-cultured with adipocytes, the expressions of IL-1β, TNF-α, IL-6 and CCL2, S100A8 and S100A9 in islets were tended to elevated (2.4-fold n.s., 2.1-fold*, 2.4-fold n.s., 3.3-fold n.s, 6.0-fold n.s. and 35.6-fold n.s.). The induction of S100A8 and S100A9 expressions by adipocytes in islets were up-regulated by the addition of macrophages (3.0-fold n.s., and 4.3 fold**). Co-culture with palmitate increased glucose-induced insulin secretion from isolated islets (3.1-fold, n.s.), and this insulin secretion was further incremented in the presence of both palmitate and macrophages (4.8-fold*). The expression levels of S100A8 and S100A9 were potentiated at high glucose concentration compared with those at low glucose concentration in the presence of palmitate (7.3-fold** and 4.6-fold**). By blocking TLR4 signaling with IMG-2011A, the rises of S100A8 and S100A9 expression in islet were cancelled even in the presence of macrophages and palmitate (0.08-fold** and 0.09-fold**). On the other hand, with IMG-2011A, the expressions of IL-1β, TNF-α, IL-6, and CCL2 in islets were modestly increased in the presence of both macrophages and palmitate (2.9-fold n.s., 1.2-fold n.s., 2.9-fold* and 1.9-fold*). (n.s.: not significant, †$p<0.1$, *$p<0.05$, **$p<0.01$)

Conclusion: These results suggest that infiltrating macrophages evoke inflammatory gene expressions in islets by the mutual interaction of islets with macrophages and free fatty acids derived from adipocytes via TLR4-mediated signaling especially under hyperglycemic situation, namely, diabetes. However, these factors did not impair insulin secretion from pancreatic islets at this stage.

Early over-nutrition and dietary fat induce beta cell failure in Swiss Webster mice

M.M. Glavas[1], Q. Hui[1], E. Tuduri[1], J.K. Fox[1], X. Hu[1], J.D. Johnson[1], T.J. Kieffer[1,2];
[1]Department of Cellular & Physiological Sciences, [2]Department of Surgery, University of British Columbia, Vancouver, Canada.

Background and aims: Childhood obesity and rapid early growth increase the risk for type 2 diabetes. Such early over-nutrition can be modelled in mice by reducing litter size, resulting in rapid weight gain, hyperinsulinemia and hyperleptinemia in early life. This chronic postnatal overnutrition (CPO) in Swiss Webster mice significantly increases susceptibility to diabetes (75% incidence vs. 36% in controls, CTR), characterised by profound hyperglycaemia followed by beta-cell death (typical onset ranges from 2 to 6 months of age).

We examined islets in young, normoglycaemic mice to determine whether beta-cell dysfunction precedes the development of hyperglycaemia.
Materials and methods: Litters from Swiss Webster mice were adjusted to 3 (CPO) or 10 (CTR) pups shortly after birth and maintained on a moderate fat (25 kcal%) diet. Insulin and glucose tolerance tests were performed in 2 to 3 month old normoglycaemic mice, and insulin regulation was assessed in the pancreas. To determine the role of dietary fat content in diabetes development, plasma triglyceride levels were measured, and a separate cohort of mice was maintained on either low-fat diet (LFD; 10 kcal% fat) or high-fat diet (HFD; 45 kcal% fat) throughout life.
Results: Normoglycaemic CPO mice exhibited significantly heavier body weight and higher circulating triglyceride levels but normal insulin and glucose tolerance. In size-matched islets, CPO mice exhibited reduced insulin and proinsulin content ($p<0.05$) but no difference in insulin secretion from islets perifused with 20 mM glucose. In situ hybridisation revealed strong Ins2 expression in islets of 4/4 CTR mice but only 1/4 CPO mice. The remaining 3 CPO mice had very low Ins2 expression, corresponding with reduced insulin and proinsulin immunoreactivity. However, CPO mice had equivalent total pancreatic insulin content, plasma insulin and proinsulin levels compared to CTR mice, likely due to their 1.8-fold greater islet number. Electron microscopy revealed that 2/3 CPO mice and 1/3 CTR mice examined had drastic reductions in insulin granules together with swollen mitochondria and increased autophagy, suggesting beta-cell failure. HFD exacerbated diabetes even further, with 83% of CPO and 50% of CTR mice developing diabetes as early as 7 weeks of age. In contrast, LFD-fed CPO mice were entirely diabetes free, maintaining normal glucose and insulin levels to 1 yr of age, despite a higher body weight than LFD-fed CTR mice.
Conclusion: These findings suggest that Swiss Webster mice have a susceptibility to diabetes that is exacerbated by early overnutrition and increased dietary fat content, whereas a low-fat diet is protective. While a higher islet number in CPO mice may compensate for their reduced insulin expression in the short term, prolonged metabolic stress eventually results in beta-cell failure.

Fatty acid composition in adipose triglyceride in high-fat fed rats treated with pioglitazone

D. Sato[1], K. Oda[1], M. Kusunoki[2], A. Nishina[3], Z. Feng[4], T. Nakamura[1];
[1]Department of Biomedical Information Engineering, Yamagata University,
[2]Department of Internal Medicine, Aichi Medical University, Nagoya,
[3]Department of Health and Nutrition, Yonezawa Women's Junior College,
[4]Department of Bio-Systems Engineering, Yamagata University, Yonezawa, Japan.

Background and aims: Pioglitazone improves insulin resistance and increases small adipocytes. We elucidated that the fatty acid (FA) composition in adipose triglyceride is closely related to insulin resistance induced with high-fat diet in rats. In addition, it was reported that adipocyte size is potentially relevant to a part of FA content. In the present study, we administered pioglitazone to insulin-resistant, high-fat fed rats to increase small adipocytes, and compared the FA composition to that in high-fat fed, control rats.
Materials and methods: Male Wistar rats were fed a high-fat diet from 6 weeks of age, and were separated into 30 mg/kg/day pioglitazone-treated (PIO(+)) and non-treated (PIO(-)) groups (n=6, respectively) at 11 weeks of age. Rats were killed at 15 weeks of age, and blood glucose (BG), plasma insulin (PI), triglyceride (TG), and free fatty acid (FFA) levels were measured. FA contents (μmol/g tissue) in triglyceride fraction in epididymal (EPI), mesenteric (MES), retroperitoneal (RET), and subcutaneous (SUB) adipose tissues were analyzed by a gas chromatography. Also, adipocyte diameters (μm) in a part of each adipose tissues were evaluated under a microscope (n=4, respectively).
Results: PI, TG, and FFA in PIO(+) group were significantly lower ($p<0.05$) than those in PIO(-) group, respectively, whereas no difference was detected in BG. In saturated (SFA) and monounsaturated fatty acids, 14:0, 16:0, and 18:1n-9 contents in SUB in PIO(+) group were lower ($p<0.05$) than those in PIO(-) group, respectively (14:0: 26.9 ± 8.3 vs. 37.1 ± 6.8; 16:0: 346 ± 86 vs. 454 ± 69; 18:1n-9: 938 ± 167 vs. 1220 ± 177). In n-3 polyunsaturated fatty acid (PUFA) content, 22:5n-3 and 22:6n-3 in all the tissues in PIO(+) group were higher ($p<0.01$) than those in PIO(-) group, respectively (22:5n-3: EPI= 0.359 ± 0.164 vs. 0.036 ± 0.059, MES= 0.282 ± 0.124 vs. 0.014 ± 0.033, RET= 0.249 ± 0.119 vs. 0.000 ± 0.000, SUB= 0.484 ± 0.166 vs. 0.052 ± 0.127; 22:6n-3: EPI= 0.745 ± 0.452 vs. 0.103 ± 0.126, MES= 0.771 ± 0.450 vs. 0.029 ± 0.045, RET= 0.590 ± 0.253 vs. 0.000 ± 0.000, SUB= 1.07 ± 0.41 vs. 0.113 ± 0.150). In n-6 PUFA, 18:3n-6 in MES in PIO(+) group was lower ($p<0.05$) than that in PIO(-) group (1.06 ± 0.20 vs. 1.47 ± 0.32) whereas 20:3n-6 in EPI and 22:4n-6 in EPI, MES, and SUB in PIO(+) group were higher ($p<0.05$), respectively (20:3n-6: 0.936 ± 0.370 vs. 0.437 ± 0.289; 22:4n-6: EPI= 0.975 ± 0.749 vs. 0.163 ± 0.118, MES= 1.11 ± 0.79 vs. 0.136 ± 0.119, SUB= 0.609 ± 0.295 vs. 0.198 ± 0.300). Average adipocyte diameter in PIO(+) group tended to be smaller than those in PIO(-) group (EPI= 98 ± 9 vs. 104 ± 7, MES= 83 ± 5 vs. 95 ± 9, RET= 89 ± 11 vs. 116 ± 13 ($p<0.05$), SUB= 84 ± 4 vs. 92 ± 11).
Conclusion: Pioglitazone reduced PI, TG, and FFA levels, and tended to increase small adipocytes. These effects of pioglitazone led to decrease in 14:0, 16:0, 18:1n-9, and 18:3n-6 contents but to increase 22:5n-3, 22:6n-3, 20:3n-6, and 22:4n-6 contents in adipose tissues. High SFAs and 18:1n-9 are usually in insulin resistant state. High contents in several C20 and C22 PUFAs in PIO(+) group, probably increased due elongation process, may have improved the insulin resistance. On the other hand, in PIO(-) group, the elongation and/or desaturation of longer than 18:3n-6 may be reduced.

Intramuscular triglyceride synthesis rate influences skeletal muscle DAG localisation in humans

B.C. Bergman, L. Perreault, D.M. Hunerdosse, A. Kerege, M.C. Playdon, S. Bacon, A. Strauss, R.H. Eckel;
Endocrinology, University of Colorado, Aurora, USA.

Background and aims: We recently reported that diacylglycerol (DAG) localisation influences insulin resistance in humans, with only DAG in membranes related to insulin resistance and PKC activation. It is currently unknown what influences DAG localization in skeletal muscle. We sought to evaluate if the basal rate of intramuscular triglyceride (IMTG) synthesis was related to DAG localisation in humans.
Materials and methods: Six obese sedentary controls (Con: 2W, 4M, Age: 39.5±2.3 yrs, BMI: 33.3±1.4 kg/m2, Si: 3.2±0.4 10-4/μU/ml), five individuals with type 2 diabetes (T2D: 0W, 5M, Age: 44±1.8 yrs, BMI: 30.1±2.3 kg/m2, Si: 2.4±0.6 10-4/μU/ml), and ten endurance trained athletes (Ath: 2W, 8M, Age: 35.4±3.1 yrs, BMI: 23.3±0.8 kg/m2, Si: 12.6±1.7 10-4/μU/ml) were studied. Insulin sensitivity was determined using an IVGTT, and basal IMTG synthesis rate (FSR) measured using a 4 hour infusion of U-13C palmitate after an overnight fast. Muscle biopsies were taken and a portion used to isolate triglyceride enrichment which was measured using GC/C/IRMS. Another portion was fractionated using ultracentrifugation, and DAG species measured using LC/MS/MS.
Results: Endurance trained athletes had significantly greater insulin sensitivity (Obese: 3.15±0.3 min-1/uU/ml, T2D: 2.58±0.7 min-1/uU/ml, Ath: 8.65±2.2 min-1/uU/ml, $p<0.0001$), and IMTG FSR compared to the other two groups (Obese: 0.51±0.18 %/hr, T2D: 0.48±0.17 %/hr, Ath: 1.58±0.15 %/hr, $p<0.0001$). The percent of DAG in the membrane fraction was significantly lower in athletes compared to the other two groups ($p=0.01$). Further, there was a significant inverse relationship between IMTG FSR and % membrane DAG ($r=-0.71$, $p=0.0004$) and total membrane DAG ($r=-0.20$, $p=0.007$), and a positive relationship between IMTG FSR and cytosolic DAG content ($r=0.48$, $p=0.002$).
Conclusion: These data suggest that the synthesis rate of IMTG in skeletal muscle promotes DAG accumulation in the cytosolic compartment, preventing membrane DAG accumulation. Therefore, the turnover rate of the intramuscular triglyceride pool appears to influence skeletal muscle diacylglycerol localisation.

Involvement of the endocrine factor FGF21 in the beneficial effects of dietary long-chain n-3 polyunsaturated fatty acids

J. Villarroya[1], P. Flachs[2], I. Redondo[3], M. Giralt[3], F. Villarroya[3], J. Kopecky[2], A. Planavila[3];
[1]Hospital de la Santa Creu i Sant Pau and University of Barcelona, Spain,
[2]Academy of Sciences of the Czech Republic, Prague, Czech Republic,
[3]University of Barcelona and CIBER Fisiopatologia de la Obesidad y Nutrición, Spain.

Background and aims: Diets rich in long-chain n-3 polyunsaturated fatty acids (n-3 PUFA) protect against insulin resistance and obesity in rodent mod-

els of metabolic disease. Fibroblast growth factor-21 (FGF21) is a hormonal factor released mainly by the liver, strongly regulated by PPARalpha, and having powerful anti-diabetic effects. We tested whether the healthy metabolic effects of n-3 PUFA involve FGF21

Materials and methods: C57BL/6J mice were exposed to an obesogenic corn-oil-based high-fat diet (cHF) or a diet in which vegetable oils were replaced by a fish-oil extract highly enriched in long-chain n-3 PUFA (cHF+F). Control mice were treated with a convential high-carbohydrate diet (HC). Food intake, body weight, systemic metabolites (glucose, triglycerides) were measured using spectrophotometric methods, hormones and cytokines using a Multiplex system (Millipore), and plasma FGF21 using ELISA (Biovendor). The expression of FGF21gene, molecular actors of cellular FGF21 responsiveness (FGF receptors 1 and 4, and β-Klotho), and marker genes of lipid metabolism (CPTII, carnitine palmitoyl transferase II; MCAD, medium chain acyl-CoA dehydrogenase; ACO, acyl-CoA oxidase) pathways in liver, white and brown adipose tissues, were evaluated by quantitative real-time PCR using standard TaqMan probes and procedures (Applied Biosystems.

Results: The cHF+F diet prevented body weight increase and reduced insulinemia and triglyceridemia, relative to cHF. The treatment of mice with cHF-F did not modify glycemia but resulted in a significant reduction in blood triglyceride levels (P = 0.008) as well as a significant reduction in insulin levels (P = 0.006) relative to cHF, indicating enhanced systemic insulin sensitivity as a consequence of L-n3 PUFA enrichment in the high-fat diet. Plasma FGF21 levels were markedly increased (1.8-fold, P = 0.03) in cHF-treated mice relative con HC but much less in cHF+F-treated mice (1.3-fold, P=0.07). Hepatic FGF21 gene expression was strongly induced by cHF (7.3-fold, P = 0.002) and only slightly increased by cHF+F (2.3-fold, P=0.04), relative to HC. In contrast, the hepatic expression of typical PPARalpha target genes (CPTII, MCAD, ACO) was much more strongly induced by cHF+F than by the cHF diets. FGF21 gene expression was unaltered by the diet conditions in white and brown adipose tissues. Expression of FGFR1, FGFR4 and β-Klotho were also unaltered by diet conditions in hepatic and adipose tissues.

Conclusion: Healthy metabolic effects caused by n-3 PUFA are not associated with enhanced levels and expression of FGF21, but, conversely, FGF21 levels are preferentially induced by an obesogenic standard high fat. Enhanced FGF21 levels appear not to be the mechanisms by which long chain n-3 PUFA prevents obesity and ameliorates the metabollic profile. Moreover, a pathway of regulation of hepatic FGF21 expression different from PPARalpha appears to take place in response to high-fat diets.

Effect of carnitine palmitoyltransferase (CPT) 1A activity regulation on the control of the food intake

D. Serra[1], P. Mera[1], J.F. Mir[1], K. Makowski[1], M.I. Malandrino[1], M. Weber[1], N. Steiner[1,2], B. Losilla[1], H. Petri[3], X. Ariza[4], L. Herrero[1], G. Asins[1], J. García[5], F.G. Hegardt[1];

[1]Bioquímica i Biologia Molecular, Universitat Barcelona, Spain, [2]Universität Graz, Austria, [3]UniQure, Amsterdam, Netherlands, [4]Quimica Orgánica, Universitat Barcelona, Spain, [5]Química Orgánica, Universitat Barcelona, Spain.

Background and aims: Hypothalamus is a key regulator of food consumption mainly through melanocortin system modulation. Despite the ongoing effort to unveil the role of lipid metabolim in the mechanism, the exact gimmick has not been fully elucidated. Levels of malonyl-CoA, which is the first intermediate in lipogenesis, and levels of long chain fatty acyl-CoA (LCFA-CoA) have been proposed to act as hypothalamic satiety molecular signals. Carnitine Palmitoyltransferase 1A (CPT1A) catalyses the first reaction in the LCFA-CoA transport from cytoplasm to mitochondria and it is directly inhibited by malonyl-CoA. Thus CPT1A is the rate-limiting step in mitochondrial fatty acid oxidation (FAO), and a LCFA-CoA modulator and a malonyl-CoA sensor. The aim of this work is the study of the effect on the control of food intake with CPT1A activity modulation; to do so, we used two experimental approaches: long-term over-expression of a malonyl-CoA insensitive isoform of CPT1A (CPT1AM) in ventromedial hypothalamus (VMH); and pharmacological inhibition of CPT1A in hypothalamus.

Materials and methods: Long-term adeno-associated virus 1 (AAV1)-mediated over-expression of a mutated malonyl-CoA insensitive isoform of CPT1A (CPT1AM) was perfomed in VMH. Viral particles were delivered with a stereotactic injection to VMH. Control animals were injected with AAV1-GFP particles, which were used to track the correct diffusion mainly into VMH. Body weight and food intake were checked weekly and mRNA levels were checked after dead in qRT-PCR assays. C75 enantiomers were sinthesized separately and injected icv to check their effect on food intake and body weight after injection. CPT1 activity was checked with a radiometric assay.

Results: On the one hand, the overexpression of CPT1AM in the hypothalamus produced hyperphagia and overweight in rats. It also up-regulated the hypothalamic mRNA levels of the transcription factor BSX, FoxO1 and CREB described to control the expression of the orexigenic neuropeptides, and of the NPY receptor (NPY1R). On the other hand, the central administration of the compound C75 decreases hypothalamic CPT1 activity, food intake and body weight. Noteworthy, we proved that only the enantiomer (+)-C75, but not (-)-C75, reduces food intake and CPT1 activity in the hypothalamus, suggesting that central inhibition of this enzyme is essential for C75-mediated anorexia.

Conclusion: The data presented demonstrate the fundamental role of hypothalamic CPT1 in the control of food intake and highlights this enzyme as a possible therapeutic target for new drugs designed to limit appetite.

Serum irisin after moderate exercise test in obese and non-obese adolescent boys

B. Skowrońska[1], M. Fichna[2], A. Gertig[1], E. Niechciał[1], I. Krzyśko[1], P. Fichna[1]; [1]Department of Pediatric Diabetes and Obesity, [2]Department of Endocrinology and Metabolism, Poznan University of Medical Sciences, Poznań, Poland.

Background and aims: Skeletal muscle was recently identified as an active secretory organ and irisin has been found to be one of its hormones. Irisin secretion is stimulated by physical activity and seems involved in the browning of the white fat tissue in mice, increased energy expenditure and reducing obesity. The aim of the study was to determine whether, and to what extent, moderate physical activity, usually recommended to overweight/obese patients, affects serum irisin levels in obese and non-obese adolescent boys.
Materials and methods: The study comprised 22 obese (BMI ≥2SDS) and 11 non-obese (BMI <2SDS) boys, aged 15.0±1.6 and 15.3±1.4 years respectively. Their body composition was evaluated by bioelectrical impedance (Body Composition Analyzer MC-980 MA). Irisin and leptin levels were estimated by means of commercial ELISA assays. Additional serum analyses comprised glucose, insulin, cortisol and lactate measurements. Patients were assessed in different metabolic conditions: after overnight fast, 2hrs after the normalised mixed meal (350kcal), and then directly after and 1 hr after 30-minutes aerobic exercise (a walk on a treadmill Precore 9.33 at 3% incline). Mean distance of the walk was 2.2 km (approx. 3.5 Metabolic Equivalent Tasks/hr). Data were presented as mean ±SD. Two-tailed p-values<0.05 were considered significant.
Results: No significant difference in baseline serum irisin (ng/ml) was found between the two studied groups (110.3±73.3 in obese individuals *vs.* 143.8±72.3 in controls, p=0.224), and irisin levels were not affected by the food ingestion (115.2±80.1 and 145.9±139.6, respectively). However, after the exercise irisin concentrations significantly decreased in obese subjects (to 76.5±65.6, p=0.007 compared to baseline) whereas the control group displayed similar levels to the baseline results (137.3±91.0; p=0.035 compared to obese subjects). After one-hour post-walk rest irisin levels were 87.9±64.5 in obese and 129.1±92.4 in the non-obese group (p=0.150). Fasting serum irisin was correlated with fat-free mass in kg (r=0.628; p=0.039) and muscle mass in kg (r=0.628; p=0.038) among non-obese adolescents, while these correlations were not significant among their obese peers (both p>0.05). No correlation was found between fasting glucose or insulin levels and irisin concentrations in any of the studied cohorts. Irisin was positively correlated with glucose level after exercise (r=0.720; p=0.013) in healthy patients but not in obese boys. Serum irisin levels were not correlated with leptin, cortisol or lactate.
Conclusion: Declining serum irisin concentration, which was found in obese boys immediately after moderate physical activity may indicate that working muscles limit the secretion of this myokine in obese status. This suppressive effect was not observed in non-obese patients who displayed irisin level correlation with muscle mass and fat-free mass. Studies suggest that obesity can affect the regulation of irisin release as well as diminish its potential metabolic benefits.

760

Serum FGF21 relation to nutritional status and physical activity in adolescent boys

P. Fichna[1], B. Skowrońska[1], M. Fichna[2], A. Gertig[1], E. Niechciał[1], I. Krzyśko[1]; [1]Department of Pediatric Diabetes & Obesity, [2]Department of Endocrinology and Metabolism, Poznan University of Medical Sciences, Poznan, Poland.

Background and aims: Fibroblast Growth Factor 21 (FGF21) is a liver hormone involved in fat burning and peripheral glucose utilization. It seems to be implicated in obesity, non-alcoholic fatty liver disease (NAFLD) and type 2 diabetes. The study was designed to investigate changes in serum FGF21 at different metabolic states: fasting, fed and after a moderate exercise in obese and non-obese adolescent boys. These circumstances mimicked frequent recommendations for obese persons.
Materials and methods: 22 obese (BMI-SDS ≥2) and 11 non-obese (BMI-SDS &lt2) were evaluated by anthropometric parameters, including body mass composition assessed using bioelectrical impedance (Tanita Analyzer MC-980 MA). Liver ultrasound was performed to detect signs of non-alcoholic fatty liver disease (NAFLD). Serum measurements of glucose, insulin, lactate, ketones, triglycerides, free fatty acids and uric acid, leptin and FGF21 (the latter two by commercial ELISA assays) were performed after overnight fast, 2h after a mixed meal (350kcal), and subsequently at the end and 1h after a 30-minute aerobic exercise (a moderate walk on Precore 9.33 treadmill at 3% incline). Mean distance of the walk was 2.2 km (approx. 3.5 Metabolic Equivalent Tasks/hr). Data are presented as mean ±SD. Two-tailed p-values<0.05 were considered significant.
Results: Fasting serum FGF21 levels (pg/ml) were significantly higher in obese subjects compared to non-obese controls (240.8±130.6 vs. 145.7±76.3; p=0.026). Two hours after mixed meal FGF21 levels were significantly decreased to 103.4±59.0 and 69.4±55.5, respectively, and statistical significance between both studied groups was lost (p=0.105). Moderate exercise induced further reduction of serum FGF21 levels in both cohorts to 82.4±46.8 in obese and 49.5±42.5 in non-obese subjects (p=0.049). An hour later FGF21 was still in decline: 54.9±37.5 and 17.8±22.4, respectively (p=0.001). FGF21 levels did not differ between subjects with moderately elevated aminotransferase activity or ultrasound features of NAFLD and those with intact liver (p>0.05) however, none of the studied individuals presented serious hepatic impairment. FGF21 was negatively correlated with age (r=-0.397, p=0.017) but not with BMI-SDS and body fat mass. A positive correlation was found between FGF21 and leptin levels (r=0.347, p=0.038), which was lost after 30min exercise, but reappeared one hour later (r=0.459, p=0.005). In obese patients, a borderline correlation was detected between FGF21 and lactate levels after physical activity (r=0.405, p=0.050). Serum FGF21 levels displayed no correlation with glucose and insulin levels, ketones, triglycerides, free fatty acids and uric acid (p>0.05).
Conclusion: Higher serum FGF21 levels in obese compared to non-obese boys at all investigated metabolic states may reflect functional resistance to FGF21. Fast promotes FGF21 secretion, while food ingestion and physical activity can decline its serum levels in obese and non-obese male adolescents. Further studies are warranted to recognize if particularly elevated FGF21 concentrations in obese subjects might be stably diminished by moderate exercise, and to explain the distinct effect of different nutrients, particularly with regard to therapeutic diet recommendations in obesity.

761

Skeletal muscle mitochondrial uncoupling induces a metabolic rescue cycle involving FGF21 as a myokine

M. Ost[1], S. Keipert[1], J. Dokas[1], M. Portero-Otin[2], E. M. van Schothorst[3], J. Keijer[3], S. Klaus[1]; [1]Department of Pharmacology/ Group of Energy Metabolism, German Institute of Human Nutrition, Nuthetal, Germany, [2]Department of Pharmacology/ Group of Energy Metabolism, Department of Experimental Medicine, University of Lleida-Biomedical Research Institute of Lleida, Spain, [3]Human and Animal Physiology Wageningen University, Netherlands.

Ectopic expression of uncoupling protein 1 (UCP1) in skeletal muscle (SM) improves whole body energy metabolism and promotes longevity in transgenic mice (UCP1-TG). However, exact physiological mechanisms underlying this metabolic improvement have not yet been resolved. Here, we show that uncoupling in SM induces Fgf21 expression using UCP1-TG mice, resulting in >5 fold elevated circulating FGF21 levels. UCP1-TG mice display maintained muscle function and morphology but reduced muscle mass. In muscle, the autophagic machinery is activated, which is reflected by increased intracellular eIF2alpha/Atf4. Moreover, ER-stress markers such as the Chop, Atf5, Atf6 and Gadd34 are induced. Furthermore, amino acid stress pathways are induced, as shown by increased amino acid response elements (AAREs), which correlate with Fgf21 expression. The serine/glycine biosynthesis pathway was strongly up-regulated in SM of UCP1-TG mice. In addition, gene expression of glucose transporter 1 (Glut1) as well as basal glucose uptake are increased in transgenic mice SM. Accelerated flux through this alternative glycolysis pathway may help SM to adapt to chronic metabolic stress. Strikingly, β-klotho, a required co-factor for global FGF21 action, is increased in skeletal muscle, liver and white adipose tissue (WAT) of UCP1-TG mice, leading to increased futile cycle (increased lipogenesis/lipolysis) in WAT depots and increased hepatic gluconeogenesis. We conclude that remote metabolic improvements caused by mitochondrial uncoupling in SM are mediated by a metabolic rescue cycle involving Fgf21 as a protective myokine to

prevent muscle wasting and linked to starvation-like response mechanisms. The results provide new insights into FGF21 function as a mediator of muscle induced regulation of whole body substrate metabolism and partitioning.

762

Specific changes in plasma lipidome in obesity and type 2 diabetes are associated with physical inactivity and muscle mitochondrial function

T. Kurdiova[1], B. Ukropcova[1], M. Balaz[1], G. Liebisch[2], M. Vician[3], M. Vlcek[1], M. Srbecky[4], J. Olejnik[3], R. Imrich[1], V. Belan[4], I. Klimes[1], G. Schmitz[2], D. Gasperikova[1], J. Ukropec[1];
[1]Department of Obesity, Institute of Experimental Endocrinology, SAS, Bratislava, Slovakia, [2]University Clinic, Regensburg, Germany, [3]Department of Surgery, Slovak Medical University, Bratislava, Slovakia, [4]Radiodiagnostic Clinic, University Hospital, Bratislava, Slovakia.

Background and aims: Type 2 diabetes associates with decreased muscle mitochondrial content&function and changes in plasma lipid composition, both of which might be related to physical inactivity, leading to obesity-related metabolic disease. We compared physical activity, skeletal muscle mitochondrial content/function and plasma lipidome of lean healthy (n=28; 23.2±2.2 $kg.m^{-2}$; body fat 18.4±4.7%), obese/overweight (n=29; 30.4±2.8 $kg.m^{-2}$; body fat 28.6±4.6%), prediabetic (n=24; 31.3±3.2 $kg.m^{-2}$; body fat 30.5±3.3%), and type 2 diabetic men (n=15; 31.4±3.9 $kg.m^{-2}$; body fat 30.9±4.1%).
Materials and methods: Complex metabolic phenotyping included euglycemic hyperinsulinemic clamp (assessment of insulin sensitivity), oral glucose tolerance test, magnetic resonance imaging (adipose tissue content and distribution) and ^{1}H-MR spectroscopy (hepatic-, intramyocellular lipids). Physical activity was monitored with accelerometers and "Beacke"-activity questionnaire. Samples of *vastus lateralis* were obtained by needle biopsy. The expression of peroxisome proliferator activated receptor coactivator 1 alpha (PGC1-α) and mtDNA content were determined by qRT-PCR. The activity of cytochrome C oxidase (COX) was measured by oximetry in permeabilised muscle fibers. Plasma lipidomics were analyzed by mass spectroscopy.
Results: Physical activity, activity of COX, mtDNA copy number and expression of PGC1-α were decreased in T2D. Decreased physical activity was associated with worsened metabolic phenotype and decreased PGC1-α expression. Lipids in plasma (phosphatidylcholine, cholesterin, phosphatidylinositol) were increased in prediabetes and diabetes, or only in diabetes (phosphatidylethanolamine) and were negatively correlated with physical activity and PGC1-α expression. Lysophosphadidylcholine unsaturated was decreased in obesity, prediabetes and diabetes and positively associated with sport and leisure-time indexes and COX activity in muscle.
Conclusion: T2D and physical inactivity is accompanied with changes in plasma lipidome, which could be connected to changes in mitochondrial parameters in muscle.

Effects of resveratrol and exercise training on HFD induced changes in white adipose tissue; role of muscle PGC-1α

S.B. Larsson, N. Brandt, C.M. Kristensen, R.S. Biensø, J. Olesen, H. Pilegaard; Department of Biology, University of Copenhagen, Denmark.

Background and aim: Obesity is a consequence of long term imbalance between calorie intake and output and is characterized by excess deposition of triglycerides as well as molecular changes in the adipose tissue such as low grade inflammation. Exercise training and resveratrol (RSV) have been shown to prevent the negative effects of excess calorie intake and have also been reported to increase the expression and/or activity of muscle PGC-1α. Whether this upregulation of muscle PGC-1α affects the white adipose tissue is unknown. Aim: To test the hypothesis that muscle PGC-1α is required for mediating the beneficial effects of exercise training and RSV on the molecular and morphological changes in white adipose tissue caused by HFD.
Materials and method: 12 weeks old muscle specific PGC-1α knockout mice (MKO) and littermate wildtypes (WT) completed 16 weeks of intervention grouped as follows: Chow, high fat diet (HFD), HFD with resveratrol (HFD+RSV), HFD with exercise training (HFD+EX) and HFD with both resveratrol and exercise training (HFD+RSV+EX). Subcutaneous (S-AT) and visceral (V-AT) adipose tissue were obtained.
Results: HFD increased S-AT and V-AT mass compared with chow ($p<0.05$) and this was rescued by RSV in S-AT for both genotypes and in V-AT in WT ($p<0.05$). The PDK4 mRNA level decreased with HFD ($p<0.05$) but this was rescued by RSV in WT only. UCP-1 mRNA levels were decreased in HFD+RSV, HFD+EX and HFD+RSV+EX ($p<0.05$) compared with HFD in both genotypes. TNFα mRNA levels were unaffected by the interventions.
Conclusion: HFD did not induce inflammation, while RSV prevented HFD induced increases in fat mass and for VAT this required muscle PGC-1α. RSV prevented a HFD induced decrease in PDK4 mRNA in WT indicating that RSV maintains glyceroneogenesis in mice on HFD and that PGC-1α is required for this effect. The lowered UCP-1 mRNA levels with EX and/or RSV may suggest reduced oxidative stress.

Effects of a combined aerobic and resistance exercise programme on C1q/TNF-related protein-3(CTRP3) and CTRP-5 levels

J. Ryu[1], H. Hong[1], H. Choi[1], Y. Kim[1], N. Kim[1], J. Ahn[1], H. Kim[1], H. Yoo[1], S. Kim[1], N. Kim[1], S. Baik[1], B.-S. Youn[2], K. Park[3], K. Choi[1];
[1]Division of Endocrinology and Metabolism, Department of Internal Medicine, Korea University College of Medicine, [2]AdipoGen,Inc, [3]Department of Internal Medicine, Seoul National University College of Medicine, Seoul, Republic of Korea.

Background and aims: Adiponectin is a well-known adipokine which has anti-inflammatory and anti-diabetic effects. Recently, the C1q/TNF-related protein (CTRP) family has been reported to have structural homologies to adiponectin. To date, 15 CTRP family members have been found that might play major roles in metabolism and inflammation. CTRP-3 is a potent anti-inflammatory adipokine that inhibits pro-inflammatory pathways induced by fatty acids, lipopolysaccharides (LPS), and toll-like receptor (TLR) ligands in adipocytes and monocytes. CTRP-5 induces the phosphorylation of AMPK and enhances glucose uptake by glucose transporter 4 (GLUT4). However, due to the unavailability of valid laboratory methods to measure circulating CTRP-3 and CTRP-5 levels, their clinical implications in humans have not been elucidated.
Materials and methods: We examined the gender-difference regarding CTRP-3 and CTRP-5 levels, and explored their relationship with cardiometabolic risk variables in 453 non-diabetic Asian subjects using newly-developed ELISA. In addition, we evaluated the impact of a three-month combined exercise program on CTRP-3 and CTRP-5 levels in 76 obese women. The exercise program consisted of 45 minutes of aerobic exercise at an intensity of 60-75% of the age-predicted maximum heart rate (300 kcal/session) and 20 minutes of resistance training (100 kcal/session) five times a week.
Results: Women had significantly higher CTRP-3 levels compared to men (429.9 [344.6-526.2] vs. 351.8 [279.2-421.9] ng/mL, P <0.001). CTRP-5 levels were also slightly higher in women than in men (50.4 [40.4-67.0] vs. 47.4 [36.4-59.8], P = 0.030). In a stepwise multiple regression analysis, log-transformed CTRP-3 levels were independently associated with age, gender, triglycerides, LDL cholesterol, adiponectin and RBP4 levels (R^2 = 0.174). In contrast, log-transformed CTRP-5 values were not significantly associated with other metabolic parameters (data not shown). When obesity was defined as a BMI of 25 kg/m^2 or higher according to the criteria recommended by Korean Society for the Study of Obesity (KSSO) (14), CTRP-3 and CTRP-5 levels were not significantly different between subjects with and without obesity (P = 0.130 and P = 0.335, respectively). After three months of a combined aerobic and resistance exercise program, CTRP-3 levels also decreased significantly (444.3 [373.8, 535.0] to 374.4 [297.2, 435.9], P <0.001) while CTRP-5 levels increased slightly (34.1 [28.6-44.3] to 38.4 [29.8-55.1], P = 0.048)
Conclusion: Similar to adiponectin, both circulating CTRP-3 and CTRP-5 concentrations showed sexual dimorphism, which is higher in women compared to men. A three-month combined aerobic and resistance exercise program significantly decreased CTRP-3 levels and modestly increased CTRP-5 levels, accompanied by improvements of cardiometabolic risk factors in obese Korean women.

Effect of exercise and rosiglitazone on neprilysin protein expression in db/db diabetic mice

K.M. Elased, S. Gutta, L.F. Alawi, H.K. Somineni, G.P. Boivin;
Pharmacology and Toxicology, Wright State University, Dayton, USA.

Background and aim: Diabetic nephropathy (DN) is one among the main microvascular complications of uncontrolled diabetes, which eventually lead to end stage renal disease. Alteration in renin-angiotensin system (RAS) is considered to be the primary cause underlying the disease process. Hyperglycemia activates RAS and causes an increase in the level of Angiotensin II (Ang II). Emerging evidence suggests that the deleterious effects of Ang II could be opposed by the formation of Ang (1-7), partly generated by the actions of Angiotensin converting enzyme 2 (ACE2) and neprilysin (NEP). NEP is a neutral endopeptidase, a member of zinc-containing metallopeptidase group, which plays a crucial role in the formation of Ang (1-7) from Ang I. Our previous studies reported that renal NEP is decreased in diabetic animal models. We tested the hypothesis that exercise training or rosiglitazone treatment improve glucose homeostasis, up regulate renal NEP protein expression and improve albuminuria in diabetic *db/db* mice. We also hypothesized that changes in renal NEP could be detected in the urine and be used as an index for intrarenal status and progression of chronic kidney disease.
Materials and methods: Seven weeks old lean and *db/db* male mice were subjected either to exercise training or rosiglitazone treatment (20 mg/kg/day) for 10 weeks. Exercise groups were run on a mouse forced exercise walking wheel system at a speed of 8 m/min for 1 hour a day, 7 days a week. Weekly monitoring included 24-hr urinary volume, albumin, creatinine and blood glucose.
Results: *db/db* mice demonstrated hyperglycemia ($p<0.0001$ Vs lean controls), albuminuria ($p<0.0001$ Vs lean controls) and decreased NEP levels in the kidney. Exercise training or rosiglitazone treatment significantly attenuated hyperglycemia ($p<0.0001$ Vs untreated *db/db* mice) and reduced urinary albumin excretion ($p<0.001$ Vs untreated *db/db* mice). Improvements were seen as early as 2 weeks after the initiation of treatment. In addition, *db/db* mice subjected to exercise or rosiglitazone treatment demonstrated a significant increase in renal and urinary NEP protein expression compared to untreated *db*/*db* mice.
Conclusion: Exercise training and rosiglitazone treatment normalized hyperglycemia and up regulated neprilysin levels in the kidney of *db*/*db* mice. Augmentation of renal neprilysin could have a pivotal role in the pathogenesis of diabetic nephropathy. The data suggest that urinary NEP reflects intrarenal RAS status in chronic kidney disease and may be used as an early marker of diabetic nephropathy.

Maturation of AMP-activated protein kinase in skeletal muscle in pre-weaning mice

J. Hansikova, P. Janovska, J. Kopecky;
Department of Adipose Tissue, Institute of Physiology Academy of Sciences of the Czech Republic v.v.i., Prague, Czech Republic.

Background and aims: AMP-activated protein kinase (AMPK) is a multisubunit protein, which plays a key role in control of skeletal muscle metabolism. Namely, lipid and glucose metabolism are modulated at both gene and protein levels. Surprisingly little is known about changes in AMPK subunits expression and AMPK activity in skeletal muscle during the early postnatal development, between birth and weaning. The aims of the present study were to (i) characterize the activity of AMPKα1 and AMPKα2 isoforms and expression of the genes encoding its catalytic subunits in murine skeletal muscle during postnatal development, namely between birth and weaning; and (ii) assess possible roles of both gender and genetic background of the mice.
Materials and methods: Male (M) and female (F) pups of the obesity prone mice C57BL/6 (B/6) and obesity resistant mice A/J were born and maintained at temperature closed to thermoneutrality (30 °C), mothers were fed Chow, and mice were weaned at 28 days (D) of age. Two animals from litter containing 4 - 6 pups were anesthetized by ketamin/xylazin and gastrocnemius muscle was collected by freeze-clamping. Activity of AMPKα1 or AMPKα2 was assessed in 10, 15, 20 and 28 D old pups (n=6). AMPK was immunoprecipitated from tissue extracts and the activity was determined using a peptide substrate. Immunoprecipitates were mixed with AMP, [γ-32P]ATP and AMARA peptide. Gene expression was assessed by real-time quantitative RT-PCR in muscle from 5, 10, 15, 20 and 28 old pups (n=5). Evaluation of data was performed by ANOVA.
Results: At 10D, the activity of AMPKα1 was significantly higher in comparison with AMPKα2 in all tested groups (A/J F ~1.9-fold; A/J M ~3.3-fold; B/6 F ~2.6-fold; B/6 M ~3.7-fold). Between 10D and 28D, the activity of AMPKα1 decreased in mice of both strains except for A/J F (A/J M ~2-fold; B/6 M ~2.6-fold; B/6 F ~3.7-fold). In A/J mice at 28D, activity of AMPKα2 was higher than that of AMPKα1 (A/J F ~1.4-fold; A/J M ~1.6-fold). Total activity of AMPK (α1+α2) in B/6 mice decreased significantly between 10D and 28D (B/6 F ~1.9-fold; B6 M ~ 1.5-fold) but it stayed constant in A/J mice. Expression of AMPKα1 gene was constant in both A/J and B/6 mice between 10D and 28D. Expression of AMPKα2 gene increased between 5D and 28D in both strains (A/J F 5D 3.10±0.96 vs. 28D 12.04±0.80 AU; A/J M 5D 3.54±0.47 vs. 28D 16.00±3.21 AU; B6 F 5D 2.24±0.28 vs. 28D 12.85±1.10 AU; B6 M 5D 2.00±0.08 vs. 28D 9.66±0.80 AU).
Conclusion: During lactation, i.e., the period of the switch from high- to low-fat intake, strain-specific changes in AMPK activity in murine skeletal muscle were observed. While in the obesity-resistant A/J mice the activity stayed constant, it declined in the obesity-prone B/6 mice. The developmental change in AMPK activity reflected the activity of AMPKα1 isoform, but not expression of the genes for the catalytic subunits of the enzyme. Changes in AMPK activity in skeletal muscle during early postnatal development may affect propensity to obesity in adulthood, depending on the genetic background of the mice.

Different feeding rhythm affects hypothalamic regulation of fatty acid metabolism in skeletal muscle

T. Shiuchi[1], S. Chikahisa[1], K. Oura[1,2], N. Shimizu[1], H. Séi[1];
[1]Department of Integrative Physiology, Institute for Health Biosciences,
[2]Student Lab, Faculty of Medicine, The University of Tokushima, Tokushima, Japan.

Background and aims: Disturbance of feeding rhythm has been understood as a risk factor for development of insulin resistance, however, it is not elucidated the detailed mechanism. Here we show a possibility that feeding only in the evening impairs insulin sensitivity because of lipid accumulation in skeletal muscle via hypothalamic regulation.
Materials and methods: In this study, three groups of C57BL/6J mice were given lab chows freely during dark phase (ZT12-24, Control group), first 4-hour in dark phase (ZT12-16; Morning group), or last 4-hour in dark phase (ZT20-24, Evening group) for 8 weeks respectively.
Results: There were no differences in spontaneous motor activity and body temperature during 24-hours among 3 groups. Mice in Evening group showed impaired whole body insulin sensitivity by insulin tolerance test (1 unit/kg) despite mice in the group ingested the smaller food intake than that of Control group, while mice in Morning group showed normal insulin sensitivity. We observed higher triglyceride (TG) content, increased gene expression of fatty acid synthase (FAS) and impaired insulin signals in skeletal muscle in Evening group compared to other group. These effects were not observed in liver. On the other hand, mRNA expression of agouti-related protein (AgRP), an endogenous antagonist for melanocortin receptor, was increased in hypothalamus in Evening group while mRNA expression of POMC, a precursor of endogenous agonist for melanocortin receptor, was decreased. Noradrenaline turnover in skeletal muscle was reduced by ICV-injection of AgRP. In addition, acute and/or chronic ICV-injection of AgRP increased FAS expression and TG content in skeletal muscle. Moreover, inhibition of central AgRP expression by antisense oligo improved insulin resistance in Evening group.
Conclusion: These results indicate that feeding rhythm like as ingestion only in the evening impairs insulin sensitivity. This phenomenon may be partly mediated by hypothalamic melanocortin system, reduced sympathetic nerve activity and TG accumulation in skeletal muscle.

Bip/GRP78 inhibits adipogenesis through Wnt/beta catenin signalling

Y. Nie[1,2], G. Xu[1,2];
[1]Shenzhen Research Institute, Shenzhen, China, [2]Medicine and Therapeutics, The Chinese University of Hong Kong, Hong Kong.

Background and aims: Bip/GRP78 is one of major molecular chaperons, accounting for protein assembly and folding in endoplasmic reticulum (ER) lumen. Adipocytes act as endocrine cells to secret larger amounts of cytokines and lipid mediators. The process requires abundant protein chaperons for the ER homeostasis and functional maintenance. The characteristic elicits an importance of chaperons in the regulation of adipocyte metabolism. In this study, we try to investigate the role of Bip/GRP78 in adipocyte biology.
Materials and methods: We over-expressed Bip/GRP78 via adenovirus-mediated gene transfer in pre- and differentiated 3T3-L1 CAR adipocyte. Morphology of adipocytes was monitored and lipid accumulation was determined by Oil Red O staining. Functional analysis was performed by real-time PCR and immunoblotting.
Results: Bip/GRP78 was first over-expressed in differentiated adipocytes. Gene related with lipid metabolism was detected, no significant change was found. Insulin signaling was then determined by AKT phosphorylation. However, Insulin-stimulated p-AKT level was not altered by Bip/GRP78, either. Subsequently, in order to investigate whether Bip/GRP78 exerts potential role in the chaperon-deficient situation, FFA was used to induce deprivation of chaperons in adipocyte, which was determined by increased ER stress and insulin resistance. Unexpectedly, over-expression of Bip/GRP78 failed to rescue cells from FFA-induced stresses. The results suggest a limited effect of Bip/GRP78 in mature fat cell. In contrast, when we over-expressed Bip/GRP78 in pre-adipocytes, inhibition of adipogenesis was found. Lipid accumulation was decreased by 40% at 6 days post-induction in Bip/GRP78 over-expressed pre-adipocyte, accompanied with decreased genes expression of lipid synthesis (PPARγ, ap2, LPL, LXRα, SREBP1c) and mature adipocytes markers (Adiponectin, Leptin). The further molecular mechanism analysis determined that wnt/β-catenin signaling was activated in Bip/GRP78 over-expressed pre-adipocytes, and inhibition of β/cateinin activity with its inhibitor restored Bip/GRP78-mediated adipogenesis inhibition.
Conclusion: The study suggests BIP plays a major role in the development of adipocyte rather than regulation of the physiology of mature adipocytes. Accordingly, Bip/Grp78 might be a potential target therapeutics therapy for obesity.

WISP1 (Wnt1 inducible signalling pathway protein 1) is a novel marker of adipose tissue differentiation and obesity

V. Murahovschi[1,2], I. Ilkavets[3], O. Pivovarova[1,2], R. Dmitrieva[4], S. Döcke[1,2], C. von Loeffelholz[5,2], S. Dooley[3], A.F.H. Pfeiffer[1,2], N. Rudovich[1,2];
[1]Department of Clinical Nutrition, German Institut for Nutrition Science, Nuthetal, Germany, [2]Department of Endocrinology, Diabetes and Nutrition, Campus Benjamin Franklin, Charité University Medicine, Berlin, Germany, [3]Department of Molecular Hepatology and Alcohol-dependent Liver Diseases Medical Clinic II, Unimedicine Mannheim, University of Heidelberg, [4]Almazov Federal Center of Heart, Blood and Endocrinology, Saint Petersburg, Russian Federation, [5]Department of Anesthesiology and Intensive Care, University-Medicine Jena, Germany.

Background and aims: WISP1 (Wnt1 inducible signalling pathway protein 1) belongs to CCN family of extracellular matrix-associated signalling proteins, which were key signalling molecules involved in the processes such as proliferation, adhesion, apoptosis and differentiation. WISP1 acts via the induction of the Wnt / beta-catenin signalling pathway and plays a leading role in the pathogenesis of fibrosis and diabetes complications. Recently study suggested involvement of CCN family proteins in adipogenesis. Here we tested hypothesis that WISP1 gene expression may be regulated by weight changes and insulin. Moreover, we examined WISP1 gene expression in subjects with nonalcoholic fatty liver (NAFL), as an example of ectopic fat accumulation.
Materials and methods: In a subcohort of "Diet, Obesity, and Genes" (DiOGenes) study (n = 45), weight loss of at least 8% of baseline body weight was achieved using a low-calorie diet. Subcutaneous fat biopsies were obtained before and after weight loss. Monocytes were isolated from the whole blood and differentiated with GM-CSF and M-CSF into macrophages. Human mesenchymal stem cells were differentiated in vitro into adipocytes. On 1st, 5th and 12th day of differentiation RNA was isolated. Differentiated adipocytes were incubated with 100nM insulin for 4 hours. In a cross-sectional study (n=29), samples of liver tissue was taken intrasurgically and graded histologically by an expert pathologist according to the NAFLD activity score. The mRNA expression of WISP1 was measured with RT-PCR in subcutaneous adipose tissue biopsy, in differentiated adipocytes, monocytes and macrophages as well as in liver samples.
Results: Weight loss of 10.9 ± 3.6 kg was achieved after low-calorie diet. Gene expression of WISP1 fell significantly after weight reduction (mean ± SEM, 0.66 ± 0.08 vs. 0.52 ± 0.06; P <0.05). A strong and significant increase in WISP1 gene expression during the differentiation of adipocytes on 5th and on 12th day and after stimulation with 100nM insulin was observed. In monocytes as well as in M-and GM-macrophages we couldn't identify WISP1 at mRNA level. We found no correlation between NAFLD activity score as well as liver fat content and WISP1 gene expression in NAFL patients.
Conclusion: Weight loss decreased WISP1 expression in subcutaneous adipose tissue in vivo, referred only to gene expression in adipocytes. Adipocytes differentiation is associated with increase of WISP1 expression and is positively regulated by insulin. WISP-1 expression was not altered in the NAFL. Thus, WISP1 plays an important role in adipogenesis and can be used as a marker of adipose tissue differentiation in obesity and lipodystrophy, but not as marker of ectopic fat accumulation.

The potential role of iron and endogenous transferrin biosynthesis in human and 3T3-L1 adipocyte differentiation

J.M. Fernández-Real[1], J. Moreno-Navarrete[1], M.G. Novelle[2], V. Catalán[3], F. Ortega[1], M. Moreno[1], J. Gomez-Ambrosi[3], G. Xifra[1], M. Serrano[1], E. Guerra[1], G. Frühbeck[3], C. Diéguez[2], W. Ricart[1];
[1]Hospital of Girona, [2]University of Santiago de Compostela, [3]Clínica Universidad de Navarra, Pamplona, Spain.

Background and aims: Cross-sectionally, iron metabolism-related protein gene expression has been found to be altered in adipose tissue in association with obesity and insulin sensitivity. Transferrin (*TF*) gene expression decreased in association with obesity and insulin resistance, whereas ferritin light chain (*FTL*) followed an opposite pattern. We aim to investigate the effects of iron overload and/or depletion in adipocyte differentiation.
Materials and methods: Human and 3T3-L1 preadipocytes were incubated with fresh media (control), fresh media containing $FeSO_4$(3 and 30 μg/ml), deferoxamine (DFO, 20 and 100 μM), and several $FeSO_4$and DFO combinations during human and 3T3-L1 adipocyte differentiation. Permanent silencing was also performed using Tf- and Ftl-targeted and control shRNA lentiviral particles.
Results: In both human and 3T3-L1 preadipocytes, iron was required for a timely adipocyte differentiation. Both iron in excess and iron chelation led to either a slight decrease in adipocyte differentiation (decreasing adipogenic gene expression) or to pronounced anti-adipogenic effects (using deferoxamine). In fact, iron replacement reversed the antiadipogenic effects of deferoxamine. As expected, added iron and iron chelation led to reciprocal changes of transferrin receptor (*TFRC*), while iron chelation resulted in decreased ferroportin (*SLC40A1*) and increased ferritin heavy chain (*FTH1*). *TF* gene expression decreased with excess iron. Interestingly *TF* followed a similar gene expression pattern to that of other adipogenic genes with iron chelation, whereas *FTL*significantly increased in these anti-adipogenic conditions. *Tf* knockdown (KD) led to a significant decrease of adipogenic mRNAs (such as *Fabp4, Cebpa, Pparg, Glut4, Adipoq*) while increasing *IL6*gene expression. In contrast, in *Ftl*KD cells, no significant effects were found in adipogenic gene expression. Furthermore, in both *Tf* KD and *Ftl* KD 3T3-L1 cells, the highest dose of iron led to increased expression of adipogenic genes in contrast to control 3T3-L1 cells, suggesting higher iron requirements necessary for adipocyte differentiation in these cells.
Conclusion: A precise and fine-tuned iron handling is essential to ensure a delicate and appropriate cross-talk among adipogenesis, adipose tissue inflammation and insulin action.

Impaired leptin regulation by epigenetic methylation as a marker of immature preadipocyte function in low birth weight subjects

N. Schultz[1], C. Broholm[1], L. Gilberg[1], B. Pedersen[2], A. Vaag[1];
[1]Department of Endocrinology, Rigshospitalet, Copenhagen, [2]Center for Inflammation and Metabolism, Rigshospitalet, Copenhagen, Denmark.

Background and aims: Low birth weight (LBW) is associated with increased risk of developing T2D. Immature development of subcutaneous adipose tissue might contribute to risk of lipotoxicity, insulin resistance and T2D in LBW subjects. Leptin is an accepted marker of adipocyte differentiation and plays a key role in the regulation of appetite. We hypothesized that leptin is dysregulated in adipocytes of LBW individuals compared to normal birth weight (NBW) individuals.
Materials and methods: We recruited 14 men born with LBW (mean birth weight 2.7±0.1 kg) and 13 controls born with NBW (mean birth weight 3.7±0.2 kg). Biopsies were obtained from subcutaneous abdominal fat depot and preadipocytes were isolated and cultured. Gene expression of leptin and selected differentiation markers were analyzed using qPCR during preadipocyte differentiation and cell culture media was collected to analyze leptin secretion. Lipid accumulation was analyzed as an end-stage measure of differentiation and lipid storage capacity. DNA methylation of specific CpG sites in the leptin promoter was measured using pyrosequencing.
Results: Differentiating preadipocytes from LBW individuals showed reduced leptin gene expression and a corresponding reduced leptin release compared to NBW individuals. Mean DNA methylation of the proximal LEP promoter was increased in LBW compared to NBW individuals. The notion of a reduced adipocyte function in LBW individuals was supported by a lower expression of fatty acid binding protein 4 (FABP4) mRNA, and a tendency of reduced expression of other differentiation markers.
Conclusion: Differentiating preadipocytes of LBW subjects have an epigenetically dysregulated leptin production which might explain the predisposition of these individuals to T2D.

Bivalent histone modification of the promoter and its resolution contribute to the epigenetic regulation of PPARγ gene expression and adipocyte differentiation

T. Yamauchi, J. Yu, H. Waki, T. Kadowaki;
Department of Diabetes and Metabolic Diseases, University of Tokyo, Japan.

Background and aims: Recent genome-wide studies of histone modification in embryonic stem (ES) cells revealed that the promoters of a subset of developmental genes are marked by both active histone H3K4 trimethylation (me3) and repressive H3K27me3, which is termed bivalent domain and proposed to represent the poised status of the developmental genes.We tried to clarify whether bivalent histone modification of the promoter and its resolution could contribute to the epigenetic regulation of PPARγ gene expression and adipocyte differentiation.
Materials, methods and results: Here we show that the PPARγ1 promoter is marked by the bivalent modification in ES cells, murine embryonic fibroblasts (MEFs) and adipocyte progenitor cells in white adipose tissue whereas it is marked by only H3K4me3 in mature adipocytes and adipogenic cell lines including 3T3-L1. Upon differentiation, MEFs lose H3K27me3 at the PPARγ1 promoter and it resolves to H3K4me3 only. Knockdown of the H3K27 demethylases Jmjd3 and Utx by siRNA attenuates the reduction of H3K27me3 and causes suppression of adipocyte differentiation, suggesting that the resolution of the bivalent domain is required for adipocyte differentiation of MEFs. Interestingly, the resolution of the bivalency is not dependent on the addition of the adipogenic inducers and differentiation per se, but rather on the serum context: It resolves to H3K4me3 in fetal bovine serum while it turns to H3K27me3-dominant pattern in calf serum, in which they lose responsiveness to the adipogenic cocktail for differentiation.
Conclusion: Our findings imply that the bivalent modification of the PPARγ1 promoter in *in vivo* adipocyte stem/progenitor cells needs to undergo chromatin remodeling and its resolution is a prerequisite for the subsequent activation of PPARγ expression in response to the adipogenic cue.

Dual effects of inflammation and insulin resistance on markers of renewal of adipose tissue

G. Pardo[1], F.J. Ortega Delgado[1], J. Moreno-Navarrete[1], N. Pueyo[1], M. Sabater[1], M. Serrano[1], D. Mayas[2], M. Serino[3], J.I. Rodriguez-Hermosa[1], W. Ricart[1], R. Burcelin[3], F.J. Tinahones[2], G. Frühbeck[4], G. Mingrone[5], J. Fernández-Real[6];
[1]Hospital of Girona, Girona, [2]Hospital Clínico Universitario Virgen de Victoria de Málaga, [3]Institut de Médecine Moléculaire de Rangueil, Université Paul Sabatier, Toulouse, France, [4]Clínica Universitaria de Navarra, Pamplona, Spain, [5]Institute of Internal Medicine, Catholic University of Rome, Italy, [6]Hospital Dr. Josep Trueta, Girona, Spain.

Background and aims: The development of adiposity is dependent on the coordinated interplay between the proliferation and differentiation of adipocytes. The tumor suppressor protein 53 (p53) is a key regulator of various cellular networks, including proliferation, differentiation, and metabolism. The purpose of this study was to investigate the expression of human adipose tissue (AT) *p53* in subjects who varied widely in terms of obesity and insulin resistance. We also analyzed different *in vivo* and *in vitro* models to try to comprehend the associations found in human AT.
Materials and methods: p53 and its modulating partner, the mouse double minute 2 (MDM2), were assessed in subcutaneous (SC) and omental (OM) AT from humans and in isolated fat cells, during *in vitro* adipogenesis, and in high-fat diet induced obese and GLP1R KO mice. The effects of the surgery-induced weight loss and *ex vivo* treatments with metformin in adipose tissue were also studied. The impact of *in vitro* high glucose concentrations, rosiglitazone, and inflammatory conditions such as the macrophage lipopolysaccharide (LPS) - conditioned medium (LPS-MCM) on *p53* expression in adipocytes was evaluated.
Results: OM *p53* gene expression (+27%, p=0.001) and protein (+11%, p=0.04) were increased in obese subjects and high fat diet-induced obese mice (+86%, p=0.018). Although the obesity-associated inflammatory milieu was associated with increased OM p53, AT *p53* was negatively related to insulin resistance and glycated hemoglobin, and positively with biomarkers for insulin sensitivity. Multiple linear regression analyses revealed that glycated hemoglobin (p<0.0001) and BMI (p=0.048) contributed independently to explain 13.7% (p<0.0001) of OM *p53* variance. Accordingly, the improvement of insulin sensitivity with surgery-induced weight loss (+51%, p=0.01) and metformin (+42%, p=0.02) led to increased *p53*, the glucose intolerant GLP-1R KO mice showed decreased AT *p53* (-45.4%, p=0.017), and high glucose led to decreased *p53* in pre-adipocytes (-27%, p<0.0001). Inflammatory treatments led to increased *p53* (+35%, p<0.0001), while rosiglitazone down-regulated this expression (-40%, p=0.005) in mature adipocytes.
Conclusion: Inflammation and insulin resistance exert dual effects on AT *p53*, which seems to be the final result of these opposing forces. Contrary to expected, inverse associations with insulin resistance and type 2 diabetes were reported.

774

A novel role of Opa-interacting protein 5 in obesity

K. Inoue[1], N. Maeda[1], T. Mori[1], M. Yamaoka[1], R. Sekimoto[1], Y. Tsushima[1], H. Nishizawa[1], T. Funahashi[1,2], I. Shimomura[1];
[1]Metabolic medicine, Graduate School of Medicine, Osaka University, [2]Metabolism and Atherosclerosis, Graduate School of Medicine, Osaka University, Japan.

Background and aims: We have shown that visceral fat adiposity plays the central role of metabolic syndrome. We hypothesized that visceral fat accumulation may reflect on gene expression profile in peripheral blood cells and recently reported the association between visceral fat adiposity and gene expressions of peripheral blood cells in human subjects. In a series of study, we searched genes of unknown function in adipocytes or adipose tissues by comparing the cDNA microarray-based gene expression patterns of human peripheral blood cells and mouse adipose tissues. OIP5 (Opa-interacting Protein 5), one of candidate genes, was nominated in this process and herein was investigated in the role of obesity.
Materials and methods: In human study, the estimated visceral fat area (eVFA) was measured by abdominal bioelectrical impedance analysis. Blood total RNA samples were obtained from 28 subjects (BMI 31.9±6.0 kg/m^2, eVFA 199.4±89.4 cm^2) and were subjected to Whole Human Genome 4 × 44 K oligo-DNA microarray (Agilent Technologies, Inc.). For in vivo study, male

C57BL/6J (B6) mice and ob/ob (Ob) mice were analyzed at the same weeks of age. White adipose tissues (WAT) of B6 and Ob mice were subjected to GeneChip Mouse Genome 430 2.0 Array oligo-DNA microarray (Affymetrix, Inc.) at 25 weeks of age. WAT was fractionated into mature adipocytes fraction (MAF) and stromal vascular cell fraction (SVF) by using collagenase. For in vitro Oip5-knockdown experiments, 3T3-L1 adipocytes were transfected with siRNA for Oip5. In the Oip5-overexpression studies, adenovirus expressing Oip5 (Ad-Oip5) was constructed and infected into 3T3-L1 cells stably expressing Coxsackie-Adenovirus Receptor (CAR-3T3-L1). Adenovirus expressing β-galactosidase was used as a control (Ad-βgal). Proliferation of 3T3-L1 preadipocytes was measured by bromodeoxyuridine (BrdU) uptake and cell count.

Results: Fourteen genes, which expressions are similar directions between human and mouse according to adiposity, were extracted by comparing the cDNA microarray-based gene expression patterns of human peripheral blood cells and mouse WAT. We narrowed candidate genes down from 14 to 7 genes in view of its unknown function in adipose tissues. Among 7 genes, OIP5 mRNA levels in peripheral blood cells were positively correlated with eVFA in human subjects. Oip5 mRNA was detected ubiquitously and its adipose mRNA level was significantly higher in Ob mice than B6 mice. Such increase was similarly observed in diet-induced obese (DIO) mice. Oip5 mRNA levels of MAF and SVF in Ob mice were significantly increased 2.1-fold and 5.7-fold, respectively, compared to B6 mice. Next, the functional role of adipose Oip5 was investigated in 3T3-L1 preadipocytes. BrdU uptake and the number of preadipocytes were significantly reduced in Oip5-knockdown cells, while proliferation of CAR-3T3-L1 preadipocytes was significantly increased by the infection of Ad-Oip5 compared to Ad-βgal. Finally, Ad-Oip5 or Ad-βgal was locally administered to subcutaneous WAT of B6 mice. Ad-Oip5-injected WAT was significantly heavier than Ad-βgal-treated WAT. Cell size of adipocytes was generally smaller in Ad-Oip5-administered WAT compared to Ad-βgal-treated WAT.

Conclusion: Oip5 may contribute to adipose tissue hyperplasia and obesity.

Clinical Trial Registration Number: UMIN 000001663

Adipocyte morphology and implications for metabolic derangements in obesity

S. Heinonen[1], L. Saarinen[2], J. Naukkarinen[1,3], A. Rodríguez[4], G. Frühbeck[4], A. Hakkarainen[5], J. Lundbom[5], N. Lundbom[5], P. Arner[6], S. Hautaniemi[2], A. Suomalainen[7], J. Kaprio[3,8], A. Rissanen[1], K. Pietiläinen[1,3];
[1]Obesity Research Unit, Research Programs Unit, Diabetes and Obesity, University of Helsinki, Finland, [2]Research Programs Unit, Genome-Scale Biology and Institute of Biomedicine, Biochemistry and Developmental Biology, Helsinki, Finland, [3]FIMM, Institute for Molecular Medicine, University of Helsinki, Finland, [4]Metabolic Research Laboratory, Clinica Universidad de Navarra, & CIBERobn, Instituto de Salud Carlos III, Pamplona, Spain, [5]Helsinki Medical Imaging Center, University of Helsinki, Finland, [6]Lipid Laboratory, Department of Medicine, Karolinska University Hospital Huddinge, Karolinska Institutet, Stockholm, Sweden, [7]Research Program of Molecular Neurology and Department of Neurology, University of Helsinki and Helsinki University Central Hospital, Finland, [8]Finnish Twin Cohort Study, Department of Public Health, Hjelt Institute, University of Helsinki, Finland.

Background and aims: Adipocyte size and number have long been suggested to predict the development of metabolic complications in obesity. However, the genetic and environmental determinants behind this phenomenon remain unclear.

Materials and methods: We studied this question in rare weight-discordant (intra-pair difference (Δ) in BMI 3-10 kg/m², n=15) and concordant (ΔBMI 0-2 kg/m², n=5) young adult (22-35 years) monozygotic twin pairs identified from ten birth cohorts of Finnish twins (n=5500 pairs). Subcutaneous abdominal adipocyte size from surgical biopsies was measured under a light microscope and adipocyte number was calculated from cell size and total body fat (DXA).

Results: The concordant pairs were remarkably similar for adipocyte size and number (intra-class correlations 0.91-0.92, p<0.01), suggesting a strong genetic control of these measures. In the discordant pairs the obese co-twins (BMI 30.6±0.9kg/m²) had significantly larger adipocytes (volume 547±59pL), than the lean co-twins (24.9±0.9kg/m²; 356±34pL, p<0.001). Intrapair differences (Δ) in cell number varied widely between pairs but on average the cell numbers did not differ between the obese ($8.29\pm0.6x10^{13}$) and lean ($8.75\pm0.7x10^{13}$, p=0.61) co-twins. In all pairs, Δadipocyte volume correlated positively and Δcell number negatively with ΔHOMA-index and ΔLDL, independent of Δbody fat. In 8/15 pairs, the obese co-twins had less adipocytes than their co-twins. These hypertrophic+hypoplastic obese had significantly higher liver fat (spectroscopy), HOMA-index, CRP and ΔLDL-cholesterol than their lean twin pair members. In the transcriptomics analyses (Affymetrix), transcripts most significantly correlating with Δadipocyte volume were related to reduced mitochondrial function, membrane modifications, DNA-damage and cell death.

Conclusion: Increased adipocyte size and decreased number in obesity are related to metabolic dysfunction, possibly through disturbances in mitochondrial function and increased cell death within the adipose tissue.

Blockade of lysophosphatidic acid receptors reduces adipose tissue fibrosis and improves insulin resistance

C. Rancoule, S. Gres, P. Valet, J.S. Saulnier Blache;
team 3, I2MC INSERM, Toulouse, France.

Background and aims: Fibrosis is one of the obesity-associated complications involved in the etiology of different diseases such as hepatic cirrhosis, nephropathies or cardiomyopathies. Recently, adipose tissue (AT) fibrosis was demonstrated in obese mice and humans and current studies suggest an involvement of this fibrotic process in the onset of associated insulin resistance. Lysophosphatidic acid (LPA) has been described as a potent pro-fibrotic mediator in several organs mainly via its G protein-coupled receptor LPA1R. LPA is a bioactive lipid produced by a lysophospholipase D called autotaxin. In both, human and mice, this enzyme is secreted by the adipose tissue and its expression is up-regulated during obesity in close association with insulin resistance. In the present study, we examined whether LPA might be involved in AT fibrosis and insulin resistance associated with obesity.

Materials and methods: Human subcutaneous AT explants were maintained for 72h in primary culture in the absence or the presence of 1-oleoyl-LPA (10μM) and/or the LPAR antagonist Ki16425 (10μM) and/or the HIF1α inhibitor YC1 (100 μM) before quantifying fibrosis genes and proteins. In parallel, six week-old db/db mice were treated for 7 weeks with the LPAR antagonist Ki16425 (5mg/kg/day, ip) before investigating glucose metabolism and quantify fibrosis genes and proteins in inguinal AT.

Results: Ex vivo, AT explants showed a spontaneous increase in autotaxin mRNAs (4.2 ± 0.8 fold; P<0.001) with accumulation of LPA in the culture medium. This was associated with an up-regulation of fibrosis marker mRNAs (collagen I: 4.8 ± 0.9 fold P<0.001; collagen III: 2.4 ± 0.5 fold P<0.01). Spontaneous fibrosis was not observed in the presence of Ki16425. On the opposite, in the presence of 1-oleoyl-LPA, spontaneous fibrosis was further amplified at both mRNA (collagene I: 7.3 ± 1.1 fold P<0.01; collagen III: 7.0 ± 2.1 fold P<0.001) and protein (collagen staining with sirius red: 29.9 ± 4.7 vs 8.6 ± 3.3 % stained surface; P<0.01 in LPA and control respectively). The pro-fibrotic activity of oleoyl-LPA was blocked by co-treatment with Ki16425 or the HIF1α-inhibitor, YC1. In vivo, db/db mice developed massive obesity, insulin resistance and up-regulation of ATX and fibrosis markers in AT when compared to non obese db/m mice. Chronic treatment of db/db mice with Ki16425 reduced types I, III and IV collagen mRNAs (0.56 ± 0.07, 0.63 ± 0.09 and 0.62±0.07 fold; P<0.05) and reduced Sirius red collagen staining (13.9 ± 1.8 vs 20.4 ± 2.4 % stained surface; P<0.05) in AT when compared to control treated mice. Ki16425-treatment also reduced insulinaemia (7581 ±212 pg/ml vs 8351 ±270 pg/ml; P<0.05), glycaemia (262±28 mg/dl vs 343 ±24 mg/dl; P<0.05) and the AUC of insulin tolerance test (11985 ± 457 vs 13778 ± 312 % x min; P<0.05). AT fibrosis decrease is associated with adipocytes hypertrophy without inflammation increase. HIF1α pathway is currently being studied in this in vivo model.

Conclusion: Our results suggest that increased production of LPA with obesity leads to AT fibrosis through a pathway involving LPARs and HIF-1a. In parallel, LPA impairs insulin-tolerance of db/db mice. Further investigations will aim to determine whether there exists a causal relationship between the pro-fibrotic action of LPA and its impact on insulin-sensitivity.

Collagen VI mRNA expression is regulated by leptin: a potential physiological feedback mechanism regulating adipose tissue expandability

L.J. McCulloch[1], T.J. Rawling[1], E.J. Price[1], B. Knight[2], N.H. Liversedge[3], K. Kos[1];
[1]Institute of Biomedical and Clinical Sciences, University of Exeter Medical School, [2]NIHR Exeter Clinical Research Facility, University of Exeter Medical School, [3]Department of Obstetrics and Gynaecology, Royal Devon and Exeter NHS Foundation Trust, Exeter, UK.

Background and aims: Reduced adipose tissue (AT) expandability is now recognised as a driver of ectopic fat deposition, impaired metabolic health and diabetes progression, and is in part modulated by alterations in extracellular matrix (ECM) composition. Collagen VIα3, a pericellular ECM protein, is upregulated in the adipose tissue of diabetic and obese mice whilst knockout of the protein in metabolically compromised animals leads to improved metabolic health. Few studies have assessed the role of *COL6A3* in humans. We therefore characterised the adipose tissue expression of *COL6A3* in obese subjects, subjects with diabetes and in individuals following diet induced weight loss. We also assessed *COL6A3* expression in adipose tissue following treatment with metabolic regulators.
Material and methods: Subcutaneous abdominal and omental biopsies were obtained from nine lean (BMI 22.6±0.5kg/m^2[mean±SEM]) and obese (32.4±4.0 kg/m^2) age and gender matched subjects. Subcutaneous adipose tissue was available from nine subjects with type 2 diabetes (T2DM) and matched non-diabetic controls. To assess expression changes during weight loss, 24 obese subjects (37.6±4.9kg/m^2) were placed on a very low calorie diet (VLCD) for 16 weeks and subcutaneous biopsies obtained pre and post study. To assess regulation of *COL6A3*, AT biopsies were minced into 1mm^3 explants and treated with recombinant human leptin or insulin (0.01nM, 10nM, 100nM) for 24 hours. mRNA expression was determined using Taqman technology or microarray. All data is expressed in Arbitrary Units.
Results: *COL6A3* mRNA was expressed at significantly higher levels in subcutaneous versus omental adipose tissue, independent of BMI (1.15±0.09 vs 0.85±0.12 [mean±SEM], n=12, p<0.05). A trend towards reduced *COL6A3* expression was observed in biopsies from obese subjects versus lean although this did not reach statistical significance. In line with these findings, caloric restriction and weight loss resulted in a significant increase in *COL6A3* mRNA expression in subcutaneous adipose tissue (1725±77.19 vs 2412±100 [mean±SEM], p<0.01). Treatment of subcutaneous explants with leptin resulted in a dose dependent decrease in *COL6A3* expression (1.66±0.23 vs 1.34±0.13 vs 1.11±0.13* vs 1.03±0.23*, Control vs 0.01nM vs 10nM vs 100nM, *=p<0.05). Treatment with insulin did not alter *COL6A3* expression across the same concentration range nor was there any significant alteration in expression in subjects with T2DM.
Conclusion: Unlike rodents, human adipose tissue *COL6A3* expression does not correlate with impaired metabolic health, does not respond to insulin but conversely decreases with obesity. The observation that *COL6A3* mRNA levels increase following weight loss, as leptin levels decrease, coupled with our data highlighting the direct repression of *COL6A3* mRNA following leptin treatment, suggest the presence of a potential paracrine regulatory mechanism in which expanding adipose tissue is able to regulate levels of pericellular collagen to permit matrix remodelling.

PS 057 Autophagy, endoplasmic reticulum and oxidative stresses

PPARβ/δ attenuates palmitate-induced endoplasmic reticulum stress and provokes autophagy in human cardiac cells

X. Palomer[1], E. Capdevila-Busquets[1], G. Botteri[1], M.M. Davidson[2], L. Michalik[3], W. Wahli[3], M. Vázquez-Carrera[1];
[1]Department of Pharmacology and Therapeutic Chemistry, Faculty of Pharmacy, University of Barcelona - IBUB, and CIBERDEM, Spain, [2]Department of Radiation Oncology, Columbia University, New York, USA, [3]Center for Integrative Genomics, National Research Center Frontiers in Genetics, University of Lausanne, Switzerland.

Background and aims: Apoptosis is an early cellular event in response to diabetes that plays a critical role in the development of diabetic cardiomyopathy. The endoplasmic reticulum (ER) stress is activated in stressed cells with the aim to restore homeostasis through autophagy. However, if it becomes chronic, ER stress will contribute to the apoptotic cell death in the myocardium. ER stress is induced after high fat diet feeding in mice and also after saturated fatty acid treatment in vitro. Therefore, since several studies have shown that PPARβ/δ activation inhibits the ER stress, the main objective of this work was to investigate whether activation of this nuclear receptor prevented lipid-induced ER stress in cardiac cells.
Materials and methods: Wild-type and transgenic mice with reduced expression of PPARβ/δ were fed a standard diet or a high fat diet for two months. For in vitro studies, a cardiomyocyte cell line of human origin, AC16, was treated with palmitate and the PPARβ/δ agonist GW501516, in the presence or absence of several other drugs in order to elucidate the mechanisms involved. After treatment, RNA and total protein extracts were obtained for subsequent gene expression and western blot analyses.
Results: Palmitate induced ER stress in AC16 cells, as confirmed by the i creased levels of spliced XBP1, ATF3 (2-fold vs. control, P<0.001), BiP/GRP78 (4.5-fold, P<0.001), and CHOP (4.5-fold, P<0.001) expression, as well as it enhanced CHOP (4.5-fold, P<0.001) and phosphorylated IRE-1α (2-fold, P<0.05) protein levels. Activation of PPARβ/δ with GW501516 abrogated palmitate-induced effects on ATF3 (P<0.01) and CHOP (P<0.05) expression, phosphorylated IRE-1α (P<0.001), and CHOP (P<0.001) protein levels. In contrast, GW501516 did not prevent the splicing of XBP1 or the enhanced expression of BiP/GRP78. Coincubation with the AMPK inhibitor compound C demonstrated that GW501516 effects on ER stress in AC16 cells were independent of AMPK activation. Interestingly, GW501516 upregulated the protein levels of beclin 1 (1.5-fold vs. control, P<0.001) and LC3II (1.5-fold, P<0.001), two well-known markers of autophagy. In accordance with this, administration of high-fat diet or suppression of PPARβ/δ in transgenic knockout mice, induced ER stress in the heart, as depicted by the augmented BiP/GRP78 and CHOP expression (1.5-fold vs. wild type, P<0.05), and the phosphorylated IRE-1α (2-fold, P<0.05) protein levels. Moreover, these transgenic PPARβ/δ knockout mice also displayed a reduction in autophagic markers (about 50% reduction in beclin 1 protein levels vs. wild type, P<0.05).
Conclusion: PPARβ/δ activation might be useful to prevent the development of diabetic cardiomyopathy and associated cardiovascular disease in obese patients, since it would inhibit the harmful effects of ER stress in heart by inducing autophagy.

Deletion of hepatic ROCK1 prevents steatosis by reducing lipid synthesis and activating autophagic flux in diet-induced obese mice

I.S. Lima[1,2], H. Huang[1], S.-H. Lee[1,3], I. Jarak[4], J.G. Jones[4,5], M.P. Macedo[2,5], Y.-B. Kim[1];
[1]Division of Endocrinology, Diabetes and Metabolism, Beth Israel Deaconess Medical Center, Harvard Medical School, Boston, USA, [2]CEDOC, Faculdade de Ciencias Medicas, Universidade Nova de Lisboa, Portugal, [3]Division of Endocrinology and Metabolism, Department of Internal Medicine, The Catholic University of Korea, Seoul, Republic of Korea, [4]Center for Neuroscience and Cell Biology, Department of Zoology, University of Coimbra, Portugal, [5]Portuguese Diabetes Association Education and Research Center (APDP-ERC), Lisboa, Portugal.

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is associated with obesity and insulin resistance and is a risk factor for hepatocellular carcinoma. The physiological mechanisms underlying NAFLD are unclear, although thought to result from impaired lipid homeostasis. Emerging data suggest that Rho-kinase 1 (ROCK1) plays an important role in regulation of glucose metabolism and insulin sensitivity. However, hepatic functions of ROCK1 have not been addressed. Autophagy is a highly regulated process in eukaryotic cells and is determinant for cellular homeostasis. The microtubule-associated protein light chain 3 (LC3) is a key molecule of the autophagy signalling pathway. Evidence shows that autophagy plays a role in lipid metabolism. However, nothing is known about hepatic ROCK1 functions in the autophagy signalling pathway. This study determined the physiological role of hepatic ROCK1 in regulating lipid metabolism in conjunction with autophagy signaling.
Materials and methods: Liver-specific ROCK1-deficient mice (LKO) fed a high-fat diet were studied. Hepatic lipid metabolism was measured by NMR and immunohistochemistry. De novo lipogenesis was determined by using U-^{14}C lactic acid as an indicator of lipogenic rate. Autophagy was assessed by immunoblotting of Beclin1, Atg7 and LC3 I/II in fast versus fed state.
Results: After 6-12 weeks of high-fat diet, hepatic triglyceride was decreased in LKO (54.53±2.58 vs. 40.37±3.49 mg/g, p<0.05), as well as cholesterol (4.96±0.58 vs. 2.86±0.81 mg/g, p<0.05), compared with control mice. Histological analysis also indicated reduced hepatic steatosis by ROCK1 deletion. The physiological mechanism underlying this is, in part, due to decreased lipogenesis; loss of ROCK1 caused a decrease in lipogenic rate (10.46±0.48 vs. 6.75±0.53 nmol/mg/hr, p<0.001), LKO mice have decreased hepatic triglycerides fractional synthetic rate in (100.0±9.91% vs. 66.86±7.61%, p<0.05). To determine whether decreased lipogenesis in LKO could be due to activation of autophagy, protein levels of autophagy signaling components were measured. Hepatic Beclin1 and Atg7 were unchanged by ROCK1 deletion. Levels of LC3-I protein in the fast state were decreased by ~40% (p<0.05) in LKO mice, compared with control mice. This implies elevation of the autophagic-vesicle associated form LC3-II, suggesting an increase of the hepatic autophagic flux in LKO mice.
Conclusion: Our data demonstrate that targeted deletion of ROCK1 in liver protects against diet-induced hepatosteatosis in mice. These effects are most likely due to decreased de novo lipogenesis in hepatocytes. Furthermore, increased autophagic flux in the liver could be involved in this regulation. Together, our data identify hepatic ROCK1 as important regulator of lipid metabolism in the context of the autophagy signalling pathway.

The PPARβ/δ agonist GW501516 inhibits endoplasmic reticulum stress-induced inflammation in skeletal muscle cells

L. Salvadó Serra[1], A. Gómez-Foix[2], M. Vázquez-Carrera[1];
[1]Pharmacology Unit, Department of Pharmacology and Therapeutic Chemistry, Faculty of Pharmacy, [2]Department of Biochemistry and Molecular Biology, Faculty of Biology. University of Barcelona, Spain.

Background and aims: Evidence is now emerging that the activation of nuclear receptor PPARβ/δ prevents fatty acid-induced inflammation and insulin resistance (IR) in skeletal muscle cells. Given that endoplasmic reticulum (ER) stress is associated with inflammation and IR, we evaluated whether the PPAR β/δ agonist, GW501516, was able to prevent the ER stress.
Materials and methods: Skeletal muscle cells of human (LHCN-M2) and mouse (C2C12) origin were incubated for 16 hours with thapsigargin (1μM in C2C12 and 100nM in LHCN-M2), tunicamycin (5μg/ml in C2C12 and 2μg/ml in C2C12 and LHCN-M2) and GW501516 (10μM). Levels of mRNA were assessed by reverse transcription-polymerase chain reaction (RT-PCR) and Western Blot analysis was performed to determine protein levels. Data are expressed as means ± S.D. of three independent experiments. Significant differences were established by one-way ANOVA and when significant variations were found, the Tukey-Kramer multiple comparisons post-test was applied. Differences were considered significant at p<0.05.
Results: Exposure of C2C12 and LHCN-M2 cells to the potent ER-stress inducer thapsigargin, increased the mRNA levels of sXBP1 (p<0.001 *vs* control in C2C12 and p<0.01 vs control in LHCN-M2), whereas in the presence of GW501516 these effects were reduced (p<0.001 *vs* thapsigargin in C2C12 and p<0.01 *vs* thapsigargin in LHCN-M2). The ER stress inducer tunicamycin also increased the mRNA levels of CHOP (p<0.001 *vs* control cells) in C2C12 cells, and thapsigargin and tunicamicyn increased CHOP and ATF3 (p<0.001 *vs* control cells) gene expression in LHCN-M2 cells. GW501516 reduced tunicamycin-induced CHOP expression in murine myotubes (p<0.001) as well as tunicamycin-induced CHOP (p<0.001) and ATF3 (p<0.01) mRNA levels in human myotubes. Moreover, GW501516 reduced thapsigargin-induced ER stress in human myotubes (p<0.001 in CHOP and ATF3 mRNA levels). Finally, TNFα mRNA levels (p<0.05 vs control) were increased in C2C12 cells exposed to thapsigargin as well as IL-6 expression (p<0.001 *vs* control) was increased in murine and human myotubes exposed to tunicamycin. Again, GW501516 prevented these effects (p<0.05 vs thapsigargin and p<0.001 *vs* tunicamycin exposed murine myotubes and p<0.01 *vs* tunicamycin exposed human myotubes). GW501516 also prevented the thapsigargin-mediated reduction in IκBα protein levels (p<0.01 *vs* thapsigargin-exposed cells) in C2C12 cells, suggesting that the PPARβ/δ agonist was able to prevent ER stress-induced inflammation.
Conclusion: Our results suggest that the PPARβ/δ agonist, GW501516, might prevent ER stress-induced inflammation in murine and human skeletal muscle cells. At present we are investigating the mechanism responsible for the effects of GW501516 on ER stress and its impact on insulin resistance.

Inhibition of autophagic flux is associated with increased endoplasmic reticulum stress during the development of non-alcoholic fatty liver disease

Á. González-Rodríguez[1,2], R. Mayoral[2,3], N. Agra[2,3], V. Pardo[2,1], M.E. Miquilena-Colina[4,3], J. Vargas-Castrillón[4,3], C. García-Monzón[4,3], P. Martín-Sanz[2,3], Á.M. Valverde[2,1];
[1]Centro de Investigación Biomédica en Red de Diabetes y Enfermedades Metabólicas Asociadas (CIBERDEM), ISCIII, [2]Instituto de Investigaciones Biomédicas "Alberto Sols" (CSIC/UAM), [3]Centro de Investigación Biomédica en Red de Enfermedades Hepáticas y Digestivas (CIBEREHD), ISCIII, [4]Liver Research Unit, Hospital Universitario Santa Cristina, Madrid, Spain.

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is an inflammatory chronic disease which is the main hepatic complication of obesity and metabolic syndrome. In fact, epidemiologic and clinical studies have shown a close association between NAFLD and insulin resistance. We have previously reported that hepatic levels of insulin signalling mediators and phosphorylation of Akt and Foxo1 are down-regulated in patients with steatohepatitis (NASH), but not in patients with steatosis (NAS). Furthermore, hepatocyte apoptosis and active caspase 3 were only present in NASH patients. In this study, we have evaluated the relationship between ER stress and the autophagic flux during the onset of NAFLD in human and murine models of hepatic steatosis and NASH.
Materials and methods: This study comprised 59 patients with a clinical diagnosis of NAS or NASH who underwent a liver biopsy and 30 patients with histological normal liver (NL). Real-time PCR, Western blot, immunohistochemistry and electronic microscopy were used to assess markers of ER and autophagy. Mice fed with high fat diet (HFD) for 7 months or methionine-choline-deficient (MCD) diet during 4 weeks were used to study ER stress and autophagy in the liver. Human Huh7 hepatocytes loaded with palmitic acid were used as an in vitro model.
Results: In human liver from patients with NAS and NASH, mRNA levels of ER stress markers were elevated together with increased p62 autophagic substrate and LC3II accumulation. However, LC3 punctuate was less evident in patients with NASH. Mice fed with HFD or MCD diet showed increased phosphorylation of mTOR/S6K1, JNK, PERK, eIF2α together with elevated

expression of ER chaperones GRP78 and CHOP. As observed in patients, p62 and LC3II were up-regulated by both diet interventions. In Huh7 hepatic cells, treatment with palmitate for 8 h activated the autophagic flux by decreasing p62 and cell death was not observed; this effect was blocked at 24 h, time at which ER stress markers and cell death were highly elevated and autophagic flux was blocked. Co-treatment with rapamycin and palmitate restored autophagic flux and protected Huh7 cells against lipoapoptosis.
Conclusion: The impaired autophagic flux associated to NAS and NASH might be the consequence of elevated ER stress in the liver, resulting in apoptosis. Our results strongly suggest that therapies aimed to restore the autophagic flux in patients with severe hepatic steatosis might prevent the progression of the non-alcoholic liver disease.

Correction of intermittent hypoxia with CPAP improves cardio-metabolic abnormalities, systemic inflammation, and adipose tissue ER stress in obese subjects with OSA
S. Perrini[1], M. Barbaro[1], A. Ciavarella[1], S. Kounaki[1], V. Quaranta[2], P. Nigro[1], R. Ficarella[1], A. Cignarelli[1], A. Peschechera[1], A. Natalicchio[1], L. Laviola[1], G. De Pergola[3], O. Resta[2], F. Giorgino[1];
[1]Endocrinology & Metabolic Diseases, [2]Pneumology, [3]Biomedical Sciences and Human Oncology, University of Bari, Italy.

Background and aims: Morbid obesity is frequently associated with cardio-metabolic abnormalities, low-grade systemic inflammation, inflamed adipose tissue, and obstructive sleep apnea (OSA). It is unclear whether in obesity chronic intermittent hypoxia (CIH) resulting from OSA could be an independent factor for the development of cardio-metabolic abnormalities. We hypothesized that treatment of CIH with continuous positive airway pressure (CPAP) in obesity associated with OSA would modify cardio-metabolic and inflammatory outcomes.
Materials and methods: Sixty-two obese patients with OSA were studied at baseline and after three months of therapeutic CPAP treatment, and compared with twenty-five BMI- and age-matched subjects who had a negative single-night polysomnogram. Both the OSA and control obese groups received general dietary and exercise advice throughout the study. Measurements of anthropometric variables, blood pressure, fasting blood glucose and lipid profile, insulin resistance (HOMA model), HbA1c, white blood cells were obtained at baseline (T0) and after three months (T1). Serum concentrations of inflammatory cytokines were measured at T0 and T1 using Luminex. Subcutaneous (Sc) adipose tissue biopsies were taken at T0 and T1 to assess expression of endoplasmic reticulum (ER) stress-related genes by quantitative RT-PCR.
Results: At T0, neck circumference (41.9 vs. 39.0 cm; p=0.01), systolic (129.8 vs. 121.2 mmHg; p=0.03) and diastolic blood pressure (83.3 vs. 75.1 mmHg; p=0.017), HOMA-IR (8.7 vs. 4.2%; p=0.005), HbA1c (6.01 vs. 5.42%; p=0.01), serum triglyceride (147.8 vs. 121.9 mg/dL; p=0.03) and white blood cells (7,829 vs. 6,135 per μL; p=0.001) were significantly increased in the OSA compared to control subjects. At T1, CPAP treatment resulted in significant mean decreases in BMI (-4 kg/m2; p=0.003), waist (-10.6 cm; p=0.01) and neck (-3 cm; p=0.01) circumferences, systolic (-15.4 mmHg; p=0.03) and diastolic (-12.3 mmHg; p=0.03) blood pressure, serum total cholesterol (-19.6 mg/dL; p=0.04), serum triglyceride (-34.0 mg/dL; p=0.003), and white blood cells (-1,172 per μL; p=0.03) in the OSA obese group, whereas no significant changes in these parameters were observed in the control obese group. Serum concentrations of IL-1ra, IL-2, IL-4, IL-6, MCP-1 and PDGF were also significantly reduced compared to T0 by CPAP therapy in OSA subjects ($p<0.05$), and remained unaltered in the controls. Dietary intakes and levels of physical activity did not differ between groups at T1 vs. T0. In Sc adipose tissue, mRNA expression levels of CHOP were significantly reduced after CPAP treatment as compared to T0 (p=0.02) in OSA subjects, and a tendency toward lower mRNA levels was also observed for ATF4 and ERO-1 (p=0.08). No significant changes in ER stress gene expression were observed in the control obese group.
Conclusion: Three months of CPAP therapy in obese patients with moderate-to-severe OSA improves anthropometric variables, cardio-metabolic abnormalities, systemic inflammation, and fat-specific ER stress, suggesting an independent role of CIH on metabolic, cardiovascular and inflammatory endpoints in obesity.

Differential effects of oleate and palmitate on beta cell autophagy

K.-Y. Chu, L. O'Reilly, C. Bartley, T.J. Biden;
Garvan Institute, Darlinghurst, Australia.

Background and aims: Increasing evidence reveals the importance of autophagy in beta-cell homeostasis and survival. Indeed deterioration of beta-cell induced by chronic exposure to fatty acids is suggested to be associated with alterations in autophagy. However, it is still controversial and unclear how fatty acids regulate autophagy. Here, we compare the effects of free fatty acids palmitate and oleate on beta-cell autophagic flux, and investigate the differential mechanisms underlying their effects.
Materials and methods: Mouse beta-cell MIN6 cells were treated with fatty acids for 0-48h and the levels of autophagic marker, LC3-II, were detected by western blot to show the steady state of autophagy. Autophagic flux was confirmed by incubating the cells with chloroquine to prevent autophagosome degradation. MIN6 cells were transfected with the RFP-GFP-LC3 plasmid prior to fatty acids treatment, the dynamic of GFP disappearance was monitored to show the autophagosome-lysosome fusion. Lysosomes in the cells were localized after fatty acids treatment with the LysoTracker Red and visualized by the microscopy. Autophagy in PBA, an ER stress inhibitor, and fatty acids co-treated cells was also studied. Finally, effect of fatty acids on cathepsin L, a lysosomal enzyme, was investigated by western blot and measuring its activity.
Results: Our results demonstrated that although palmitate treatment only minimally altered steady state of LC3-II, it did increase the autophagic flux. Palmitate enhanced ER stress and PBA reduced ER stress as well as the LC3-II levels. Palmitate also induced autophagosome-lysosome fusion, which might due to either increased lysosome number or size; but it did not alter cathepsin L activity. Oleate, on the other hand, increased both autophagic basal levels and flux. Oleate also augmented autophagosome-lysosome fusion and lysosomal labeling. Cathepsin L activity was also elevated by oleate and its inhibition abolished the oleate-induced autophagy.
Conclusion: Saturated and unsaturated fatty acids exhibit remarkably divergent effects on beta-cell autophagy. Palmitate appears to activate autophagy solely to ER stress and dependently regulates downstream pathways. Oleate, on the other hand, stimulates autophagy via novel mechanism involving activation of catheipsin L.

DNAJB3/HSP-40 cochaperone role in obesity
A. Jehad, M. Abufarha, F. Al-Ghimlas, I. Alkhairi, P. Cherian, N. Elkum, J. John, S. Kavalakatt, A. Khadir, A. Tiss, S. Warsame, S. Dermime, K. Behbehani, M. Dehbi;
Dasman Diabetes Institute, Kuwait.

Background and aims: Obesity is a major risk factor for insulin resistance and diabetes. Heat shock response; a crucial host-defence mechanism against stressful conditions, is one of the key pathways that was shown to be deregulated in obesity-induced insulin resistance. Patients with T2D have reduced expression of Heat shock proteins that correlates with increased insulin resistance and therapies known to induce heat shock response such as heat therapy or physical exercise are associated with improved outcomes. The objectives of this study are: 1) Investigate the expression pattern of Hsps and other chaperones and stress related proteins between lean and obese subjects, 2) Evaluate the effect of a defined exercise protocol on their expression pattern and 3) Correlate their expression with the inflammatory, metabolic and oxidative stress biomarkers.
Materials and methods: The current investigation is part of a large cohort study aimed at investigating the effect In the present study, we selected 120 non-diabetic subjects consisting of 66 obese and 54 lean that were enrolled in a defined exercise protocol for 6 months. Blood samples and abdominal subcutaneous adipose biopsies were collected before and after the exercise. Gene expression profile was done by RT-PCR using RT-profiler-heat shock protein array kit consisting of 84 heat shock related genes and validated by Western blotting and immunohistochemistry techniques. Cytokine and metabolic markers were investigated by multiplexing technology (Bioplex) using plasma samples. Markers of oxidative stress, namely ROS and TBARS were measured on plasma or serum using commercially available kits.**Results:**

Our data indicate a downregulation of DNAJB3 mRNA and protein in obese subjects that negatively correlated with triglycerides ($P = 0.013$) and IP-10 inflammatory chemokine ($P < 0.05$). Interestingly, within 6 months of regular exercise, the levels of DNAJB3 in obese subjects were comparable to the lean subjects with a concomitant decrease of phosphorylated JNK, suggesting that exercise can antagonise obesity-mediated DNAJB3 repression. DNAJB3 was also shown to coimmunoprecipiate with JNK and IKKβ stress kinases along with HSP-72 with concomitant inhibition of JNK phosphorylation following treatment with PMA. Using cell lines, DNAJB3 protein was reduced following treatment with palmitate and tunicamycin which is suggestive of the link between the expression of DNAJB3 and the activation of the endoplasmic reticulum stress.
Conclusion: Our result demonstrated a downregulation in the expression of DNAJB3 mRNA and protein in obese subjects that was restored by physical exercise. The existence of a negative correlation between DNAJB3 expression and the inflammatory markers, its restoration by physical exercise and its inhibitory effect on JNK activation is suggestive of a protective role of DNAJB3 against obesity and could therefore represent a potential therapeutic target for the control and management of obesity and insulin resistance.

Des-acyl ghrelin protects microvascular endothelial cells from oxidative stress-induced apoptosis through sirtuin 1 signalling pathway
H. Furuta, T. Shimada, A. Doi, M. Nishi, H. Sasaki, T. Akamizu;
The First Department of Medicine, Wakayama Medical University, Japan.

Background and aims: Ghrelin is a stomach-derived hormone. Acylation of ghrelin has been essential for its biological activities such as stimulating growth hormone release and appetite. On the other hand, the function of des-acyl ghrelin (Des-G) has not been fully elucidated. Here, we examined the effects of Des-G on oxidative stress--induced apoptosis in human retinal microvascular endothelial cells.
Materials and methods: After the cells were pretreated with or without 100nM Des-G, apoptosis was induced by incubating the cells with 0.1 mM H2O2. For inhibition of surtuin 1 (SIRT1), the cells were treated with 10 μM Ex-527 which is a SIRT1-selective inhibitor. The quantitative estimation of DNA fragmentation was used as a marker of apoptosis. Furthermore, total SIRT activity in nuclear extracts and mRNA expression levels of SIRT1, manganese superoxide dismutase (MnSOD) and catalase were determined.
Results: Des-G pretreatment protected endothelial cells from oxidative stress-induced apoptosis (3.43 ± 0.92-fold of control vs. 2.12 ± 0.63-fold of control, $p<0.01$). Des-G pretreatment increased total SIRT activity (0.47 ± 0.04 OD/min/mg vs. 1.46 ± 0.10 OD/min/mg, $p<0.01$) and the mRNA expression levels of SIRT1 (3.05 ± 0.86-fold of control, $p<0.01$), while pharmacological inhibition of SIRT1 attenuated the anti-apoptotic effect of Des-G ($p<0.05$) and the increment of activity ($p<0.01$). Moreover, Des-G increased the mRNA expression levels of antioxidant enzymes downstream of SIRT1, MnSOD (2.78 ± 0.84-fold of control, $p < 0.01$) and catalase (2.13 ± 0.38-fold of control, $p < 0.01$).
Conclusion: Our data suggest that SIRT1 signaling pathway contributes to the protective effect of Des-G against oxidative stress-induced apoptosis.

Plasma URB protein is positively associated with human obesity and URB gene expression is inversely regulated by hydrogen peroxide and IL-1beta in cultured adipocytes
O. Osorio-Conles[1,2], M. Guitart[1,2], X. Escoté[3,2], J. Moreno-Navarrete[4,5], J. Fernández-Real[4,5], J. Vendrell[3,2], A. Gómez-Foix[1,2];
[1]Bioquímica i Biologia Molecular, Universitat de Barcelona, [2]CIBERDEM, Isciii, Spain, [3]Joan XXIII University Hospital, Rovira i Virgili University IISPV, Tarragona, [4]Service of Diabetes, Endocrinology and Nutrition, Institut d'Investigació Biomèdica de Girona, [5]CIBERobn, Isciii, Spain.

Background and aims: The URB (upregulated in bombesin receptor subtype-3 (BRS-3) deficient mice)/CCDC80/DRO1/SSG1 gene is mostly expressed in adipose tissue and its expression is downregulated in diet-induced, ob/ob and KKAy obese mice. URB protein is secreted from adipocytes, yet its local or systemic effects remain to be elucidated. The aims of our study were to determine URB plasma levels in relation to obesity and insulin resistance in human subjects and URB gene expression and protein secretion regulation in cultured SGBS adipocytes by obesity-associated factors.
Materials and methods: Subjects: Two independent cohorts, one composed of subjects with different degree of obesity (n= 48, BMI range: 20 to 40 kg/m2) and a second cohort of morbid obese subjects (n=32, BMI range: 35 to 60 kg/m2) were recruited. Study of insulin sensitivity and secretion, artery vasodilation, carotid atherosclerosis (high resolution ecography) and liver steatosis were performed. Cultured cells: human preadipocyte SGBS cell line was differentiated to mature adipocytes and treated with varied factors. Methods: URB gene expression was assessed by quantitative real time PCR relative to the control 18S rRNA. ELISA assay was used to quantify URB protein.
Results: In the first cohort, negative associations of plasma URB with parameters of insulin secretion and circulating IGF1. In contrast, there were positive associations with blood neutrophil count, MCP-1 and lipocalin-type prostaglandin D synthase. In the second cohort, there was a strong and positive association of URB with visceral fat, fatty liver disease and carotid atherosclerosis. In cultured SGBS adipocytes URB gene expression was higher in mature adipocytes than in preadipocytes. URB mRNA levels in mature adipocytes were downregulated by hydrogen peroxide and upregulated by IL-1β, TNFα and insulin, whereas IL-6 had no effect. URB protein cell content decreased in response to hydrogen peroxide and was increased by IL-1β. A small proportion of the IL-1β-mediated increase in URB protein was detected in SGBS conditioned culture media.
Conclusion: The findings observed in plasma URB protein levels suggest a potential role of this protein in metabolic homeostasis mediated by fat accretion and insulin secretion. In human adipocytes, inflammatory and oxidative stress stimuli influence the response of this gene being IL-1β one of the responsible of its secretion by mature adipocytes.

Palmitate induced repression of GLUT4 protein involves activation of nuclear factor-kappa B (NF-kB)
P.E. Silva, A. David-Silva, M.M. Okamoto, H.S. Freitas, U.F. Machado;
Department of Physiology and Biophysics, University of Sao Paulo, Brazil.

Background and aims: High concentrations of saturated fatty acids trigger insulin resistance in skeletal muscle. Reduction in the expression of the glucose transporter GLUT4 is a feature in this process; however the involved mechanisms are not yet fully elucidated. Recent investigations suggest that the endoplasmic reticulum (ER) stress may be involved in this process. GRP78 (glucose-regulated protein 78) is a central regulator for ER stress due to its role as a major ER chaperone with anti-apoptotic properties, as well as its ability to control the activation of transmembrane ER stress sensors as IRE1α (inositol-requiring kinase-1 alpha) through a binding-release mechanism. ER stress results in the activation of a cellular response known as unfolded protein response (UPR), and different studies have demonstrated the activation of the transcription factor NF-kB through these pathways. Therefore, this study aimed to verify the effects of palmitate on GLUT4 expression, ER stress proteins and on the activation of NF-kB in L6 muscle cells.
Materials and methods: L6 myotubes were treated with 0,75 mM of palmitate during different time intervals (2, 6 and 12 hours). Protein (Western blotting), and mRNA (Rq-PCR) were quantified, and NF-kB transcriptional activity as evaluated (EMSA). Data were analyzed using ANOVA followed by Bonferroni post-test.
Results: Palmitate reduced GLUT4 protein content (control: 99.99±3.39, 2H: 66.37±7.20*, 6H: 67.73± 6.52*, 12H: 58.88±5.56* arbitrary units (AU), *P<0.05) and Slc2a4 mRNA (control: 1.00±0.04; 2H: 0.86±0.03*; 6H: 0.78±0.02*; 12H: 0.87±0.05* AU, *P<0.05). GRP78 protein (Control: 100.34±3.46, 2H: 128.23±7.76*, 6H: 117.63±6.26, 12H: 89.16±10.19, AU, n=7) and IRE1α protein content (Control: 100.00±0.00, 2H: 150.72±24.14*, 6H: 105.27±22.44, 12H: 80.18±17.00 AU, *P<0.05) presented a significant increase at the second hour of treatment. Activation of IRE1α results in the recruitment of TRAF2, which also showed an increase within 2 hours of treatment (Control: 100.28±0.35, 2H: 114.49±4.35*, 6H: 89.31±4.87, 12H: 89.52±4.54 AU, *P<0.05). It has been reported that TRAFs may induce the phosphorylation of the IKK complex and participate in the activation of NF-kB. By analysis of NF-kB mRNA there was a significant increase of this transcription factor at 6 and 12 hours (Control: 1.01±0.03, 2H: 1.05±0.03, 6H: 1.18±0.09*, 12H: 1.45±0.05* AU, *P<0.05), and an increase on the binding activity of NF-κB into the Slc2a4 gene promoter at 2 and 12 hours of incubation with the fatty acid (Control: 102.58±2.28, 2H: 131.96±11.54*, 6H: 80.58±6.55, 12H: 119.53±11.23 AU, *P<0.05).
Conclusion: It was observed that palmitate represses the expression of GLUT4 and induces only a transient activation of reticulum stress in L6 mus-

cle cells due to activation of GRP78 and IRE1α. Moreover, without excluding other regulatory mechanisms, palmitate increases NF-kB binding activity, is an important mechanism in the controlling of GLUT4 expression.

MicroRNA-196a is a potential regulator of body fat distribution in humans

C.Z.E. Hilton[1], M. Neville[1], K. Pinnick[1], K. Mackay[1], F. Karpe[1,2];
[1]Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, [2]NIHR Oxford BRC, Oxford, UK.

Background and aims: MicroRNAs are endogenous small non-coding RNAs that have emerged as important post-transcriptional regulators of mRNA expression. There is growing evidence for a role of microRNAs in regulating pathways in adipose tissue that control a range of processes including adipogenesis, insulin resistance and inflammation. It is well established that fat depots differ in terms of the metabolic risk that they confer and that different fat distributions are associated with different metabolic phenotypes. In this study we identify miR-196a as candidate for modulating body fat distribution.
Materials and methods: A microarray screen was performed on human subcutaneous abdominal and gluteal adipose tissue. Significant results were confirmed by qPCR on 40 paired subcutaneous abdominal and gluteal human whole adipose tissue biopsies. Following the identification of miR-196a as being a strongly differentially expressed miRNA between depots the mRNA expression of putative targets of miR-196a was investigated. In addition, 4464 individuals from the Oxford Biobank were genotyped for rs11614913, a SNP in mir-196a-2.
Results: miR-196a was confirmed by qPCR to have 2.1-fold higher expression within subcutaneous gluteal compared with subcutaneous abdominal adipose tissue (P=0.0001). mir-196a is expressed from within *HOX* gene clusters and is predicted to target the developmental genes *HOXA5, HOXB8* and *HOXC8*. The mRNA expression of these *HOX* genes was correspondingly higher in subcutaneous abdominal than subcutaneous gluteal adipose tissue. These findings were replicated in immortalised preadipocyte cell lines and in primary preadipocytes derived from abdominal and gluteal adipose tissue. This suggests that this differential expression is intrinsic to preadipocytes rather than being a function of their environment in different depots. Furthermore, we found that the SNP rs11614913, found in mir-196a-2, was significantly associated with both an increase in waist circumference of ~ 1.6cm (p=0.0004) and an increase in waist hip ratio of 1.5% (p=0.009), independently of BMI.
Conclusion: It is proposed that miR-196a acts as a depot-specific regulator of *HOX* genes, contributing to functional and developmental differences between fat depots, and that a SNP in mir-196a-2 predisposes to increased central body fat distribution.

Depot-specific changes of fat metabolism with ageing in a type 2 diabetic animal

S. Park[1], C.-Y. Park[1], M. Lee[1], J. Kim[1], W. Jeon[1], E.-J. Rhee[1], W. Lee[1], K. Oh[1], S. Park[1], H. Lee[2], B. Cha[3];
[1]Kangbuk Samsung Hospital,Sungkyunkwan University School of Medicine, [2]Department of Endocrinology and Metabolism, Department of Internal Medicine, Yonsei Unversity, College of Medicine, [3]Department of Endocrinology and Metabolism, Department of Internal Medicine, Yonsei Unversity, College of Medicine, Seoul, Republic of Korea.

Background and aims: Visceral fat accretion is a hallmark of aging and is associated with aging-induced metabolic dysfunction. Many studies have reported that the peroxisome proliferator-activated receptor (PPARγ) agonist rosiglitazone improves insulin sensitivity by redistributing fat from visceral fat to subcutaneous fat. The purpose of this study was to investigate the underlying mechanisms by which aging affects adipose tissue remodeling in a type 2 diabetic animal model and through which PPARγ activation modulates aging-related fat tissue distribution.
Materials and methods: At the ages of 21, 31 and 43 weeks, Otusuka Long-Evans Tokushima Fatty (OLETF) rats, an animal model of type 2 diabetes mellitus, were evaluated for aging-related effects on adipose tissue metabolism in subcutaneous and visceral fat depots.
Results: Aging increased adipocyte cell size and the ratio of visceral fat weight to subcutaneous fat weight (V/S ratio). The serum levels of glucose, in-

sulin and free fatty acid (FFA) were also increased. During aging, the mRNA expression of the genes involved in lipogenesis and fatty acid recycling were highly expressed in visceral fat as compared to subcutaneous fat. Aging increased mRNA expression related to lipolysis in both types of fat depots. The changes in the genes involved in lipid oxidation and energy expenditure, such as PDK2, mCPT1 and Acadl, varies during aging. After six weeks of rosiglitazone treatment in the OLETF rats, starting at 15 weeks of age, the PPARγ agonist resulted in fat redistribution with a decreasing V/S ratio and improved glucose intolerance. Compared with the untreated OLETF rats, the genes involved in lipogenesis and fatty acid cycling were decreased in visceral fat, whereas there were no significant changes of mRNA expression associated with lipid oxidation.
Conclusion: Our data suggests that fat distribution was changed by stimulating the lipid uptake and esterification in the visceral fat as compared to the subcutaneous fat, thus altering the lipid oxidation during aging. Conversely, these changes might be modulated by PPAR γ action in a type 2 diabetic animal model.

Role of PGC-1alpha in exercise induced regulation of inflammatory markers in visceral and subcutaneous adipose tissue
J.F. Halling, A. Lundgaard, S. Ringholm, H. Pilegaard;
Section for Molecular Integrative Physiology, University of Copenhagen, Denmark.

Background and aims: Obesity and physical inactivity are major risk factors in developing many lifestyle related diseases. Inflammation of adipose tissue is suggested to be involved in the pathogenesis of peripheral insulin resistance and ultimately type 2 diabetes. Regular physical activity reduces the risk of developing type 2 diabetes. Peroxisome proliferator-activated receptor gamma coactivator (PGC)-1α is suggested to mediate many of the beneficial effects of exercise and has been shown to exert anti-inflammatory effects. The aim of the present study was to test the hypothesis that an acute exercise bout reduces the mRNA content of pro-inflammatory markers in both inguinal subcutaneous adipose tissue (SAT) and epididymal visceral adipose tissue (VAT) in a PGC-1α dependent manner in mice.
Materials and methods: Male whole-body PGC-1α knockout (KO) and littermate wildtype (WT) mice were subjected to an acute 1 hour treadmill exercise bout and euthanised either immediately or 2 hours after exercise. Control mice were euthanised after resting for 1 hour on the treadmill. SAT and VAT samples were analysed by reverse transcription real-time PCR.
Results: In the rested state, the mRNA content of interleukin (IL)-6, IL-18 and tumor necrosis factor (TNF)α in SAT was similar in PGC-1α KO and WT mice, whereas in VAT, the mRNA content of IL-6, IL-18 and TNFα was significantly lower in PGC-1α KO compared with WT mice. Immediately after an acute exercise bout, the mRNA content of IL-6 was increased ~50% in SAT in both PGC-1α KO and WT mice, while in VAT, the exercise induced increase in mRNA content of IL-6 was blunted in PGC-1α KO relative to WT mice. No effects of an acute exercise bout were observed on the mRNA content of IL-18 and TNFα in SAT in either genotype. In VAT, the mRNA content of IL-18 was decreased at 2 hours of recovery in WT mice only. An increase in VAT TNFα mRNA content at 2 hours of recovery was observed in PGC-1α KO mice, reaching similar levels as WT mice.
Conclusion: Exercise induces a larger fold acute increase in IL-6 mRNA content in VAT than SAT. Acute exercise only modestly affects the mRNA content of IL-18 and TNFα in adipose tissue. PGC-1α does not seem to regulate the mRNA content of IL-6, IL-18 and TNFα in SAT, whereas in VAT, PGC-1α may be important for both the basal and exercise regulated mRNA content of inflammatory markers.

Identification of CCDC3 as a possible novel biomarker for visceral adiposity
S. Maeda[1], S. Ugi[2], Y. Kawamura[3], M. Kobayashi[1], M. Imamura[1], M. Rokushima[3], O. Sekine[2], K. Morino[2], T. Yoshizaki[2], H. Yamamoto[4], T. Tani[4], A. Kashiwagi[2], H. Maegawa[2];
[1]Laboratory for Endocrinology, Metabolism and Kidney Diseases, RIKEN Center for Integrative Medical Science, Yokohama, [2]Department of Medicine, Shiga University of Medical Science, Otsu, [3]Shionogi Pharmaceutical Research Center, Shionogi & Co., Ltd., Osaka, [4]Department of Surgery, Shiga University of Medical Science, Otsu, Japan.

Background and aims: Obesity is a major health problem associated with various comorbidities, including type 2 diabetes, dyslipidemia, hypertension, and cardiovascular diseases. There is increasing evidence to show that an increase in visceral adiposity is critical for the development of obesity-related morbidities rather than obesity itself. Currently, visceral adiposity is evaluated by measuring waist circumference or waist-hip ratio in clinical practice, but these parameters are still not sufficient for estimating the amount of visceral fat precisely, and thus useful and accurate markers for visceral adiposity remain to be identified. To search for novel markers of visceral adiposity, we conducted comprehensive human study for mRNA expression profiles using visceral (omental) and subcutaneous adipose tissues obtained from subjects with abdominal obesity and lean subjects.
Materials and methods: Omental and subcutaneous adipose tissue biopsies were obtained from 43 men during elective abdominal surgery. We first selected five men with abdominal obesity and five non-obese (control) men, who had normal plasma glucose levels (HbA1c <6.0%), out of the 43 subjects, and conducted a comprehensive analysis for mRNA expression profiles in omental and subcutaneous adipose tissues to search for gene(s) up-regulated specifically in omental adipose tissues in subjects with abdominal obesity. We further compared the expression pattern of candidate genes discovered from the human study in mouse models of adiposity (high-fat diet and db/db mice).
Results: Among 30,500 genes evaluated in the present study, the mRNA expression of *CCDC3* (encoding coiled-coil domain-containing protein 3) was up-regulated in omental adipose tissues from subjects with abdominal obesity (3.1-fold), but not in subcutaneous adipose tissues (0.9-fold) compared to those from control subjects. The omental adipose-specific increase of *Ccdc3* was consistently observed in two distinct mouse models of obesity. In an expanded analysis using all 43 men, *CCDC3* mRNA levels in omental adipose tissues, but not in subcutaneous adipose tissues, were positively correlated with waist circumference ($r = 0.483$, $P < 0.001$) or with body mass index ($r = 0.364$, $P < 0.05$). *CCDC3* was preferentially expressed in human adipose tissues and the expression of murine *Ccdc3* was induced during adipocyte differentiation in cultured 3T3-L1 cells. CCDC3 was predicted to be a secretory protein, and by western blotting analyses using HEK293 cells overexpressing *CCDC3*, we confirmed that overexpressed CCDC3 was secreted into culture media.
Conclusion: We have found that the expression of *CCDC3* is increased specifically in visceral adipose tissues in subjects with abdominal obesity. These results indicate that CCDC3 could be a potential biomarker for estimating visceral adiposity.

Perihilar fat: another specialised and functionally very active perivascular fat tissue which differs from subcutaneous and visceral fat
D.I. Siegel-Axel[1], M. Guthoff[1], N. Stefan[1], S. Nadalin[2], K. Rittig[1], H.-E. Schaller[3], N. Heyne[1], H.-U. Häring[1];
[1]Department of Internal Medicine, Medical Clinic IV, Division of Endocrinology, [2]Department of General, Visceral and Transplant Surgery, University Clinic, [3]Department of Plastic, Hand and Reconstructive Surgery, BG Trauma Center, Tuebingen, Germany.

Background and aims: Recently we could show that perivascular adipose tissue (PVAT) represents a novel and important fat compartment for the regulation of insulin sensitivity, vascular function, inflammation and angiogenesis in atherosclerosis which differs substantially from other fat tissues, such as visceral or subcutaneous fat. Furthermore, there is evidence that obesity is also associated with diabetic nephropathy risk. In addition, our group found that perihilar adipose tissue (PHAT) - representing the perivascular fat of renal arteries - could influence microalbuminuria. Thus, the secretion pattern of human primary perihilar fat cells in coculture with human primary human

arterial endothelial cells (EC) and smooth muscle cells (SMC) was examined in the present study.
Materials and methods: Cells from PVAT, PHAT, EC and SMC were isolated from human adipose tissue and artery specimens of the renal hilus or radial arteries of three different patients. These cells were characterized by FACS methods and immunostainings, subcultured in monocultures or cocultured in transwell systems. In one part 600 μg/ml human fetuin-A was added. After 6, 24, 48, and 72 h, supernatants were collected and cells were lysed for mRNA extraction. For the quantification of the release of pro-inflammatory and angiogenic proteins, ELISA assays or the luminex technology was used and for the quantification of the mRNA expression realtime PCR was performed.
Results: Similar to preadipocytes from PVAT, preadipocytes from PHAT expressed and secreted the angiogenic factors IL-6, IL-8, MCP-1, HGF, VEGF, bFGF, PLGF, PAI-1 and TIMP-1. In the presence of cocultured EC or SMC, predominantly the proinflammatory proteins IL-6, IL-8 and MCP-1 were upregulated significantly after 24-72 h, whereas the angiogenic factors HGF, VEGF and PLGF where slightly downregulated. In contrast, the HGF and VEGF mRNA expression in EC and the HGF and bFGF mRNA expression in SMC was upregulated after 48 h by the coculture with preadipocytes. When these preadipocytes were differentiated to mature adipocytes, cocultured EC expressed higher levels of MCP-1. Treatment of preadipocytes with fetuin-A stimulated the IL-6 and IL-8, but inhibited the mRNA expression and protein release of the strong angiogenic factor HGF in both cells from PVAT and PHAT.
Conclusion: In our previous studies we could already show that PVAT secretes not only cytokines but more importantly also angiogenic factors and that the secretion profile differs according to the localisation of PVAT in the vascular tree. We found also that PVAT is a regulator of insulin-induced vasoreactivity. Further, there is evidence that defective podocyte-specific insulin signalling plays a role in the aetiology of proteinuria through podocyte damage. Thus, the described interactions between (pre-)adipocytes from PHAT with vascular cells or also podocytes may explain effects of insulin-signalling on vasoreactivity and the podocyte cytoskeleton leading to proteinuria but maybe also on other vascular diseases. This might lead to a better understanding of processes involved in both human diabetic nephropathy and atherosclerosis.

Effect of high FFA level on the anti-contractile response of perivascular adipose tissue in rat aorta
X. Sun[1], N. Hou[1], F. Han[2];
[1]Department of Endocrinology, [2]Department of Pathology, Affiliated Hospital of Weifang Medical University, China, Weifang, China.

Background and aims: Perivascular adipose tissue (PVAT) plays important roles in the modulation of vascular function and attenuates vasoconstriction response by releasing various relaxation factors. This anti-contractile response of PVAT involves endothelium-dependent and endothelium-independent mechanism. However, PVAT-related anti-contraction was impaired in obesity. As high FFA level is a common feature of obesity and could cause impaired endothelium-dependent vasodilatation through inflammation pathway and oxidative stress, it is logical to hypothesize that PVAT dysfunction in obesity is also related to elevated FFA level. Therefore, the aim of the study was to test whether high FFA level could affect the anti-contractile effects of PVAT.
Materials and methods: Male Wistar rats were randomly divided into normal group, obesity group and fenofibrate group, which were fed with normal diet, high-fat diet, and high-fat diet plus fenofibrate (100mg/kg/d, to reduce FFA level), respectively. The thoracic aorta with or without PVAT (PVAT+ and PVAT−) were prepared with either intact endothelium (E+) or with removed endothelium (E−). To study the acute effect of high FFA on the anti-contraction effect of PVAT, we pretreated the aorta from normal rats with 500 μmol/L palmitic acid (PA) or physiological salt solution (PSS) as control. The concentration-dependent responses of aorta to norepinephrine (NE, 10^{-9}-10^{-5} mol/L) were studied in organ bath.
Results: After 8 weeks, body weight (BW), plasma FFA level, PVAT area and adipocyte area increased significantly in obese rats compared to normal rats (BW, 436 ± 34 g vs 370 ± 25 g; FFA, 620 ± 104 umol/L vs 236 ± 46 umol/L; PVAT, 0.56 ± 0.06 mm^2 vs 0.25 ± 0.05 mm^2; adipocyte,473± 61um^2 vs 201± 45 um^2, $P < 0.05$). In normal rat, the presence of PVAT exerted a significant anti-contractile effect to NE on the aorta both in the presence and absence of endothelium($P < 0.05$). However, the anti-contractile effect of PVAT was attenuated in obese rats in the presence of endothelium (attenuation rates, 5% vs 19%, $P < 0.05$). This attenuation of anti-contractile effect of PVAT was restored by reducing FFA level in fenofibrate group (attenuation rates, 16% vs 5%, $P < 0.05$). Transferring the solution from PVAT+ E+ in normal rats to PVAT- E+ in obese rats caused 12% attenuation of anti-contractile response, compared with 4% when transferred from PVAT+ E+ in the obese rats($P < 0.05$). An in vitro study showed that incubation with PA caused an attenuation of the anti-contractile response to NE in the presence rather than the absence of endothelium and this attenuation of anti-contractile effect was disappeared when PVAT was removed ($P < 0.05$). Transferring the solution from PVAT+ E+ incubated with PA to PVAT- E+ incubated with PSS caused only a 7% attenuation of anti-contractile response, compared with 14% when transferred from the PSS incubation($P < 0.05$). Incubation of the aorta (PVAT+ E+) from obese rats or pretreated with PA in vitro with anti-TNF-α antibody or catalase were able to restore the anti-contractile effect of PVAT($P < 0.05$).
Conclusion: Under both acute and chronic conditions, high FFA level could attenuate the anti-contractile properties of PVAT by endothelium-dependent rather endothelium-independent mechanism, in which inflammation and oxidative stress may play important roles.

794

Impact of the peripancreatic adipose tissue on beta cell adaptation to obesity: an integrated, multi-platform analysis
R. Malpique[1,2], H. Figueiredo[1], S. Rebuffat[1,2], M. Vinaixa[3,2], O. Yanes[3,2], X. Correig[3,2], S. Barceló[4], S. Kalko[5], R. Gomis[1,2];
[1]Diabetes and Obesity, IDIBAPS - Hospital Clínic, Barcelona, [2]CIBERDEM, Barcelona, [3]Metabolomics Platform, IISPV - Universitat Rovira i Virgili, Tarragona, [4]IDIBELL, Barcelona, [5]Bioinformatics Core Facility, IDIBAPS - CEK, Barcelona, Spain.

Background and aims: We have recently demonstrated that changes in the peripancreatic white adipose tissue (pWAT) due to diet induced obesity may play a key role in the regulation of beta cell adaptation to obesity. To elucidate this effect we examined transcriptome variations in pancreatic islets and combined them with changes in pWAT gene expression and protein and metabolite secretion in a rat model of diet induced obesity.
Materials and methods: Male Wistar rats were exposed to a 30 days high caloric cafeteria (CAF) or standard (STD) chow diet (n=6/group). Changes in the transcription profiles of pWAT and pancreatic islets were analyzed using Affymetrix Rat 230.2 arrays. pWAT secretome, obtained by 24 hours culture in serum-free medium, was analysed using 2D Differential Gel Electrophoresis proteomics and untargeted metabolomics (1HNMR, GC/MS). Significant alterations were validated through real time PCR, ELISA and mass spectrometry. The Ingenuity Systems Pathway Analysis software was used for functional enrichment analysis and cross-platform integration in interaction networks.
Results: Transcriptome analysis identified T Cell Signalling and Haematological System Development as major disrupted pathways in both tissues, involving mainly down-regulated genes. Proteomic analysis resulted in the identification of 19 proteins differentially secreted by the pWAT in response to diet induced obesity (T-test, p-value < 0.05). Functional analysis revealed that these proteins were mainly involved in disruption of LXR/RXR receptors activation and acute-phase response signalling pathways. Metabolomic analysis identified significant changes in 18 metabolites secreted from pWAT of CAF in comparison to STD rats (Mann-Witney test, p-value < 0.05). Decreased glucose consumption and lactate secretion, and increased glutamine consumption and α-ketoglutarate and oleic acid secretion suggested decreased pWAT glycolysis and enhanced TCA anaplerosis and lipolysis due to diet induced obesity. Transcriptomic analysis of pWAT revealed the up-regulation of 81 genes and down-regulation of 60 genes, while 59 up-regulated and 52 down-regulated genes were found in islets from CAF with respect to STD rats (Rank Prod test, q-value < 0.05). Increasing the level of data integration significantly enriched the related canonical pathways and increased the network connectivity. The highest level of integration, linking genes differentially expressed in both tissues with secretome perturbations, pointed to LXR/RXR Activation, Triacylglycerol Degradation and Immune Response Signalling as the main molecular pathways involved in the pWAT effect on islet adaptation to obesity. Analysis of functional network clusters allowed correlating key pWAT perturbations with islet transcriptome changes, such as the effect of altered lipid and cholesterol transport on disrupted islet circadian rhythm and increased acute-phase response.
Conclusion: The combination of all data subsets underscored functional clusters and integrative hubs, such as cholesterol, the fatty acid binding pro-

tein 4 and the protease plasminogen, as key mediators of the pWAT effect on beta cell adaptation to obesity.

In vivo AAV-mediated genetic engineering of white and brown adipose tissue in adult mice
V. Jimenez[1,2], S.A. Munoz[1,2], E. Casana[1,2], C. Mallol[1,2], I. Elias[1,2], A. Ribera[1,2], T. Ferre[1,2], S. Franckhauser[1,2], F. Bosch[1,2];
[1]CBATEG and Department of Biochemistry and Molecular Biology, School of Veterinary Medicine, Universitat Autonoma de Barcelona, Bellaterra (Cerdanyola del Valles), [2]CIBERDEM, Barcelona, Spain.

Background and aims: Obesity and type 2 diabetes (T2D) are very strongly associated and are a major health problem because of their alarmingly growing prevalence worldwide. Deregulation of metabolic and endocrine functions of white adipose tissue (WAT), as well as impaired brown adipose tissue (BAT) activity and/or decreased mass, are considered among the main contributors to obesity, insulin resistance and T2D both in experimental animal models and in humans. To fully understand the metabolic and molecular mechanism(s) involved in adipose dysfunction, in vivo postnatal genetic modification of adipocytes holds great potential. However, this goal has not been achieved to date. In this study, we assessed the ability of adeno-associated viral (AAV) vectors of serotypes 1, 2, 4, 5, 6, 7, 8 and 9 to transduce murine WAT and BAT in vivo.
Materials and methods: AAV vectors encoding for GFP, RFP or the secreted alkaline phosphatase (SeAP) as marker genes, the enzyme hexokinase II (HKII) or the vascular endothelial growth factor (VEGF) were generated by triple transfection in 293 cells and were purified by double cesium chloride gradient. AAV vectors were injected into the epididymal white adipose tissue, into the interscapular brown adipose tissue or systemically in adult mice.
Results: AAV vectors, especially serotypes 8 and 9, mediated efficient transduction of white (WAT) and brown adipose tissue (BAT) in adult mice after intra-depot or systemic administration. The use of short versions of the aP2 or UCP1 promoters enabled highly specific, long-term AAV-mediated transgene expression in white or brown adipocytes. As proof of concept, delivery of AAV vectors encoding for HKII or VEGF to WAT or BAT resulted in increased glucose uptake or increased vessel density in targeted depots. This gene transfer methodology also enabled the secretion of stable high levels of the SeAP marker protein into the bloodstream by transduced WAT.
Conclusion: All together, this work demonstrates the value that AAV vectors hold as new tools for the long-term postnatal genetic engineering of adipose tissue, which could be used in metabolic and pathophysiology studies as well as in the development of new therapies for obesity and type 2 diabetes. Gene therapy strategies based on AAV-mediated genetic engineering of white adipocytes may also be envisioned for diseases in which supply of the therapeutic protein into the bloodstream is required.

Brown adipose tissue metabolic activity assessed with FDG-PET/CT correlates with BMI and glucose tolerance in insulin resistant subjects
M.S. Buchsbaum[1], L. Morrow[2], D. Meyers[3], A. Krentz[2], G. Peterson[2], T. Swan[3], A. DeCastro[4], M. Hompesch[2], D. Laurent[5];
[1]Neuro PET Center, University of California, San Diego, USA, [2]Profil Institute for Clinical Research Inc,, San Diego, USA, [3]Novartis Institutes for Biomedical Research, Cambridge, USA, [4]NeuroPET Center, University of California, San Diego, USA, [5]Novartis Institutes for Biomedical Research, Basel, Switzerland.

Background and aims: Unlike white adipose tissue (WAT), brown adipose tissue (BAT) is a heat-generating fat that burns energy, and may have beneficial effects on obesity. This study explored the relationship between FDG-PET assessment of BAT activity, body weight, and glucose tolerance.
Materials and methods: We studied 9 insulin resistant subjects (HOMA-IR=5.2±2.5, mean±SD) and 2 overweight healthy volunteers with fluorodeoxyglucose positron emission tomography and x-ray computed tomography (FDG-PET/CT) of the thorax (C6-T8) to assess the glucose metabolic rate (GMR) of brown and white fat. Subjects were exposed to a 90-min period of either cold (67-68 F) or warm (72-73 F) temperature on separate days and then moved to the PET/CT scanner, which was kept at the same temperature for FDG uptake. CT was used to co-register the cold and warm PET scans. Segmented CT masks of 7 Hounsfield unit (HU) bands: -600 to -160 (mainly lung), -160 to -120, -120 to -80, -80 to -40, -40 to 0, 0 to 100 (muscle) and 100-600 (bone and some muscle) were computed. GMR was quantified as μmol glucose/100g/min using an arterial input function from the aorta image. Cold minus warm GMR values were obtained at 5 thoracic levels. All 11 subjects had BMI measured, but only the 9 IR subjects had glucose metabolism quantification with fasting insulin and oral glucose tolerance tests (OGTT).
Results: A higher cold than warm GMR was observed to the greatest extent in the -120 to -80 and -80 to -40 bands of thoracic levels (Figure 1), consistent with earlier reports of BAT metabolic rate sensitivity to thermal exposure. This was confirmed with MANOVA on the whole thorax and the lower 6 HU bands from -600 to 100 for GMR ($F=4.46$, df=4,5; $p=0.048$). Segmented CT scans (Figure 1) and PET cold-minus-warm overlays demonstrate the distribution of regions of cold condition metabolic increase. In the -120 to -40 HU range for whole thorax, a mean increase of 6.4% in GMR was observed in the cold condition compared to the warm condition. Whole thoracic GMR in the cold condition was correlated with fasting glucose in the two fat HU bands ($r=-0.65$ to -0.68, $p<0.03$), but correlations with fasting insulin levels were not significant. The volume of fat tissue in the -80 to -40 HU band significantly correlated with body weight ($r=0.67$, $p=0.023$), BMI ($r=0.93$, $p=0.0001$), and 2-h OGTT plasma glucose ($r=-0.77$, $p=0.015$) values. The volume in the -40 to 0 HU band in the cold condition also had trend level correlations with fasting insulin levels ($r=0.62$, $p=0.076$) and HOMA-IR values ($r=0.64$, $p=0.062$) for mid-thoracic levels.
Conclusion: These results in humans provide further evidence that BAT is associated with body weight, BMI and glucose homeostasis in IR subjects. CT can quantitatively assess fat volume, locate metabolically thermosensitive fat and provide a correlate of BMI. Additionally, FDG-PET may prove sensitive enough to detect metabolic effects of therapeutic interventions on functional BAT volume and activity.

The effect of cold exposure on hepatic fatty acid uptake and brown adipose tissue function: relations to glycaemic control
J.R.H. Raiko, T. Saari, P. Nuutila, K. Virtanen;
Turku PET Centre, University of Turku, Finland.

Background and aims: Functionally active brown adipose tissue (BAT) has been connected to healthy glycemic control. One of the most potent activators of BAT metabolism is cold but virtually non-existent data is available about the effects of cold on liver metabolism - one of the most essential tissues in glucose homeostasis. The aim of this study was to examine the effects of environmental temperature (cold vs warm) on liver fatty acid (FA) uptake and correlations to glycemic control (fasting glucose concentration and HbA1c). BAT perfusion was measured as a marker of BAT functional activity.
Materials and methods: Healthy human volunteers (n = 8) underwent two imaging sessions using 18F-FTHA PET (liver FA uptake) and 15O-H2O PET (BAT perfusion). The studies were performed at room temperature and during nonshivering cold exposure (using a cooling blanket with an adjustable temperature range, started 2 hours prior to the onset of PET study). Fasting blood samples were taken for plasma glucose and HbA1c, and a 2-hour oral glucose tolerance test (OGTT) was performed at room temperature. Correlation analyses were performed with Pearson's correlation and comparisons of mean levels with paired two-way T-test.
Results: BAT perfusion was twofold in cold vs warm conditions. Similarly, liver FA uptake increased almost twofold (0.07±0.02 mmol/l/min vs. 0.04±0.02 mmol/l/min, P=0.14) but nonsignificantly during cold exposure compared to room temperature. Free FA concentration was nonsignificantly higher (0.83±0.30 mmol/l vs. 0.53±0.27 mmol/l, P=0.14) during cold than at room temperature. Liver fractional FA uptake rate (FUR) during cold exposure correlated inversely with plasma HbA1c ($r=-0.75$, $P=0.05$) and directly at room temperature ($r=0.74$, $P=0.04$). Correlations with fasting glucose concentration and 2-hour plasma glucose concentration in OGTT were not found.
Conclusion: Functionally active BAT seems to be in relation to higher hepatic uptake of FAs in cold. Liver FA uptake correlates inversely with serum HbA1c during cold exposure and directly at room temperature. This may partly explain the connection between functionally active BAT and glycemic control.

Insulin glargine does not increase breast cancer growth in an animal model

E.J. Gallagher[1], A. Tobin-Hess[1], J. Blank[1], N. Buffin[1], A. Polin[1], N. Tennagels[2], U. Werner[2], D. LeRoith[1];
[1]Samuel Bronfman Dept of Medicine, Mount Sinai School of Medicine, New York, USA, [2]Sanofi, Frankfurt, Germany.

Background and aims: Individuals with type 2 diabetes are at greater risk of developing breast cancer. Of the contributing factors, endogenous hyperinsulinaemia appears to play an important role. Some epidemiological studies suggest that exogenous insulin therapy may increase the risk of developing cancer in those with diabetes, while other studies report no increased risk. We previously found that rhIGF-1 and the insulin analog, AspB10 increase mammary tumor growth in a mouse model of insulin resistance and endogenous hyperinsulinaemia. In this study, we aimed to determine whether insulin glargine and increased orthotopic mammary tumor growth in a mouse with insulin resistance and endogenous hyperinsulinaemia (MKR mouse).
Materials and methods: 50,000 MVT1 (c-myc/vegf overexpressing) and 250,000 Met1 (polyoma virus middle T antigen expressing) cells were injected orthotopically into 8-10 week old MKR mice. Mice were divided into groups with equal tumor volume and treated with vehicle, rhIGF1 (1mg/kg) or glargine (12.5 U/ kg) twice daily for 2 weeks.
Results: rhIGF1 treated mice had significantly larger MVT1 (229.1±19.8mm3) and Met1 tumor volumes (246.9±18.8mm3) than the vehicle treated group (MVT1 121.99±9.6 mm3, $p<0.05$, Met1 162.4±14.1mm3, $p<0.05$). Tumor volumes in mice treated with insulin glargine did not differ from the vehicle treated groups and were significantly lower than rhIGF1 treated groups. Ex-vivo analysis of protein lysates from MVT1 and Met1 tumors revealed that rhIGF1 treatment led to activation of the IGF1 receptor (IGF-1R), hybrid IGF-1R/insulin receptors (IR) and the Akt signaling pathway, with sustained activation of the receptors and Akt an hour after rhIGF1 injection. Treatment with glargine led to Akt phosphorylation that was reduced an hour after injection in both Met1 and MVT1 tumors.
Conclusion: Our studies show that chronic administration of insulin glargine in an animal model of endogenous hyperinsulinaemia did not increase the growth of orthotopic mammary tumors, an important finding for the management of patients with diabetes.

Insulin glargine (GLA) metabolites do not stimulate cell growth in human cancer initiating cells (CICs)

C. Belda-Iniesta[1], R. Perona[2], O. Arrizabalaga Garde[2], M. Cortés-Sempere[1], E. Holgado[1], O. Pernía[1];
[1]Thoracic, Head & Neck and Brain Oncology Unit, CIOCC Centro integral Oncológico Clara Campal Grupo HM Hospitales, Madrid, [2]Instituto de Investigaciones Biomédicas CSIC/UAM, Madrid and CIBER de Enfermedades Raras, Valencia, Spain.

Background and aims: [AspB10]insulin (X10) is a long-acting insulin analog that displays greater affinity for IGF1R than either the long-acting insulin analog GLA or human insulin (HI) in vitro. X10 is tumorigenic in animal models whereas GLA is not. GLA is rapidly metabolized to the metabolites, M1 and M2. These metabolites exhibit metabolic and mitogenic profiles similar to that of HI in vitro. CICs are cancer cells with self-renewing, stem cell-like properties with the ability to proliferate and differentiate into specific cells found in tumor types and thus they are able to maintain tumor bulk. Many cancers are thought to be initiated by CICs, and there is evidence that they cause cancer recurrence, metastatic progression and resistance to therapies. Avoiding growth factors, like insulin, estrogen or testosterone, is a current strategy to keep cancer incidence or recurrence under control. Our aim was to compare the mitogenic activity of HI, GLA, X10, M1 and M2 on human CICs in vitro.
Materials and methods: CICs derived from 10 human cell lines including glioma, lung, breast, colon, and prostatic cancers were isolated and grown in defined growth medium (no serum) with either HI, GLA, X10, M1 or M2. Growth was estimated using the MTS colorimetric assay.
Results: HI, GLA and X10 stimulated CIC growth to a similar extent, whereas M1 and M2 had growth promoting activity similar to medium without insulin. Similar results were obtained when measuring diametric sphere growth. Additionally, AKT phosphorylation levels were increased 2-fold after stimulation with HI, GLA or X10, whereas stimulation with M1 or M2 did not produce a significant increase.
Conclusion: This is the first study that has explored the biology of CICs treated with insulin analogs. The data show that GLA displays a mitogenic profile comparable to that of human insulin for all CIC lines tested, whereas M1, the main GLA metabolite in vivo, has even less growth promoting activity. Our results do not support GLA increasing CICs growth and thus the involvement of GLA in cancer promotion or relapse.

Use of glucose lowering drugs and the risk of adenocarcinoma among patients with type 2 diabetes: a case-control study in the Netherlands

A.C.R. Simon[1], G.W. 't Jong[2], V.E. Valkhoff[2], M. Sturkenboom[2], J.B.L. Hoekstra[1], F. Holleman[1];
[1]Internal medicine, Academical Medical Center, Amsterdam, [2]Medical Informatics, Erasmus University Medical Center, Rotterdam, Netherlands.

Background and aims: Epidemiological studies suggest that certain glucose lowering drugs may increase or reduce the risks of cancer among patients with type 2 diabetes. The objective of this study was to compare different glucose lowering drugs with respect to the risk of developing adenocarcinoma.
Materials and methods: The primary care research databases in the Netherlands (IPCI) were used to conduct a case-control study among patients with type 2 diabetes from 1996-2011 (n=29,383). Cases with a first-time diagnosis of colorectal-, mamma-, prostate- or pancreascarcinoma, and 30 controls per case were matched on age, sex, duration of diabetes and duration of follow-up. Odds ratios (OR) and 95% Confidence Interval (CI) were calculated by conditional logistic regression analyses. We repeated the analyses when shifting the index date backwards in time by two years.
Results: In total, 702 case patients were identified. Mean age was 64.9 ± 11.8 years. Diet compared to metformin monotherapy was not associated with a difference in risk of developing adenocarcinoma (matched OR: 0.98, 95% CI: 0.77-1.24). Furthermore, sulfonylurea monotherapy compared to metformin monotherapy did not lead to a significant higher risk of developing adenocarcinoma (matched OR: 0.92, 95% CI: 0.65- 1.31). Also, the adding of sulfonylurea to metformin, insulin to metformin or both sulfonylurea and insulin to metformin was not linked to an increased in risk of developing adenocarcinoma (matched OR: 0.90, 95% CI: 0.72-1.12; matched OR: 0.87, 95% CI: 0.61-1.25; matched OR: 1.27, 95% CI: 0.85-1.90) when compared to metformin monotherapy. Furthermore, shifting the index date backwards in time did not lead to substantial changes in outcomes.
Conclusion: The findings of this study do not provide evidence for an increased or reduced risk associated with the use of commonly used glucose lowering drugs on developing adenocarcinoma.

Metformin decreases the tumour death ratio accelerated by a high calorie diet in the RasH2 mouse, a model for evaluating and designing tumour prevention or regression therapies

S. Otabe, X. Yuan, T. Fukutani, M. Migita, H. Nakao, S. Shigemoto, J. Kameo, M. Harada, K. Tanaka, N. Wada, T. Hashinaga, S. Kakino, H. Nakayama, Y. Tajiri, K. Yamada;
Department of Internal Medicine, Kurume University, Japan.

Background and aims: The objective of the current study was to investigate whether metformin intake changed the rate of tumor death under different diet conditions in the rasH2 transgenic mouse, a model for evaluating and designing tumor prevention or regression therapies.
Materials and methods: Male rasH2 transgenic mice at 8 weeks of age were divided into four groups: one fed regular chow of 352 kcal/100 g and drinking water *ad libitum*; another fed a high calorie diet of 592 kcal/100 g and drinking water *ad libitum*; and the others fed the regular chow or the high calorie diet with metformin at a dose of 25 mg/kg body weight per day added to the drinking water from the initiation of the experimental diets to death.
Results: The rasH2 transgenic mice fed a high calorie diet with or without metformin were significantly heavier compared to those fed regular chow after the age of 10 weeks ($p < 0.0001$). Mice fed the high calorie diet without metformin had a shorter average life span ($n = 15$; 60.9 ± 24.4 weeks) than

those fed regular chow (n = 15; 76.5 ± 17.6 weeks; $p < 0.02$). In contrast, the lifespan of mice fed a high calorie diet with metformin (n = 15; 75.3 ± 17.4 weeks) was longer than those fed a high calorie diet without metformin ($p < 0.05$), regardless of no differences in body weights. However, mice fed regular chow with metformin did not show the gain in longevity (n = 19; 72.7 ± 20.6 weeks) compared to mice fed regular chow without metformin (n = 19; 76.8 ± 16.5 weeks). At autopsy, multiple occurrences of tumors in the lung, liver, and digestive organs were found in all groups and malignancy was considered as the cause of death.

Conclusion: Findings from the current study suggest that a constitutional predisposition to tumor may be enhanced by a high calorie diet, and that high incidence of tumor death may be suppressed by a small dose of orally administered metformin.

802

Direct inhibition of hexokinase II underlies a new anticancer property of metformin

B. Salani[1], C. Marini[2], A. Del Rio[3], S. Ravera[4], M. Massollo[5], A. Orengo[6], A. Amaro[7], M. Passalacqua[8], S. Maffioli[1], U. Pfeffer[7], G. Sambuceti[5], R. Cordera[1], D. Maggi[1];
[1]Department of Internal Medicine (DIMI), University of Genova, [2]CNR Institute of Molecular Bioimaging and Physiology (IBFM), Milano, Genova Section, [3]Department of Experimental, Diagnostic and Specialty Medicine (DIMES), Alma Mater Studiorum - University of Bologna, [4]Department of Pharmacy (DIFAR), University of Genova, [5]Nuclear Medicine, Department of Health Science (DISSAL), University of Genova, [6]Nuclear Medicine, Department of Health Science (DISSAL), University of Genova, [7]Italian Institute of Biostructures and Biosystems (INBB), University of Genova, [8]Department of Experimental Medicine (DIMES), University of Genova, Italy.

Background and aims: Recent evidence indicates that the widely used anti-hyperglycaemic drug metformin has important anticancer properties. Besides these epidemiological observations, a wide experimental literature documented that this benefit at least partially reflects the drug capability to directly inhibit the proliferation of various types of cancer cells. Most solid cancers avidly use large amounts of glucose as a source for both energy production and cell building blocks. Critical to this phenotype is the production of β-D-glucose-6-phosphate (G6P), catalysed by hexokinases (HK) I and II whose role in glucose retention and metabolism is highly advantageous for cell survival and proliferation. We studied the effect of metformin on the first steps of glucose metabolism in Calu-1 cells, derived from human non-small cell lung cancer.

Materials and methods: Human GLUTs and HKs expression was evaluated by Western blot and Real Time PCR analysis. To assay the HK I and II enzymatic activity, the reduction of NADP+ was followed, through a coupled reaction with glucose-6-phosphate dehydrogenase (G6PD). Mitochondrial membrane potential was determined using the cationic dye JC-1. Apoptosis was measured by annexin V-FITC and propidium iodide double staining. HK I and II mitochondrial localization was determined using MitoTracker probe. Molecular docking on Hexokinase II models simulations were performed with Glide software on a Linux x86_64 platform machine equipped with an Intel Core2 Quad CPU.

Results: Metformin directly inhibits the enzymatic function of HKI and II in the human non-small-cell lung cancer (NSCLC) cell line Calu-1. The inhibition is selective for these isoforms and virtually abolishes cell uptake and phosphorylation of glucose in a dose and time dependent manner, as documented by the reduced entrapment of 18F-fluorodeoxyglycose (FDG). In silico models indicate that this pharmacological action relates to metformin capability to mimic G6P features by steadily binding its pocket in HK II, thus preventing further glucose phosphorylation. The impairment of this energy source results in mitochondrial depolarization and subsequent cell death.

Conclusion: These results demonstrate a novel action of metformin targeting the enzymatic activity of HKI and II. The impairment of these important promoters of cancer cell proliferation contributes to explain the anticancer properties of this biguanide and represents a starting point to open new strategies in cancer prevention and treatment.

803

Hyperglycaemia and hyperinsulinaemia promote fibrogenesis: increased risk of pancreatic cancer

L. Li[1,2], Z. Sun[1], J. Yang[1], R.T. Waldron[2,3], A. Lugea[2], S.J. Pandol[2,3];
[1]Endocrinology, Zhongda Hospital of Southeast University, Nanjing, China, [2]VA Greater Los Angeles Healthcare System, University of California, Los Angeles, USA, [3]Cedars-Sinai Medical Center, Los Angeles, USA.

Background and aims: Epidemiological studies clearly indicate that the risk of pancreatic cancer (PC) is increased in type 2 diabetic patients. Insulin resistance and associated hyperglycemia, hyperinsulinemia, and abnormalities in insulin/IGF receptor pathways have been suggested to be the underlying mechanisms contributing to development of diabetes-associated pancreatic cancer. The key effector cells responsible for pancreatic fibrogenesis and pancreatic cancer progression are activated pancreatic stellate cells (PSC). The aim of this study was to investigate the effects of hyperglycemia and hyperinsulinemia on PSC.

Methods: In a novel immortalized mouse pancreatic stellate cell line (imPSC), we examined the effects of different culture conditions. Cells were stimulated with glucose and insulin, either individually or concomitantly. We measured matrix synthesis of Collagen I and Fibronectin, analyzed the expression of insulin/IGF-1 signaling pathway components and their operation as profibrotic and/or proliferative pathways and assessed the potential contributions of imPSC to a procarcinogenic microenvironment.

Results: Both Collagen I and Fibronectin were significantly increased when imPSC were incubated with either glucose or insulin. imPSC express receptors for both insulin (IR) and insulin-like growth factor 1 (IGF-1R), and respond to insulin/IGF-1 stimulation with increased tyrosine phosphorylation at specific autophosphorylation sites. Insulin at 100 nM induced peak stimulation of Akt phosphorylation that remained elevated at levels of 5-8 fold above basal from 10 min to at least 60 min. IGF-1 at 10 nM also produced peak stimulation, maximally at 10 min. Whereas the basal level of ERK1/2 phosphorylation was high even in serum-starved cells, stimulation with either 100 nM insulin or 10 nM IGF-1 produced transient increases which peaked at approximately 3 min. Interestingly, we also found effects of different culture conditions on mRNA and protein expression of IR/IGF-1R β subunits. In particular, in cells shifted to physiologic glucose level (5 mM), marked enhancement of IR and IGF-1R expression levels was exhibited.

Conclusion: In conclusion, this study suggests that hyperglycemia and hyperinsulinemia are key-factors in the activation of PSC and progression of fibrosis. Abnormalities in insulin/IGF receptor signaling network are involved in development and progression of diabetes-associated pancreatic cancer.

Impaired gastrointestinal-mediated glucose disposal in patients with non-alcoholic fatty liver disease

A.E. Junker, L.L. Gluud, F.K. Knop, T. Vilsbøll;
Diabetes Research Division, Copenhagen University Hospital Gentofte, Hellerup, Denmark.

Background and aims: Non-alcoholic fatty liver disease (NAFLD) is associated with insulin resistance and an increased risk of diabetes. The aim of this study was to evaluate gastrointestinal-mediated glucose disposal (GIGD) in relation to NAFLD and diabetes.
Materials and methods: Healthy controls were compared with patients who had biopsy-verified NAFLD and either normal glucose tolerance (NGT) or type 2 diabetes. All subjects underwent a 50g-oral glucose tolerance test (OGTT) and an isoglycaemic intravenous glucose infusion (IIGI). GIGD was calculated as the percent difference in the amount of glucose given during the OGTT and IGII divided by the amount given during the OGTT [100% × (glucoseOGTT - glucoseIIGI / glucoseOGTT)]. Results are presented as means ±standard errors.
Results: In all three groups of participants: 1) healthy controls (n=10; age: 56±3 years; body mass index (BMI): 29±2 kg/m2; HbA1c: 5.4±0.1%), 2) NAFLD patients with NGT (n=10; age: 51±5 years; BMI: 31±2 kg/m2; HbA1c: 5.4±0.1%), and 3) NAFLD patients with type 2 diabetes (n=9; age: 60±4 years; BMI: 31±1 kg/m2; HbA1c: 6.7±0.3%), isoglycaemia was obtained. Isoglycaemia during IIGIs was obtained using 25±2 g of glucose in the healthy control group and 34±3 g and 42±2 g of glucose in two groups of NAFLD patients, respectively ($p<0.05$ and $p<0.05$ vs. the healthy control group), resulting in a GIGD of 52±6% in the healthy control group and 31±6% and 16±4% in the two groups of NAFLD patients ($p<0.05$ and $p<0.05$ vs. the healthy control group, respectively).
Conclusion: Patients with NAFLD have impaired GIGD independently of their glucose tolerance. This indicates that lipid accumulation in the liver, negatively affects handling of orally delivered glucose - even before prediabetes or overt diabetes has developed.

805

Marked reductions in hepatic fat after a cardiovascular prevention programme persist after one year despite weight regain

S. Jenni[1,2], T. Tillin[1], L. Thomas[3], K. March[1], C. Tuson[1], C. Park[1], M.D. Baker[1], J. Bell[3], S.B. Connolly[1], D.A. Wood[1], A.D. Hughes[1], N. Chaturvedi[1];
[1]International Centre for Circulatory Health, Imperial College, London, UK, [2]Endocrinology, Diabetes and Clinical Nutrition, University Hospital, Inselspital, Bern, Switzerland, [3]MRC Clinical Sciences Centre, London, UK.

Background and aims: We have previously observed marked reductions in total BMI affecting multiple adipose tissue depots to equivalent extents after a 3 month cardiovascular disease (CVD) prevention programme. We have followed-up patients for a further 9 months after cessation of the programme to establish potential reversal of phenotypic changes. We hypothesized that at least some weight regain would occur as is usually observed in weight reduction studies, but with different effects on different fat depots.
Materials and methods: The MyAction CVD prevention programme is a twelve week family based multi-factorial cardiovascular prevention programme including lifestyle and medication changes offered to patients with cardiovascular risk >20% over 10 years. 29 male patients completed MyAction and 25 were followed-up after one year (9 months off the programme). Adipose tissue depots were determined using whole body magnetic resonance (MR) imaging. Ectopic lipid deposition in liver and muscle (tibialis) was determined using MR spectroscopy, and pancreatic lipids by multi-echo MRI.
Results: Participants were aged 68.2±4.0 (mean±SD) years. Weight reduction after the 12 week CVD prevention programme was 2.27± 0.54kg ($p<0.001$ compared with baseline), weight reduction was 1.02±0.68kg ($p=0.13$ compared with baseline) at 1 year. The regain in weight was accompanied by a regain in adipose tissue in subcutaneous and visceral depots (table); such that there was no statistical difference from baseline. In contrast, reductions in hepatic and pancreatic lipids were maintained ($p=0.002$ and $p=0.09$, respectively vs. baseline). The small but non-significant changes in hepatic fat during weight regain were associated with an increase in fasting plasma triglycerides (Spearman's rho 0.51, $p=0.013$).
Conclusion: Half of the weight loss in association with a 12 week CVD prevention programme was regained at 1 year; however the beneficial effects at ectopic sites, specifically in the liver, persisted. The benefits of a CVD prevention programme on accumulation of ectopic lipids may persist for longer periods than reflected by conventional weight measurements.

The relationship between liver fat content in patients with type 2 diabetes and liver disease outcome

L. Zhang, X. Gao;
Department of Endocrinology, Zhongshan hospital Fudan University, Shanghai, China.

Background and aims: It has been found that the liver fat content was significantly higher in newly diagnosed type 2 diabetic patients (NT2DM) than who were previously diagnosed (PT2DM) in our past studies. The aim of this study is to investigate the alteration of the liver fat content in type 2 diabetic patients along with diabetic duration, and explore its influencing factors and relationship with the outcome of liver disease.
Materials and methods: A cross-sectional study was performed of 650 type 2 diabetic hospitalized patients, who were recruited from the department of endocrinology, Zhongshan hospital Fudan University, between September 2010 and January 2013. The liver fat content (LFC) were obtained from hepatic ^{1}H magnetic resonance spectroscopy (MRS), and defined fatty liver as LFC≥5.56%. NAFLD fibrosis scores (NFS) were calculated from blood tests taken at time of MRS. The NAFLD fibrosis score was calculated according to the following formula:-1.675+0.037×age (years)+0.094×BMI (kg/m^2)+1.13×impaired fasting glycaemia or diabetes(yes=1,no=0)+0.99×AST/ALT ratio-0.013×platelet(×10^9/litre)-0.66×albumin (g/dl). By applying the high cutoff score (0.676), the presence of advanced fibrosis could be diagnosed with high accuracy, and use of the low cutoff score (-1.455) can reliably exclude advanced fibrosis.
Results: Excluding alcoholic and other systemic diseases that may cause fatty liver, 435 patients (235 male (54%), 82 NT2DM (19%)) were included. The mean age was 57±14 years and mean body mass index was 25.4±3.7 kg/m^2. There were 183 subjects taking insulin secretagogues, 154 subjects taking metformin, 44 subjects taking TZDs, and 50 subjects taking α-glucosidase inhibitors in PT2DM patients. There was no significant difference of LFC between subjects taken insulin-sensitizing drugs or not. Mann-Whitney U test showed that the LFC(%) of NT2DM was significantly higher than that of PT2DM (24.66(14.39-41.38) vs 15.20(7.52-25.94), $P<0.01$). In all subjects that diagnosed of NAFLD (LFC≥5.56%), the chi-square test showed that proportion of patients excluded advanced fibrosis (NFS<-1.455) in NT2DM was significantly higher than that of PT2DM (26.3% vs 15.5%,$\chi^2=4.808$, $P<0.05$). Spearman partial correlation analysis showed that LFC was negatively correlated with duration of diabetes ($\gamma=-0.233$,$P<0.01$), and significantly associated with NFS

(γ=-0.164,P<0.01) after adjustment for gender, age, BMI, and oral anti-diabetic drugs. Meanwhile, duration of diabetes was also correlated with NFS positively (γ=0.236,P<0.01). Multiple linear regression analysis showed that the liver fat content was independently associated with duration of diabetes.
Conclusion: With the extension of the duration of diabetes, the reduction of liver fat content of type 2 diabetic patients with NAFLD is related to the development of advanced fibrosis. Decline in liver fat content of type 2 diabetic patient is associated with poor outcome of non-alcoholic fatty liver disease.

The change in plasma triglycerides during an OGTT strongly predicts nonalcoholic fatty liver disease and the effectiveness of a lifestyle intervention to reduce liver fat

K. Kantartzis[1,2], I. Rettig[1], J. Machann[3], F. Schick[3], A. Fritsche[1], L. Scheja[4], H.-U. Häring[1], N. Stefan[1];
[1]Department of Internal Medicine IV, University of Tübingen, [2]Institute for Diabetes Research and Metabolic Diseases of the Helmholz Center Munich at the University of Tübingen (Paul Langerhans Institute Tübingen), German Center for Diabetes Research (DZD), Tübingen, [3]Section on Experimental Radiology, University of Tübingen, [4]Department of Biochemistry and Molecular Biology II, University Medical Center Hamburg-Eppendorf, Germany.

Background and aims: It was recently shown that the change of plasma triglyceride levels during a standard oral glucose tolerance test (OGTT) is associated with visceral fat and insulin resistance. We therefore hypothesized that it may also be a predictor of nonalcoholic fatty liver disease (NAFLD) and may be associated with the change of liver fat content during a lifestyle intervention in humans.
Materials and methods: In 330 individuals at risk of type 2 diabetes, liver fat content was quantified by ^{1}H-magnetic resonance spectroscopy. Liver enzymes, lipids and lipoprotein levels were measured during fasting and after a 2hr-75g OGTT. A subgroup of 213 individuals underwent these measurements before and after participating for 9 months in the Tübingen Lifestyle Intervention Program (TULIP).
Results: In all subjects at baseline, the change in plasma triglycerides during the OGTT (120min-0min; ΔTG_{OGTT}) more strongly associated with liver fat content (r=0.51; r=0.28 after adjustment for gender, age, total body- and visceral fat), and more accurately predicted NAFLD (ROC-AUC=0.75 and 0.83) than fasting liver enzymes, lipids and lipoproteins and 2h-triglycerides (all r<0.49 and ROC-AUCs<0.82). During the lifestyle intervention, ΔTG_{OGTT} at baseline strongly predicted (adjusted estimate±SE: 1.04±0.29) change of liver fat content (estimates for all other parameters <0.24±0.08). After correction for confounders, the odds ratio for 1 standard deviation decrease in TG_{OGTT} at baseline for subjects to experience a reduction in liver fat content during the intervention was 1.90 (95% confidence interval, 1.25-2.97).
Conclusion: We provide novel data that, among commonly measured blood parameters, ΔTG_{OGTT} strongly and independently predicts NAFLD. Moreover, ΔTG_{OGTT} may become an interesting parameter being able to predict the change of liver fat content during a lifestyle intervention in subjects who are at risk for type 2 diabetes.

808

Alteration in lipid metabolism after an oral fat load in subjects with NAFLD

A. Gastaldelli[1], M. Gaggini[1], L. Mezzabotta[2], C. Rosso[2], F. Carli[1], D. Ciociaro[1], R. Gambino[2], S. Carenzi[2], F. Saba[2], M. Cassader[2], E. Bugianesi[2];
[1]Metabolism Unit, CNR Institute of Clinical Physiology, Pisa, [2]University of Torino, Italy.

Background and aims: Subjects with non alcoholic fatty liver disease (NAFLD) are at high risk to develop type 2 diabetes and cardiovascular diseases. Hepatic fat accumulation (IHTG) is the results of insulin resistance (IR) and the impairment in hepatic lipid metabolism. Hepatic TG accumulate because after synthesis they cannot be exported as VLDL or oxidized. In subjects with NAFLD VLDL secretion is often increased as well as hepatic fat oxidation, so probably these two processes are saturated determining IHTG. Thus, we have studied the effect of a lipid load on peripheral lipolysis and hepatic lipid metabolism.
Materials and methods: We have studied glucose and lipid metabolism after a lipid load (200ml dairy cream and egg yolk) in 21 subjects, 15 with biopsy proven NAFLD and 6 controls, CT (mean age 35, BMI 25 kg/m2). Tracers (6,6-2H2-glucose and 2H5-glycerol) were infused for 120min before meal, and 240min after lipid load to evaluate glucose metabolism (EGP and clearance) and lipolysis. Throughout the test we measured glucose, insulin, FFA, triglyceride, cholesterol profiles. During fasting Peripheral IR was measured as HOMA (peripheral), hepatic IR as Hep_IR=EGPxINS, adipose IR as Adipo_IR=lipolysisxINS)
Results: Subjects with NAFLD had higher LFTs (ALT 68±8 vs 16±2 U/l, AST 34±3 vs 19±2 U/l, GGT 92±20 vs 15±6 U/l, all p<0.03), triglycerides (TG 121±12 vs 45±5 p<0.01), insulin (INS 11±2 vs 6±1 p<0.01) but similar fasting plasma concentrations of glucose (98±3 vs 90±2 mg/dl), FFA (0.57±0.08 vs 0.61±0.06 mmol/l), total cholesterol (198±8 vs 163±13 mg/dl), HDL cholesterol (49±2 vs 54±11 mg/dl), ApoB (90±8 vs 64±9 mg/dl). During fasting EGP was similar in both groups (8.8±0.4 vs 8.2±0.4 umol/kg min) while lipolysis was increased in subjects with NAFLD (2.2±0.2 vs 1.5±0.1 umol/kg min p=0.05) that were also more insulin resistant than CT (HOMA 2.8±0.5 vs 1.3±0.2, Hep_IR 101±18 vs 45±6, Adipo_IR 25±5 vs 9±2 all p<0.01). After the oral lipid load insulin increased slightly and as a consequence EGP and glucose concentrations did not change from baseline in CT and slightly decreased in NAFLD (from 8.8±0.4 at t=0 vs 7.8±0.4 umol/kg min at t=240, p<0.05). On the other hand lipolysis did not change in NAFLD, while it was significantly suppressed at 30 min in CT (to 0.9±0.1 umol/kg min p=0.02) to return to baseline at 240min. Cholesterol profile did not change while FFA concentrations increased similarly in the two groups. On the other hand TG increase after lipid load was more pronounced in NAFLD vs CT, AUC-TG increased by 50% (p<0.02) and iAUC-TG was increased 2 folds (p<0.03), reaching a maximum at 4h.
Conclusion: The metabolic handling of an oral fat load is impaired in subjects with NAFLD: basal increased lipolysis was not suppressed after a lipid load, as occurred in CT, and postprandial triglyceride increase was more pronounced. All these alterations might contribute to the development and progression of fatty liver disease.

Interaction between obesity status and dietary intakes of sucrose and ω-6/ω-3-polyunsaturated fats and the Ile148Met in the PNPLA3 gene

I.A. Stojkovic[1], U. Ericson[1], G. Rukh[1], S. Romeo[2], M. Orho-Melander[1];
[1]Diabetes,Cardiovascular disease and Genetic Epidemiology, Lund University, Malmoe, [2]Department of Molecular and Clinical Medicine, University of Gothenburg, Sweden.

Background and aims: The Ile148Met (rs738409) in the patatin-like phospholipase domain-containing protein 3 gene (PNPLA3) associates with non-alcoholic fatty liver disease (NAFLD) and the PNPLA3-148M (G-allele) has been suggested to lead to both loss-of-function (hydrolysis) and gain-of-function [CoA- dependent lysophosphatidic acid acyltransferase (LPAAT)] defects. PNPLA3 is up-regulated by dietary carbohydrates (CHO), it has a higher affinity for unsaturated fatty acids and interactions between rs738409 and dietary intakes of CHO, sucrose and ω-6/ω-3-polyunsaturated fats (ω-6/ω-3-PUFA) on hepatic fat accumulation have been reported. We examined the interaction between rs738409 and obesity status on fasting triglyceride and alanine aminotransferase (ALT) levels, and the interaction between rs738409 and intakes of CHO, sucrose and ω-6/ω-3-PUFA on fasting triglyceride levels.
Materials and methods: From the Malmo Diet and Cancer Cardiovascular Cohort (MDC-CC) 4827 non-diabetic individuals aged 58±6.0y, 3343 with BMI≤27kg/m2 and 1481 with BMI>27kg/m2 were included in analyses. Dietary data was collected by a modified diet history method.
Results: Obesity status modified the association between rs738409 and fasting triglyceride- and ALT-levels (Pinteraction=0.006 and 0.01). The NAFLD-risk G-allele associated with lower triglyceride and higher ALT levels only among overweight individuals (P=0.005, P=0.0002). Significant interactions on triglyceride levels were observed between rs738409 and sucrose among normal weight individuals (Pinteraction=0.02) and ω-6/ω-3-PUFAs among overweight individuals (Pinteraction=0.03). G-allele associated with lower triglycerides only among overweight individuals in the lowest intake tertiles of CHO, sucrose and ω-6/ ω-3-PUFAs (P=0.007, P=0.03, P=0.0004) and with higher triglycerides only among normal weight individuals in the highest intake tertile of sucrose (P=0.02).
Conclusion: Obesity status and dietary sucrose and ω-6/ω-3-PUFA intakes modify the association between rs738409 and fasting triglyceride levels. Our

results suggest that the function of PNPLA3-148Met mutant protein is modulated by the obesity and nutritional status.

Organ-specific fat accumulation and insulin resistance among the liver, skeletal muscle and adipose tissue in people with non-alcoholic fatty liver disease

T. Takamura, K.-I. Kato, H. Misu, Y. Takeshita, S. Kaneko;
Department of Disease Control and Homeostasis, Kanazawa University Graduate School of Medical Sciences, Japan.

Background and aims: Accumulating evidence suggests that network among insulin-target organs may play a role in the development of distant organ insulin resistance (IR). The humoral and nutritional factors and a neuronal pathway may govern the inter-organ networks that may be disrupted by over-nutrition. However, causal relationship between fat accumulation and organ-specific IR still remains unclear in humans. The aim of this study is to examine the association between ectopic fat and organ-specific IR among the liver, skeletal muscle and adipose tissue in people with nonalcoholic fatty liver disease (NAFLD).
Materials and methods: Organ-specific IR in the liver (hepatic glucose production (HGP) × fasting plasma insulin (FPI) and suppression of HGP by insulin [%HGP]), skeletal muscle (insulin-stimulated glucose disposal [Rd]), and adipose tissue (suppression of free fatty acids by insulin [%FFA]) was measured in 45 patients with NAFLD (age 48±2 years, BMI 30.9±1.2 kg/m^2, mean±SE) using a euglycemic hyperinsulinemic clamp with tracer infusion ([6,6-$^2H_2$]glucose). Liver fat, intramyocellular lipid (IMCL), and body composition were measured by liver biopsy, proton magnetic resonance spectroscopy, and a bioelectrical impedance analysis, respectively.
Results: Both liver steatosis score and IHL were significantly correlated with Rd (r = -0.63, P <0.001; r = -0.50, P <0.01, respectively) as well as HGP × FPI (r = 0.50, P <0.01; r = 0.45, P <0.05, respectively). In the multiple regression analysis, both liver steatosis score and IHL were significantly correlated with HGP × FPI and Rd after adjusting for age, sex, and BMI. When stratified by steatosis score, HGP × FPI was significantly higher and Rd was significantly lower in the score 3 steatosis group compared to the score 1 steatosis group. Unexpectedly, indices of fat accumulation in the skeletal muscle (IMCL) and adipose tissue were not associated with their own organ-specific IR. IMCL and fat-free mass were not correlated with Rd (r = 0.01, P = 0.94; r = -0.24, P = 0.12, respectively). Total fat mass and its percentage were correlated with HGP × FPI (r = 0.60, P <0.001; r = 0.61, P <0.001, respectively) and Rd (r = -0.57, P <0.001; r = -0.65, P <0.001, respectively), but not with %FFA (r = 0.01, P = 0.95; r = -0.16, P = 0.32, respectively).
Conclusion: Unexpectedly, fat accumulation in the skeletal muscle and adipose tissue was not associated with organ-specific IR. Instead, in addition to the previously well-recognized relationship between adipose tissue mass and IR in the liver and skeletal muscle, the present study showed a distinct relationship between liver fat and skeletal muscle IR independently of age, sex, and BMI. Liver fat was also associated with hepatic IR. These findings suggest a central role of fatty liver in systemic IR and that a network exists between liver and skeletal muscle to maintain homeostasis of whole body energy metabolism.

TWEAK/Fn14 in human hepatic steatosis: sTWEAK reduces triglyceride accumulation in human liver cells

M.R. Chacón[1], E. Maymó-Masip[1], J. Fernández Real[2], A. Lecube[3], J. Moreno-Navarrete[2], J. Vendrell[1], A.H. Patel[4], J. Garcia-Fontgivell[5], M. Rodríguez[2];
[1]Unitat de Recerca, Joan XXIII University Hospital. IISPV. CIBERDEM., Tarragona, Spain, [2]Department of Diabetes, Endocrinology and Nutrition, IdIBGi. CIBERObn, Girona, Spain, [3]Diabetes and Metabolism Research Group, Vall d'Hebron University Hospital, Barcelona, Spain, [4]MRC University of Glasgow Centre for Virus Research, Glasgow, UK, [5]Pathology Department. Joan XXIII University Hospital, Tarragona, Spain.

Background and aims: Liver steatosis is associated with inflammation, cell death, and fibrosis (referred to as Non-alcoholic fatty liver disease; NAFLD); which can progress to cirrhosis. NAFLD is considered as the hepatic manifestation of the metabolic syndrome due to its strong association with obesity, dyslipidemia, and altered glucose regulation. The cytokine TWEAK (TNF-like weak inducer of apoptosis) and its receptor Fn14 have been implicated in the inflammatory/anti-inflammatory imbalance that occurs in obesity and insulin resistance. This cytokine exists in two isoforms: as a full-length membrane bound (mTWEAK) and as a soluble secreted form (sTWEAK). sTWEAK circulating levels have been found decreased in severely obese subjects, Type 2 diabetic patients and Type 1 diabetic patients. Our aim is to study TWEAK/Fn14 axis within the context of human hepatic steatosis from an observational point of view in human liver biopsies of patients with different degree of steatosis and fibrosis and, in vitro by evaluating the effect of sTWEAK treatment on triglyceride (TG) accumulation.
Materials and methods: Subjects: n=30 severely obese subjects with different degree of steatosis and fibrosis. Real time PCR (RT-PCR) from human hepatic biopsies for the genes: *TWEAK*, *Fn14*, *TNFα, CASP3, BAX*, *GRP78* and *IL*-6 were assessed. Human hepatocyte line (HHL) was subjected to different inflammatory stimuli and processed by immunoblot analysis. Steatosis was induced *in vitro* by palmitic acid treatment. Expression levels of TG transport and synthesis/storage genes were assessed. Intracellular TG content was measured by Oil Red staining technique.
Results: In human liver biopsies, *Fn14* gene expression increases progressively with the grade of fibrosis, steatosis and with the presence of T2D. In cultured human hepatocyte cell line, Fn14 protein expression is enhanced by pro-inflammatory stimuli and in a dose dependent manner by palmitic acid stimulus. *In vitro* pretreatment of human hepatocyte cells with sTWEAK reduces significantly TG accumulation induced by palmitic acid by 30%. Gene expression of *PLIN* and *CD36* were significantly reduced after sTWEAK pretreatment followed by palmitic acid stimulus.
Conclusion: While Fn14 expression increased in human steatosis, its soluble ligand, sTWEAK, has protective/modulator effect on TG deposition in the liver.

A chronic apelin treatment improves hepatic steatosis in obese and insulin resistant mice by modulating de novo lipogenic pathway

C. Bertrand[1,2], A. Batut[1,2], E. Wanecq[1,2], K. Louche[1,2], C. Moro[1,2], P. Valet[1,2], I. Castan-Laurell[1,2];
[1]INSERM U1048, I2MC (Institut des Maladies Métaboliques et Cardiovaculaires), [2]Université Paul Sabatier, Toulouse, France.

Background and aims: Apelin, a widely expressed peptide, acting through the GCPR receptor APJ, has recently emerged as a new player in energy metabolism. Notably, a chronic apelin treatment improves insulin sensitivity in high fat diet (HFD)-fed obese and insulin resistant mice, by enhancing glucose uptake and lipid utilization through fatty acid oxidation in skeletal muscle. However, the role of apelin on the liver in this model has not been addressed so far, although the liver is a major player in energy metabolism. In fact, APJ expression in the liver is very weak, but it is upregulated in severe liver pathologies. Liver steatosis, the lipid accumulation in hepatocytes, is one of the major features of obesity and insulin resistance. We aimed to evaluate the effects of apelin treatment on hepatic lipid metabolism, as well as the regulation of APJ expression in insulin resistance, in order to determine whether apelin can directly act on the liver.
Materials and methods: Male adult C57BL/6J mice were fed with a normal diet (ND) or a HFD containing 45% fat, during 12 weeks until the onset of insulin resistance, and then daily treated with an intraperitoneal apelin dose of 0.1µmol/kg or with PBS as the control group, during 28 days. Body weight, fasted glycemia and insulinemia were monitored during the treatment. At sacrifice, liver was taken to assess *ex vivo* ^{14}C-palmitate beta-oxidation on fresh homogenate, triglyceride content, histology and gene expression, to explore the hepatic lipid metabolism.
Results: As previously shown, this chronic apelin treatment reduced fasted glycemia and insulinemia and fat mass gain of HFD-fed mice, with no significant effect on the body weight. In the liver, triglyceride content was decreased after apelin treatment (ND: 0.241 ± 0.023 gTG/g tissue, HFD-PBS: 0.728 ± 0.110 gTG/g tissue, p<0.001 vs ND, HFD-Apelin: 0.440 ± 0.071 gTG/g tissue, p<0.05 vs HFD-PBS). The Fatty Acid Transporter (FAT) expression wasn't modulated by the treatment, neither was the *ex vivo* liver ^{14}C-palmitate beta-oxidation. However, Sterol Regulatory Element Binding Protein 1c (SREBP1c) expression was decreased (ND: 100 ± 10.6 AU, HFD-PBS: 267.4 ± 19.3 AU, p<0.001 vs ND, HFD-Apelin: 191.1 ± 15.8 AU, p<0.01 vs HFD-PBS) as well as its target gene Fatty Acid Synthase (FAS) expression (ND: 100 ± 12.9 AU, HFD-PBS: 182.4 ± 22.2 AU, p<0.01 vs ND, HFD-Apelin: 101.6 ± 15.4 AU, p<0.01 vs HFD-PBS) after 28 days of apelin administration. Compared to ND-fed mice, the insulin resistant HFD-fed mice exhibited an increase in APJ expression in the liver (ND: 100.0 ± 5.56 AU, HFD: 143.0 ± 16.1 AU, p<0.05), that was not modified by the apelin treatment.
Conclusion: Liver steatosis in HFD-induced insulin resistant mice was attenuated after a 28-days apelin treatment. The *de novo* lipogenic pathway seems to be the privileged target of apelin in our model, since the expression of FAT wasn't modified by the apelin treatment, neither was the ^{14}C-palmitate beta-oxidation performed on fresh liver homogenates.The small increase in the expression of APJ in HFD mice suggests that it could be localized in a particular cell type, such as stellate cells, as previously reported in cirrhosis. APJ needs to be precisely localized in the liver, in order to determine whether the Apelin/APJ system has a direct effect in the liver.

P2X$_7$ receptor deficiency attenuates non-alcoholic steatohepatitis (NASH) induced by high-fat diet: possible role of the NLRP3 inflammasome

G. Pugliese[1], C. Blasetti Fantauzzi[1], S. Menini[1], C. Ricci[1], C. Rossi[2], E. Santini[2], C. Iacobini[1], A. Solini[2];
[1]Department of Clinical and Molecular Medicine, La Sapienza University, Rome, [2]Department of Internal Medicine, University of Pisa, Italy.

Background and aims: Visceral obesity is associated with inflammatory, metabolic and vascular abnormalities including insulin-resistance, atherosclerosis and non-alcoholic steatohepatitis (NASH). The purinergic receptor P2X$_7$ (P2X$_7$R) might contribute to progression from steatosis to NASH, since it is modulated by NEFA and, in turn, mediates ATP-induced activation of the NLRP3 inflammasome. This study was aimed at investigating the role of P2X$_7$R through activation of the NLRP3 inflammasome in NASH induced by a high fat diet (HFD), an established experimental model of the metabolic syndrome.
Materials and methods: To this end, P2X$_7$R knockout (KO) mice and coeval wild type (WT) controls were fed a HFD (60% saturated fat) or a normal fat diet (NFD, 10% saturated fat) for 4 months. Metabolic parameters were assessed using standard methods. Liver sections stained with hematoxylin-eosin and Masson's trichrome were analysed for grading and staging of non-alcoholic fatty liver disease (NAFLD) and NASH using the American Association for the Study of Liver Disease (AASLD) criteria. Immunohistochemistry and real time PCR were used to assess the expression of markers of inflammation, fibrosis and lipid metabolism.
Results: Body weights were significantly higher in KO vs. WT mice and increased in both genotypes upon HFD. Likewise, blood glucose and insulin concentrations, the HOMA-IR index, and triglyceride and cholesterol levels were higher HFD- vs. NFD-fed mice, with no difference between the two genotypes. HFD-induced hepatic lesions were attenuated in KO vs. WT mice. This was confirmed by morphometric analysis, showing mixed, macro- and micro-vesicular, steatosis in both genotypes on a HFD, though it was less severe and predominantly of the micro-vesicular type in the KO as compared with the WT mice. The majority of WT animals (4 out of 7) met the AASLD criteria for diagnosis of moderate-to-severe NASH, i.e. lobular inflammation, ballooning, Mallory's bodies and fibrosis. In contrast, only 1 out of 7 KO mice showed signs of NASH of mild degree, with the remaining 6 animals showing stage 1 or 2 NAFLD, i.e. simple steatosis, predominantly micro-vesicular, with little or no inflammation. The expression of pro-fibrotic (fibronectin, collagen I and TGF-β), pro-inflammatory (MCP1, CXCR3 and TNF-alfa), and lipid metabolism (FAS, SREBP1c, CPT1 and LXR-alfa) genes increased to a significantly lesser extent in KO vs. WT mice on a HFD. Immunohistochemical analysis showed a strong positivity for P2X$_7$R and NLRP3 (in sinusoids, bile ducts and infiltrating inflammatory cells) in the WT mice, whereas staining was absent for P2X$_7$R and very low for NLRP3. These data were confirmed by RT-PCR analysis of gene expression. Preliminary experiments in liver sinusoidal endothelial cells showed that P2X$_7$R and the NLRP3 inflammasome components (NLRP3, caspase-1 and IL-1ß) are expressed under basal conditions and are upregulated in response to the pro-inflammatory cytokine TNF-alfa.
Conclusion: These data show that P2X$_7$R ablation protects mice from HFD-induced NASH, possibly through a blunted activation of NLRP3 inflammasome. This suggests that P2X$_7$R and NLRP3 may represent novel targets for therapeutic intervention.

814

Beta cryptoxanthin improves hepatic insulin resistance and inflammation through alternative activation of macrophages in diet-induced nonalcoholic fatty liver disease

M. Nagashimada, Y. Ni, F. Zhuge, N. Nagata, M. Kobori, M. Sugiura, S. Kaneko, T. Ota;
Brain/Liver Interface Medicine Research Center, Kanazawa University, Japan.

Background and aims: Nonalcoholic fatty liver disease (NAFLD) can be defined as a lipotoxic liver injury, and could worsen whole-body insulin resistance as well as progress to steatohepatitis (NASH). In our previous study, we developed a cholesterol- and saturated FA-induced model of lipotoxic NASH and revealed that excessive hepatic lipid accumulation promotes activation of macrophage/kupffer cells, resulting in exacerbating insulin resistance and hepatic inflammation. β-cryptoxanthin is a carotenoid compound that is known to have a potent anti-inflammatory effect by primarily modulating innate immune response. In the present study, we examined the effect of β-cryptoxanthin on diet-induced NAFLD to clarify the significance of lipotoxicity-mediated hepatic activation/polarization of macrophages in insulin resistance and inflammation in the pathogenesis of NAFLD.
Materials and methods: 7-week-old C57BL/6 mice were fed on a high-cholesterol/high-fat diet (CL) or a CL diet containing β-cryptoxanthin 3 mg/kg (CL+CX), for a total of 12 weeks. The liver histology, insulin sensitivity, and hepatic gene expression profile were examined. Next, we quantified intrahepatic immune cells by fluorescence-activated cell sorter (FACS).
Results: After 12 weeks of feeding, histological examination revealed hepatic steatosis and inflammation in mice fed CL diet. They showed hyperinsulinemia (CL 2.5±0.3 vs normal chow (NC) 0.5±0.1 ng/ml, p<0.01) even

though weight and adiposity were similar. β-cryptoxanthin administration improved glucose intolerance, hyperinsulinemia, and enhanced insulin signal assessed by IRβ and Akt phosphorylation in the liver. β-cryptoxanthin reduced hepatic TG, TC, and FA levels by 36%, 22%, and 48% respectively (all p<0.01), and decreased F4/80$^+$ macrophage infiltration in liver of CL group. Integrated pathway analysis using cDNA microarray showed that β-cryptoxanthin significantly downregulated both macrophage activation signal and T cell differentiation-related genes without affecting most of either FA, cholesterol or bile acid metabolism-related genes. To further assess the impact of β-cryptoxanthin on hepatic inflammation, intrahepatic leukocytes were quantified by FACS. Hepatic macrophages identified as CD45$^+$CD11b$^+$F4/80$^+$ cells were increased in CL group by 7.1-fold compared with NC-fed mice. In addition to slight reduction of total macrophage content in liver, mice fed CL+CX had 51% fewer CD11c$^+$CD206$^-$ (M1)-type macrophages whereas 170% more CD11c$^-$CD206$^+$ (M2)-type macrophages than CL diet fed mice, resulting in a predominance of M2 over M1 macrophage population. Moreover, the numbers of either CD3$^+$, CD4$^+$, or CD8$^+$ T cells were decreased by 39%, 42%, or 34% respectively (all p<0.05) in liver of CL+CX group. In parallel experiments, β-cryptoxanthin (50-200 nM) decreased LPS-induced M1 markers mRNA expression (TNF-α, IL-1β, RANTES) of peritoneal macrophage whereas it augmented IL-4-induced M2 markers mRNA expression (IL-10, CD209a, Mrc2) in a dose-dependent manner.

Conclusion: β-cryptoxanthin improves hepatic insulin resistance and inflammation through an M2-dominant shift in macrophge/Kupffer cells in diet-induced NAFLD. Hepatic M2 polarization or alternative activation of macrophages could contribute to the attenuation of lipid-induced insulin resistance and inflammation in liver.

Dysfunctional adipose tissue-liver crosstalk contributes to short-term HFD-induced insulin resistance

M.S.F. Wiedemann[1,2], S. Wueest[1], I. Flurin[1], E.J. Schoenle[1], D. Konrad[1,2];
[1]Division of Pediatric Endocrinology and Diabetology, University Children's Hospital, [2]Center for Integrative Human Physiology, University of Zurich, Switzerland.

Background and aims: Short-term high-fat diet (HFD) leads to an impairment of glucose tolerance and hepatic insulin sensitivity. Whether this is due to an acute lipid overload or the result of induced adipose tissue inflammation, or both, remains unclear. Besides its well documented apoptosis-promoting effect, Fas (CD95) was demonstrated to activate inflammatory pathways in white adipose tissue (WAT) among others. The aim of the present study was to investigate whether a dys-functional adipose tissue-liver crosstalk contributes early to the development of insulin resistance.

Materials and methods: Adipocyte-specific Fas knockout (Fas$^{\Delta adipo}$) mice, generated on a C57BL/6J background, and control mice (Fas$^{f/f}$) were put on a 4-day HFD or chow control diet. Intraperitoneal glucose tolerance test and hyperinsulinemic-euglycemic clamp studies were performed. Total liver lipids were extracted and measured by a sulfo-phospho-vanillin reaction. Protein levels and mRNA expression were determined by Western blot technique and quantitative real-time PCR, respectively.

Results: Four days of HFD led to marked glucose intolerance in control mice (AUC, 1761 ± 78 mmol/l*min in HFD vs. 1433 ± 50 mmol/l*min in chow, p<0.01). Clamp studies revealed a reduction in glucose infusion rate (GIR) in HFD vs. chow animals (74.5 ± 2.3 vs. 122.8 ± 6.2 mg/kg*min, respectively, p<0.001) as well as a blunted response to insulin-mediated inhibition of endogenous (mainly reflecting hepatic) glucose production (18.7 ± 4.6 mg/kg*min and -5.8 ± 11.0 mg/kg*min for HFD and chow-fed animals, respectively, p <0.05). In a second set of HFD experiments, Fas$^{\Delta adipo}$, compared to Fas$^{f/f}$, had markedly improved glucose tolerance (AUC 1556 ± 66 mmol/l*min vs. 1717 ± 42 mmol/l*min, p<0.05). In clamp studies, GIR was slightly, albeit not significantly improved in Fas$^{\Delta adipo}$ mice. However, insulin-mediated inhibition of endogenous glucose production was almost completely preserved in Fas$^{\Delta adipo}$ whereas it was clearly blunted in Fas$^{f/f}$ mice. Similarly, insulin-stimulated Akt phosphorylation was sustained in livers of Fas$^{\Delta adipo}$ when compared to Fas$^{f/f}$ mice. Total liver lipid content increased with 4-day HFD, however, was not different between HFD-fed Fas$^{\Delta adipo}$ and Fas$^{f/f}$ mice (5.1 ± 0.1 vs. 5.1 ± 0.3 % of total liver weight) suggesting a similar degree of hepatic steatosis. Four days of HFD, compared to chow, did not affect gene expression of inflammatory or macrophage markers in liver, but, specifically, increased tumor necrosis factor alpha (TNF-α) expression in epididymidal WAT and, to a higher degree, in mesenteric WAT. Strikingly, HFD-fed Fas$^{\Delta adipo}$ mice revealed an overall reduced inflammatory profile in both epididymidal and mesenteric WAT compared to Fas$^{f/f}$ mice.

Conclusion: Our results identify adipose tissue inflammation and consecutive dys-functional adipose tissue-liver crosstalk as an early event in the development of HFD-induced deterioration of hepatic insulin sensitivity.

Dietary lipids do not contribute to fructose induced hepatic triglyceride accumulation in mice

P.M. Nunes[1], A.J. Wright[1], A. Veltien[1], J.J.A. van Asten[1], C.J. Tack[2], J.G. Jones[3], A. Heerschap[1];
[1]Radiology, Radboud University Nijmegen Medical Centre, Netherlands, [2]General Internal Medicine, Radboud University Nijmegen Medical Centre, Netherlands, [3]Centre for Neurosciences and Cell Biology, University of Coimbra, Portugal.

Background and aims: Consumption of western diets rich in fat and fructose - present in soft-drinks - contribute to excessive energy intake and development of non-alcoholic fatty liver disease (NAFLD). In these patients, fructose intake is associated with alterations on hepatic high energy phosphate (HEP) content. Hepatic fructose metabolism bypasses key regulatory steps, and "fructolysis" represents an unrestrained ATP use and a constant supply of acetyl-CoA carbons for de novo lipogenesis (DNL). Fructose also stimulates the enterocyte secretion of apoB48 and chylomicron formation, which altogether may expose the liver to greater dietary lipid levels. The aims of this study were to test in vivo, these hypotheses: 1- lipogenic effects of fructose are independent of caloric intake; 2- dietary fructose supply disturbs hepatic HEP content; 3- fructose promotes greater dietary lipid absorption to hepatic triglyceride (HTG) pool.

Materials and methods: C57Bl6J mice (n=29) were fed with 60% fructose or glucose diets for 8 weeks. Caloric intake was determined for 24h in metabolic cages. Intraperitoneal glucose and insulin tests were performed (1.5g/Kg and 0.75U/Kg respectively). Abdominal adipose tissue (WAT) volume was determined by magnetic resonance imaging (MRI) at 0, 4 and 8 weeks of diets. Intracellular lipid pools in muscle and liver were determined at the same dietary time points by 1H magnetic resonance spectroscopy (MRS). Intramyocellular lipids (IMCL) were normalized to total creatine (tCr) and HTG was normalized to water (%). Hepatic HEP content was determined by 31P MRSI after 6 weeks of diets. Dietary lipid incorporation into HTG was determined 5h after a bolus of [U-13C]algal lipids (5g/Kg) by 1H{13C}MRS. Contribution of DNL to HTG pool was determined by 2H nuclear magnetic resonance (NMR) using 2H2O as tracer (21g/Kg).

Results: Caloric intake was similar between the fructose and glucose fed mice (0.31±0.08 vs 0.47±0.13Kcal/gbw/24h). After 8 weeks of diet glucose tolerance was decreased in both mice groups (p<0.05 vs baseline). Glucose clearance was similar between the mice groups. Throughout the course of the diets, glucose and fructose fed mice had a constant WAT volume of ~4%. IMCL/tCr ratios were unaltered after 8 weeks of diet, range [1.4-1.9] for fructose and [1.5-2.0] for glucose fed mice. HTG levels were more elevated after 8 weeks of fructose (3.2±2.0% vs 7.8±2.4%) than after glucose diet (2.4±1.2% vs 4.8±2.5%), p<0.05. The contribution of dietary lipids to the HTG pool was 1.6±0.8% vs 2.2±1.1%, respectively for fructose and glucose fed mice. Simultaneously, DNL contributed to 2.5±1.5% vs 1.1±0.7% of HTG pool in fructose and glucose fed mice, p=0.01. Hepatic ATP levels were 1.9±1.1mM vs 1.6±1.2mM and inorganic phosphate levels were 2.9±0.7mM vs 3.0±1.4mM for fructose and glucose fed mice respectively. These data show that fructose diet did not alter HEP content differently from glucose diet.

Conclusion: Independently of the caloric intake, fructose diet specifically induced HTG accumulation but abdominal adipose tissue and IMCL levels remained unaltered. HTG accumulation is better explained by fructose stimulation of DNL rather than by an increase of dietary lipid absorption. Fructose diet did not alter hepatic HEP content.

Depletion of S-adenosylmethionine promotes non-alcoholic steatohepatitis by upregulating sphingomyelin synthase 1

K.-U. Lee[1], S. Woo[1], J. Leem[1], J. Jang[1], M. Lee[1], E. Koh[1], I.-K. Lee[2];
[1]Department of Internal Medicine, Asan Medical Center, Seoul, [2]Department of Internal Medicine, Kyungpook National University School of Medicine, Daegu, Republic of Korea.

Background and aims: Methionine and choline-deficient diet (MCDD)-induced fatty liver disease is a widely used animal model of nonalcoholic steatohepatitis (NASH). Depletion of S-adenosylmethionine (SAMe) is considered a major contributor to the development of NASH.
Materials and methods: We examined the expression of enzymes involved in sphingolipid metabolism in C57BL/6J mice and *db/db* mice given MCDD for 6 weeks (n = 6 each). Hepatic levels of ceramide, sphingomyelin and diacylglycerol were measured by LC/MS/MS. In a separate set of experiments, C57BL/6J mice were given MCDD supplemented with SAMe.
Results: Feeding MCDD caused NASH, and also increased the expression of ceramide biosynthetic enzymes. Contrary to our expectation, it did not change hepatic total ceramide level, but increased diacylglycerol and sphingomyelin levels. Interestingly, feeding MCDD increased hepatic expression of sphingomyelin synthase 1 (SMS1), which converts ceramide and phosphatidylcholine into sphingomyelin and diacylglycerol, and acid sphingomyelinase (ASMase), two enzymes having apparently opposite action in sphingolipid metabolism. Adeno-associated virus-mediated knockdown of SMS1 decreased hepatic ASMase expression and prevented NASH in MCDD-fed mice. Feeding MCDD in mice and incubation of hepatocytes with MCD medium profoundly decreased expression of stearyl CoA desaturase 1 (SCD1). Knockdown of SCD1 increased SMS1 expression in cultured hepatocytes. Administration of SAMe reversed changes in the expression of SCD1, SMS1 and ASMase, and prevented NASH in MCDD-fed mice.
Conclusion: MCDD-induced depletion of SAMe causes downregulation of SCD1 and upregulation of SMS1 and ASMase, contributing to the progression of simple steatosis to NASH. Our findings identify SMS1 as a key mediator of NASH development.

Protection of high-fat diet induced non-alcoholic steatohepatitis with the combination of n-3 polyunsaturated fatty acids and IgY targeted for NPC1L1

J.-S. Bae[1], E.-H. Kim[2], K.-B. Hahm[3], B.-C. Oh[1], J.-Y. Cha[1];
[1]Lee Gil Ya Cancer and Diabetes Institude, Gachon University, Incheon, Republic of Korea, [2]Laboratory of Translational Medicine, College of Pharmacy, CHA University, Seoul, [3]Department of Gastroenterology, CHA University, CHA Medical Center, Seongnam, Korea, Republic of Korea.

Background and aims: Non-alcoholic fatty liver disease (NAFLD) and non-alcoholic steatohepatitis (NASH), the most severe form of NAFLD, has an increased risk for progression to liver cirrhosis and accompanied with comorbidities such as cardiovascular disease. Treatment of NAFLD includes diet and lifestyle modification, some pharmacological interventions without clear benefits and there is no definitive treatment for NASH. Nieman Pick C1 like 1 (NPC1L1) transporter located in hepatocytes and enterocytes is essential for dietary cholesterol absorption and molecular target for ezetimibe (EZM). Since EZM blocked the internalization of NPC1L1 and caused their retention in the plasma membrane, this drug is a clinically used cholesterol absorption inhibitor. Recent evidence suggests that EZM has a beneficial effect in the treatment of NAFLD. Based on our previous publication that n-3 polyunsaturated fatty acid (n-3 PUFA) significantly ameliorated high fat diet-induced NAFLD, in this study, we have explored the therapeutic efficacy of combination of n-3 PUFAs and immunoglobulin Y targeted to NPC1L1 (N-IgY) on high fat diet-induced NASH.
Materials and methods: We generated N-IgY and confirmed its blocking efficacy in hepatoma cell line HepG2 and intestinal cell line Caco2. Wild-type and *fat-1* transgenic mice were fed normal chow diet (AIN-76A) or high-fat diet (HFD, 40% beef tallow modified AIN-76A purified rodent diet) with or without N-IgY (daily 9 mg per kg body weight) or EZM (positive control, daily 1.8 mg per kg body weight) administration in drinking water for 5 months beginning at 6 weeks of age.
Results: On functional assay to block NPC1L1, N-IgY showed similar blocking efficacy of EZM in HepG2 and Caco2 cells. Animal study revealed that N-IgY and endogenously synthesized n-3 PUFAs led to significant reductions in either body weight or liver wet weight, but EZM showed significant reduction in body weight only. N-3 PUFAs combined with either N-IgY or EZM led to statistically significant decreases in either hepatic fibrosis or steatosis. The changes in biochemical parameters were more significant; Either serum alanine transaminase (ALT) or aspartate transaminase (AST) was significantly decreased and the total cholesterol and LDL cholesterol was also significantly decreased with n-3 PUFAs and N-IgY/EZM. Combination of n-3 PUFAs and N-IgY led to significant reductions in either liver triglyceride (TG) or serum TG levels. Gene expression analysis showed that N-IgY and n-3 PUFAs synergistically up-regulate genes involved in cholesterol uptake (LDLR), bile cid biosynthesis (CYP7A1) or excretion (ABCG5, ABCG8 and *Ostb*) and down-regulate cholesterol synthetic gene (*Hmgcs2*) in liver. N-IgY and n-3 PUFAs also upregulate genes involved in bile acid transporter (*Asbt, Osta and Ostb*) and downregulate cholesterol synthase (*Hmgcs2*) in small intestine.
Conclusion: This study provide first evidence that combination of n-3 PUFAs and N-IgY can be promising treatment strategy to prevent HFD-induced NAFLD. However, extensive clinical trial will be required to stand as potential therapeutics under the well-acknowledged safety.

Liver overexpression of GLUT2 and Slc2a2 are associated with nonalcoholic steatohepatitis in obese diabetic mice

A.D. Silva[1], R.R. Favaro[2], D.T. Furuya[1], M.M. Okamoto[1], P.E. Silva[1], H.S. Freitas[1], F. Barrence[2], T.M.T. Zorn[2], U.F. Machado[1];
[1]Department of Physiology and Biophysics, [2]Department of Cell and Developmental Biology, University of Sao Paulo, Brazil.

Background and aims: Glucose transporter GLUT2, encoded by Slc2a2 gene, participates in the final step of hepatic glucose efflux, playing a key role in glycaemic homeostasis. The nonalcoholic steatohepatitis (NASH) is associated with insulin resistance, diabetes and obesity, situations that could induce alterations of GLUT2/Slc2a2 expression. Thus, we hypothesize that alterations in GLUT2/Slc2a2 expression can occur during development of NASH. The present study aims to investigate GLUT2/Slc2a2 expression during evolution of NASH in a model of obese mice fed with hyperlipidic diet.
Materials and methods: Obesity was induced by neonatal treatment with monosodium glutamate (MSG): 2mg/g (subcutaneously) during 5 days, 4mg/g at the 7th day of life. Control animals (C) were treated with saline during the same period. After the weaning, the animals were fed with normal (ND) and high fat diet (HD - 60% of fat) by 4, 8 and 16 weeks. Four groups of animals were investigated: C-ND, C-HD, MSG-ND and MSG-HD. Obesity was evaluated by measurement of Lee index (body weight related to naso-anal length) and weigh of periepididymal adipose tissue. Plasma glucose and cholesterol were analyzed by commercial kits. NASH was evaluated by regular hematoxylin-eosin (HE) staining of liver samples, analyzing hepatocellular steatosis, ballooning and inflammation).The GLUT2 and Slc2a2 content were analyzed by Western blotting and Rq-PCR, respectively). Data were statistically analyzed by ANOVA, Student Newman-Keuls as post test.
Results: Based on Lee index and fat mas, it was observed that obesity progressively increased from 4 to 16 weeks of treatment in MSG mice, and high fat diet exacerbated the development of obesity. Glycaemia and cholesterolemia also progressively increased, reaching the highest values in 16-week MSG mice, despite high fat diet ($P<0.05$ vs ND and HD, at same age) group. Although signals of steatosis could be observed in early periods, nonalcoholic steatohepatitis was detected only in MSG-HD mice fed by 16 weeks. Finally, increased GLUT2 protein and Slc2a2 mRNA was also observed only in 16-week-treated MSG-HD mice ($P<0,05$).
Conclusion: The present study shows that treatment of MSG obese mice with high fat diet by 16 weeks leads to development of nonalcoholic steatohepatitis, which is accompanied by increased expression of Slc2a2 mRNA and GLUT2 protein, This suggests that increased Slc2a2/GLUT2 expression can contribute to impair hepatic glucose fluxes, and points out Slc2a2/GLUT2 as a potential molecular marker of NASH.

Implication of mitochondria associated membranes regulation in insulin resistant and fatty liver

P. Theurey, E. Tubbs, G. Vial, N. Bendridi, H. Vidal, J. Rieusset;
CarMeN laboratory, Lyon, France.

Background and aims: Hepatic Insulin Resistance (HIR) and fatty liver disease (FLD) are associated with both mitochondrial and endoplasmic reticulum (ER) dysfunction. These two organelles are tightly link through contact points, known as Mitochondria Associated Membranes (MAMs). Even if an increasing number of studies point to several roles of MAMs in cellular processes such as lipid and Ca2+ exchange or mitochondrial dynamics, there is currently no data describing any potential physiological and/or pathological regulation. Our laboratory recently demonstrated a new role of altered MAMs in HIR. The aim of the study was to determine whether nutritional status was able to regulate MAM amount in liver in both physiological and pathological context, and identifying the different actors and cellular pathways involved.
Materials and methods: Using cell fractionation, in situ proximity ligation assay (PLA) and electronic microscopy stereology we quantified the interaction between ER and mitochondria in liver of fasted and fed wild type (wt) and ob/ob mice, as a model of HIR and FLD. In addition, we measured the repercussions of several metabolites and hormones related to nutritional state like glucose, lipids, glucagon and insulin on organelle interactions in rodent primary hepatocytes and HuH7 cells by quantifying the VDAC1/IP3R1 interaction, two interactors mediating Ca2+ transfer between both organelles, by in situ PLA.
Results: We demonstrated a reduction of MAM amount in the liver of fed wt mice compared to fasted ones (-60%, p<0,001). In addition we observed a reduction of MAM amount in liver of ob/ob mice in both fasted and fed states (-50% and -60% respectively, p<0.001), which is confirmed by in situ PLA on primary hepatocytes (-50%, p<0.01). Interestingly there was no significant difference between fed and fasted obese mice, suggesting the absence of a nutritional regulation of MAMs in the liver of obese and diabetic mice. In vitro, the addition of glucose (25mM, 4H) in the culture medium of either HuH7 cells or primary hepatocytes reduced VDAC1/IP3R1 interactions (-50% and -60% respectively, p<0,001). Insulin (10-7M, 4H) also reduced these interactions in primary hepatocytes (-70%, p<0.001). Interestingly, addition of 2-deoxyglucose (25mM, 4H) or fructose (25mM, 4H) reproduced the reduction of interorganelle interactions in HuH7 cells (-50% p<0.01 and -40 % p<0,001, respectively), whereas glucagon (100nM, 4H) and palmitate (200µM, 4H) showed no significant effect.
Conclusion: Our data point to an alteration of the ER-mitochondria interactions, as well as their regulation by nutritional state, in the insulin resistant and fatty liver. The fact that either glucose, fructose, 2-deoxyglucose and insulin similarly reduced VDAC1/IP3R1 interactions suggest that the pentose phosphate pathway is potentially involved, requiring further investigations to identify the key players.

PS 062 Signalling in adipocyte metabolism

821

Involvement of Tpl2 kinase in COX-2 expression and prostaglandin production in adipocytes

F. Berthou, F. Ceppo, K. Dumas, M. Cormont, J.-F. Tanti;
INSERM 1065 C3M, Nice, France.

Background and aims: Obesity is associated with a low-grade inflammation of adipose tissue that leads to insulin resistance and to the onset of type 2 diabetes. A crosstalk between adipocytes and macrophages within adipose tissue contributes to the production of inflammatory mediators and promotes adipocytes dysfunction. Prostaglandins (PG) play a key role in inflammatory response and are produced by cyclooxygenases (COX) from arachidonic acid. COX-2 expression and PGE2 production are increased in adipose tissue from obese patients. However, inflammatory signaling pathways controlling its expression in adipose tissue remain ill-defined. Our previous work has shown that the MAP3Kinase Tpl2 is overexpressed in adipose tissue of obese patients and rodents and is involved in lipolytic effect of cytokines. The aim of this work is to study the involvement of Tpl2 in COX-2 induction and PGE2 production in adipocytes.
Materials and methods: Different in vitro experiments were performed : 1- treatment of 3T3-L1 adipocytes with IL-1β or IL-1β+TNF-α ; 2- direct coculture between adipocytes and RAW264.7 macrophages ; 3- incubation of adipocytes with conditionned medium from macrophages treated with LPS 0.5 ng/ml. In each approach, Tpl2 was inhibited by using a pharmacological inhibitor or a siRNA. Moreover, explants of adipose tissue from obese wild-type and Tpl2 KO mice were incubated with LPS 100 ng/ml. COX-2 gene expression was analysed by RT-qPCR. COX-2 protein expression was studied by Western-blot. PGE2 production was measured by enzyme immunoassay.
Results: In 3T3-L1 adipocytes, IL-1β and IL-1β+TNF-α induce COX-2 gene and protein expression and PGE2 production. These effects are decreased by 50% with Tpl2 inhibitor or siTpl2. COX-2 expression and PGE2 production are also increased in a direct coculture between adipocytes and macrophages. A pharmacological inhibition of Tpl2 in the coculture or Tpl2 silencing in adipocytes markedly reduces these inductions. Further, a pharmacological inhibition of Tpl2 in adipocytes reduces by 60% COX-2 expression induced by a conditionned medium from LPS-treated macrophages. Collectivelly, these data demonstrate that Tpl2 activation in adipocytes is necessary for COX-2 epxression and PGE2 production induced by cytokines-derived from macrophages. Importantly, Tpl2 expression in obese adipose tissue is necessary for LPS-induced COX-2 expression since we found that LPS is less efficient to induce COX-2 mRNA in explants of adipose tissue from obese Tpl2 KO mice as compared to obese wild-type mice (2.4 vs 6.5 fold respectively).
Conclusion: We have identified Tpl2 as an important inflammatory kinase necessary for COX-2 expression and PGE2 production in adipocytes in response to inflammatory cytokines derrived from macrophages. Thus, a deregulation of Tpl2 in adipocytes could participate to the overexpression of PG and to inflammatory state in adipose tissue.

Bombesin receptor subtype-3: expression/function/role in cell signalling pathway and glucose transport, in adipose tissue from human and animal model

Z. Moreno-Villegas[1], I. Ramos-Álvarez[1], R. Sanz[1], S. Portal-Núñez[1], N. González[1], R.T. Jensen[2];
[1]IIS- Fundación Jiménez Díaz/CIBERDEM, Madrid, Spain, [2]NIH, Bethesda, USA.

Background and aims: previously, we described that Bombesin Receptor Subtype-3 (BRS-3) expression is lower than normal (N), in skeletal muscle from obese (OB) or type 2 diabetic (T2D) patients. Moreover, agonist [D-Phe^{6},β-Ala^{11},Phe^{13},Nle^{14}]bombesin$_{6-14}$ (BRS-3-AP) induced a concentration-related lipogenesis stimulation, in isolated adipocytes from normal rats (totally abolished by wortmanin -PI3K/PKB inhibitor-, and partially by rapamicin -p70s6K inhibitor-). Here we studied: A) BRS-3 expression in human and rat pieces from adipose tissue with/without metabolic alterations, B) characteristics of the receptor signalling pathways by using BRS-3-AP, and

its effect on glucose transport (GT) in normal human mature and rat isolated adipocytes.
Material and methods: RNA and protein were extracted from human (5 N, 5 OB and 6 T2D) and rat models [5 normal (n), 5 Hyperlipidemic (HL) and 4 T2D]. Human mature adipocytes were differentiated from a normal preadipocyte cell line, and normal rat adipocytes isolated by enzymatic digestion from epididymal fat pads (18 normal male Wistar rats 250 g, kept in a standard chow and water *ad libitum*). We measured: BRS-3 gene expression -qPCR-, BRS-3 protein, PKB and p70s6K -Western Blot-, glucose transport as ^{3}H-2-deoxy-D-glucose incorporation, in cells incubated in the absence (control) or presence of BRS-3-AP (10^{-13}-10^{-7}M) and with/without 10^{-6}M wortmanin, 10^{-7}M rapamycin.
Results: Human BRS-3-mRNA level was lower than normal in fat tissue from OB and T2D patients (11.2±0.9; 13.5±0.9 times down-regulated, $p<0.001$; respectively), as detected in rat adipose tissue from HL and T2D models (1.96±0.04; 10.3±0.36 times down-regulated, $p<0.001$; respectively). Human (T2D: 66±5% of N control, $p<0.05$) and rat (T2D: 57±11% of n control, $p<0.05$) protein values corresponded with mRNA expression reduced levels. In human adipocytes, 10^{-8}M BRS-3-AP increased ($p<0.05$) PKB and p70s6K phosphorylation (130±2% of control; 183±28%, respectively) like insulin (10^{-9}M: 147±5% and 152±10%, $p<0.05$, respectively); at 10^{-9}M, BRS-3-AP clearly induced p70s6K (152±5%, $p<0.05$), but not PKB phosphorylation (117±6%). However, in rat adipocytes, 10^{-8} and 10^{-9}M agonist produced a significant increase, in both, phosphorylation enzymes (PKB: 134±5% of control and 133±5%, $p<0.05$; p70s6K: 156±10% of control and 195±20%, $p<0.05$) like insulin (144±11% of control; 163±22%, $p<0.05$, respectively). In human adipocytes, BRS-3-AP caused a concentration-related stimulation of GT, maximal at 10^{-8}M (165±17% of control, $p<0.05$) which was blocked by wortmanin (98±5% control), and partially reduced by rapamacin (118±6% of control, $p<0.05$ *vs* control; $p<0.05$ *vs* 10^{-9}M BRS-3-AP); however, in rat adipocytes, BRS-3 maximal effect on GT (10^{-9}M: 155±8% of control, $p<0.02$) was abolished, by the additional presence of both, wortmanin (102±6%) and rapamycin (106±7%, $p<0.05$).
Conclusion: The results confirm a specific role of BRS-3 in human and rat adipose tissue, and not only describe the insulin-mimetic effect of its synthetic agonist on glucose transport, but also reveal the receptor signaling pathway. These facts support the notion that BRS-3 receptor, and/or its agonist peptide, might be considered as a molecular target with therapeutic purposes in diabetes and obesity.

CDK4 is an essential insulin effector in adipocytes
L. Fajas[1], S. Lagarrigue[1], C. Chavey[2], S. Hure[1];
[1]Physiology, UNIL, Lausanne, Switzerland, [2]IGMM, Montpellier, France.

Background and aims: Insulin signaling is one of the most versatile systems that coordinate growth, proliferation and development with metabolic processes that accommodates energy needs to cellular function. Insulin response depends on tissue and cellular function. In white adipose tissue insulin signaling regulates lipid synthesis, lipolysis and glucose transport. However, the exact mechanism of how the insulin signaling produces its own specific pattern of regulated cellular functions is not yet fully understood.
Materials and methods: CDK4-/- mice were used in this study. Primary cultures of adipocytes and 3T3L1 cell line were also used.
Results: We show in this study that the cell cycle regulatory kinase CDK4 is a key insulin effector in adipocytes. Adipose tissue from CDK4-/- mice, or adipose tissue from mice treated with a CDK4 inhibitor have decreased lipogenesis and glucose transport and increased lipolysis. Consequently CDK4-/- mice are lean. In sharp contrast, mice that express a mutant hyperactive CDK4 (R24C) are obese as a result of decreased lipolysis and increased lipogenesis. We show here that CDK4 genetic or chemical inhibition blocks, as measured by whole kinome analysis AKT insulin signaling. Most interestingly we show that CDK4 phosphorylates and activates the insulin receptor substrate IRS2 creating a positive feed-back loop that maintains insulin action in adipocytes.
Conclusion: These findings place CDK4 at the initiation of the signaling pathway triggered by insulin in adipocytes.

Down-regulation of calcineurin-like phosphoesterase domain containing 1 (CPPED1) expression improves glucose metabolism in vitro in adipocytes
M. Vaittinen[1], M. Kolehmainen[1], J. Pihlajamäki[1,2], M. Uusitupa[1,3], L. Pulkkinen[1];
[1]Clinical Nutrition, University of Eastern Finland, Kuopio, [2]Departments of Medicine and Clinical Nutrition, Kuopio University Hospital, [3]Research Unit, Kuopio University Hospital, Finland.

Background and aims: We have shown that the expression of CPPED1 is down-regulated in adipose tissue (AT) in response to weight reduction in persons with features of metabolic syndrome. However, the function of CPPED1 in AT is unknown. In this study we aimed to investigate the localization of CPPED1 protein expression in cultured SGBS preadipocytes and adipocytes, and to elucidate the role of CPPED1 in adipocyte glucose metabolism.
Materials and methods: Immunofluorescence was used for localization of CPPED1 protein expression in SGBS preadipocytes and adipocytes. The effect of reduced CPPED1 expression by RNAi technique on insulin action was measured using insulin-stimulated glucose uptake. Furthermore, the effect of CPPED1 knock-down on the expression of genes related to adipocyte function was studied in SGBS adipocytes by RT-qPCR and western blot.
Results: Immunofluorescence showed cytoplasmic expression of CPPED1 in preadipocytes and adipocytes. CPPED1 knock-down increased insulin-stimulated glucose uptake by 74% ($p<0.05$) which was abolished by wortmannin treatment ($p<0.01$). Moreover, CPPED1 knock-down increased the mRNA expressions of adiponectin ($p<0.01$), adiponectin receptor 1 ($p<0.01$) and glucose transporter 4 ($p<0.01$), and decreased glucose transporter 1 ($p<0.001$) and leptin ($p<0.05$). CPPED1 knock-down increased adiponectin protein expression time-dependently leading to a significant increase at 96h after CPPED1 knock-down (+32%, $p<0.05$). Furthermore, CPPED1 knock-down tended to increase adiponectin secretion ($p=0.057$) into the conditioned medium.
Conclusion: We demonstrate that CPPED1 is a novel molecule involved in adipocyte biology, potentially related to insulin action and improved glucose metabolism in adipocytes.

Role of ChREBP and PPARa in the regulation of glucose and lipid metabolism in brown adipocytes
K. Iizuka[1], W. Wu[1], T. Hattori[1], Y. Horikawa[1], M. Saito[2], J. Takeda[1];
[1]Department of Diabetes and Endocrinology, Gifu University, [2]Department of Nutrition, Tenshi College, Sapporo, Japan.

Background and aims: Carbohydrate response element binding protein (ChREBP) plays an important role in the regulation of lipogenesis in the liver. Chrebp mRNA levels in brown adipose tissue are as abundant as those in the liver; however the function of ChREBP in brown adipose tissue is still unclear. In this study, we clarified the role of ChREBP in brown adipocytes and identified a functional involvement of peroxisome proliferator-activated receptor alpha (PPARα).
Materials and methods: Mouse immortal brown adipose HB2 cells were obtained from the interscapular brown adipose tissue of mice deficient for the tumor-suppressor gene p53. Six-week-old male wild-type (WT) and ChREBP-/- C57BL/6J mice were starved for 24 h or fed ad libitum (n=3, each group). To measure mRNA levels of ChREBP and ChREBP target genes in brown adipocytes, we performed quantitative RT-PCR and DNA microarray analysis. Relative mRNA levels were determined by real-time RT-PCR and normalized to mouse RNA polymerase II mRNA as the invariant control. To measure PPARα and ChREBP transactivities in differentiated HB2 cells, we performed a reporter assay using a pGL3 promoter vector containing the PPAR response element of acyl-CoA oxidase or carbohydrate response element of Fasn and Chrebpb.
Results: Chrebpb mRNA levels in brown adipose tissue from fasting mice were lower than those in mice fed ad libitum (0.042±0.021 and 3.98±0.042, respectively), while Ppara mRNA levels in brown adipose tissue of fasting mice were much higher than those in fed mice (1.23±0.033 and 0.69±0.006, respectively). In differentiated HB2 cells, glucose increased mRNA levels of ChREBP target genes such as Fasn and Glut4 in a dose-dependent manner, but reciprocally decreased Chrebp and Ppara mRNA levels. DNA microar-

ray data revealed that most ChREBP target genes (Fasn, Acaca, Fgf21, Scd1, Elovl6, Tkt, Acly, and Me1) were reduced more than two-fold (22.1 fold, 18.4 fold, 49.9 fold, 8.63 fold, 5.66 fold, 3.13 fold, 23.06 fold, and 5.27 fold, respectively), while Ppara mRNA levels were elevated 3.06 fold. Quantitative RT-PCR confirmed that (1) Fasn mRNA levels in brown adipose tissue from ChREBP-/- mice were much lower than those in WT mice (0.079±0.0026 and 0.72±0.0028, respectively), and (2) Ppara mRNA levels in ChREBP-/- mice were 3.38±0.17 fold higher than those in WT mice (2.64±0.13 and 0.78±0.075, respectively). Adenoviral overexpression of ChREBP and reporter assays showed that ChREBP suppressed PPARα transactivity in HB2 cells. In contrast, 100 μM Wy14643, a selective PPARα agonist, partially suppressed glucose-mediated induction of Chrebpb and Fasn mRNA and ChREBP transactivity in HB2 cells.
Conclusion: ChREBP and PPARα coordinately regulate glucose and lipid metabolism in brown adipocytes.

Unsuppressed lipolysis in adipose tissues by insulin is critical for glucose homeostasis under high fat diet
E. Lee[1], K. Sakurai[2], C. Toda[3], Y. Minokoshi[3], T. Miki[1];
[1]Department of Medical Physiology, Chiba University, Graduate School of Medicine, [2]Department of Clinical Cell Biology and Medicine Chiba University, Chiba University, Graduate School of Medicine, [3]Department of Developmental Physiology, National Institute for Physiological Sciences, Okazaki, Japan.

Background and aims: Excessive consumption of animal fat has been considered to contribute to the recent upsurge in the incidence of diabetes mellitus. However, molecular mechanism of impaired glucose metabolism under high fat diet (HFD) still remains uncertain, since few animal models develop overt hyperglycemia only under HFD. We found that marked hyperglycemia was induced by HFD feeding in a mutant IR (mIR) mouse, which harbors a loss of function mutation in the insulin receptor. In this study, we examined the pathophysiology of HFD-induced diabetes mellitus using mIR.
Materials and methods: mIR and wild-type mice were fed with high fat diet (60% fat in calorie) and the metabolic changes in insulin target tissues, including white adipose tissue (WAT) and liver, were examined.
Results: Marked hyperglycemia developed in mIR under HFD (mIR/HFD) but not in wild-type (WT) mice under HFD (WT/HFD) (mIR/HFD, 376 ± 30 mg/dl; WT/HFD, 189 ± 9 mg/dl, n=9-10, $p < 0.001$, after 8 week HFD at 16 weeks of age). By contrast, the increase in body weight was significantly less in mIR/HFD than in WT/HFD. Oral glucose tolerance test and insulin tolerance test revealed that mIR/HFD have apparent glucose intolerance and severe insulin resistance. Considering that gluconeogenesis might be increased in mIR/HFD, we measured the mRNA expressions of PEPCK and glucose-6-phosphatase (G6P) in the liver, both of which are critical in the regulation of gluconeogenesis. The PEPCK expression in mIR/HFD was similar to that in WT/HFD, while the G6P expression in mIR/HFD was significantly increased (1.9 folds in mIR/HFD vs WT/HFD, n=10-12, $p < 0.05$). PEPCK mediates gluconeogenesis from amino acids and pyruvate, while G6P is also involved in the gluconeogenesis from glycerol as well as from amino acids and pyruvate. Thus, we measured the increase in blood glucose levels after pyruvate or glycerol administration in vivo to assess the activity of gluconeogenesis from these substrates. Interestingly, gluconeogenesis from glycerol but not from pyruvate was found to be increased in mIR/HFD. Glycerol is generated from triglyceride through lipolysis. Lipolysis in WAT is inhibited by insulin through inhibition of phosphorylation of hormone sensitive lipase (HSL). Thus, we performed Western blot analysis of phosphorylated HSL in white adipose tissues (WAT), and found that phosphorylation of HSL was inhibited markedly by HFD in WT, but much less in mIR (3 folds in mIR/HFD vs WT/HFD, n=6-7, $p < 0.05$). These results indicated that suppression of lipolysis by HFD is impaired in mIR and this leads to the increase in glycerol influx to the liver and resultant rise in gluconeogenesis, contributing to the development of overt hyperglycemia in mIR/HFD.
Conclusion: Unsuppressed lipolysis in WAT and increased gluconeogenesis in the liver from glycerol both contribute to the development of hyperglycemia under HFD in insulin resistance.

Cyclosporin A and tacrolimus impair dynamics of GLUT4 traffic in insulin-responsive cells
M.J. Pereira[1,2], J. Palming[3], M. Rizell[4], M. Aureliano[5], E. Carvalho[2], M.K. Svensson[3], J.W. Eriksson[1,6];
[1]Uppsala University, Department of Medical Sciences, Uppsala, Sweden, [2]Center of Neuroscience and Cell Biology, University of Coimbra, Portugal, [3]Dept of Molecular and Clinical Medicine, Sahlgrenska University Hospital, Gothenburg, Sweden, [4]Dept of Surgery, Sahlgrenska University Hospital, Gothenburg, Sweden, [5]Center of Marine Sciences, FCT, University of Algarve, Faro, Portugal, [6]AstraZeneca, Mölndal, Sweden.

Background and aims: The calcineurin inhibitors cyclosporin A (CsA) and tacrolimus (FK), are immunosuppressive agents (IAs) frequently used after transplantation and they are associated with several side effects including hyperglycaemia and new-onset diabetes. However, the mechanism for glucose intolerance is not known and the direct effects of the IAs on insulin-responsive cells including human adipocytes have not been well characterized previously.
Materials and methods: Glucose uptake and protein expression of insulin signalling proteins were measured in human isolated adipocytes, obtained from 42 non-diabetic volunteers, incubated in the absence and presence of either CsA or FK and insulin (1000 μU/mL). Effects of either CsA or FK on cellular distribution of GLUT4 in human preadipocytes differentiated into adipocytes and in 3T3-L1 adipocytes, was evaluated by immunohistochemistry and fluorescence microscopy. In addition, effects of CsA or FK on endocytotic and exocytotic rates of the GLUT4 transporter were studied in L6 myoblasts stably expressing GLUT4 with an exofacially directed Myc-tag, by an enzyme-linked immunosorbent-like assay.
Results: CsA and FK had a concentration dependent-inhibitory effect on basal and insulin-stimulated 14C-glucose uptake in human adipocytes (up to 40% reduction, $p<0.05$). Although the phosphorylation of the insulin receptor at Tyr1146 was inhibited by CsA and FK, phosphorylation and/or protein levels of insulin signalling proteins (IRS1/2, p85-PI3K, PKB, AS160, mTORC1) and GLUT4 and 1 content were not changed. Furthermore, CsA or FK reduced the insulin-induced redistribution of GLUT4 to the cell surface of differentiated human adipocytes (~60%, $p<0.05$) and 3T3-L1 adipocytes. In addition, CsA and FK similarly reduced the cell surface levels of GLUT4 in L6 muscle cells and increased the GLUT4 endocytosis rate, by up to 30%, with no change in exocytosis rate.
Conclusion: In conclusion, these results suggest that therapeutic concentrations of cyclosporin A and tacrolimus, inhibit glucose uptake by removing GLUT4 from the cell surface via increased endocytosis and this is independent of the insulin signalling cascade. The described effects of immunosuppressive agents in adipocytes and other insulin-sensitive cells may contribute to the development of insulin resistance and new-onset diabetes associated with immunosuppressive therapy.

Amyloid beta42 administration impairs energy metabolism in vivo and in vitro
J.K. Czeczor, T. Connor, A.J. Genders, K. Walder, S. McGee;
School of Medicine, Metabolic Research Unit, Waurn Ponds, Australia.

Background and aims: Amyloid β_{42} ($A\beta_{42}$) is a protein implicated in the onset of Alzheimer's Disease (AD), in part through impaired neuronal metabolism. Obese and diabetic patients have increased circulating $A\beta_{42}$, yet it is unknown whether circulating $A\beta_{42}$ contributes to altered metabolism in these conditions. The aim of our study was to determine whether $A\beta_{42}$ alters metabolism of insulin sensitive cells *in vitro*, and whole body metabolism *in vivo*.
Materials and methods: Both 3T3-L1 adipocytes and FAO hepatocytes were treated with either $mA\beta_{42}$ or aggregated $A\beta_{42}$ ($aA\beta_{42}$) for 48h, with respective controls being monomeric or aggregated scrambled $A\beta_{42}$ ($scrA\beta_{42}$). After 48h of treatment, basal and insulin stimulated glucose uptake and glucose production was measured in 3T3-L1 adipocytes and FAO cells respectively. For *in vivo* studies, 8 week old, male C57Bl/6J mice (n=10 per group) were treated with $mA\beta_{42}$ or $scrA\beta_{42}$ (control) for two weeks (1μg/day; I.P injections). Bodyweight and food intake were monitored daily. Indirect calorimetry was performed after 14 days of treatment and oxygen consumption, respiratory quotient and substrate oxidation determined.

Results: Monomeric $A\beta_{42}$ ($mA\beta_{42}$) increased glucose production in FAO hepatocytes, while $aA\beta_{42}$ had no effect. Similarly, $mA\beta_{42}$ impaired glucose uptake in 3T3-L1 adipocytes, while $aA\beta_{42}$ had no effect. Administration of $mA\beta_{42}$ had no effect on bodyweight or food intake compared with control treated mice. However, administration of $mA\beta_{42}$ reduced oxygen consumption and total carbohydrate oxidation compared with control animals ($p \leq 0.05$).
Conclusion: This data shows that monomeric $A\beta_{42}$ impairs glucose metabolism while aggregated $A\beta_{42}$ had no effect. This data suggests that not only is $A\beta_{42}$ involved in the pathology of AD, but it may also be involved in the dysregulation of metabolism in obesity and type 2 diabetes, where circulating $A\beta_{42}$ levels are elevated.

Metabolic profiling of cultured human adipocytes from metabolically malign versus benign obese individuals
A.A. Böhm[1,2], A. Halama[2], J. Adamski[2], H.-U. Häring[1,2], M. Hrabe de Angelis[2], H. Staiger[1,2];
[1]Internal Medicine, Eberhard Karls University Tübingen, [2]Helmholtz Centre Munich, Germany.

Background and aims: Among obese subjects, benign (metabolically healthy) and malign obesity exists; the latter revealing whole-body insulin resistance, hepatic steatosis, and subclinical inflammation. The underlying pathomechanisms aren't well understood yet, the prevention strategies insufficient. Thus, aim of this study was to characterize the metabolic profile of subcutaneous human adipocytes from insulin-resistant (IR) versus comparatively insulin-sensitive (IS) morbidly obese subjects.
Materials and methods: 10 IR versus 10 IS non-diabetic Caucasians (BMI>40kg/m2) were matched for gender, age, BMI, and percentage of body fat; primary preadipocytes were isolated and in vitro differentiated to adipocytes. Metabolites were detected by a targeted metabolomic approach in cell lysates and supernatants. Multi- and univariate methods were used for statistical analysis, correction for multiple testing was done.
Results: Among others, aspartate was found to be lower in IR adipocyte lysates (3-fold, p=0.0005), maybe pointing to a relative depletion of citric acid cycle metabolites. Regarding the supernatants, four phosphatidylcholines emerged (PC aa C32:3, PC aa C40:4, PC aa C40:5, PC ae C34:3, p<0.0004; all lower in IR subjects) as well as an altered arachidonic acid (AA) metabolism: 15(S)-HETE (15-hydroxy-eicosatetraenoic acid; 0 vs. 120pM; p=0.0089), AA (1.5-fold; p=0.0046) and docosahexaenoic acid (DHA, C22:6; 2-fold; p=0.0041) were higher in IR group, emphasizing a direct contribution of adipocytes to the inflammatory state of insulin resistance. As DHA serves as an inhibitor of prostaglandin synthesis, higher DHA levels might be a hint for counterregulatory mechanisms in IR subjects.
Conclusion: With our study we were able to identify adipocyte-specific metabolic alterations that are associated with malign (insulin-resistant) obesity.

Protective effect of physical activity on atherogenic lipoproteins in type 1 diabetes
L. Brugnara[1,2], R. Mallol[1,3], M. Guardiola[1,4], M. Vinaixa[1,3], M.A. Rodríguez[1,3], J.C. Vallvé[1,4], M. Gonzalez[1,4], S. Murillo[1,2], M. Balfegó[1,2], X. Correig[1,3], J. Ribalta[1,4], A. Novials[1,2];
[1]CIBERDEM – Spanish Biomedical Research Centre in Diabetes and Associated Metabolic Disorders, Barcelona, [2]IDIBAPS/Hospital Clínic de Barcelona, [3]Center for Omic Sciences (COS) - Institut d'Investigació Sanitària Pere Virgili (IISPV) - Universitat Rovira i Virgili (URV), Reus, [4]Unitat de Recerca en Lípids i Arteriosclerosi, Facultat de Medicina, Hospital Universitari de Sant Joan de Reus, URV, IISPV, Reus, Spain.

Background and aims: Cardiovascular disease is the main cause of mortality in type 1 diabetes (T1D), with physical activity (PA) creating controversial effects in this population. The aim of this study was to analyze the lipoprotein subclass profiles in the physically active T1D population.
Materials and methods: 94 T1D patients and 125 control (CT) subjects were recruited. PA was assessed by IPAQ questionnaire, and subjects were classified as active (A) or non-active (NA) following IPAQ criteria. Serum samples were analyzed using LipoProfile (LipoScience Inc.). A subgroup of 32 T1D and 66 CT was also analysed by a new test based on diffusion-ordered nuclear magnetic resonance spectroscopy (DOSY).
Results: Both groups were similar in terms of age, gender, hypertension and smoking and physical activity habits. T1D patients presented HbA1c 7.4 ± 1.3%. Any macro or microvascular complications were present, except for 4 subjects that presented incipient retinopathy. There were no differences in the usual diets of T1D and CT groups concerning cholesterol, saturated and unsaturated fat intake, but there was a higher intake of total carbohydrates, simple carbohydrates and alcoholic beverages in the CT group. No participants were using lipid lowering drugs. DOSY test revealed that LDL-Ps were similar in A and NA CT subjects (751.0 nmol/L ± 206.7 vs. 781.1 ± 150.3), but different between A and NA T1D ones (649.8 nmol/L ± 165.4 vs. 917.8 ± 222.6, p=0,015). Total LDL-cholesterol (LDL-c) was similar in A and NA CT subjects (73.8 mg/dL ± 16.5 vs. 74.3 ± 9.1), but again different between A and NA T1D ones (66 mg/dL ± 13.2 vs. 89.6 ± 15.0, p=0.010), with this difference mainly due to Medium LDL-c (29.6 mg/dL ± 5.8 vs. 40.2 ± 6.1, p=0.006, in A and NA T1D subjects, respectively). VLDL-triglyceride (VLDL-TG) was lower in A CT subjects than in NA ones (33.8 mg/dL ± 19.5 vs. 50.3 ± 29.4, p=0,049) and was similar in A and NA T1D subjects (28.1 mg/dL ± 13.1 vs. 28.1 ± 13.7). This difference in CT groups was confined to the Large VLDL-TG (27.1 mg/dL ± 16.6 vs. 41.6 ± 25.3, p=0,031, in A and NA, respectively). Additional trends identified by LipoProfile showed that the T1D group presented lower Medium VLDL particles (medium VLDL-P) than the CT group (10.84 nmol/L ± 8.59 vs. 17.01 ± 14.92, p=0.014). Total LDL particles (LDL-P) were similar in A and NA CT subjects (1083.1 ± 290 vs. 1104.9 ± 337.3), but there was a significant difference between A and NA T1D subjects (948.7 ± 233.5 vs. 1264.3 ± 209, p=0.027), confirming observations made with DOSY. For clinical data, the Wilcoxon rank sum test was used, and for lipoprotein profiles, lineal models, adjusted for BMI, hypertension, active smoking, tryglicerides and HDL cholesterol.
Conclusion: T1D subjects that regularly practice physical activity present a lower proaterogenic lipid profile than their non-active T1D counterparts, suggesting that physical activity should be encouraged in T1D.

Anti-oxidant and anti-inflammatory properties of HDL are inhibited by apolipoprotein A-I antibodies isolated from type 2 diabetes patients
J.R. Batuca[1], F. Paula[1,2], C. Favas[2], M.C. Amaral[1,2], J. Delgado Alves[1,2];
[1]Farmacologia, CEDOC, Faculdade de Ciências Médicas, Universidade Nova de Lisboa, [2]Serviço de Medicina IV, Hospital Fernando da Fonseca, Amadora, Portugal.

Background and aims: Several evidences points the a role for islet inflammation in pathogenesis of type 2 diabetes. HDL suppression of the lipid induced macrophage inflammation enhances insulin sensitivity. Moreover infusions of recombinant HDL in patients with type 2 diabetes increase the anti-inflammatory properties of the resulting plasma HDL fraction. Recently, our group identified the presence of antibodies towards HDL and its main

apolipoprotein (ApoA-I) in patients with type 2 diabetes. Herein we intend to investigate the effect of anti-ApoA-I (aApoA-I) antibodies isolated from patients with type 2 diabetes in the anti-inflammatory and anti-oxidant activities of HDL *in vitro*.
Materials and methods: aApoA-I antibodies were isolated from patients serum by immunoaffinity chromatography using an HiTrap NHS- activated HP (1 mL) column. A possible inhibitory effect of aApo A-I antibodies on paraoxonase 1 (PON1) activity was addressed by performing dose dependent inhibition assays by incubating HDL (100 μg/mL) plus aApo A-I antibody (0.001-10μg/mL) isolated from patients. PON1 activity was assessed by quantification of nitrophenol formation by spectrophotometry. To investigate the effect aApo A-I antibodies on the expression of vascular adhesion molecules (VCAM-1), HUVECs were incubated with human HDL (1.6 mg/mL) without or with aApoA-I antibodies (50 μg/mL) isolated from patients serum and/or TNF-α (10 ng/mL). Expression of VCAM-1 was assessed by flow cytometry using a fluorescein-conjugated mouse monoclonal anti-human VCAM-1.
Results: PON1 activity was inhibited in a dose-dependent fashion from 5% to 37% by the aApoA-I antibodies isolated from patients, after correction for a non-specific human IgG used as control. Pre-incubation of HDL with aApo A-I antibodies abrogated the inhibitory effect of HDL on VCAM-1 expression, in more than 65%, when compared with the non-specif human IgG.
Conclusion: This study shows that aApo A-I antibodies isolated from patients with type 2 diabetes inhibit HDL-associated anti-oxidant and anti-inflammatory properties in vitro, and may contribute to the pathogenesis of type 2 diabetes.

VLDL-Apo B 100 fractional synthesis rate (FSR) is decreased in type 2 diabetes mellitus patients with diabetic nephropathy and hypertriglyceridaemia: possible defect in VLDL-Apo B 100 removal
P. Tessari[1], M. Vettore[1], R. Barazzoni[2], G.M. Toffolo[3], I. Cortella[1], E. Manesso[3], C. Gabelli[1], M. Zanetti[2];
[1]Medicine (DIMED), University of Padova, [2]Medical, Surgical and Health Sciences, University of Trieste, [3]Information Engineering, University of Padova, Italy.

Background and aims: Patients with diabetic nephropathy (DN) and albuminuria often exhibit increased triglyceride concentrations, suggesting an altered lipoprotein metabolism. We have previously shown that in T2DM patients with albuminuria, the hepatic fractional synthesis rate (FSR) of both albumin and fibrinogen, two liver-synthesized secreted proteins, are increased, that of albumin possibly representing a compensatory mechanism for the increased urinary albumin loss. Since VLDL-Apo B 100 is synthesized by the liver too, we argued whether also the FSR of this protein is increased in T2DM subjects with DN and albuminuria, thus accounting for their hypertriglyceridaemia.
Materials and methods: We employed isotope dilution, precursor-product methods, using leucine stable isotope infusion to measure VLDL-Apo B 100 FSR (in addition to that of albumin and fibrinogen FSR, data previously published), in T2DM male subjects with DN (n=9, age: 53±2 yrs; BMI: 31±2 kg/m^2) and without DN (n=4; age: 44±6; BMI: 28±1 kg/m^2), as well as in healthy male controls (n=6, age: 42±7 yrs; BMI: 28±2 kg/m^2). Of the T2DM patients with DN, four had microalbuminuria and five macroalbuminuria. A primed continuous infusion of ^{13}C-leucine was administered to reach a tracer steady state of the precursor pool plasma α-ketoisocaproate (KIC). Plasma protein synthesis were assessed by modelling analysis of tracer-to-trace ratio dynamics in the protein product pool, monitored in the 6 hr period following tracer infusion. Data are expressed as Mean±SE.
Results: In T2DM patients with DN, both plasma triglyceride (TG) (2.2±0.3 mmol/L) and VLDL-Apo B 100 concentrations (16.4±3.3 mmol/L) were ≈1-fold greater than in nondiabetic controls (TG: 1.2±0.2 mmol/L, p<0.01; VLDL-Apo B 100: 8.1±0.6 mmol/L, p<0.05). In contrast, VLDL-Apo B 100 FSR in the T2DM patients with DN was ≈60% lower (5.2±0.7 pools/day) than that in controls (12.5±3.7 pools/day, p<0.04). In the T2DM patients without DN, plasma triglyceride (1.2±0.1 mmol/L) and VLDL-Apo B 100 concentrations (8.6±0.7 mg/dl), as well as VLDL-Apo B 100 FSR (10.7±2.3 pools/day) were similar to those of controls.
Conclusions: The hypertriglyceridaemia accompanying T2DM patients with DN is not due to hepatic VLDL-Apo B 100 overproduction, which is instead decreased, but it is should rather be due to decreased removal rates. Protein synthesis of liver-synthesized, secreted proteins appears to be selectively regulated.

LDL receptor knock-out mice impaired spatial cognition with hippocampal vulnerability to apoptosis and synapse
Y. Huang, W.-Q. Xia, Y. Zhou, P. Wang, Y. Yang, R.-R. Cai, S.-H. Wang;
Endocrinology, ZhongDa Hospital of Southeast University, Nanjing, China.

Background and aims: Evidences from clinical studies support that abnormal cholesterol metabolism in the brain lead to the progress of cognitive dysfunction. LDL receptor (LDLR) is well known for its role in regulating brain cholesterol homeostasis. We investigated whether LDLR played roles in spatial cognition and the potential mechanisms.
Materials and methods: Twelve-month-old Ldlr$^{-/-}$ mice (n =10) and wild-type littermates C57BL/6J (n =14) maintained on a standard lab chow diet were subjected to the morris water maze test. All animals were killed for synapse and apoptosis study uses one week after the completion of the behavioral test.
Results: The plasma cholesterol concentrations of Ldlr$^{-/-}$ mice increased limitedly than C57BL/6J ($t(4) = 4.076$, $P = 0.015$). The results of behavioral test revealed that Ldlr$^{-/-}$ mice displayed impaired spatial memory with decreased expression levels of synaptophysin and number of synaptophysin-immunoreactive presynaptic bouton in the hippocampal CA_1 and dentate gyrus areas (all $P<0.05$). Ultrastructural changes in DG area of the hippocampus were observed by transmission electron microscopy. Furthermore, the apoptosis occurred in the hippocampus of Ldlr$^{-/-}$ mice was discovered with the elevated Bax/Bcl-2 ratio for gene and protein expression (t=4.369, P=0.012; t= 6.163, P=0.004, respectively), and activated-caspase3.
Conclusion: LDLR deficiency induced deteriorations of brain cholesterol homeostasis contributing to impaired spatial cognition, probably via its negative effects on hippocampal vulnerability to apoptosis and synapse deficits.

834

Early improvement of postprandial lipaemia after bariatric surgery in obese type 2 diabetic patients
E. Griffo[1], R. Lupoli[1], G. Nosso[1], G. Saldalamacchia[1], M. Cotugno[1], G. Vitagliano[1], L. Angrisani[2], P.P. Cutolo[2], A.A. Rivellese[1], B. Capaldo[1];
[1]Department of Clinical Medicine and Surgery, Federico II University of Naples, [2]General and Endoscopic Surgery Unit, S. Giovanni Bosco Hospital, Naples, Italy.

Background and aims: Bariatric surgery (BS) for the treatment of morbid obesity is able to positively influence glucose homeostasis in obese type 2 diabetic patients (T2DM). This improvement occurs early after surgery and is related, at least in part, to restoration of entero-insular axis. Fasting lipid profile also improves after BS, but no data is available on the impact of BS on postprandial lipid metabolism. To evaluate the short-term effects (2 weeks) of BS on fasting and postprandial lipid metabolism in patients with T2DM and obesity and the relationship between changes in lipid levels and incretin hormones (GLP-1 and GIP).
Materials and methods: We studied 25 patients with T2DM and obesity (age = 46 ± 8 years, BMI = 44 ± 7 kg / m²), of which fifteen patients underwent sleeve gastrectomy and ten underwent roux-en-y gastric bypass. Since the changes in body weight and in the main metabolic parameters were similar with the two interventions, data were pooled all together. Lipid and incretin hormone levels were evaluated fasting and for 3 hours after ingestion of a standard liquid mixed meal both at baseline and 2 weeks after BS.
Results: After surgery, there was a significant reduction in body weight (p<0.001), fasting plasma glucose (p<0.001), fasting plasma insulin (p<0.05), HOMA-IR (p<0.005) and fasting plasma lipids (-26% in plasma triglycerides, p<0.005; -13% in total cholesterol, p<0.005; -16% in LDL cholesterol, p<0.05; -19% in HDL cholesterol, p<0.001). During the meal, the response of plasma triglycerides, total cholesterol and HDL cholesterol was significantly lower compared to baseline (p<0.05 - p<0.001). In particular, the incremental area under the curve (IAUC) of plasma triglycerides decreased by 70% (p <0.001). The meal-response of GLP-1, rather flat preoperatively, increased significantly after 2 weeks (IAUC 36 ± 30 vs. 1794 ± 374 pmol / l • 180 min, p <0.001), while the response of GIP did not change significantly. No relation was found between changes in incretin hormones and postprandial triglyceride concentration. The reduction of fasting triglycerides correlated positively with the reduction of insulin resistance (p <0.05).
Conclusion: BS leads to an early improvement of postprandial lipemia, in particular triglyceridemia, which decreases by 70%. This effect does not seem not to be influenced by the decrease in body weight and/or changes in incretin hormones, but is likely to be ascribed to reduced intestinal lipid absorption.

835

Short-term changes of HDL-C related parameters during transition from insulin to GLP-1 in type 2 diabetics

K. Yagi[1], A. Nohara[1], J. Kobayashi[2], O. Miyazaki[3], J. Liu[1], Y. Mori[1], A. Obatake[1], S. Okazaki[1], Y. Takeda[1], M. Yamagishi[1];
[1]Department of Internal Medicine, Kanazawa University Graduate school of medical science, [2]Department of General Medicine, Kanazawa Medical University, [3]Tsukuba Research Institute, Sekisui Medical Co. Ltd., Japan.

Background and aims: We previously observed that HDL-C decreased during the therapeutic transition from insulin to GLP-1 analogue (GLP1a). We made a closer examination of HDL metabolism in patients with GLP1a monotherapy (Gm) and with GLP-1 analog (GLP1a) and basal insulin (INS) combination therapy (GbIc).
Materials and methods: Fifty-three Japanese type 2 diabetics treated with INS monotherapy were enrolled in this study. Liraglutide (LIR) was introduced during the three-week admission period. GbIc was introduced to those with elevated fasting glucose over 126 mg/dl. Fasting blood samples were obtained before and 15 days after LIR introduction for the following measurements; TC, TG, HDL, Apolipoproteins (AI, AII, B, B48, CII, CIII, E), lathosterol, sitosterol, pre beta1-HDL, CETP activity, LCAT activity, soluble phospholipase A2 (sPLA2), lipoprotein lipase mass (LPL), bile acid (BA), free fatty acid (FFA), glucagon, adiponectin, resistin and C-peptide (CPR).
Results: Clinical features of all subjects were as follows; M/F 37/16, age 65±13 years old, HbA1c 7.5±1.4 %, TC 166±33 mg/dl, TG 124±79 mg/dl, HDL 50±15 mg/dl. To achieve similar pre-meal plasma glucose levels, 40 patients recieved Gm and 13 patients received combination therapy with GIc. The following parameters decreased in both Gm and GbIc; TC (166→145 mg/dl), LDL-C (92→76 mg/dl), HDL-C (50→43 mg/dl), ApoAI, ApoAII, ApoB, ApoE, preβ1HDL, sitosterol, FFA, BMI, BA, sPLA2. The following additional parameters showed no change in both Gm and GbIc; TG, lathosterol, LPL, glucagon. Gm specific changes were shown as follows; an increase in ApoB48, sPLA2, BA, resistin, and CPR, and a decrease in adiponectin. GbIc specific changes were as follows; a decrease in ApoCII, LCAT, and CETP.
Conclusion: From the results, three possible mechanisms for HDL-C reduction should be considered. The first is reduced insulin signaling for lipoprotein metabolism. Generally, insulin resistance-like profiles were observed in Gm, and some of these profiles looked corrected in GIc. We speculated that previous treatment with insulin suppressed TG generation and activated LPL. The second is weight reduction. GLP1a induces weight reduction for short periods which would have contributed to the observed changes. The third is increased BA, which suggested the activation of farnesoid X receptor (FXR) resulting in increased ApoAI efflux into the gastrointestinal tract. Even with similar glycemic control, the elimination of extra portal insulin administration affects lipoprotein metabolism relating to HDL.
Clinical Trial Registration Number: UMIN000005565

Comparison of the HDL-C-raising effects of statins in high-risk hypercholesterolaemia with diabetes: TOHO-LIP diabetes sub-analysis for 96 weeks

T. Shiba[1], S. Okahata[1], K. Sakamoto[1], T. Mitsumatsu[1], T. Ikeda[2], J. Yamazaki[2], T. Hirose[2], Y. Iwasaki[2], S. Yamamura[3], K. Sugi[2], T. Fujioka[2], H. Noike[4], I. Tatsuno[4], K. Shirai[4];
[1]Division of Diabetes and Metabolism, Toho University Ohashi Medical Center, Tokyo, [2]Toho University, Tokyo, [3]Josai International University, Chiba, [4]Toho University, Chiba, Japan.

Background and aims: HDL-Cholesterol (HDL-C) has attracted notice for its anti-atherosclerotic properties. A lower HDL-C level is definitively linked to a higher risk of cardiovascular disease. Few clinical studies, however, have examined how potent statins administered over a long term affect HDL-C in diabetic subjects with hyperlipidemia.
Materials and methods: The TOHO-LIP (TOHO-Lipid Intervention trial using Pitavastatin) is a prospective study to compare how two agents, pitavastatin 2mg/day and atorvastatin 10mg/day, affect cardiovascular prognosis, lipid profiles, laboratory parameters, and safety in patients with high-risk hypercholesterolemia over a treatment period of 5 years. The trial is conducted with 652 enrolled subjects at three TOHO University hospitals in Japan. In this report we present laboratory data at 96 weeks of treatment in 414 diabetic patients as a sub-study for TOHO-Lip.
Results: TC, LDL-C, and non HDL-C were significantly improved at 96 weeks with both statin treatments. These statins slightly increased HDL-C, but not to a statistically significant level. We conducted a quartile analysis with respect to baseline HDL-C, since baseline HDL-C values affected the percent change of the HDL-C at 96 weeks (as showen in the table). In quartile 1, the lowest HDL-C group (baseline HDL-C≦45mg/dl), the subjects receiving pitavastatin exhibited a significant increase of HDL-C (13.1%) at 96 weeks, whereas those receiving atorvastatin exhibited an increase of only 3.3%. This analysis in quartile 1 also brought about statistically significant difference between the two treatment depending on the prescribed statins (p = 0.0090). In another analysis in which hypo-HDL-C was defined as baseline HDL-C below 40 mg/dl, the differential effect of pitavastatin was confirmed by a significant percent increase in HDL-C (14.5%) at 96 weeks (versus a 6.2% increase in the subjects receiving atorvastatin). This effect of pitavastatin did not differ between genders. Glucose metabolism parameters (FPG or HbA1c) remained unchanged in both groups. In univariate analysis, the change in HDL-C was significantly correlated with the changes in HbA1c and the baseline HDL-C below 40 mg/dl. In a stepwise multi-variate analysis, the changes in HbA1c and baseline HDL-C below 40 mg/dl had significant independent effects in the total group, whereas the treatment drug did not.
Conclusion: Both strong statins showed comparable effects on lipid profiles in diabetic subjects. In patients with hypo-HDL cholesterolemia, HDL-C was improved only in the pitavastatin group. The evidence suggests that pitavastatin was effective in preventing cardiovascular events.

Time-course of changes in the HDL-C of quartile1

	week	0	12	24	48	72	96	p
HDL-C	pitava	39	43	45	44	45	45	0.012
	atrova	39	42	42	42	42	40

JAZF1 improves hepatic insulin resistance in C57bl/6j mice and attenuates atherosclerosis in apoE-knockout mice

W. Ran[1,2], L. Li[1,2], G. Yang[1];
[1]College of Laboratory Medicine, Chongqing Medical University, Chongqing, [2]the Key Laboratory of Laboratory Medical Diagnostics in Ministry of Education, Chongqing Medical University, China.

Background and aims: Genomewide association studies have suggested an association of Juxtaposed with another zinc finger gene 1(JAZF1) with type 2 diabetes mellitus (T2DM). As an inhibitor of the TAK1/TR4 signaling pathway, JAZF1 has been shown to be involved in gluconeogenesis, lipid metabolism and insulin sensitivity. In previous studies, we reported that the overexpression of JAZF1 in 3T3-L1 adipose cells and hepatic carcinoma Hepa1-6 cells suppressed lipid synthesis and accumulation and increased lipolysis. It remains unclear, however, whether chronic, ubiquitous JAZF1 activation in vivo ultimately benefits or impairs metabolic control, insulin sensitivity and atherosclerotic vascular disease. To address this question, we sought to determine whether an increase in JAZF1 expression in vivo was sufficient to affect both metabolic control and atherosclerotic plaque development.
Materials and methods: Adenovirus-mediated JAZF1 overexpression was used to characterize the role of JAZF1 in the regulation of lipid metabolism and the development of atherosclerosis in normal chow- or high fat diet(HFD)-fed ApoE-/- mice. Insulin sensitivity was examined by euglycaemic-hyperinsulinaemic clamping. Glucose rates of appearance (GRa) were determined with 3-[3H] glucose. Whole body GRa and glucose uptake (GRd) were calculated using the non-steady-state equation. Liver tissue was procured for histological examination, real-time RT-PCR and western blot analysis. Cholesterol de novo synthesis was measured by intraperitoneal [1-14C] acetate injection and atherosclerotic plaques were quantified by histological analysis.
Results: JAZF1 overexpression improved HFD-induced hepatic insulin resistance in C57BL/6J mice. In HFD-fed ApoE-/- mice, JAZF1 overexpression decreased serum cholesterol levels and hepatic cholesterol synthesis by inhibiting expression of 3-hydroxy-3methylglutaryl coenzyme A reductase (HMGCR). Furthermore, the en face and cross-sectional plaque areas of aorta and aortic sinus were reduced, and CD68+ macrophages in the central region of the plaques were significantly decreased.
Conclusion: We report the first evidence that JAZF1 overexpression was protective against development of atherosclerosis and insulin resistance in-

duced by a HFD in apoE-/- mice and C57BL/6J mice. Our findings illustrate a heretofore unrecognized link between JAZF1 and atherosclerosis and insulin resistance in the HFD-fed a mouse model. Whether or not JAZF1 has also antiatherogenic and anti-insulin activity in human subjects remains to be explored.

Cholesterol as a novel activator of HIF-1 pathway in hepatocytes under hypoxia
S. Anavi, S. Sofer, Z. Madar, O. Tirosh;
Faculty of Agriculture, The Hebrew University Of Jerusalem, Rehovot, Israel.

Background and aims: Non alcoholic steatohepatitis (NASH) is associated with obesity, insulin-resistance and diabetes and promotes progression to liver damage. Recently, free cholesterol has been linked to the pathogenesis of NASH. A growing body of evidence demonstrates a role for hypoxia inducible factor-1 (HIF-1) in the development of liver fibrosis, inflammation, hepatic cellular carcinoma as well as other liver diseases. The aim of the present study was to investigate possible activation of HIF1 by cholesterol in hepatocytes.
Materials and methods: AML12-hepatocytes were incubated with water-soluble cholesterol under normoxic conditions. HIF-1 and iNOS induction and mitochondrial dysfunction were evaluated by the use of reporter gene plasmids, RT-PCR, western blot, flow cytometry and biochemical analysis.
Results: Increased HIF-1α protein accumulation was evident in hepatocytes after 2h of incubation with cholesterol while enhanced HIF-1 transcriptional activity was observed after 6h of incubation ($p<0.05$). Investigations into the molecular mechanism showed that cholesterol inhibited HIF-1α subunit hydroxylation and thus proteasomal degradation ($p<0.001$) whereas HIF-1α gene expression was not significantly altered by cholesterol. Hepatocytes incubated with cholesterol exhibited augmented Nitric oxide (NO) levels at 2h and 6h, which corresponded with increased iNOS induction ($p<0.05$). Treating the cells with L-NAME, a potent inhibitor of iNOS, had no effect on HIF-1α stabilization at 2h but effectively attenuated cholesterol-induced HIF-1 accumulation and transcriptional activity at 6h ($p<0.05$). The role of reactive oxygen species (ROS) in initial HIF-1α stabilization was further determined. Mitochondrial dysfunction and enhanced mitochondrial ROS generation were observed in 2h cholesterol-treated cells ($p<0.05$). In order to establish a role for mitochondria-derived ROS in HIF-1α protein stabilization, mitochondrial DNA-depleted cells (p0AML12) were utilized. In these cells, the ability of cholesterol to induce HIF-1 stabilization and transactivation was significantly abolished.
Conclusion: Together, these results demonstrate that cholesterol promotes HIF-1 activation in hepatocytes in a ROS-dependant manner. Therefore, it is speculated that alterations of HIF-1 may contribute to the deleterious effects of cholesterol in the liver.

Deficiency of clusterin aggravates insulin resistance in high fat fed mice
S.-Y. Park[1], M. Kwon[1], T. Ju[1], Y.-W. Kim[1], J.-Y. Kim[1], K.-C. Won[1], J. Dan[2], H.-J. Kim[3];
[1]College of Medicine, Yeungnam Uni, Daegu, [2]Gumi Cha Hospital, Gumi, [3]College of Medicine, Eulji University, Seoul, Republic of Korea.

Background and aims: Clusterin is a multifunctional glycoprotein and is known to be involved in lipid transportation. Clusterin levels in high-densitiy lipoprotein are lower in man with reduced insulin sensitivity and clusterin single nucleotide polymorphism in Japanese diabetic patients is associated with the prevalence of type 2 diabetes. Although the physiological role of clustserin and previous epidemiological studies implicates the close relationship between clusterin and insulin resistance or diabetes, there is no direct evidence suggesting the involvement of clusterin in insulin sensitivity. The aim of present study was to investigate whether clusterin is involved in insulin resistance.
Materials and methods: Male 8-week-old C57B/6 wild-type (WT) and clusterin knockout (KO) mice were randomly assigned into chow fed and high fat fed mice for 8 weeks and insulin sensitivity was measured with intraperitoneal glucose tolerance test (IPGTT) and hyperinsulinemic euglycemic clamp test.
Results: After high fat feeding, body weight, fat mass, and plasma levels of triglyceride and free fatty acids were not different between the two groups. Fasting glucose and insulin levels were higher in clusterin KO mice. In IPGTT, glucose levels were not different except for basal glucose levels (0 min) between these two groups in high fat fed group. However, insulin levels tended to be higher in clusterin KO mice at all time points. Area under curve for insulin was higher in clusterin KO mice. In hyperinsulinemic euglycemic clamp study, clamp insulin levels were higher in clusterin KO mice than WT mice after high fat feeding. High fat feeding reduced glucose infusion rate (GIR) and whole body glucose uptake (WB) both in WT and clusterin KO mice and there was no difference between these two groups. However, after adjusted for increased plasma insulin level during clamp, GIR (GIR/insulin) and WB (WB/insulin) were lower in clusterin KO mice. Skeletal muscle glucose uptake was reduced both in WT and clusterin KO mice after high fat feeding and there was no difference between these two groups. After adjusting increased clamp insulin levels, it was lower in clusterin KO mice. C-peptide levels were higher in clusterin KO mice than WT mice after fasting or feeding in high fat fed mice. Clamp c-peptide levels were also higher in clusterin KO mice. Gene expression of insulinase was higher in liver and lower in kidney. Clusterin mRNA level was higher in the skeletal muscle of high fat fed WT mice. Gene expression of antioxidant enzyme was lower and gene expression of cytokines levels was higher in clusterin KO mice than WT mice in high fat fed group.
Conclusion: These results suggest that deficiency of clusterin induces insulin resistance in high fat fed mice through increased oxidative stress and inflammation.

In vivo proteomics reveals increased galectin-1 levels in subcutaneous interstitial fluid in newly diagnosed type 2 diabetes patients

E. Fryk, T. Larsson, L. Strindberg, J. Perman, J. Borén, P.A. Jansson;
Department of Molecular and Clinical Medicine, Institution of Medicine, Gothenburg, Sweden.

Background and aims: Obesity spreads over the world like an epidemic and a third of all obese individuals will develop type 2 diabetes (T2DM). Adipose tissue becomes insulin resistant when adipocytes increase in size and inflammatory cells invade the tissue. This transformation is followed by a changed expression and release of proteins manifesting adipose tissue as a significant endocrine organ. Galectin-1 was recently suggested to be a novel circulating biomarker in T2DM. The source of galectin-1 is less clear, but it is known that preadipocytes secrete galectin-1 during differentiation. Moreover, galectin-1 is regulated by hypoxia-inducible factor-1 and shows an association with neovascularization. Interestingly, subcutaneous adipose tissue is considered poorly circulated and hypoxic in T2DM patients. Our overall aim was, using avante-guard methodology, to unconditionally identify novel adipose tissue secretory factors relevant in the development of T2DM.
Materials and methods: Subcutaneous microdialysis enables sampling from the interstitial fluid and can be perfomed in vivo in human subjects with minimal invasiveness. Combining protein sampling using an ultrafiltrating membrane (Asahi, Plasmaflo OP-02, cut off 3 MDa) with LC-MS/MS is an innovational approach to characterize the adipose tissue secretome. We employed these procedures and investigated 7 male newly diagnosed T2DM patients in good metabolic control and 8 gender- and age-matched (55±3 vs 54±3 years, mean±SEM) healthy controls after fasting over night. Average duration of T2DM was 1.6±0.8 years, while BMI was higher in T2DM patients than in controls (25.9±0.7 vs 23.4±0.6 kg/m2, p<0.05).
Results: In total, 856 proteins were identified in the subcutaneous interstitial fluid. Of the proteins found in all samples > 80% were known secreted proteins. Based on the relative detection rate of peptides in the LC-MS/MS, we demonstrated that 36 proteins had a significantly different expression (students t-test, p<0.05) in T2DM patients compared with healthy controls. One of these proteins was galectin-1, the previously proposed biomarker in T2DM patients. We showed that galectin-1 is increased in subcutaneous interstitial fluid in T2DM (p< 0.05) and we also confirmed previous observations that serum galectin-1 was increased in T2DM patients compared with controls (p<0.05).
Conclusion: Our in vivo proteomics method for characterization of the subcutaneous interstitial fluid has identified 36 proteins as potential biomarkers in newly diagnosed T2DM patients. Furthermore, we show that insulin-resistant adipose tissue may be a source of galectin-1.

841

Circulating chemerin level is associated with arterial stiffness in patients with type 2 diabetes

H. Park, H. Kim, D. Byun, K. Suh, M. Yoo;
Soonchunhyang Univ. Hospital, Seoul, Republic of Korea.

Background and aims: The prevalence of diabetes is rapidly increasing worldwide, and cardiovascular disease (CVD) is the main cause of mortality in patients with type 2 diabetes (T2DM). A number of studies have demonstrated that several adipokines are implicated in the development of atherosclerosis. Recently, chemerin and omentin-1 have been shown as potential adipokines linking inflammation, obesity, and CVD. However, there have been scant clinical data relating these adipokines to atherosclerosis in T2DM patients. Therefore, we investigated the relationship of circulating chemerin and omentin-1 levels with atherosclerosis in patients with T2DM.
Materials and methods: A total of 113 T2DM subjects (61 M/52 F, age 58 ± 1 yr) were enrolled. Subjects with known CVD, cancer, chronic kidney disease, or active infection were excluded. We assessed subclinical atherosclerosis by measuring doppler-derived aortic pulse-wave velocity (PWV) and carotid intima-media thickness (IMT). Circulating chemerin, omentin-1, leptin, adiponectin, resistin, and high-sensitivity C-reactive protein (hsCRP) levels were also measured.
Results: Chemerin was significantly related to leptin (r=0.26, $P < 0.01$), estimated glomerular filtration rate (eGFR; r= -0.29, $P < 0.01$), and albumin-to-creatinine ratio (ACR; r=0.20, $P < 0.05$). Also, chemerin was associated with aortic PWV (r=0.31, $P < 0.01$), but not carotid IMT. Aortic PWV was significantly correlated with age, body mass index (BMI), eGFR, ACR, resistin, and chemerin. Multiple regression analysis showed that circulating chemerin level was independently associated with aortic PWV. Omentin-1 was significantly related to age (r=0.26, $P < 0.01$), BMI (r= -0.27, $P < 0.01$), hsCRP (r= -0.19, $P < 0.05$), adiponectin (r=0.31, $P < 0.01$), triglyceride (r= -0.30, $P < 0.01$), high-density lipoprotein cholesterol (r=0.26, $P < 0.01$). However, there was no association of omentin-1 with aortic PWV, or carotid IMT.
Conclusion: Circulating chemerin level was independently associated with arterial stiffness in T2DM patients without known CVD. These results suggest that chemerin is related to subclinical atherosclerosis in T2DM.

842

Serum omentin significantly predicts cardiovascular events both in patients with the metabolic syndrome and in subjects who do not have the metabolic syndrome

A. Muendlein[1], C.H. Saely[2,3], A. Leiherer[1], A. Vonbank[2,3], D. Zanolin[1], K. Geiger[1], P. Rein[2], H. Drexel[2,4];
[1]Vorarlberg Institute for Vascular Investigation and Treatment, Feldkirch, Austria, [2]Academic Teaching Hospital Feldkirch, Feldkirch, Austria, [3]Private University of the Principality of Liechtenstein, Triesen, Liechtenstein, [4]Drexel University College of Medicine, Philadelphia, USA.

Background and aims: Some recent small cross-sectional studies have described associations of the novel adipocytokine omentin with atherosclerosis. However, no prospective data on the power of omentin to predict cardiovascular events are available.
Materials and methods: We therefore measured serum omentin in a series of 297 patients undergoing coronary angiography for the evaluation of established or suspected stable CAD; the metabolic syndrome (MetS) was defined according to national cholesterol education programme adult treatment panel III criteria; cardiovascular events were recorded over a mean follow-up period of 3.2 years.
Results: During the follow-up period, 18.4% of our patients suffered cardiovascular events, corresponding to an annual event rate of 5.8%. In the total study population, serum omentin significantly predicted cardiovascular events both univariately (standardized adjusted HR = 1.47 [1.21-1.78]; p <0.001) and after adjustment for age, gender, BMI, diabetes, hypertension, LDL cholesterol, HDL cholesterol and smoking (HR = 1.49 [1.21-1.82]; p <0.001). From our patients, 98 had the MetS and 199 did not have the MetS. In both of these patient subgroups serum omentin strongly predicted cardiovascular events both univariately (HRs = 1.51 [1.15-2.00]; p = 0.003 and 1.41 [1.08-1.84]; p = 0.011, respectively) and after adjustment for age, gender, BMI, diabetes, hypertension, LDL cholesterol, HDL cholesterol and smoking (1.56 [1.09-2.25]; p = 0.016 and 1.48 [1.12-1.97]; p = 0.006, respectively).
Conclusion: From this first prospective evaluation of the cardiovascular risk associated with serum omentin we conclude that elevated serum omentin is a strong predictor of cardiovascular events both among patients with the MetS and among subjects who do not have the MetS.

843

Ghrelin and its relationship with insulin resistance markers in myocardial infarction complicated with acute heart failure

O. Barbarash, E. Uchasova, O. Gruzdeva, E. Belik, Y. Dyleva, E. Shurygina;
Research Institute for Complex Issues of Cardiovascular Diseases, Kemerovo, Russian Federation.

Background and aims: The main reason for myocardial infarction (MI), which remains one of the most common causes of mortality and morbidity, is atherosclerotic lesions of large or medium-sized coronary arteries with their further thrombotic occlusion. The most severe MI complication having an impact on both in-hospital and post-hospital periods as well as patient's wellfare is acute heart failure (AHF). The mechanisms of AHF are being studied, adipokines and insulin resistance (IR) markers being considered to contribute greatly. In particular, the role of ghrelin, which was first a marker of cardiac cachexia syndrome, is being discussed: its positive impact on cardiovascular system, including left ventricular pump function, was described. Considering the fact that ghrelin is able to inhibit insulin secretion,

it can have a role in IR development, being a part of MI pathogenesis and its complications. The study was aimed at assessing the levels of ghrelin and its relationship with IR markers in MI patients complicated with AHF.
Materials and methods: 133 patients (90 males and 43 females, aged 60,8±1,69 years) with ST elevation MI were enrolled in the study. According to the presence of acute heart failure at day 1 from MI onset all the patients were divided into 2 groups: group 1 included 102 Killip I MI patients and group II enrolled 31 Killip II-IV MI patients. The control group included 33 patients with no cardiovascular disease; their age and gender were similar to those of the treatment group patients. At days 1 and 12 from MI onset serum ghrelin and insulin concentrations were measured by ELISA.
Results: Both groups had lower ghrelin concentrations at days 1 and 12 of the hospital stay as compared to the healthy subjects; group II having a more pronounced decrease. In MI patients with no clinical manifestations of AHF serum insulin levels at day 1 had a tendency towards increasing but were not significantly different from those in the controls and decreased by day 12. In patients with clinical symptoms of AHF these levels were 1.4-fold higher than those in the controls and 1.2-higher than those in Killip I patients; they significantly decreased by day 12. Glucose concentrations in both groups at day 1 were higher than those in the controls, at day 12 glucose levels slightly decreased in Killip I patients but were still higher than the control ones; and, on the contrary, glucose levels increased in Killip II-IV patients. The correlation analysis showed a negative correlation between ghrelin and glucose concentrations in group I patients (R=-0,3 p=0,01) and a negative correlation between ghrelin and insulin concentrations in group II patients (R=-0,72 p=0,0007). A stepwise selection method was used to determine the most significant parameters in AHF development and ghrelin and insulin were selected to be included in the logistic regression models. In order to assess the efficacy of the parameters under study ROC-analysis was applied and it demonstrated that the areas under the curve (AUC) of the studied parameters were good: AUC=0,78 p=0,047 for insulin and AUC=0,79 p=0,002 for ghrelin. Consequently, these parameters can be used for AHF prediction in MI patients.
Conclusion: Thus, ghrelin can be regarded not only as IR marker but also as a predictor of AHF in these patients.

844

Alterations in the levels of the endocrine factors FGF21 and FGF19, and in the expression of their receptors, are associated with impaired glucose homeostasis in obese patients

J.M. Gallego-Escuredo[1], J. Gómez-Ambrosi[2], V. Catalan[2], P. Domingo[3], M. Giralt[1], G. Fruhbeck[2], F. Villarroya[1];
[1]University of Barcelona and CIBER Fisiopatologia de la Obesidad y Nutrición, Barcelona, [2]Clinica Universitaria de Navarra and CIBER Fisiopatologia de la Obesidad y Nutrición, Pamplona, [3]Hospital de la Santa Creu i Sant Pau, Barcelona, Spain.

Background and aims: FGF19 and FGF21are endocrine factors involved in glucose homeostasis. Studies in rodents indicate that FGF21 and FGF19 protect against type II diabetes and obesity. However, the levels of FGF21in obese patients are high. Based on rodent models, it has been proposed that obesity may be a situation of FGF21 resistance which contributes to impaired glucose homeostasis. We investigated the circulating levels of FGF21 and FGF19 in obese patients with varying degrees of abnormal glucose homeostasis and type II diabetes. We also determined gene expression for the components of tissue responsiveness to FGF21 and FGF19, namely FGF receptor-1 and -4 (FGFR1, FGFR4), and the co-receptor beta-Klotho (KLB), in liver and adipose tissue from patients.
Materials and methods: We analysed 61obese patients (BMI, median: 40.5, IQR: 34.7-46.2), sub-classified as normoglycaemic (NG, 36), showing impaired glucose tolerance (IGT,15) or with type II diabetes (T2D,10); and lean healthy controls (35). Biopsies from liver, visceral fat and subcutaneous fat from obese patients were obtained on occasion of bariatric surgery. Tissue samples from healthy controls were also analysed (5, liver; 7, subcutaneous fat; 6, visceral fat). Anthropometric data, and DEXA analysis of adiposity were recorded. Plasma metabolic and hormone parameters were determined using standard procedures. FGF19 and FGF21 levels were measured using ELISA (Biovendor). Gene expression was analysed by quantifying specific transcripts using TaqMan probes and qRT-PCR(Applied Biosystems).
Results: FGF21 serum levels were significantly increased in obese patients compared to controls, while FGF19 levels were decreased. FGF21 levels were positively correlated with markers of insulin resistance (HOMA-R; r=0,37, P=0,0002; insulin, r=0,32, P=0,0012. Obese patients with compromised glycaemia (IGT and T2D) showed a significant increase in serum FGF21 compared to obese normoglycaemic patients (P=0.03 versus IGT, P=0.02 versus T2D). Conversely, FGF19 levels were negatively correlated with insulin levels (r=-0.28, P=0.0034) and HOMA-R (r=-0.27, P=0.0073). In obese patients, the hepatic expression of FGF21 and KLB were increased relative to healthy controls (P = 0.049, P = 0.040, respectively), but no clear trend was found in relation to the glycaemic homeostasis status. FGF21 expression was undetectable in adipose tissues. FGFR1 expression was unaltered in adipose tissues from patients while KLB expression was strongly decreased in visceral fat from obese patients (P = 0.0027). The reduction in KLB was progressively more marked as glycaemic status was worsened, being the lowest in T2D obese patients.
Conclusion: Our results are consistent with the hypothesis of FGF21 resistance in obesity, being much more intense in patients with type II diabetes. Resistance to FGF21 may be mediated by the reduction in KLB expression, an essential component of FGF21 action, in visceral fat. The decrease in FGF19 levels, in combination with reduced KLB expression, may also contribute to metabolic dysregulation in obese patients.

Circulating osteopontin levels are associated with whole body insulin resistance in type 2 diabetes mellitus in humans

G. Daniele[1], T. Fiorentino[2], R. Guardado Mendoza[1], F. Andreozzi[2], D. Winnier[1], C. Jenkinson[1], A. Davalli[3], R. DeFronzo[1], D. Tripathy[1], F. Folli[1];
[1]UT Health Science Center, San Antonio, USA, [2]Università Magna Grecia, Catanzaro, Italy, [3]Istituto Scientifico Ospedale San Raffaele, Milano, Italy.

Background and aims: Obesity and type 2 diabetes (T2DM) are associated with insulin resistance and low-grade inflammation. Osteopontin (OPN) is a multifunctional protein expressed in activated macrophages and T-cells, osteoclasts, hepatocytes, smooth muscle and endothelial cells. OPN plays a role in the release of inflammatory cytokines such as TNF-α and IL-6 which are known to be increased in atherosclerosis, diabetic vascular diseases and hepatic inflammation. Plasma OPN levels are increased in obese as compared to lean subjects. The aim of the study was to compare the circulating concentrations of OPN in normal glucose tolerance (control subjects) and T2DM subjects and its relation with insulin sensitivity and insulin secretion. Low-dose pioglitazone (15 mg/day) effects on OPN levels were evaluated in T2DM patients.
Materials and methods: In a cross-sectional study, 20 T2DM patients treated with metformin and/or sulfonylurea and 18 control subjects were studied. T2DM patients were randomized to receive low-dose pioglitazone or placebo for 6 months. All subjects received: (I) OGTT; (II) euglycemic hyperinsulinemic clamp to directly evaluate whole body insulin sensitivity in vivo; and (III) measurement of plasma OPN levels. In T2DM patients all procedures were repeated after 6 months treatment.
Results: Type 2 diabetics exhibited significantly increased circulating OPN concentrations as compared with control subjects (6.1±1.2 vs. 3.1±0.7 ng/ml, p=0.04). A correlations were found among OPN levels, fasting plasma glucose (r=0.45, P=0.005), 1 hour OGTT plasma glucose (r=0.37, p=0.02), 2 hours OGTT plasma glucose (r=0.36, P=0.02) and fasting insulin (r=0.42, p=0.008). A negative correlations were found between OPN levels and M/I value (r=-0.41, p=0.01) and disposition index (r=-0.32, P=0.04). The area under the ROC curve for OPN levels as a predictor of M/I value less than 4 (insulin resistant state) was 0.79 (95% CI, 0.63-0.94; p=0.004). Adipose tissue insulin resistance index (fasting FFA x fasting insulin) was higher in T2DM subjects as compared to control subjects (4.1±0.9 vs. 3.0±0.5, p=0.03) and it was correlated with OPN levels (r= 0.33, p=0.04). OPN levels were inversely correlated with total cholesterol (r=-0.36, p=0.02) and LDL cholesterol (r=-0.48, p=0.002) while were directly positively correlated with triglycerides levels (r=0.33, p=0.04).OPN levels correlated with MCP-1 (r=0.52, p=0.001), TNF-α (r=0.45, p=0.006), IL-6 (r=0.38, p=0.02) and Fractalkine (r=0.38, p=0.03) levels. After pioglitazone treatment, baseline OPN levels were reduced although not significantly (5.5±1.5 vs. 5.1±1.4 ng/ml, P=0.63). OPN levels were reduced during clamp after pioglitazone treatment although not significantly (5.4±1.5 to 4.0±1.5 ng/ml at 120 min, p=0.2 and 5.6±1.6 to 2.9±1.3 ng/ml at 180 min, p=0.1) as compared to placebo (7.8±2.5 to 7.7±2.2 ng/ml at 120 min, p=0.3 and 7.7±2.5 to 6.9±1.7 ng/ml at 180 min, p=0.2).
Conclusion: Higher OPN levels are associated with reduced whole body insulin sensitivity and reduced disposition index. These findings reveal a potential therapeutic impact of targeting OPN and inflammation, which could lead to improvement in insulin sensitivity while reducing cardiovascular risk in T2DM patients.

DPP4 shedding is mediated by ADAM17 and is upregulated by severe hypoxia

D. Röhrborn, J. Eckel, H. Sell;
Paul-Langerhans Group for Integrative Physiology, German Diabetes Center, Düsseldorf, Germany.

Background and aims: DPP4 has recently been identified as a novel adipokine by comprehensive proteomic profiling of the adipocyte-secretome by our group. Expression of this protease is upregulated in visceral adipose tissue of obese patients and circulating DPP4 correlates with the metabolic syndrome. How DPP4 is shedded from the membrane is currently unknown. Our aim was to understand how DPP4 release is regulated and which enzymes are responsible for the shedding of DPP4 from the cell membrane.
Materials and methods: We used human smooth muscle cells (hSMC) and primary human adipocytes, which showed a high DPP4 release (300 pg/mL and 1000 pg/mL respectively) to elucidate the shedding mechanism *in vitro*. Inhibitors for different classes of proteases were used to identify potential shedding enzymes. To narrow down the prospective members of the involved protease family we used specific inhibitors or silencing of the respective enzyme. To study the regulation of DPP4 release, we applied acute hypoxic conditions of 1% oxygen in a Biospherix hypoxia work chamber. DPP4 release to the culture medium was measured by ELISA. Expression of target genes was assessed by qRT-PCR measurements. Selected experiments were also conducted in primary human adipocytes.
Results: Of the tested protease inhibitors, the general MMP and ADAM inhibitor Batimastat, the serine protease-inhibitor AEBSF and the cysteine protease-inhibitor E64 showed significant reduction of DPP4 release in hSMC (remaining DPP4 release: Batimastat 50%, E64 70%, AEBSF 60%). We could observe no additive effects of AEBSF, E64 and Batimastat in combination, which suggests that the effects are not independent. A specific inhibitor against MMP2 showed a significant decrease of DPP4 release, whereas a specific MMP9 inhibitor and silencing of MMP1 and 14 showed only slight effects on DPP4 shedding in hSMCIn contrast, silencing of ADAM17 (aka TACE) resulted in a decrease of DPP4 release by about 40% in hSMC. In this cell type, we observed a significant increase of DPP4 release by hypoxia of 1% oxygen for 48 hours (1,5-fold), which is associated with increased expression of ADAM17 (1,4-fold) and MMP1 (2,5-fold). Hypoxia had no effect on MMP14 and DPP4 expression itself. To confirm that the involvement of the ADAM or Metalloproteinase family in DPP4 shedding is not only restricted to hSMC, we treated primary human adipocytes with the broad spectrum inhibitor Batimastat. Also in adipocytes, Batimastat significantly reduced DPP4 release by about 40%. Further experiments to prove the involvement of ADAM17 in the shedding process are ongoing at the moment.
Conclusion: Our results suggest that MMPs contribute only to a minor extent to DPP4 shedding whereas ADAM17 is a key player in the shedding process. DPP4 shedding is sensitive to severe hypoxia. A disbalanced interaction between MMPs and ADAMs in obesity and artherosclerosis in relation to hypoxia could be responsible for the elevated serum levels of DPP4.

Serum follistatin is reduced in gestational diabetes mellitus: association with anthropometric parameters in offspring

S. Näf[1], X. Escote[1], M. Ballesteros[2], R.E. Yañez[1], I. Simón-Muela[1], P. Gil[1], G. Albaiges[2], J. Vendrell[1], A. Megia[1];
[1]Endocrinology and Diabetes Unit, Joan XXIII Hospital, [2]Obstetrics and Gynecology Service, Joan XXIII Hospital, Tarragona, Spain.

Background and aims: The Activin A-Follistatin system has emerged as an important regulator of lipid and glucose metabolism with possible repercussions on fetal growth. In the current study we analyze circulating activin A, follistatin and follistatin-like-3 (FSTL3) levels and their relationship with glucose metabolism in pregnant women and influence on fetal growth and neonatal adiposity.
Materials and methods: A prospective cohort was studied comprising 207 pregnant women, 129 with normal glucose tolerance (NGT) and 77 with gestational diabetes mellitus (GDM) and their offspring. Activin A, follistatin and FSTL3 levels were measured in maternal serum collected in the early third trimester of pregnancy. Serial fetal ultrasounds were performed during the third trimester to evaluate fetal growth. Neonatal anthropometry was measured to assess neonatal adiposity.
Results: Serum follistatin levels were significantly lower in GDM than in NGT pregnant women (9.22 $\pm$ 3.41 vs. 8.21 $\pm$ 2.32 ng/ml, $P = 0.012$) whereas serum FSTL3 and activin A levels were comparable between the two groups. Serum follistatin concentrations were negatively correlated with HOMA-IR ($r = -0.153$; $P = 0.030$) and positively with ultrasound growth parameters such as fractional thigh volume estimation in the middle of third trimester ($r = 0.212$; $P = 0.005$) and percent fat mass at birth ($r = 0.239$; $P = 0.002$). Also, in the stepwise multiple linear regression analysis serum follistatin levels were negatively predicted by HOMA-IR (B= -0.199; $P = 0.008$) and the diagnosis of gestational diabetes (B= -0.138; $P = 0.049$). Likewise, serum follistatin levels positively predicted fractional thigh volume estimation in the middle of third trimester (B= 0.214; $P = 0.005$) and percent fat mass at birth (B= 0.231; $P = 0.002$).
Conclusion: Circulating follistatin levels are reduced in GDM compared with NGT pregnant women and they are also independent positive determinants of fetal growth and neonatal adiposity. The Activin-Follistatin system should be considered as a new player influencing maternal and fetal metabolism during pregnancy.

The novel role of oncostatin m, a GP130 cytokine secreted in adipose tissue, in the development of obesity and type 2 diabetes

D. Sanchez-Infantes[1,2], R.F. Morrison[3], E. Ravussin[4], J.M. Stephens[2];
[1]Endocrinology, Sant Joan de Deu, Barcelona, Spain, [2]Adipocyte Biology, Pennington Biomedical Research Center, Baton Rouge, USA, [3]Nutrition, UNC-Greensboro, Greensboro, USA, [4]Obesity and Diabetes Energy Metabolism, Pennington Biomedical Research Center, Baton Rouge, USA.

Background and aims: Adipose tissue is a highly active endocrine organ secreting several factors that comprise a new hormonal network linking adipose tissue with other tissues. The adipocytes, the primary constituent of adipose tissue, are responsive to several gp130 cytokines, which have been targeted as potential therapeutic agents in obesity. Oncostatin m (OSM) is one of these cytokines, but its effects on adipocytes have not been previously examined. The aim was to assess the effects of OSM *in vitro* (adipocytes) and to examine its expression *in vivo* (adipose tissue from mice and humans with obesity-induced insulin resistance).
Materials and methods: *In vitro:* Murine 3T3-L1 adipocytes were treated with OSM in different conditions and cell monolayers were harvested to test activation of STATs by western blot, and PAI-1 and IL-6 gene expression by PCR. *In vivo: Animals-* Fifty male C57BL/6J mice 6 weeks of age were fed either low- or high-fat diets for 2, 4, 6 and 12 wk. Visceral adipose tissue was isolated to examine OSM levels by western blot. *Humans-* Subcutaneous and visceral adipose tissue from obese patients prior to bariatric surgery were used to examine the OSM gene expression by PCR.
Results: OSM was up-regulated in adipose tissue of obese/type 2 diabetic mice and humans. The specific receptor of OSM (OSMRβ) was identified in adipocytes demonstrating that OSM activates STAT5 in a dose-dependent manner. In addition, OSM induced the expression of target genes implicated in metabolic diseases such as PAI-1 and IL-6.
Conclusion: All these novel findings suggest a key role of OSM in the development of metabolic disorders including type-2 diabetes.

LBP is not merely a liver acute phase reactant: adipose tissue is an important source of this proinflammatory adipokine

J. Moreno-Navarrete[1], J. Vendrell[2], D. Langin[3], M.-C. Michalski[4], M. Laville[4], P. Domingo[5], W. Ricart[1], G. Frühbeck[6], F. Villarroya[7], G. Mingrone[8], A. Zorzano[9], H. Vidal[4], R. Burcelin[3], A. Vidal-Puig[10], J. Fernández-Real[1]; [1]Endocrinology, Institut d'Investigació Biomèdica de Girona, Spain, [2]Endocrinology, Hospital Joan XXIII, Rovira i Virgili University, Tarragona, Spain, [3]Institut National de la Santé et de la Recherche Médicale Université Paul Sabatier, Toulouse, France, [4]CarMeN Laboratory and CENS, Lyon 1 University, France, [5]Hospital de la Santa Creu I Sant Pau, Barcelona, Spain, [6]Endocrinology, Clínica Universitaria de Navarra, Pamplona, Spain, [7]Institute of Biomedicine of the University of Barcelona, Spain, [8]Catholic University of Rome, Italy, [9]University of Barcelona, Spain, [10]University of Cambridge Metabolic Research Laboratories, UK.

Background and aims: Circulating lipopolysaccharide binding protein (LBP) is an acute phase reactant known to be increased with obesity. We hypothesised LBP production by the adipose tissue in association with obesity.
Materials and methods: *LBP* mRNA and protein levels expression were analyzed in adipose tissue from 3 cross-sectional (n=210, 144, 28) and 3 longitudinal human cohorts, in adipose tissue fractions, during adipocyte differentiation, in genetic mice models and testing the effects of high fat diet, LPS and PPARγagonists. Functional *in vitro* and *ex-vivo* experiments were also performed.
Results: LBP synthesis and release is demonstrated in whole human and mice adipose tissue (AT), in isolated adipocytes and in different human and mice cell lines (hMADs, and 3T3-L1 cells), increasing with adipocyte differentiation. AT LBPexpression was robustly associated with inflammatory markers and increased with obesity, metabolic deterioration and insulin resistance in 2 independent cross-sectional human cohorts. AT LBP also increased longitudinally with weight gain and excessive fat accretion (in both humans and mice); and decreased with weight loss (in 2 other independent cohorts), in humans with acquired lipodystrophy and after PPARγ agonists ex-vivo. Inflammatory agents such as LPS and TNF-α led to increased adipose tissue LBP expression in vivo in mice and in vitro, while this effect was prevented in CD14 knockout mice. Functionally, LBP gene knockdown using shRNA or antibodies anti-LBP led to increased markers of adipogenesis and decreased adipocyte inflammation in human adipocytes.
Conclusion: LBP is a novel adipokine that seem to display an essential role in inflammation- and obesity-associated adipose tissue dysfunction.

Deletion of myeloid-cell protein tyrosine phosphatase-1B improves glucose tolerance and suppresses inflammatory responses in high-fat fed and endotoxaemic mouse models

M. Delibegovic, L. Grant, K. Shearer, A. Czopek, E. Lees, C. Owen, A. Agouni, H. Wilson, N. Mody;
University of Aberdeen, UK.

Background and aims: *Protein tyrosine phosphatase-1B* (*PTP1B*) negatively regulates insulin and leptin signalling; properties which render it an attractive drug target for the treatment of conditions associated with metabolic syndrome. However, some studies suggest caution when targeting macrophage-*PTP1B*, due to its potential anti-inflammatory role. The aim of this study was to investigate *in vivo*, the role of macrophage-*PTP1B* in inflammation and whole body metabolism, using myeloid-cell specific (*LysM*) *PTP1B*-knockout mice.
Materials and methods: Male *LysM-PTP1B* and control littermates were fed high-fat (HF) diet and whole body glucose/lipid metabolism, inflammatory status, and response to inflammatory challenges were analysed.
Results: *LysM-PTP1B* mice demonstrated improved glucose tolerance compared to age-matched controls after prolonged HF-feeding despite no alteration in body weight/adiposity. In HF obese mice injected intraperitoneally with low-dose lipopolysaccharide (LPS), *LysM PTP1B* displayed no evidence of hyperinsulinemia after three hours, in contrast to controls. Moreover, endotoxin-induced liver damage was decreased in *LysM-PTP1B* mice, as demonstrated by lower levels of serum alanine aminotransferase ($P<0.01$). qRT-PCR of white adipose tissue revealed lower F4/80 expression ($P<0.01$), indicating reduced macrophage migration, and diminished levels of TNFα ($P<0.01$) in the absence of *PTP1B*. Remarkably, *LysM-PTP1B* mice had increased basal and post-LPS ($P<0.05$ and $P<0.01$, respectively) serum IL-10 levels, suggesting a possible mechanism for the improvements in whole body glucose and inflammatory status.
Conclusion: This is the first study to demonstrate that myeloid-specific *PTP1B* deletion improves glucose tolerance and protects against endotoxic shock in mouse models of HF-feeding and LPS challenge. This is contrary to the popular hypothesis that myeloid *PTP1B* negatively regulates TLR4-mediated inflammatory signalling.

Siglec-7 is down-regulated in inflamed islets and activated peripheral mononuclear cells and restores beta cell function and survival

G. Dharmadhikari[1], J. Kerr-Conte[2], S. Kelm[1], K. Maedler[1];
[1]University of Bremen, Germany, [2]Thérapie Cellulaire du Diabète, INSERM, Université de Lille, France.

Background and aims: In, both, type 1 and type 2 diabetes mellitus; cytokine and chemokine production and infiltrating immune cells are the hallmarks of islet inflammation. Siglecs (Sialic-acid binding immunoglobulin like lectins) are cell surface receptors expressed on haematopoietic cells which participate in such immune responses. Upon investigation, a β-cell specific expression of Siglec-7 was observed, which was altered in diabetic conditions in islets and in activated PBMCs. Here, we aimed to investigate whether such changes in Siglec-7 expression directly modulate β-cell function and survival.
Materials and methods: To investigate the role of Siglec-7 in β-cell function and survival, over-expression was carried out in isolated human islets with or without diabetic stimuli, followed by glucose stimulated insulin secretion (GSIS) and TUNEL assay. Cytokine secretion was analyzed by the Meso Scale Discovery® multi array technology. To ascertain its role in immune cells, Siglec-7 expression was analyzed by RT-PCR and FACS in freshly isolated PBMCs from non- diabetic individuals cultured with the same diabetogenic conditions or 100 ng/ml Lipopolysaccharide (LPS) for 12 hours.
Results: Siglec-7 was markedly down-regulated in islets isolated from patients with T2DM and in pancreases from autopsy from patients with T2DM (70% decrease vs non-diabetic islets; 85% vs non-diabetic pancreases). Overexpression of Siglec-7 improved β-cell function and survival in human islets isolated from patients with T2DM. The overexpression also prevented

glucolipotoxicity- and cytokine-induced β-cell apoptosis. To investigate the mechanisms of this protective effect cytokine secretion was analyzed in these cultured islets. Cytokines IL1β, IL-6 and TNFα were induced under glucolipotoxicity (1.75-, 4- and 2-fold respectively) and cytokine treatment (19-; 4.6-, 1.7-fold respectively), which were significantly inhibited by Siglec-7 overexpression. In isolated human islets from patients with T2DM, Siglec-7 overexpression caused a reduction in basal IL1β (40%) and TNFα (50%) expression. In PBMCs, LPS, glucolipotoxicity, as well as cytokine mixture induced activation as seen by the induction of IL-6 mRNA and CD25 expression; a simultaneous decrease was observed in Siglec-7 mRNA levels. The flow cytometric analysis of cell surface expression of Siglec-7 showed 35% decrease in percentage of Siglec-7 positive cells as well as a 25% decrease in the mean fluorescence intensity.
Conclusion: Our data suggest that Siglec-7 is regulated in T2DM and influences β-cell function and survival. Also, decreased Siglec-7 in activated PBMCs, hints towards the inhibitory role of Siglec-7 in the activation of these immune cells during the development and progression of diabetes mellitus.

The relationships between macrophage infiltration and amyloid deposition in the islets of humans with type 2 diabetes
S. Dhayal, S.J. Richardson, N.G. Morgan;
Institute of Biomedical and Clinical Sciences, University of Exeter Medical School, Devon, UK.

Background and aims: In humans, β-cell dysfunction and the loss of β-cell mass are often considered as two defining features of type 2 diabetes and it is suggested that these responses represent the culmination of prolonged exposure of islet cells to various stressors. Among such factors are amyloid deposition and chronic islet macrophage infiltration. This is important since it has been suggested that islet amyloid deposits may lead to inflammasome activation within islet cells and that this could contribute to the development of a chronic inflammatory milieu. However, it is not known whether islet amyloid deposits serve as a direct stimulus for macrophage infiltration. In the present study, we have assessed this relationship.
Materials and methods: Formalin-fixed, paraffin embedded pancreatic sections from 24 type 2 diabetes (T2D; 68.2±7.7y; range 46-79y) cases were examined using immunohistochemical techniques. To confirm earlier findings that macrophage infiltration is enhanced in the islets of patients with T2D, sections from 5 non-diabetic adults (NDA; age 51.4±9.3y; range 35-58y) were also included for comparative purposes. Sections were analysed for macrophage infiltration by staining with anti-CD68 serum and for amyloid deposition by thioflavin T staining.
Results: Amyloid deposition was found in the islets of 17 of 24 (71%) patients with type 2 diabetes. Macrophages were detected at a low frequency in both the islets of control individuals and in those with type 2 diabetes, although the frequency was increased 4.5-fold in type 2 diabetes (0.7±0.1 macrophages per islet in NDA to 3.2±0.1 in T2D; $p<0.001$). Among the patients with T2D, islets containing amyloid had increased macrophage numbers compared to those with no amyloid deposits. Analysis of 41 amyloid negative islets across 6 T2D patients revealed that a mean of 1.3 ± 0.21 macrophages were present per islet section. By contrast, analysis of 116 islets with amyloid deposits revealed the presence of 3.7 ± 0.3 macrophages per islet section ($p<0.001$). However, in patients with type 2 diabetes macrophage numbers also increased with islet size, irrespective of amyloid deposition. Islets with a cross-sectional area less than 350μm2 contained an average of 1.8 ± 0.24 macrophages per islet, whereas islets with an area more than 650μm2 contained a mean of 4.5 ± 0.3 macrophages per islet; $p<0.001$ (analysed across 343 islets from 12 patients). Importantly, amyloid negative islets were usually smaller in cross-sectional area than amyloid positive islets suggesting that macrophage infiltration might be related mainly to islet size rather than to the presence of amyloid per se. Therefore, islets of equivalent surface area were compared. In islets matched for cross-sectional area, a mean of 2.9±0.3 macrophages per islet were seen in amyloid negative islets (164 islets analysed in 4 T2D patients) whereas a mean of 2.1 ± 0.2 macrophages per islet section were found in amyloid positive islets (105 islets analysed).
Conclusion: Islets from patients with type 2 diabetes contain significantly more infiltrating macrophages than those without diabetes, consistent with the presence of chronic low grade inflammation under these conditions. Both macrophage number and amyloid content are correlated with islet size but that these relationships are independent. Therefore, it is concluded that the enhanced infiltration of islets by macrophages seen in type 2 diabetes is not a direct response to amyloid deposition.

TIMP3 modulates CD11c$^+$ recruitment through IL6/Il6Ralpha complex in a model of metabolic disease
V. Marchetti, M. Mavilio, M. Fabrizi, M. Cavalera, M. Federici;
University of Rome, Italy.

Background and aims: Immune cells recruitment into adipose, hepatic, and vascular tissues disturbs tissue homeostasis and promotes the development of insulin resistance and diabetes. The net effect of immune cells infiltration into tissues depends on a delicate balance between salutary, reparative functions and pathogenic, proinflammatory influences. The complex formed by transmembrane protein A Metalloprotease and Disintegrin Domain 17 (ADAM17) and its tissue inhibitor of metalloproteinase 3 (TIMP3) is a unique central switch to the recruitment of circulating leukocytes from the bone marrow to inflamed sites. Among TIMP3 substrates, ADAM17 regulates TNF and its receptors, EGFR, and IL6R signaling pathways. Here we plan to investigate whether this axis affect immune cells phenotype and activity elucidating their function during the progression of metabolic diseases. We hypothesize that the modulation of ADAM17/TIMP3 axis on IL6 signalling will deviate immune cells from acute inflammation toward protection.
Materials and methods: In this proposal we applied emerging technologies in immune cell biology, animal models of metabolic disease, large-scale cytokine profile, transcriptomics and metabolomics to address a new role to ADAM17/TIMP3 pathway for the treatment of metabolic inflammation.
Results: (1) We characterized systemic and tissue resident F4/80$^+$, F4/80$^+$ CX-3CR1$^+$, CX3CR1$^+$, CX3CR1$^+$CD11c$^+$ that were found increased in TIMP3KO mice compared to the WT animals (1.9, 3.8, 2.3, 2.9 fold increase respectively, $p<0.001$) under high fat diet conditions; (2) level of circulating IL6 and IL6Rα were found significantly increased in TIMP3 ko animals compared to WT animals; IL6 was increased in adipose and hepatic tissue of TIMP3KO animals at 4 months of HFD; we determined the IL6 transignaling pathway as the mechanism responsible for the recruitment of circulating and tissue resident dendiritic and macrophagic cells like. (4) When the IL6/IL6R complex pathway was blocked the number of circulating and tissue resident inflammatory cells was reduced. As a consequence, the metabolic dysfunction was significantly improved.
Conclusion: Because myeloid cells accumulation and resident macrophage polarization is a critical event regulated by TIMP3 for the coordination of inflammatory events within fat tissue, increasing its release from cells directly at tissue injury site may be a valid approach for decreasing inflammatory signals in adipose tissue. If successful these studies will lead to a novel therapeutic paradigm for metabolic disorders.

Fructose supplementation exacerbates glucose intolerance and causes adipose tissue inflammation in PPARb/d-deficient mice
E. Barroso[1,2], R. Rodríguez-Rodríguez[2], X. Palomer[1,2], L. Salvadó[2], L. Michalik[3], W. Wahli[3], M. Vázquez-Carrera[1,2];
[1]CIBER de Diabetes y Enfermedades Metabólicas Asociadas, Barcelona, Spain, [2]Pharmacology and Therapeutic Chemistry, Faculty of Pharmacy, Barcelona, Spain, [3]Center for Integrative Genomics, National Research Center Frontiers in Genetics, Lausanne, Switzerland.

Background and aims: Strong evidence exists that chronic moderate fructose intake (e.g. 30% fructose solution as only fluid source) results in increased de novo lipogenesis and insulin resistance. On the other hand, PPARb/d-has been proposed as a therapeutic target for the treatment of inflammation and insulin resistance. In this study we aimed to examine whether fructose intake exacerbates metabolic dysfunction in PPARb/d-deficient mice.
Materials and methods: Wild-type and transgenic mice with reduced expression of PPARb/d were fed with plain water or water containing 30% fructose ad libitum for a period of 8 weeks. After treatment, RNA and total protein extracts were obtained from epididymal white adipose tissue for subsequent mRNA expression and western blot analyses.
Results: Fructose supplementation exacerbated the glucose intolerance (glucose tolerance test) already present in PPARb/d-null mice. Body weight,

liver weight and hepatic triglycerides increased only in PPARb/d-null mice fed with fructose ($p<0.05$). Likewise, chronic intake of fructose increased the size of adipocytes in both wild type and PPARb/d-null mice, but only in white adipose tissue of knockout mice an increase was observed in TNF-α (approximately 2-fold, $p<0.05$) and Mcp-1 (4-fold, $p<0.05$) expression. Interestingly, a significant increase was observed in the mRNA levels of F4/80 (approximately 2.5-fold, $p<0.05$) and Cd68 (5-fold, $p<0.05$) only in PPARb/d-deficient mice fed with fructose, suggesting macrophage infiltration in white adipose tissue. Interestingly, when we explored whether the activation of the CD36-JNK pathway was involved in inflammation and glucose intolerance, we noticed an increase in CD36 protein levels and JNK phosphorylation in PPARb/d knockout mice fed with water, but these changes were of higher intensity in fructose-fed PPARb/d-deficient mice.
Conclusion: Fructose exacerbates the CD36-JNK pathway in the white adipose tissue of PPARb/d-deficient mice. These changes might contribute to the increase in inflammation and glucose intolerance observed in these mice when fed with fructose.

Obesity induces CD11c$^+$ macrophages in murine adipose tissue which are distinctive from, but resemble, dendritic cells
K. Wouters[1], E. Wijnands[2], J.J.G. van Wegberg[1], E.A.L. Biessen[2], C.D.A. Stehouwer[1], C.G. Schalkwijk[1];
[1]Internal Medicine, Maastricht University, [2]Pathology, Maastricht University, Cardiovascular Research Institute Maastricht, Netherlands.

Background and aims: Obesity is hallmarked by immunological events in adipose tissue (AT) that contribute to the development of a chronic inflammatory state, leading to insulin resistance and atherosclerosis. During obesity, AT resident anti-inflammatory (so-called M2) macrophages are replaced by inflammatory (so-called M1) macrophages. These "M1" AT macrophages (ATMs) express the dendritic cell marker CD11c. Dendritic cells are important immune regulators shown to promote insulin resistance and atherogenesis. Currently, it is unclear whether and how CD11c$^+$ ATMs differ from dendritic cells and if they are activated by obesity. Our aim was to define a strategy for discriminating between resident CD11c$^-$ ATMs, inflammatory CD11c$^+$ ATMs and dendritic cells and to investigate the effect of obesity on their presence and phenotype.
Materials and methods: Male C57Bl/6 mice were fed chow or high fat diet (45 kcal% from lard) for 10 weeks and the stromal vascular fraction, containing immune cells, from epididymal AT was analyzed by flow cytometry. Furthermore, ATMs were isolated for mRNA analysis.
Results: Monocytes, but not CD8 and CD4 T-cells, B-cells or granulocytes, were increased in obese vs lean epididymal AT (6.1 ± 0.77 vs 3.6 ± 0.21% of stromal vascular cells, $p< 0.05$). Additionally, CD11c$^-$ macrophages were markedly increased in obese vs lean AT (15.08 ± 0.79 vs 7.95 ± 1.04 % of stromal vascular cells, $p<0.01$). Within CD11c$^+$ cells, we identified 2 cell populations based on CD11b and F4/80 surface expression, *i.e.* CD11b^{high} F4/80$^+$ CD11c$^+$ cells, corresponding to "M1" macrophages and CD11b^{low} F4/80$^-$ CD11c$^+$ cells, which are most probably DCs. Indeed, expression of the dendritic cell marker FLT3 was high and expression of the key macrophage genes F4/80 and CD64 was absent, confirming their identity as dendritic cells. Obesity resulted in the accumulation of CD11c$^+$ ATMs (5.98 ± 0.72 vs 3.43 ± 0.22 % of stromal vascular cells, $p<0.05$), but not of dendritic cells. Intriguingly, CD11c$^+$ ATMs expressed the typical macrophage markers F4/80 and CD64 but also intermediate levels of FLT3 and even higher CD11c levels compared to dendritic cells, indicating that these macrophages are distinctive from, but resemble, dendritic cells. These so-called "M1" CD11c$^+$ ATMs were characterised by high expression of TNF and Arginase-1 while expression of Mannose Receptor and MCP1 was lower compared to the putative "M2" CD11c$^-$ ATMs. Additionally, gene expression levels of both M1 and M2 markers in all macrophage subsets were only marginally affected by 10 weeks of high fat diet.
Conclusion: We present a novel and highly discriminative flow cytometry strategy to discriminate CD11c$^+$ ATMs from dendritic cells. Furthermore, we identify a "pro-inflammatory" CD11c$^+$ ATM subset, enriched in obese AT, expressing DC-markers and displaying a mixed M1/M2 profile. Importantly, obesity affects cell numbers rather than inflammatory phenotype of ATMs.

Background and aims: Obesity is associated with a low-grade inflammation, leading to insulin resistance and type 2 diabetes via Toll-like Receptor (TLR) and TNF-family cytokine receptor (TNFR) signaling pathways. Ubc13 is an ubiquitin-conjugating enzyme responsible for non-canonical K63-linked polyubiquitination of TNF receptor-associated factor (TRAF)-family adapter proteins involved in TLR and TNFR pathways. However, the relationship between Ubc13 and metabolic disease remains unclear. In this study, we investigated the role of Ubc13 in high-fat diet (HFD)-induced obesity and insulin resistance.
Materials and methods: We compared Wild-type (WT) and Ubc13 haploinsufficient (Ubc13+/-) mice under normal diet (ND) and HFD, because homozygous knockout mice (Ubc13-/-) were embryonic lethal. Animals were subjected to metabolic characterization: body weight (BW), food intake, energy expenditure, glucose tolerance test (GTT), and insulin tolerance test (ITT). HFD-fed WT and Ubc13+/- mice were sacrificed and metabolically active organs were collected for molecular and histological studies.
Results: No significant differences were observed in BW, GTT, and ITT between WT and Ubc13+/- mice under ND. However, HFD-fed Ubc13+/- mice showed lower levels of blood glucose and insulin secretion in GTT than HFD-fed WT mice, whereas BW was not significantly different. HFD-fed Ubc13+/- mice also showed increased insulin sensitivity in ITT compared to HFD-fed WT mice. Consistent with the improved insulin sensitivity measured by GTT and ITT, Akt Ser473 phosphorylation was enhanced in livers of HFD-fed Ubc13+/- mice after insulin stimulation. In addition, Ubc13+/- macrophages showed reduced TLR and TNFR signaling after lipopolysaccharide (LPS) and TNFα stimulation compared to WT macrophages. These results indicate that Ubc13 haploinsufficiency improves insulin resistance caused by HFD.
Conclusion: Ubc13 may play an important role in HFD-induced insulin resistance by regulating obesity-related inflammatory responses. Reducing Ubc13 activity could have therapeutic potential in the prevention of insulin resistance associated with obesity.

Obesity-associated macrophage infiltration has a paracrine effect to induce skeletal muscle insulin resistance
N.A. Talbot, C.P. Wheeler-Jones, M.E. Cleasby;
Comparative Biomedical Sciences, Royal Veterinary College, London, UK.

Background and aims: Insulin resistance (IR) in skeletal muscle is commonly associated with overweight or obesity, accompanied by elevated levels of triglycerides and fatty acids (FAs) in plasma. Obesity is now recognised to be a chronic sub-clinical inflammatory condition, characterised by increased macrophage (mφ) infiltration into adipose tissue. Although ectopic deposition of lipids is known to induce IR directly, it is not known whether local infiltration of mφ into muscle also plays a role in mediating the local effects of elevated FA levels, nor whether there are distinct effects of different FA classes.
Materials and methods: Cohorts of rats (n=8) were fed a chow or high fat diet (HFD; 60% calories as fat) for 5 weeks and the number of mφ present were counted in adipose tissue and muscle after anti-CD68 immunostaining. To explore the mechanisms of this effect, J774 mφ were incubated with or without saturated FA (palmitic acid), unsaturated FA (palmitoleate) or lipopolysaccharide (LPS; positive control) for 8 hours to generate conditioned medium. Medium content of cytokines/chemokines was assayed by ELISA. Mφ phenotype was established by measurement of nitric oxide (Griess assay) and arginase activity. Differentiated C2C12 myotubes were incubated with each type of mφ-conditioned medium for 16 hours and the relative effects on intracellular signalling and glycogen synthesis assessed. All experiments consisted of n=4-5 independent repeats.
Results: HFD-feeding resulted in increased macrophage infiltration into adipose tissue and a 138% increase in tibialis cranialis muscle compared to

chow (P<0.01). In the in vitro model, both LPS and palmitic acid resulted in increased nitric oxide production (p<0.05) and reduced arginase activity (p<0.05), indicative of an M1-type pro-inflammatory mφ phenotype. Conditioned medium contained TNF-α, IL-1β, CXCL2 and MCP-1. Whereas LPS treatment of mφ increased the concentration of all of these, only TNF-α was significantly increased by ~3-fold in palmitic acid-treated mφ compared to control medium (P<0.001). Addition of palmitoleic acid negated the effects of palmitic acid, implying an anti-inflammatory effect of unsaturated FAs on mφ. Incubation of myotubes with palmitic acid-treated mφ-conditioned medium lead to reductions in phosphorylation of PI3-kinase pathway intermediates of 45% for AS160 (Thr 642; p<0.05) and 65% for GSK3β (Ser9; p<0.01), accompanied by a 53% reduction in insulin-stimulated glycogen synthesis (p<0.01). These changes were mirrored by the effects of LPS-conditioned medium. In contrast, palmitoleic acid-treated mφ-conditioned medium enhanced glycogen synthesis by 36% and increased phosphorylation of IRS-1, AS160 and GSK3β. When added in combination, palmitoleic acid-conditioned medium negated the effect of palmitic acid to impair signalling.
Conclusion: Our data demonstrate that obesity in rats is associated with infiltration of mφ into skeletal muscle as well as adipose tissue. We have shown that saturated FA induce a pro-inflammatory phenotype in mφ, which can then directly induce IR in myotubes. This effect is strikingly abrogated in the presence of unsaturated FA. Thus, local mφ infiltration associated with obesity and elevated saturated FA can induce IR in skeletal muscle by a paracrine mechanism.

Characterisation of macrophage infiltration and polarisation in adipose tissue of children
D. Rockstroh[1], K. Landgraf[1], R. Tauschert[1], I. Wagner[1], J. Gesing[1], S. Weise[1], M. Blüher[2], W. Kiess[1], H. Till[3], M. Wojan[4], A. Körner[1];
[1]Dept. of Women's & Child Health, Pediatric Research Center, [2]University Hospital for Endocrinology and Nephrology, [3]University Hospital for Pediatric Surgery, [4]University Hospital for Orthopaedic Surgery, Leipzig, Germany.

Background and aims: Obesity is a disease that is accompanied by a low-grade chronic inflammatory state. It has recently been shown that adipose tissue (AT) from adults contained increased amounts of macrophages which may contribute to the inflammatory state. Human macrophages can be classified into proinflammatory M1 and anti-inflammatory M2 macrophages. However, there is only little information about the occurrence and polarisation of macrophages in AT of children.
Materials and methods: Therefore, we aimed to characterize macrophage infiltration and polarisation in AT of children. In order to assess macrophage infiltration and the polarisation status we performed immunohistochemical analysis and *qRT*-PCR of the stromal vascular fraction (SVF) of AT obtained from 169 biopsies lean (n=112; age= 0-18) and obese (n= 57; age= 0-18) children.
Results: *CD68* expression indicated a positive correlation of macrophage infiltration with BMI-SDS (r=0.56; *P*<0.001), adipocyte size (r=0.59; *P*<0.001) and the number of crown-like structures (CLS) (r=0.4; *P*<0.001) in subcutaneous AT of children. CLS were detected in 37% of obese, but only in 9% of lean children. Furthermore, obese children showed an increased expression of *CD68* (*P*<0.001) in the SVF which was accompanied by an increased expression of the specific M1 marker *CD86* (*P*<0.001). In contrast, no expression changes of the M2 marker *MRC1* were detectable in obese children compared to lean controls.
Conclusion: Adipocyte hypertrophy is a hallmark of obesity, which is thought to trigger an inflammatory response. Here we show a positive correlation of macrophage infiltration, adipocyte size and obesity in children. Furthermore, obese children showed an increased expression of M1 macrophages which could indicate a shift in the M1/M2 ratio.

Circadian regulation of MCP1 serum levels and expression in monocytes and adipose tissue upon switching from high to low carb diets with replacement by fat in humans
O. Pivovarova[1,2], S. Hornemann[1], M. Kruse[1], Y. Lu[1], A.-C. Seltmann[1], J. Mazuch[3], N. Rudovich[1], A. Kramer[3], A. Busjahn[4], A.F.H. Pfeiffer[1];
[1]Department of Clinical Nutrition, German Institute of Human Nutrition Potsdam-Rehbruecke, Nuthetal, [2]Department of Endocrinology, Diabetes and Nutrition, Campus Benjamin Franklin, Charité University Medicine, Berlin, [3]Laboratory of Chronobiology, Institute for Medical Immunology, Charité University Medicine, Berlin, [4]HealthTwiSt GmbH, Berlin, Germany.

Background and aims: The monocyte chemotactic protein-1 (MCP-1)/chemokine (C-C motif) ligand 2 (CCL2) is a proinflammatory chemokine primarily secreted by monocytes, macrophages and adipocytes and contributing to the pathogenesis of obesity, diabetes and cardiovascular disease. Exercise and weight loss induced by caloric restriction reduce circulating levels of MCP1. However, there is little information about the effect of nutrient composition on MCP1 levels and mRNA expression in humans. To address this, we analysed MCP1 levels in human serum, and its mRNA expression in monocytes and adipose tissue after 6 weeks high carbohydrate - low fat (HC/LFD, 55% carbohydrate, 30% fat) followed by 6 weeks of low carbohydrate - high saturated fat (LC/HFD, 40% carbohydrate, 45 % fat) isocaloric diet interventions.
Materials and methods: The NUtriGenomics Analysis in Twins (NUGAT) study included 92 non obese healthy twins (35 monozygotic and 11 dizygotic twin pairs). Three investigation days were dated after 6 weeks HC/LFD and after 6 and 42 days of the LC/HFD. MCP1 serum level and mRNA gene expression in blood monocytes was measured at three time points (in the morning, at noon and in the afternoon). Gene expression in subcutaneous adipose tissue biopsies was studied at one time point at noon.
Results: Serum levels of MCP1 demonstrated significant circadian variation with the highest level in the morning, a trough level at noon and increase again in the afternoon. The same trend was found for mRNA expression in monocytes. Moreover, serum MCP1 and its mRNA expression in adipose tissue correlated with the expression of core clock genes in adipose tissue. MCP1 serum level correlated with age, waist circumference, BMI and waist-hip ratio, as well as with total cholesterol and LDL cholesterol level in the afternoon. In the stepwise multivariate regression analysis, only age, waist circumference, waist-hip ratio and total cholesterol remained in the final predictive model as significant variables associated with serum MCP1 (adjusted R2= 0.435, p<0.01). Serum MCP1 was significantly decreased after six weeks of LC/HFD with the largest effect in the afternoon. In contrast, the MCP1 mRNA expression was increased in adipose tissue, and not changed in monocytes under the LC/HFD diet intervention. Furthermore, the correlation of MCP1 serum level with mRNA expression was found only in adipose tissue for CID1, but not in monocytes. Estimating of heritability in twins using ACE model revealed that the serum MCP1 and its circadian rhythms were about 70% genetically determined, whereas the diet-induced changes had a lower genetic impact.
Conclusion: Serum MCP1 level in humans demonstrates circadian regulation and correlates with total and LDL cholesterol levels. Isocaloric LC/HFD induces the decrease of MCP1 serum level obviously due to posttranscriptional regulation. The mRNA expression in adipose tissue or monocytes is not a good predictor of serum MCP1 levels in humans.

A community-based intervention for diabetes risk reduction in inner-city obese adolescents

M. Savoye[1], S. Caprio[1], J. Dziura[1], A. Camp[2], F. Li[1], M. Shaw[1], B. Pierpont[1], F. Depourcq[1], G. Kim[1], W.V. Tamborlane[1];
[1]Pediatric Endocrinology, Yale University, [2]Endocrinology, Fair Haven Community Health Center, New Haven, USA.

Background and aims: Childhood obesity has been accompanied by an increasing prevalence of type 2 diabetes (T2D), particularly in minority children. 20-30% of obese youth have "pre-diabetes" a precursor to diabetes marked by insulin resistance, β-cell dysfunction and impaired glucose tolerance (IGT). The Diabetes Prevention Program demonstrated T2D could be prevented/delayed by lifestyle modification in adults with pre-diabetes, but efficacy of similar interventions in youth has not been established. Therefore, we evaluated the effects of the Bright Bodies Healthy Lifestyle Program on 2-hr OGTT glucose in comparison to children receiving standard of care.
Materials and methods: Parallel-group randomized controlled trial comparing Bright Bodies (BB) with standard clinical care (CC) in obese adolescents (10-16 yo) with elevated OGTT 2-hr blood glucose (130-199 mg/dl) from a racial/ethnically-diverse population. OGTTs, including anthropometric and metabolic syndrome criteria assessments, were conducted at baseline and 6 months. Children attended BB twice weekly for exercise and nutrition/behavior modification at one of two community sites and CC group received clinical care from their pediatrician. Primary outcome was change in 2-hr OGTT glucose and % conversion from elevated 2-hr blood glucose to non-elevated (<130 mg/dl) 2-hr blood glucose. Changes in outcomes were compared between groups using a mixed model with covariate adjustment for baseline outcome and multiple imputation for missing data. Least squares means and 95% CIs were estimated for changes in outcomes.
Results: Reductions in 2-hr glucose were more favorable in BB compared to CC (-27.2 vs. -10.1 mg/dl; diff=-17.1, 95% CI ;p= 0.005). Moreover, greater conversion to <130 mg/dl 2-hr glucose occurred in BB than CC (p=0.03). Other insulin sensitivity indices were significantly improved, as well as the prevalence of metabolic syndrome in the BB group (p=0.004).
Conclusion: Compared to standard of care, the Bright Bodies Program is a more effective means of reducing the risk of T2D in obese adolescents with elevated 2-hr blood glucoses.

Big breakfast rich in protein improved glycaemic control and satiety feeling in adults with type 2 diabetes mellitus

H. Rabinovitz[1], M. Boaz[2], T. Ganz[3], Z. Madar[1], D. Jakubowicz[4], J. Wainstein[4];
[1]The Hebrew University of Jerusalem, Rehovot , [2]Epidemiology and Research Unit, The Hebrew University of Jerusalem, Holon, [3]Diabetes Unit, E. Wolfson Medical Center, Holon, [4]Diabetes Unit, E.Wolfson Medical Center, Holon, Israel.

Background and aims: Consuming breakfast has been inversely associated with BMI, fasting lipids and postprandial insulin sensitivity. The present study was designed to evaluate the effect of breakfast size and composition on glycemic control, and its association with hormone profile in adults with type 2 diabetes.
Materials and methods: The present study is a randomized, controlled, open clinical trial, including overweight/obese, non-insulin-dependent adults with type 2 diabetes. Participants were randomized to balanced hypocaloric diabetic diets with either big breakfast (BB) or small breakfast (SB), (33% vs. 12.5% of total daily energy intake). The BB diet included higher percentage of protein and fat. Anthropometric measures were assessed every 2 weeks. Fasting adipokines, hormones, proinflammatory cytokines and lipid profile were performed at baseline and after a follow-up period (Week 13).
Results: Of the 59 enrolled participants, 47 completed the study. At end of follow-up, greater HbA1c and systolic blood pressure reductions were observed in the BB than SB group (HbA1c: -4.62% vs. -1.46 %, p=0.047; SBP -9.58 vs. -2.43 mmHg; p=0.04). Additionally, DM medication doses were reduced in a greater proportion of the BB participants (31% vs. 0%; p=0.002) while in the SB, a greater proportion of participants had a dose increases (16.7% vs. 3.4%; p=0.002). Hunger scores were lower in the BB group and greater improvements in fasting glucose were observed in the BB group comparison to the SB group.
Conclusion: A simple dietary manipulation of BB diet rich in protein and fat appears to have additional benefits compared to a conventional low-calorie diet in individuals with type 2 diabetes.
Clinical Trial Registration Number: NCT01178723

The impact of high fat meal frequency on metabolic profile and energy expenditure in obese subjects

M.K. Piya[1,2], N. Reddy[1,2], A. Harte[2], A. Campbell[1], J. Hattersley[1,3], L. Halder[1], A.A. Tahrani[4], G. Tripathi[2], S.A.S. Aftab[1,2], T.M. Barber[1,2], P.G. McTernan[2], S. Kumar[2,1];
[1]Human Metabolism Research Unit, University Hospitals Coventry and Warwickshire NHS Trust, Coventry, [2]Division of Metabolic and Vascular Health, Warwick Medical School, University of Warwick, Coventry, [3]University of Warwick, Coventry, [4]Centre for Endocrinology, Diabetes and Metabolism, University of Birmingham, UK.

Background and aims: Whilst obesity remains a critical risk factor for developing type 2 diabetes mellitus (T2DM), it is clear that dietary habits also have a key role in the earlier onset of metabolic dysfunction, as well as late complications of T2DM. Clinically, consumption of small frequent meals versus fewer large meals is considered beneficial for weight loss and to reduce future cardiovascular (CVD) risk, although there is limited evidence to support this popular belief. Therefore, in this study, our aim was to (1) compare the effect of 2 versus 5 isocaloric high fat meals on the metabolic profile in lean and obese women; and (2) examine the effect of meal frequency on 24 hour energy expenditure.
Materials and methods: In a crossover study, 24 white Caucasian non-diabetic lean (age: 34 (mean±SD) ± 10 years, BMI: 22.9 ± 2 kg/m^2) and obese (age: 42 ± 9 years, BMI: 36 ±8 kg/m^2) women were given 2 or 5 isocaloric high fat meals (50% fat) per day. Each subject attended on two separate visits, less than two weeks apart. On each occasion, following an overnight fast, blood samples were taken every 2 hours at 7 time points, from 9am to 9pm. Biochemical assessment was undertaken for glucose, insulin, HOMA-IR, lipid profile and non-esterified fatty acids (NEFA). Concurrently, subjects were assessed for 24 hour energy expenditure in a purpose built whole body room calorimeter, on both instances. Subjects also completed visual analogue scales for hunger, satiety, fullness and appetite every 2 hours, for the duration of each visit.
Results: The obese subjects had significantly increased insulin and decreased HDL ($p<0.001$), as well as increased glucose, HOMA-IR and triglyceride (TG) levels ($p<0.01$), throughout the day, compared with the lean subjects for both the 2 and 5 meal visits. Despite the change in meal size and frequency, there were no significant differences in either weight group for glucose, insulin, HOMA-IR, cholesterol, LDL, HDL, TG or NEFA. However, there was a noted difference in metabolic response to an individual standardised high fat meal at lunchtime between lean and obese subjects (insulin, HOMA-IR, TG, $p<0.01$), independent of meal frequency. Furthermore, there was no significant difference in 24 hour expenditure, whether 2 or 5 meals were consumed in either the obese group (2124 ± 312 vs 2142 ± 365 Kcal/day) or lean group (1724 ± 160 vs 1683 ± 166 Kcal/day). The obese group had higher hunger scores and lower fullness scores on the visual analogue scale in the 2 meal visit compared with the 5 meal visit ($p<0.05$); whilst this was not observed in the lean group.
Conclusion: In summary, consumption of 2 large or 5 small high fat meals in either obese or lean women had no significant impact on their respective metabolic profiles or 24 hour energy expenditure. Obese women had a much more dysfunctional metabolic profile compared with lean subjects, which was further exacerbated by individual high fat meal challenges. Taken together, these data suggest that the amount of calories and content per day may have a more significant impact on metabolic profile and energy expenditure than the frequency of meals over a 24 hour period.

Combining dietary polyphenols increase energy expenditure and improve parameters of adipose tissue and skeletal muscle in healthy overweight humans

J. Most, G.H. Goossens, J.W.E. Jocken, E.E. Blaak;
Human Biology, Maastricht University Medical Centre, Netherlands.

Background and aims: Impaired regulation of lipid oxidation (metabolic inflexibility) is associated with obesity, insulin resistance and type 2 diabetes mellitus. Dietary polyphenols have recently gained attention attributed to their modulating effects on lipolysis, fat oxidation and mitochondrial function. The objective of the present study was to test short-term (3 days) additional or synergistic effects of combinations of polyphenols, with distinct mechanisms of action, on energy and substrate metabolism in overweight subjects.
Materials and methods: 18 healthy overweight volunteers (9 females, 9 males, age 35±2.5 yrs, BMI 28.9±0.4 kg/m2) participated in a randomized, double-blind cross-over study. Combinations of Epigallocatechin-gallate (EGCG, 282mg/d) + Resveratrol (RSV, 200mg/d), and EGCG+RSV + 80mg/d soy isoflavones (SI), or placebo capsules (PLA) were supplemented twice daily, for a period of 3 days. On day 3, circulating metabolites, energy and substrate metabolism (indirect calorimetry) were measured during fasting and postprandial conditions (high-fat-mixed meal (2.6MJ, 61.2 E% fat)) and a subcutaneous adipose tissue biopsy was taken. Differences between supplementation periods are analyzed by ANOVA using SPSS 19.0 for MAC and P,0.05 was considered statistically significant. Post-hoc analyses with Bonferroni correction were applied when ANOVA indicated significant effects or interactions.
Results: EGCG+RSV increased resting energy expenditure (EE) compared to placebo (5.45±0.17 vs 5.22±0.18 kJ/min, p<0.05). Postprandially, EE was increased by both treatments vs PLA 2-4h after the meal (p=0.01). Metabolic flexibility, calculated as difference between fasting and maximal postprandial RQ, tended to be improved by EGCG+RSV as compared to PLA in men (0.11±0.02 vs 0.06±0.02, p=0.079), whilst in women there was no effect. EGCG+RSV tended to increase the glucose-insulin-ratio, a marker for insulin sensitivity during early postprandial phase (0-120 min, p=0.06). The latter effects were not seen during additional SI supplementation. EGCG+RSV+SI increased circulating free fatty acid and free glycerol as compared to PLA.
Conclusion: EGCG+RSV increased fasting and postprandial EE, whilst there was a tendency towards improved postprandial insulin sensitivity. This was accompanied by an improved metabolic flexibility in males. These metabolic changes were not seen with EGCG+RSV+SI, suggesting that addition of SI reversed these effects. If these effects of EGCG+RSV remain after long-term treatment (under investigation), this may have positive consequences for body weight control and insulin sensitivity.

Combination naltrexone/bupropion therapy resulted in clinically meaningful improvements in weight and quality of life (QOL): integrated analysis of four phase 3 trials

R.L. Kolotkin[1], C. Burns[2], B. Walsh[2], P. Klassen[2];
[1]Quality of Life Consulting, PLLC, Durham, [2]Orexigen Therapeutics, Inc., La Jolla, USA.

Background and aims: Comprehensive treatment for obesity ideally will improve physical, psychological, and social aspects of health in addition to facilitating weight loss. This integrated analysis of the four Phase 3, 56-week trials of combination naltrexone sustained-release (SR) / bupropion SR (NB) vs placebo (PBO) investigated changes in body weight and weight-related QOL using the Impact of Weight on Quality of Life-Lite (IWQOL-Lite) scale at baseline and at 8, 16, 28, and 56 weeks of treatment.
Materials and methods: All patients (NB [n=2043], PBO [n=1319]) were overweight/obese (BMI: ≥27 and ≤45 kg/m^2). Treatment group differences (LS mean±SE) in the modified ITT-LOCF population (≥1 post-baseline weight while on study drug) were evaluated by ANCOVA with treatment, study, and baseline values as covariates.
Results: Baseline characteristics (mean±SD) were similar between treatment arms: 81% female, 79% Caucasian, 46±11 y, 36±4 kg/m^2, type 2 diabetes: 12.6%, IWQOL-Lite total score: 71±18. Completion rate was 66% (NB) and 59% (PBO). Weight loss with NB was significantly greater than PBO at all time points (Week 56: -7.0±0.2% NB vs -2.3±0.2% PBO; p<0.001). At Week 56, NB resulted in significantly greater improvement in IWQOL-Lite total score (+11.9±0.3 vs +8.2±0.3; p<0.001) and all subscores (Physical function, Self-esteem, Sexual life, Public distress, Work; all p<0.05 vs PBO). At Week 56, significantly more patients reduced body weight by ≥5% with NB (53% vs 21%; p<0.001), and greater mean improvement in IWQOL-Lite total score was observed in these patients. The safety/tolerability profile of NB was consistent with its individual components; the most common adverse events were nausea (32%), constipation (19%), headache (18%), and vomiting (11%).
Conclusion: NB improved both weight and psychosocial outcomes, with 36% of NB patients (vs 12% PBO; p<0.0001) achieving clinically meaningful improvement in both IWQOL-Lite and body weight (≥5% reduction) after 1 year.

An integrated analysis of weight loss with combination naltrexone/bupropion therapy by BMI (obesity) classification

B. Walsh[1], C. Burns[1], K. Taylor[1], C. Apovian[2];
[1]Orexigen Therapeutics, Inc., La Jolla, [2]Boston University School of Medicine, Boston, USA.

Background and aims: Naltrexone sustained-release (SR) / bupropion SR (NB) significantly reduced body weight vs placebo (PBO) in the four, 56-week, Phase 3 trials of overweight/obese patients (BMI ≥27 and ≤45 kg/m^2). This integrated analysis investigated weight loss in these 4 trials when stratified by baseline BMI (obesity class): Class-I (30.0-34.9 kg/m^2), Class-II (35.0-39.9 kg/m^2), Class-III (≥40 kg/m^2).
Materials and methods: Treatment group differences (LS mean±SE) in the modified ITT-LOCF population (≥1 post-baseline weight on study drug) were evaluated by ANCOVA with treatment, study, and baseline values as covariates.
Results: Baseline characteristics (mean±SD) were similar between treatment arms (NB [n=2043] or PBO [n=1319]): 81% female; 79% Caucasian; 46±11 y; 36±4 kg/m^2; obesity Class-I: 37%, Class-II: 36%, Class-III: 25%. Completion rate was 66% for NB and 59% for PBO. At Week 56, NB resulted in significantly greater weight loss vs PBO (-7.0 ±0.2% NB vs -2.3±0.2% PBO; p<0.001) and proportion of patients who attained ≥5% weight loss (53% NB vs 21% PBO; p<0.001). NB patients experienced favorable shifts in BMI class from baseline relative to PBO (NB vs PBO: improved = 45% vs 20%, no change = 53% vs 74%, worsened = 2% vs 6%; p<0.001), and a larger proportion of NB vs PBO subjects shifted to a non-obese BMI from Class-I obesity (17% NB vs 6% PBO) and from Class-II obesity (3% vs 1%). Of note, weight loss with NB was similar across the 3 obesity classes (NB range: -6.1% to -7.3%; PBO-corrected range: -4.0% to -5.0%, all p<0.001), as was achievement of ≥5% weight loss (NB range: 49% to 54%, odds ratio relative to PBO: 3.5 to 4.3; all p<0.001). The safety/tolerability profile of NB32 was consistent with its individual components; the most common adverse events were nausea (32%), constipation (19%), headache (18%), and vomiting (11%).
Conclusion: The clinically significant weight loss associated with NB was consistent across a wide BMI range, and resulted in an approximately 3-fold greater transition from Class-I/II obese to non-obese BMI.

Early improvement in control of eating is associated with long-term weight loss: integrated analysis of four phase 3 trials of combination naltrexone/bupropion treatment

K. Fujioka[1], C. Burns[2], B. Walsh[2], P. Klassen[2];
[1]Scripps Clinic, [2]Orexigen Therapeutics, Inc., La Jolla, USA.

Background and aims: Combination treatment with naltrexone sustained-release (SR) / bupropion SR (NB) results in substantial and sustained weight loss that is postulated to be partially mediated by effects on the mesolimbic dopaminergic reward system that modulate control of eating behavior. In the Phase 3 trials of NB in overweight/obese individuals, eating behavior was evaluated with the Control of Eating Questionnaire (CoEQ, twenty 100mm

visual analog scales) at baseline and Weeks 8, 16, 28, and 56. This integrated analysis of all four Phase 3, 56-week clinical trials of NB in overweight/obese patients (BMI ≥27 and ≤45 kg/m^2) evaluated the change in CoEQ question 19 (CoEQ 19: "Generally how difficult has it been to control your eating?") and the relationship between changes in CoEQ 19 and body weight.
Materials and methods: Treatment group differences (LS mean±SE) in the modified ITT-LOCF population (≥1 post-baseline weight on study drug) were evaluated by ANCOVA with treatment, study, and baseline values as covariates.
Results: Baseline characteristics (mean±SD) were similar between treatment arms (NB [n=2043] or placebo [PBO; n=1319]): 81% female, 79% Caucasian, 46±11 y, 36.3±4.3 kg/m^2, CoEQ 19 score: 60±24. Completion rate was 66% for NB and 59% for PBO. At Week 56, weight loss was significantly greater with NB (-7.0±0.2%) vs PBO (-2.3±0.2%; p<0.001). NB-treated subjects reported significantly greater improvement in CoEQ 19 at all time points (p<0.001 vs PBO), with the greatest effect observed at Week 8 (-23.3 vs -13.5 mm; p<0.001). In both groups, reduction in CoEQ 19 at Week 8 was positively correlated with body weight reduction at Week 56 (r=0.20 (NB), r=0.22 (PBO); both p<0.001), such that the quartile of NB subjects with the greatest CoEQ 19 improvement at Week 8 (> 43 mm) exhibited -9.4% mean weight change at Week 56.
Conclusion: These results suggest that NB is associated with rapid improvement in control of eating behavior that may, in part, contribute to the weight loss associated with treatment.

Oral formulation of UGP302, a novel amylin and calcitonin dual receptor agonist, exerts anti-obesity effects in diet-induced obese (DIO) rats
K.V. Andreassen[1], M. Feigh[1], S.T. Hjuler[1], N. Mehta[2], W. Stern[2], S. Gydesen[1], I.A. Ottosen[1], M.A. Karsdal[1], K. Henriksen[1];
[1]Diabetes Group, Nordic Bioscience, Herlev, Denmark, [2]Unigene Laboratoies, Inc, Boonton, USA.

Background and aims: Salmon calcitonin (sCT) is associated with anorectic effects mediating weight loss, and oral delivery of sCT have previously been published to have glucoregulatory and weight-reducing effects in obese diabetic rats; however, increasing peptide potency could have further beneficial effects. Here we describe a novel sCT mimetic (UGP302), and we performed a thorough head-to-head comparison of UGP302 and sCT in vitro, as well as orally formulated UGP302 and sCT in vivo.
Materials and methods: The in vitro studies were conducted in mammalian cell lines from DiscoverX expressing human calcitonin receptor (CTR) or human amylin receptor (AMYR). GPCR downstream signalling was investigated with dose response profiles for cAMP accumulation and β-arrestin recruitment by sCT and UGP302 during short term (< 2 hours) and prolonged (up to 72 hours) stimulation. Binding affinity for both ligands was assessed by competitive binding using I-125 radio-labeled sCT for both receptors. The in vivo study was conducted in the diet-induced obese rat model (DIO). Male DIO rats were treated with oral sCT (1mg/kg) or UGP302 (1 mg/kg) or oral vehicle twice daily for 4 weeks. A pair-fed group to UGP302 was included to evaluate the impact of food intake on body weight regulation. Furthermore, an oral glucose tolerance test (OGTT) was performed to investigate postprandial glycaemic control. Levels of plasma insulin and leptin were measured at study end to evaluate the resistance to the action of these hormones.
Results: In vitro, UGP302 was demonstrated to be more potent compared to sCT with respect to cAMP accumulation and β-arrestin recruitment for both receptors (CTR p < 0.01, AMYR p < 0.01), and UGP302 scored a lower IC50 value in a competitive binding assay when compared to sCT for both receptors, indicating improved receptor affinity. Intriguingly, UGP302 and sCT did not activate the CGRP-receptor. In vivo, over the 4 week period oral UGP302 caused a significant reduction in accumulated food intake, when compared to sCT and oral vehicle (p < 0.01 vs. sCT and p<0.001 vs. oral vehicle). At study end, oral UGP302 administration induced a 10% reduction in bodyweight compared to vehicle (p < 0.001). In contrast, only a 6% vehicle-corrected weight-loss was observed for pair-fed and oral sCT groups (p < 0.01), thus, resulting in a more pronounced anti-obesity effect for oral UGP302 (p < 0.05). Furthermore, oral sCT and UGP302 improved glucose intolerance evaluated as reduced incremental area under the curve (iAUC) during OGTT when compared to vehicle (p < 0.001) and UGP302 pair-feeding (p < 0.01). At study end, oral UGP302, but not oral sCT, significantly reduced hyperinsulinemia (p<0.05, vehicle and pair-fed) indicating improved insulin sensitivity. In addition, UGP302 and sCT both significantly reduced hyperleptinemia when compared to vehicle (UGP302 p< 0.001, sCT p<0.05) indicating reduced leptin resistance. In contrast, the pair-fed group showed no reduction in any of the measured hormones.
Conclusion: In conclusion, we have demonstrated oral UGP302 to be superior to oral sCT in both an in vitro and in vivo setting. The results support that this novel dual receptor agonist could be a new treatment for obesity and potentially T2DM due to the improved glycaemic control, improved hormonal homeostasis and weight reducing effects.

Beneficial effect of lingonberry, blackcurrant and bilberry consumption on weight gain and adiposity in C57BL/6J mice
L. Heyman, U. Axling, A. Gormand, C. Holm, K. Berger;
Experimental Medical Science, Lund University, Lund, Sweden.

Background and aims: The prevalence of obesity and diabetes is increasing dramatically worldwide. Obesity is associated with several metabolic disorders such as cardiovascular disease, non-alcoholic fatty liver disease and type 2 diabetes. Many of these multifactorial conditions are preventable by adopting dietary patterns that promote maintenance of a healthy body weight. Diets rich in fruits and berries have been associated with reduced risk of type 2 diabetes. This study was designed to screen eight species of berries for their ability to counteract negative effects induced by a high-fat diet.
Materials and methods: Male C57BL/6J mice were fed a high-fat diet (45 E%) for 13 weeks supplemented with different berries (20%); lingonberry, blackcurrant, bilberry, raspberry, blackberry, açai, crowberry and prunes. The control group received high-fat diet without berries. Body weight and food intake was monitored continuously, and in the end of the study organs were collected. Plasma parameters were measured and epididymal fat pads and liver tissue were subjected to gene and protein expression analysis.
Results:

Table 1. Metabolic parameters after 13 weeks on high-fat diet with berry supplement

*p<0.05, **p<0.01, ***p<0.001 statistical comparisons are to the control group. Mean ±SEM (n=12).

Supplementation with lingonberries, blackcurrants or bilberries reduced weight gain, decreased body fat content and had positive effects on glucose homeostasis (Table 1). In addition to improving weight regulation, the lingonberries lowered inflammatory marker plasminogen activator inhibitor-1 (PAI-1), reduced liver weights and decreased levels of the liver enzyme alanine aminotransferase (ALT). The opposite was true for the group receiving açai berry. In addition, phosphorylation of protein kinase B as well as expression of hormone-sensitive lipase and other proteins involved in adipose lipid handling were significantly altered by lingonberries.

Conclusion: Lingonberries, as well as blackcurrants and bilberries, prevented the high-fat diet-induced metabolic abnormalities. In the case of lingonberries, this could to be mediated by mechanisms involving the adipose tissue.

Proteomic analysis in type 2 diabetes patients before and after a very low calorie diet reveals disease state and intervention specific biomarkers

M.A. Sleddering[1], A.J. Markvoort[2], H.K. Dharuri[3], S. Jeyakar[2], M. Snel[1], P. Juhasz[4], M. Lynch[4], W. Hines[4], X. Li[4], I.M. Jazet[1], A. Adourian[4], P.A.J. Hilbers[2], J.W.A. Smit[1], K. Willems van Dijk[3];
[1]General Internal Medicine and Endocrinology & Metabolism, C7-Q, Leiden University Medical Center, [2]Department of Biomedical Engineering, Eindhoven University of Technology, [3]Human Genetics, Leiden University Medical Center, Netherlands, [4]BG Medicine Inc., Waltham, USA.

Background and aims: Very low calorie diets (VLCD) with and without exercise programs lead to major metabolic improvements in obese type 2 diabetes (T2DM) patients. Using proteomic analysis, we aimed to further investigate the underlying mechanisms of a VLCD with or without exercise and to uncover possible biomarkers associated with these interventions.
Materials and methods: Blood samples were collected from 27 obese T2DM patients before and after a 16-week VLCD (Modifast®, ± 450 kcal/day). Thirteen of these patients followed an exercise program in addition to the VCLD. Plasma was obtained from 27 lean and 27 obese controls as well. Proteomic analysis on all available subjects was performed using mass spectrometry (MS) and targeted multiple reaction monitoring (MRM) for 13 proteins. A large scale Isobaric tags for relative and absolute quantitation (iTRAQ) approach was used in the T2DM patients only to identify a diet and/or exercise effect.

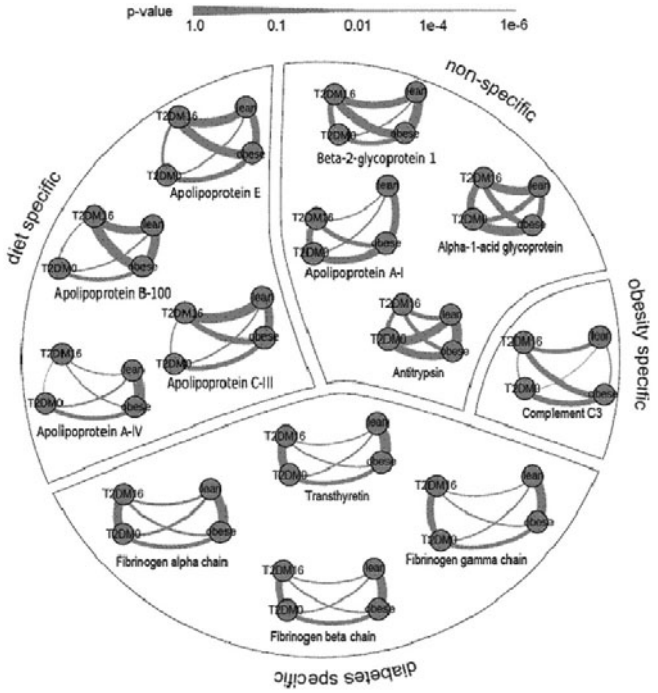

Figure 1. Graph representation of group wise comparisons for the proteins in the MRM data set. Comparisons between the four groups (diabetes patients at baseline (T2DM0) and after the 16-week VLCD (T2DM16) and obese and lean controls) are represented by edges. The thickness of the edge represents the p-value. Proteins have been clustered into groups (obesity, diabetes, diet and non-specific) based on similarity in patterns of differences between the groups.

Results: After the 16-week VLCD, there was a significant decrease in body weight (−27.2±1.9 kg VLCD+exercise; −23.7±1.6 kg VLCD-only, p=NS) and HbA1c (VLCD+exercise 7.8±0.4 vs. 6.3±0.4%; VLCD-only 7.8±0.3 vs. 6.7±0.3%, p=NS). Targeted MRM analysis in the T2DM patients and controls revealed differences in several proteins, which could be divided in obesity specific (complement C3), diet specific (apolipoproteins, especially apolipoprotein A-IV) and diabetes specific markers (Figure 1). The diabetes specific markers were related to coagulation (fibrinogens) and transport of thyroid hormones (transthyrethin). With the large scale iTRAQ analysis, for 87 of the 232 proteins that could be measured in all 27 patients at both time points, a significant VLCD effect after multiple-test correction was found. No proteins were found showing an exercise effect.
Conclusion: This study shows that proteomic analysis reveals possible biomarkers that are differentially expressed in type 2 diabetes patients versus controls and before and after a VLCD.

PS 067 Preventing and treating diabetes: the nutrition impact

870

Consuming snacks at mid-afternoon reduced the incremental area under the glucose curve after dinner in patients with type 2 diabetes

S. Imai[1], M. Fukui[2], N. Ozasa[3], S. Kajiyama[4,2];
[1]Graduate School of Comprehensive Rehabilitation, Osaka Prefecture University, [2]Graduate School of Medical Science, Kyoto Prefectural University of Medicine, [3]Graduate School of Medicine, Kyoto University, [4]Kajiyama Clinic, Kajiyama Clinic, Kyoto, Japan.

Background and aims: Postprandial plasma glucose and glycaemic spikes are associated with cardiovascular diseases in patients with diabetes. The aim of this study was to evaluate whether consuming snacks at different time of the day could change the postprandial glucose excursions in Japanese patients with type 2 diabetes.
Materials and methods: This was a randomized, controlled, two-treatment, crossover study. Thirteen patients with type 2 diabetes (Male 46%, Age 68.5 ± 6.1 yrs, HbA1c 7.4 ±1.2%: mean ± SD) were assigned to perform continuous glucose monitoring system (CGMS, Medtronic Minimed Gold, Northridge, CA) for 72-h by eating snacks at different time of the day. At 12:00 of the first day, each participant wore a CGMS at the clinic, and the 2nd and the 3rd day all subjects consumed the test meals at 7:00, 12:00, and 19:00, and snacks at 12:30 or 15:30 at home, and at noon of the 4th day a CGMS was removed at the clinic. The test meals consist of rice/bread, meat/fish, 500 g of vegetables, and contain 21 g of dietary fiber: the energy ratio was 58, 17, and 25% from carbohydrates, proteins, and fat, respectively. Snacks (biscuits 18 g, 75 kcal, carbohydrate 13.5 g, protein 1.2g, fat 1.8 g) were consumed after lunch (12:30) or between lunch and dinner (15:30) in a random order on the 2nd and the 3rd day. The daily glucose fluctuations were assessed by the following parameters obtained from CGMS and compared between two different days: the mean blood glucose (MBG), standard deviation (SD), mean amplitude of glycaemic excursions (MAGE), large amplitude of glycaemic excursions (LAGE), incremental glucose peak (IGPs), postprandial blood glucose, and the incremental area under the curve for blood glucose (IAUCs).
Results: The IAUCs 0-5 after lunch, and dinner were significantly reduced 20 to 30% by consumption of the snacks at 15:30 compared to consuming immediately after lunch. The incremental glucose peak after lunch was significantly higher by consumption of the snacks at 12:30 compared to consuming at 15:30. However, the levels of MBG, SD, MAGE, and LAGE did not differ between two treatments.
Conclusion: Consuming snacks at mid-afternoon leads to a reduction by 30% the IACU after dinner in patients with type 2 diabetes, possibly because of second-meal like effect.

Characteristics of glycaemic excursion when patients consumed snacks at 12:30 and 15:30

	Patients with type 2 diabetes (n=13)						
	Snacks at 12:30			Snacks at 15:30			P
MBG (mmol/L)	9.5	±	2.6	9.5	±	2.5	n.s.
SD (mmol/L)	2.1	±	0.6	2.0	±	0.7	n.s.
MAGE (mmol/L)	6.8	±	1.9	6.0	±	2.3	n.s.
LAGE (mmol/L)	9.1	±	2.2	8.3	±	3.0	n.s.
IGP after lunch (mmol/L)	6.6	±	2.7	5.4	±	2.1	< 0.01
IGP after dinner (mmol/L)	5.0	±	2.0	4.1	±	3.2	n.s.
IAUC 0-5 after lunch (mmol•min/L)	1144	±	588	936	±	493	< 0.05
IAUC 0-5 after dinner (mmol•min/L)	761	±	439	547	±	476	< 0.05

Data are expressed as mean ± SD. Snacks consumed at 12:30 vs.15:30.

Abbreviations: MBG, mean blood glucose; SD, standard deviation; MAGE, mean amplitude of glycaemic excursions ; LAGE, large amplitude of glycaemic excursions; IGP, incremental glucose peak; IAUC: incremental area under the curve for blood glucose.

Effects of vitamin D supplementation on insulin sensitivity and secretion in subjects with type 2 diabetes: a randomised controlled trial

H.L. Gulseth[1], C. Wium[1,2], E.F. Eriksen[1,2], K.I. Birkeland[1,2];
[1]Department of Endocrinology, Morbid Obesity and Preventive Medicine, Oslo University Hospital, [2]Institute of Clinical Medicine, University of Oslo, Oslo, Norway.

Background and aims: Low serum levels of 25 hydroxy-vitamin D (25(OH) D) are common and have been linked to impaired glucose metabolism and development of type 2 diabetes. We tested whether cholecalciferol supplementation could improve insulin sensitivity and insulin secretion.
Materials and methods: In a 6-month parallel group, placebo-controlled, double-blind, randomized trial patients with type 2 diabetes and hypovitaminosis D (25(OH)D)<50 nmol/L) received oral vitamin D_3 or placebo. A dose of 400,000 IU vitamin D_3 was given at baseline, followed by 200,000 IU after 6 weeks if 25(OH)D <100 nmol/L. Insulin sensitivity was measured by euglycaemic, hyperinsulinaemic clamp, with endogenous glucose production measured by tracer dilution method, giving the total glucose disposal rate (GDR). Insulin secretion was measured as insulin incremental area under curve from 0-10 minutes ($iAUC_{0-10}$) after an intravenous glucose tolerance test (IVGTT). Vitamin 25(OH)D was measured using radioimmunoassay (DiaSorin).
Results: Subjects (n=61, 48% females) were of Nordic (n=43) and South-Asian (n=18) ethnicity: Mean (SD) age was 57.7 (9.6) years, BMI 31.9 (5.2) kg/m2, HbA1c 7.8 (1.4)% and diabetes duration 10.3 (6.2) years. Serum 25(OH)D was 37.4 (12.1) nmol/L at baseline, and increased in the intervention group (D_3 group) to 73.2 (13.7) nmol/L after 3 months, and remained unchanged in the control group, p<0.001. Supplementation with vitamin D_3 had no effect on glycaemic control. We observed no changes in insulin sensitivity or insulin secretion between baseline and six months, neither within nor between groups (**table 1**).
Conclusion: In a 6-month placebo-controlled, double-blind randomized trial of oral vitamin D_3 or placebo, patients with type 2 diabetes and hypovitaminosis D did not improve glycaemic control, insulin sensitivity or insulin secretion.

Table 1. Effects of vitamin D supplementation on insulin secretion and insulin sensitivity

	Vitamin D_3 group		Placebo group		p-value (D_3 vs pl)
	Baseline	Change	Baseline	Change	
Glucose disposal rate (μmol/m²/min)	1163[661]	105 (-173, 383)	969[730]	106 (-70, 235)	0.99
Insulin $iAUC_{0-10}$ (pmol/l/min)	118 [164]	- 1,5 (-49, 46)	205[367]	16 (-144, 175)	0.83
HbA1c (%)	7.5 [2.1]	0.3 (-0.1, 0.6)	7.4 [1.6]	0.3 (0.0, 0.4)	0.82

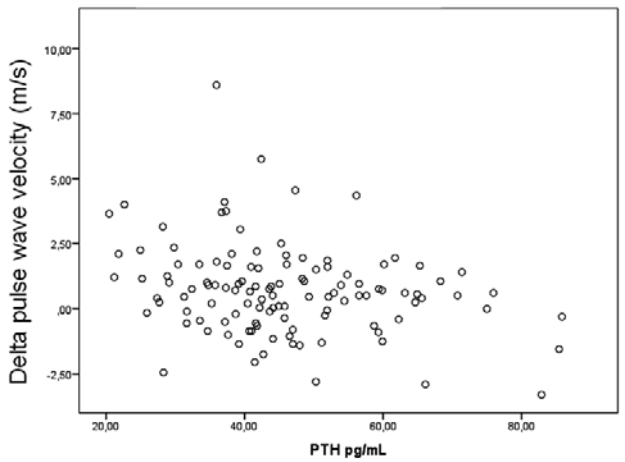
Vitamin D is positively related to the increase of pulse wave velocity during 4 years in men with type 2 diabetes while PTH levels are related to less such arteriosclerosis in women

F.H. Nystrom, H. Guldbrand, T. Lindström, P. Jennersjö, T. Länne, C. Östgren;
Department of Medical and Health Sciences, Faculty of Health Sciences, Linköping, Sweden.

Background and aims: Levels of Vitamin D have been shown to be negatively associated with obesity in many cross-sectional studies and some studies have suggested, although not entirely conclusive, that Vitamin-D levels relate favourably to pulse wave velocity (PWV). The aim of this analysis was to cross-sectionally, and also prospectively, explore associations between levels of Vitamin-D and PTH to PWV in patients with type 2 diabetes.
Materials and methods: PWV was measured with applanation tonometry over the carotid and femoral arteries. The baseline measurements of PWV were started in 2006 and it was repeated at a follow-up investigation four years later. Vitamin-D, PTH and other potential cardiovascular risk markers were measured in serum at baseline
Results: The cohort comprised of 454 male and 239 female patients with type 2 diabetes aged 55--65 years at the baseline investigation. Sagittal abdominal

diameter (SAD) correlated negatively with Vitamin-D in both genders (men: r = -0.129, p = 0.006, women: r= -0.189, p= 0.003). In men there was no correlation between PWV at baseline and Vitamin-D or PTH levels (p >0.4 for both) while there was a borderline significant correlation between Vitamin-D and PWV in women (Vitamin-D r= -0.124, p= 0.063, PTH p= 0.98). At follow up 278 men and 117 women were alive and participated in the re-investigation. Baseline Vitamin-D, but not PTH, correlated positively with the change (increase) in PWV at follow-up in men (Vitamin-D r= 0.134, p= 0.02, PTH p=0.7) while PTH levels at baseline were negatively correlated with increased PWV in women (Vitamin-D r= 0.105, p= 0.24, PTH r= -0.26, p=0.004). In multivariate analyses the correlations between Vitamin-D in men and PTH in women with delta PWV were independent of ApoB/ApoA1, corrected s-Ca, SAD, statin-use and ambulatory systolic blood pressure levels.

Conclusion: While we verified a cross-sectional negative relationship between Vitamin-D levels and obesity in this cohort, Vitamin-D levels were related to increased arterial stiffness in men while serum PTH in women was associated with a lower increase in this measure of arteriosclerosis. These prospective findings do not support the idea that an increased use of Vitamin-D would be beneficial with regard to cardiovascular disease in men with type 2 diabetes.



Relationship between baseline serum PTH and 4-year change (increase) of PWV in women with type 2 diabetes. r= -0.265, p= 0.004

Randomisation to a low-carbohydrate diet improves health related quality of life compared with a low-fat diet at similar weight loss in type 2 diabetes

T. Lindström, M. Bachrach-Lindström, H. Guldbrand, B. Dizdar, B. Bunjaku, C. Östgren, F.H. Nyström;
Department of Medical and Health Sciences, Linköping, Sweden.

Background and aims: While some studies have investigated the effect of weight reduction on health related quality of life (HRQoL) in patients with obesity or type 2 diabetes there are very few data comparing the effect of different diet regimens. The aim was to compare the effects on HRQoL of a 2-year intervention in patients with type 2 diabetes with a low-fat diet (LFD) or a low-carbohydrate diet (LCD) based on four group-meetings to achieve compliance.

Materials and Methods: Prospective, randomized trial of 61 adults with type 2 diabetes. The SF-36 questionnaire was used at baseline, 6, 12 and 24 months. Patients on LFD aimed for 55-60 energy percent (E%) and those on LCD for 20E% from carbohydrates.

Results: Mean body-mass-index was 32.7±5.4 kg/m^2 at baseline. Weight-loss did not differ between groups and was maximal at 6 months, LFD: -3.99±4.1 kg, LCD: -4.31±3.6 kg, (p<0.001 within groups). At 12 months the Physical Function, Bodily Pain, General Health and Vitality improved in the LCD group compared to baseline (Table 1) while there was no change in the LFD group. There was an increase in the Physical Component Score of SF-36 from 44.1 (10.0) to 46.7 (10.5) at 12 months in the LCD group (p<0.009) while no change occurred in the LFD group (p<0.03 between groups). Mental Component Score was unchanged in both groups.

Conclusion: Weight-changes did not differ between the diet groups while improvements in HRQoL only occurred after one year during treatment with LCD. No changes of HRQoL occurred in the LFD group in spite of a similar reduction in body weight. Thus based on the results from SF-36 our data suggest that a LCD is preferable compared with a LFD for HRQoL after one year follow-up.

SF-36 domain	baseline	12 months	P value
Physical Function	77.7 (19.3)	83.6 (18.2)	0.009
Bodily Pain	61.0 (23.0)	71.4 (22.1)	0.021
General Health	63.2 (22.3)	70.7 (22.7)	0.031
Vitality	62.2 (19.9)	69.8 (19.3)	0.042

Nutritional screening in elderly type 2 diabetic patients admitted in a ward

M.C. Carvalho, T. Santos, I. Silva, R. Carvalho, H. Figueiredo;
Medicine, Hospital de Seia, Seia, Portugal.

Background: Elderly patients are more prone to malnutrition and, among many factors, Diabetes can contribute to this increased risk. There are few data correlating Diabetes and malnutrition in older people (≥ 65 years).

Aim: To evaluate nutritional state in type 2 Diabetic patients over 65 years admitted for various reasons to the internal medicine ward in our hospital.

Materials and methods: The authors performed an observational study evaluating consecutively 244 elderly diabetic patients from 1st June 2009 to 31st January 2013 and compared them to a group of 358 non-diabetic elderly patients. The clinical tool was the Mini Nutritional Assessment (MNA).The MiniNutritional Assessment (MNA) stratifies nutritional state from 0 to 30: malnutrition (<17), malnutrition risk (17,5-23,5) and normal (>24).This tool was validated in Portugal in 2008.Statistical analysis was performed by SPSS 17.0 for Windows, when appropriate.

Results: The 244 elderly diabetic patients (59% female and 41% male) had a mean age of 81,89 ± 7,77 years. There was no statistical significant difference from the 358 non-diabetic control group (56,1% female, 43,9% male with a mean age of 81,06 ± 7,87 years, p > 0,05). Mean MNA score in diabetic elderly patients was significantly lower than in the control group (15,39 ±5,62 vs 18,89±5,28, p < 0,001). In diabetic patients, 14,3% were well nourished, 64,8 % were classified with malnutrition e 20,9 % with malnutrition risk (values of 26,5%, 35,8 % e 37,7% respectively for control group, p< 0,001). Overall, we have found 64,2% Diabetic patients with nutritional problems vs 35,2% in the control group. The item that was observed more frequently in the diabetic population and therefore responsible for this nutritional state was limited mobility (83% vs 58% (p<0,001)). We have also observed significantly more elderly diabetic patients with malnutrition coming from institutions than from home setting. (MNA score diabetic 14,42 +/-4,79 vs MNA score controls 19,52 +/- 5,25,p < 0,001).

Conclusion: Our results show that malnutrition is more prevalent in elderly people with type 2 diabetes admitted to a medical ward for various reasons, which implies that they must be identified for specific nutritional intervention. There will be necessarily more studies to evaluate the causes and the complex relationship between type 2 diabetes and malnutrition in elderly patients.

Higher urinary sodium excretion is weakly associated with albuminuria, but not with retinopathy in type 1 diabetes: the EURODIAB study

L. Engelen[1,2], S.S. Soedamah-Muthu[3], J.M. Geleijnse[2,3], N. Chaturvedi[4], J.H. Fuller[5], C.G. Schalkwijk[1,2], C.D.A. Stehouwer[1,2];
[1]Internal Medicine, Maastricht University, [2]Top Institute Food and Nutrition, Wageningen, [3]Human Nutrition, Wageningen University, Netherlands, [4]National Heart and Lung Institute, Imperial College London, [5]Epidemiology and Public Health, Royal Free and University College London Medical School, UK.

Background and aims: Nutritional advice that favourably affects cardiovascular risk factors, such as blood pressure (BP), may also have a favourable effect on microvascular complications. Restriction of salt intake is known to reduce BP. Population-based studies have shown positive associations of 24-hour urinary sodium excretion, which is currently regarded the reference standard for salt intake estimation, with microalbuminuria. In individuals with type 1 diabetes (T1DM), urinary sodium excretion has been associated with all-cause mortality and end-stage renal disease. The association of salt intake with (early) microvascular complications in individuals with T1DM, however, has not yet been established. We studied the association of urinary sodium excretion with the prevalence of microalbuminuria, macroalbuminuria, non-proliferative and proliferative retinopathy in individuals with T1DM.
Materials and methods: We measured sodium and potassium concentrations in two 24-hour urine samples in 1,212 individuals with T1DM who participated in the EURODIAB Prospective Complications study. We used multiple logistic regression analyses to investigate cross-sectional associations of urinary sodium excretion with the prevalence of microvascular complications. Adjustments were made for age and sex and additionally for BMI, smoking, urinary potassium excretion, use of antihypertensive medication, physical activity, and total energy, alcohol, saturated fat and fiber intake.
Results: Individuals (51% men) were (mean ± SD) 40 ± 10 years old, with a diabetes duration 22 ± 9 years, HbA1C 8.4 ± 1.5%, SBP 121 ± 19 and DBP 74 ± 12 mm Hg. Of the 1,212 individuals currently investigated, 205 and 143 individuals had micro- and macroalbuminuria; 507 and 224 individuals had non-proliferative and proliferative retinopathy, respectively. The 24-hour urinary sodium excretion was 3.96 ± 1.60 g/day, which corresponds to a dietary salt intake of 9.90 g/day. After adjustment for age and sex, 1 g/day higher salt intake was positively associated with microalbuminuria [OR: 1.06 (95%CI: 1.02; 1.10)], but not with macroalbuminuria [1.00 (0.95; 1.04)], non-proliferative retinopathy [1.02 (0.98; 1.05)] or proliferative retinopathy [0.99 (0.94; 1.03)]. After excluding individuals with CVD and/or antihypertensive medication (n=433), the association with microalbuminuria became borderline significant [1.05 (1.00; 1.10)], with no significant associations for macroalbuminuria [1.04 (0.96; 1.12)], non-proliferative retinopathy [1.01 (0.97; 1.05)] or proliferative retinopathy [1.02 (0.95; 1.09)]. Essentially the same results were found in the fully adjusted models.
Conclusion: In individuals with T1DM, high salt intake, as determined by urinary sodium excretion, may be positively associated with albuminuria, but not with retinopathy. Further investigation in prospective studies is warranted to address the role of dietary salt intake in the development of microvascular complications in T1DM.

876

Breastfeeding and the risk of developing type 1 diabetes or islet autoimmunity

N.A. Lund-Blix[1,2], L. Frost Andersen[1], K. Skjold Rønningen[2];
[1]Department of Nutrition, University of Oslo, [2]Department of Pediatric Research, Oslo University Hospital, Norway.

Background and aims: The increased incidence of type 1 diabetes (T1D) suggests a role for environmental factors in the development of the disease. Early nutrition, as an important environmental source of exposure, may contribute significantly to the development of T1D, but there is a lack of evidence for this from prospective studies in humans. The effect of breastfeeding on T1D and islet autoimmunity clearly varies between studies, showing inconsistent results. The aim of this study was to investigate the association between breastfeeding and the risk of developing T1D or islet autoimmunity.
Materials and methods: Data were derived from a prospective cohort study (MIDIA) with inclusion of children identified with the high-risk HLA genotype, with follow-up from three months up to 15 years of age. Close to 48000 newborns were genotyped, and 1047 were identified with the high-risk genotype. A questionnaire was filled out by the parents when the child was 3, 6, 9 and 12 months of age. Blood samples were obtained from children at the same intervals. The WHO definitions were used to categorise breastfeeding into "full breastfeeding" and "any breastfeeding". Full breastfeeding was categorised into two groups: <3 months and ≥3 months. Any breastfeeding was categorised into two groups: ≤6 months and >6 months. Logistic regression analyses were applied to study T1D and islet autoimmunity in relation to full breastfeeding, any breastfeeding and other parental and infant characteristics. Data were then adjusted for variables associated with T1D and islet autoimmunity.
Results: The multivariate analysis included full breastfeeding and any breastfeeding separately, and having a first degree relative with T1D as the only variable associated with T1D or islet autoimmunity ($p < 0.001$). There was no significant association between T1D and full breastfeeding (OR 1.28; $p = 0.66$), or any breastfeeding (OR 1.01; $p = 0.99$), after adjusting for first degree relatives with T1D. There was no significant association between islet autoimmunity and full breastfeeding (OR 1.30; $p = 0.41$), or any breastfeeding (OR 1.25; $p = 0.51$), after adjusting for first degree relatives with T1D.
Conclusion: Based on the data from the MIDIA study, we explored the association between breastfeeding and the risk of developing T1D or islet autoimmunity. Our key finding was that full breastfeeding was not significantly associated with either T1D or islet autoimmunity, and neither was any breastfeeding.

Effect of omega 3/ALA supplementation on inflammatory markers and ER stress in diabetic rats

M.C. Foss-Freitas, T.R. Vidal, T.N. Griffo, N.B. Gonçalves, M.A.N. Ferreira, M.C. Foss;
Department of Internal Medicine - Division of Endocrinology and Metabology, Ribeirao Preto School of Medicine - Sao Paulo University, Ribeirao Preto, Brazil.

Background and aims: A state of chronic and subclinical inflammation is often observed in diabetic patients and more recently it has been associated to activation of the endothelium reticulum stress (ERS). Previous studies have shown that polyunsaturated fatty acids ω3 eicosapentaenoic acid (EPA; C20:5n-3) and docosahexaenoic acid (DHA; C22:6n-3) can reduce inflammation, but little is known about the effect of ω3 α-linolenic acid (ALA; C18:3n-3). The ω3/ALA is the primary fatty acid of the n-3 pathway found in seeds oils, notably those of flaxseeds and chia. The aim of this study was to evaluate the effects of ω3/ALA supplementation on inflammation and ERS in animal models of diabetes mellitus.
Materials and methods: 40 wistar rats (150g) were divided into four groups: control, control+ω3, diabetes and diabetes+ω3. Induction of diabetes was performed using 40mg/kg of streptozotocin iv. The control+ω3 and diabetes+ω3 received supplementation of 3g of ω3/ALA from flaxseed, daily for a period of 8 weeks. Measurements of serum glucose, lipid profile serum cytokines (TNF-α, IL-6 and INF-γ) and body weight were performed before the beginning of the supplementation (T1) and by the end of this period (T2). Data of liver and epididimal fat weight were collected no T2. Protein expression of AKT, TNF-α, IL-6, BIP, IRE1a, PERK, XBP-1, DAPK1 and GADD153 were evaluated by western blot in liver tissue of the diabetic groups.
Results: The diabetes+ω3 group had lower liver ($p<0.001$) and greater epididimal adipose tissue ($p=0.04$) weight in relation to the diabetes group, besides no difference in total body weight. On the other hand, the control+ω3 group showed increased liver ($p=0.001$), epididimal ($p<0.001$) and body weight ($p<0.001$). Diabetes+ω3 group showed lower glucose ($p=0.01$) and triglyceride ($p<0.001$) levels on T2, but no difference in total cholesterol. Serum levels of TNF-α and IL6 were lower in the diabetic groups compared to the control groups but the ω3/ALA supplementation did not determine significant changes. However, the diabetic+ω3 group showed a decrease in the INF-γ serum levels after the supplementation period. We also observed that diabetes+ω3 group had increased expression of BIP (50.4%;$p=0.01$) and AKT (37.5%;$p=0.03$) and decreased expression of XBP-1 (7.0%;$p=0.004$), IRE1a (23.3%;$p=0.03$) and TNF-α (12.2%;$p=0.04$). There were no difference in the expression of PERK, GADD153, DAPK1 and IL-6.
Conclusion: Supplementation of ω3/ALA was able to reduce blood glucose and triglyceride in diabetic rats associated to a reduction in systemic inflammation as observed by the lower levels of INF-γ. Our data also shows that ω3/ALA supplementation was able to influence important pathways involved in the ERS, suggesting that this polyunsaturated fatty acid may modulate the ERS.

Glucose tolerance and gastrointestinal-mediated glucose disposal in women with previous gestational diabetes mellitus

S. Foghsgaard[1], L. Vedtofte[1], E.R. Mathiesen[2], J.A. Svare[3], P. Damm[4], F.K. Knop[1], T. Vilsbøll[1];
[1]Diabetes Research Division, Department of Medicine, Copenhagen University Hospital Gentofte, Hellerup, [2]Center for Pregnant Women with Diabetes, Department of Endocrinology, Rigshospitalet, Copenhagen, [3]Department of Obstetrics and Gynaecology, Copenhagen University Hospital Herlev, [4]Center for Pregnant Women with Diabetes, Department of Obstetrics, Rigshospitalet, Copenhagen, Denmark.

Background and aims: Women with previous gestational diabetes mellitus (GDM) are at high risk of developing type 2 diabetes mellitus later in life, and constitute an excellent opportunity for studying the early stages of diabetes. Gastrointestinal-mediated glucose disposal (GIGD) is the result of all factors affecting glucose disposal differently during oral glucose ingestion versus an i.v. glucose infusion. GIGD is decreased in patients with type 2 diabetes, and the aim of this study is to explore whether reduced GIGD precedes the type 2 diabetic state and already can be detected in high-risk individuals, i.e. women with previous GDM.
Materials and methods: Twenty-six non-diabetic women with previous GDM (age: 37±1 years (mean±SEM); BMI: 30.9±1.0 kg/m^2; waist-hip ratio: 0.9±0.0; fasting plasma glucose (FPG): 5.5±0.1 mM; HbA_{1c}: 5.4±0.1 % (36±1 mmol/mol) were examined on two separate occasions: 1) 4h 75g-OGTT and 2) isoglycaemic i.v. glucose infusion (IIGI). Based on the FPG and the 2h value of the OGTT, the women were classified as having normal glucose tolerance (NGT) or prediabetes (defined as impaired fasting glucose (IFG), and/or impaired glucose tolerance (IGT)). Using the isoglycaemic clamp technique, GIGD was calculated as the percent difference in the amount of glucose given during the OGTT and IGII divided by the amount given during the OGTT [100% × (glucose$_{OGTT}$ - glucose$_{IIGI}$ / glucose$_{OGTT}$)].
Results: Nine out of 26 women were NGT (35%) and 17 (65%) were diagnosed with prediabetes. Two-hour plasma glucose concentrations during OGTT differed significantly between the groups (6.9±0.2 vs. 9.3±0.3, p<0.001). The groups were similar with respect to age, BMI, waist-hip ratio, FPG, and HbA_{1c}. No difference in GIGD was seen (57±7 vs. 49±3%, p=0.26).
Conclusion: Our results show that prediabetes is prevalent in women with previous GDM. No significant difference in GIGD was seen between women with NGT and prediabetes.

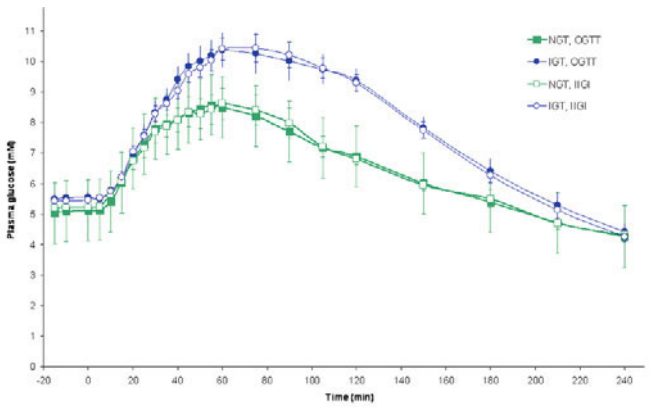

Figure 1. Plasma glucose profile during OGTT (filled symbols) and isoglycaemic i.v. glucose infusion (IIGI) (open symbols) for normal glucose tolerant women (green) and prediabetic women (blue). NGT: normal glucose tolerant, IGT: impaired glucose tolerance.

The impact of dipeptidyl peptidase 4 inhibition on incretin effect, glucose tolerance, and gastrointestinal-mediated glucose disposal in healthy subjects

N.A. Rhee[1], S.H. Østoft[1], J.J. Holst[2], T. Vilsbøll[1], F.K. Knop[1];
[1]Department of Internal Medicine, Gentofte Hospital, Diabetes Research Division, Hellerup, [2]Department of Biomedical Sciences, the Panum Institute, Copenhagen, Denmark.

Background and aims: Inhibition of the enzyme dipeptidyl peptidase 4 (DPP-4), which under normal circumstances degrades and inactivates the incretin hormones glucose-dependent insulinotropic polypeptide (GIP) and glucagon-like peptide-1 (GLP-1), is thought to intensify the physiological effects of incretins. We aimed to investigate the effects of DPP-4 inhibitor-induced increments of active GIP and GLP-1 levels on glucose tolerance, incretin effect, gastrointestinal-mediated glucose disposal (GIGD) and gastric emptying in healthy subjects.
Materials and methods: Ten healthy subjects (age: 40±5 years (mean±SEM); body mass index: 24±3 kg/m2, fasting plasma glucose: 5.1±0.2 mmol/l; HbA1c: 5.3±0.1% [34 mmol/mol]) were subjected to two paired study days each constituting a 4h 50 g-OGTT (A) and an isoglycaemic i.v. glucose infusion (IIGI) (B) with (A1+B1) and without (A2+B2) preceding administration of the DPP-4 inhibitor sitagliptin (100 mg 12 hours and 2 hours before each experimental day).
Results: Isoglycaemia was obtained with and without DPP-4 inhibition in all subjects. Significant increases in active GLP-1 and active GIP levels were seen during fasting conditions and especially during OGTT after DPP-4 inhibitor administration. No significant impact of DPP-4 inhibition on fasting plasma glucose (5.1±0.1 vs 4.9±0.1 mmol/l, p=0.3), glucose tolerance (evaluated as AUC for plasma glucose: 151±35 vs 137±26 mmol/l×min, p=0.7) or peak plasma glucose during OGTT (8.5±0.4 vs 8.1±0.3 mmol/l, p=0.3) was observed. Neither incretin effect (40±9 without DPP-4i vs. 40±7% with DPP-4i, p=1.0), glucagon responses (1,395±165 vs. 1,223±195 pmol/l, p=0.41), GIGD (52±4 vs. 56±5%, p=0.40) or gastric emptying (measured as peak concentration time (86±9 without vs. 80±12 min with DPP-4i, p=0.60) changed following DPP-4 inhibition.
Conclusion: These results suggest that acute increases in active incretin hormone levels (achieved via inhibition of DPP-4) do not affect GIGD, incretin effect, glucagon responses, glucose tolerance or gastric emptying in healthy subjects.
Clinical Trial Registration Number: NCT01342939

Substantial posprandial appearance of active GLP-1 in the gut lymphatics in mice with marked increase after DPP-4 inhibition

L. Ohlsson[1], A.B. Kohan[2], P. Tso[2], B. Ahrén[1];
[1]Dept of Clinical Sciences, Lund, Sweden, [2]Dept of Pathology and Laboratory Medicine, Cincinnati, USA.

Background and aims: After secretion from intestinal L-cells, the incretin hormone glucagon-like peptide-1 (GLP-1) is rapidly degraded by dipeptidyl peptidase-4 (DPP-4) before reaching the portal system leaving only a small fraction of active GLP-1 in peripheral blood. This inactivation hampers measurements of GLP-1 secretion under in vivo conditions, since peripheral plasma GLP-1 determinations only weakly reflect secretion rates. To quantify GLP-1 secretory rates, we have harnessed on the fact that GLP-1 appears in the gut lymphatics after its release from L-cells, and have developed a technique analyzing lymphatic GLP-1 levels after macronutrient ingestion. The aim of this study was to validate this novel technique and examine gut lymphatic GLP-1 after macronutrient ingestion with or without concomitant DPP-4 inhibition.
Materials and methods: Anesthetized C57BL6/J mice were fitted with both a mesenteric lymph duct and stomach cannula before being infused with either glucose or fat emulsion (IntralipidR) (both 0.3 kcal) into the stomach, with or without concomitant administration of an orally active DPP-4-inhibitor (10 µmol/kg NVP DPP728). Lymph was collected sequentially in 30 min intervals up to four hours. DPP-4 activity (enzymatic method) and active GLP-1 concentrations (ELISA) were measured in lymph and plasma (orbital plexus) at corresponding time points.
Results: DPP-4 activity in lymph was only 18±2% of that in peripheral plasma (P<0.001) with no significant variation after macronutrient ingestion. The DPP-4-inhibitor NVP DPP728 decreased DPP-4 activity by 57% and 43 % in lymph and plasma for 2 hours (both P<0.001). Basal concentrations of active GLP-1 in lymph were 4.7 times higher than in plasma (1.17 ± 0.2 vs. 0.25 ± 0.05 pg/ml, p=0.04), whereas peak levels after glucose infusion were 140 times higher in lymph than in plasma (42±17 vs. 0.3±0.02 pg/ml, p= 0.09). Peak GLP-1 was raised three-fold by DPP-4 inhibition (to 152±46 and 1.2 ± 0.21 pg/ml p=0.08). The concentrations of active GLP-1 in lymph after intralipid were similar with and without NVP DPP728 during the initial 60 minutes (27± 5.8 and 24 ± 16 pg/ml). Thereafter, GLP-1 levels decreased without NVP DPP728, but remained high for a prolonged period of time with NVP DPP728 (40±15 pg/ml after 150 min).
Conclusion: There is a substantial release of active GLP-1 into mesenteric lymph after macronutrient ingestion, resulting in a many fold higher GLP-1 concentration in lymph than in peripheral plasma. DPP-4 inhibition further increased the concentration of active GLP-1 by a factor of three in both lymph and plasma. Thus, we conclude that measurement of active GLP-1 in mesenteric lymph is a valuable tool for quantifying GLP-1 secretion in vivo, and oral DPP-4 inhibition has substantial effect on the pool of active GLP-1 emerging from the lymph into the subclavian vein after intake. Figure: DPP4 activity in plasma and lymph (a) and GLP-1 concentration in lymph (b) after intake of glucose or Intralipid.

Effects of miglitol, sitagliptin and combination of both on plasma incretins' responses to a mixed meal and visceral fat in over-weight Japanese type 2 diabetic patients

T. Narita[1], H. Yokoyama[2], R. Yamashita[2], M. Suzuki[2], Y. Horikawa[3], A. Mikada[1,3], K. Tsukiyama[4,3], Y. Yamada[1,4];
[1]Department of Endocrinology, Diabetes and Geriatric Medicine, Akita University Graduate School of Medicine, Akita, [2]Internal Medicine, Jiyugaoka Medical Clinic, Obihiro, [3]Gastroenterology and Diabetes Unit, Hiraka General Hospital, Yokote, [4]Department of Metabolism and Clinical Nutrition, Akita University School of Medicine, Akita, Japan.

Background and aims: Alpha-glucosidase inhibitors (AGIs) induce reduced gastric inhibitory polypeptide (GIP) and enhanced glucagon-like peptide-1 (GLP-1) responses after a meal. Dipeptidyl peptidase-4 (DPP-4) inhibitors induce enhanced active GIP and GLP-1 levels. In combination of both, although additive enhancement of plasma active GLP-1 levels has been reported, changes in active GIP levels have not been examined. Further, effects of combination of both on body fat compositions have not been examined although AGIs induce body weight (BW) reduction and DPP-4 inhibitors have neutral effect on BW.

Materials and methods: In this multicenter, open 24-week trial, Japanese over-weight (BMI of 25 or more) type 2 diabetic patients (T2Ds) without medication or with metformin and/or sulfonylurea were randomized assigned to receive 50 mg of miglitol (M, n=14) three times per day, sitagliptin (S, n=14) 50 mg once a day or combination of both (M+S, n=13). We measured plasma active GIP and GLP-1 at 0, 30, 60, 120 min during a meal tolerance test (MTT) at baseline and 24 weeks after the treatment. Active GLP-1 was measured using a commercially available kit (Linco Research). Active GIP was measured by LC-MS/MS/MS method. Visceral fat (VF) mass was measured with body composition analyzer X-Scan plus (JAWON MEDICAL). Data are expressed as mean (SE). *, ** indicate p<0.05 and p<0.01 by Wilcoxon signed-ranks test, respectively.
Results: During MTTs before and after M, S and M+S, plasma glucose-AUCs were significantly reduced from 364.9 (13.1), 394.4 (17.8), 414.4 (19.4) to 320.2 (17.1)*, 346.9 (15.4)*, 289.7 (13.6)** mg•hr/dl, respectively. M and M+S significantly reduced serum insulin-AUCs whereas S increased serum insulin-AUC significantly. As seen in figure, M decreased active GIP at 30 min and increased 120 min during MTT. S increased active GIP significantly throughout MTT. The combination of both significantly increased active GIP at 0 and 120 min during MTT despite of significant decrease at 30 min during MTT without an AUC change. S and M+S increased active GLP-1 with significantly increased AUCs (approximately two and three folds, respectively). Changes in VF mass by M, S and M+S were -0.27 (0.11), -0.15 (0.17) and -0.45 (0.11)** kg.
Conclusion: The effects of the combination of M+S on glycemic control and active GLP-1 were additive whereas enhancement of active GIP by S is abolished by M+S with reduced VF mass. In over-weight T2Ds, the combination of both drugs may have a beneficial effect on adiposity with relation to different effects on two incretins.

Pharmacological characterisation of a novel long-acting CarboCarrier® D-Ala[8]GLP-1 for treatment of type 2 diabetes
S. Patterson[1,2], M. de Kort[3], W.H.A. Dokter[3], E.S. Bos[3], A.M.M. Miltenburg[3], P.R. Flatt[2];
[1]Department of Life Sciences, Glasgow Caledonian University, Glasgow, [2]SAAD Centre for Pharmacy and Diabetes, University of Ulster, Coleraine, UK, [3]Merck, Oss, Netherlands.

Background and aims: Novel long-acting GLP-1 analogues were synthesized using CarboCarrier® technology. Pharmacological properties of Org 249305-1 in which an ATIII binding pentasaccharide, derived from Idraparinux, was conjugated to Lys37 of D-Ala[8]-GLP-1 amide are reported.
Methods and results: In vivo half-life of Org 249305-1 in rat and mouse was ~ 11h, with resistance to DPP-IV degradation. Insulin secretion from clonal BRIN-BD11 cells and mouse islets was increased 2.1 - 4.1- fold (P<0.01-0.001) by Org 249305-1 at 10^{-8}M - 10^{-6}M. Org 249305-1 had EC-50 values of $10^{-6.7}$M and $10^{-7.0}$M for GLP-1 receptor binding and cAMP generation, respectively. Glucose tolerance in normal mice both immediately and 4-h post Org 249305-1 administration (25 nmol/kg) resulted in significant (P<0.001) reductions in blood glucose (AUC 41% and 65% lower, respectively). These effects persisted 48h post administration. Long-term treatment (21 days) of glucose intolerant high fat-fed Swiss NIH mice and C57/6J ob/ob mice with 25 nmol/kg Org 249305-1 resulted in significant improvement in glucose tolerance and reductions in HbA_{1c} of 0.5 - 1.0% (P<0.05-0.01). Treatment of diabetic C57/KsJ db/db mice for 15 days with 100 nmol/kg Org 249305-1 reduced (P<0.05-0.001) non-fasting glucose with raised plasma insulin. Oral glucose tolerance was significantly improved (P<0.001) and HbA1c reduced 1.8% compared to saline controls. Islet size and pancreatic insulin content were increased whereas glucagon content was decreased.
Conclusion: Org 249305-1 exerts significant antidiabetic actions and has a projected PK/PD profile compatible with once-weekly subcutaneous dosing in humans.

Long-term effects of liraglutide on pancreatic beta cell function and glycaemic control in type 1 diabetes with residual insulin secretion
Y. Hamamoto, S. Honjo, Y. Kawasaki-Ogita, H. Tatsuoka, K. Fujimoto, A. Matsuoka, H. Ikeda, Y. Wada, H. Koshiyama;
Center for Diabetes and Endocrinology, Kitano Hospital, Osaka, Japan.

Background and aims: Previously we reported that one-year liraglutide (Lira) added on ongoing insulin (Ins) therapy improved glycaemic control without increase in hypoglycaemia in patients with type 1 diabetes (T1D) with residual insulin secretion. In the study, however, no obvious beneficial effect on beta-cell function could be observed with Lira treatment. To investigate the longer-term effects of Lira and to compare the effects between Ins only and Lira plus Ins in the same arm, extension study was performed for another one year over the original study.
Materials and methods: This is an open-labelled, randomised, parallel-group study. A total of 15 subjects with type T1D (age 51.5±13.2yrs, BMI 22.5±3.1; mean±SD) who were positive for GADAb or IA-2Ab and had been treated with insulin more than one year with residual insulin secretion [C-peptide (CPR) level >0.3ng/ml] were enrolled in the original study, and 8 subjects have completed second-year evaluation. The subjects were randomised into two groups; Group A was administered Lira 0.9mg in addition to Ins therapy for 2 years, and group B continued the ongoing Ins for the first year and the second year Lira 0.9mg was added-on. As a primary outcome, changes in C-peptide response to glucagon- and arginine-stimulation test that were performed annually were evaluated. Changes in HbA1c, blood glucose (BG) by self-monitoring (SMBG), body weight, daily insulin dose, and adverse events (AE) were also investigated. For the first year, comparison was performed between the two arms, and as for the second year, the comparison was also performed between the first year and second year in the same arm.
Results: In group A, HbA_{1c} tended to decrease from 7.6±1.4 to 7.4±1.5% with decreased Ins dose from 0.66±0.29 to 0.58±0.24U/Kg/day in the first year but did not change in the second year. In group B, HbA_{1c} remained unchanged in the first year (from 7.7±0.6 to 8.1±0.5%) but decreased from 8.1±0.9 to 7.1±0.4% by addition of Lira with a significant decrease in Ins dose (from 0.66±0.29 to 0.58±0.29U/Kg/day, P<0.05). CPR response to arginine-stimulation varied among the subjects (mean 9.3±54.8%, range -55.6% to +66.4% compared to baseline in group A, and mean 7.1±33.2%, range -19.5% to +44.4% in group B in the first year; and mean -5.2±43.1%, range -53.5% to +47.4% in the second year in group A&B) suggesting that the response to Lira was different in the individual cases. Addition of Lira decreased glucagon response to arginine-stimulation by -11.9±13.9% (p<0.05 at the peak level).
Conclusion: The present findings suggest that adding Lira on Ins therapy may have a therapeutic potential to improve glycaemic control in T1D with a decrease in insulin dose. Although the effects of Lira on pancreatic beta-cell showed variation among the subjects, the major effect was considered to be exhibited through extra-beta-cell effects such as suppression of glucagon secretion rather than an increase of insulin secretion.

Dipeptidyl peptidase-4 inhibitors improve glycaemic control in latent autoimmune diabetes in adults (LADA) patients insufficiently controlled despite insulin therapy

O. Araki[1,2], R. Nakahara[2], K. Ujiie[2], K. Tsunekawa[1], T. Aoki[1], T. Morimura[1], T. Kimura[1], M. Nara[1], H. Sumino[1], T. Ogiwara[1], M. Murakami[1];
[1]Clinical Laboratory Medicine, Gunma University Graduate School of Medicine, Maebashi, [2]Tone-Chuo Hospital, Numata, Japan.

Background and aims: Latent autoimmune diabetes in adults (LADA) patients share many genetic and immunological similarities with type 1 diabetes (T1D), suggesting that LADA is an autoimmune disease. Dipeptidyl peptidase-4 inhibitors (DPP4i) have emerged as a new class of agents for the treatment of type 2 diabetes (T2D), and currently have been extending for their use to early T1D, because of their potential for shutting off autoimmunity and stimulating beta cell regeneration. It is possible that the therapeutic benefit of the DPP-IV inhibition on the immune system, in addition to resulting in increased circulating levels of GLP-1, may improve pathophysiological process of autoimmune mediated diabetes, we compared the impact of treatment with the DPP4i (sitagliptin) on HbA1c reductions and improvements of 1,5-anhydroglucitol (1,5AG) value in patients retrospectively identified with LADA who had insufficient glycemic control despite insulin therapy.
Materials and methods: Patients were classified as LADA if the GAD65 autoantibody was present at baseline or any on-treatment visit. GAD antibody was assessed with RIA.
Results: Of 118 patients with assumed T2D, 10.2% (n=12) had LADA, and 9.3%(n=11) had others (pancreatitis, liver cirrhosis, steroids diabetes, etc.). At baseline, patients age (64.7±12.6 yrs, mean ± SD), BMI 24.2±3.9 kg/m2, HbA1c (8.09±1.40 %), and dose of daily insulin (19.5±13.8 units) were not significantly different between LADA, T2D, and others. HbA1c reductions in LADA at 3 month and 6 month after the initiation of administration of sitagliptin (25mg; n=47, 50mg; n=71, once daily) were significantly (*; $p<0.05$) better than those of T2D and others (Figure). 1,5 AG at the same time points in LADA were significantly (*; $p<0.05$) increased than those of T2D and others.
Conclusion: DPP4i could have more beneficial impacts on glycemic control in LADA than T2D and others who were treated with insulin. Further research exploring the molecular mechanism of potential modulating effects of DPP4i on LADA is required.

Figure: Changes in HbA1c and 1,5AG over time by treatment with DPP4i and insulin

Exenatide blunts hyperactivation in CNS reward and satiety circuits elicited by viewing food cues in obese individuals

L. van Bloemendaal[1], R.G. IJzerman[1], J.S. ten Kulve[1], F. Barkhof[2], D.J. Veltman[3], M. Diamant[1];
[1]Diabetes Centre / Internal Medicine, [2]Department of Radiology, [3]Department of Psychiatry, VU University Medical Centre, Amsterdam, Netherlands.

Background and aims: It has been hypothesised that changes in central nervous system (CNS) reward and satiety responses to food stimuli play an important role in the development of obesity and type 2 diabetes (T2DM). Food ingestion activates the secretion of several gut-derived mediators, including the incretin glucagon-like peptide 1 (GLP-1). Based on animal studies, these hormones have been proposed to relay information to the CNS about nutritional status and regulate appetite. The GLP-1 receptor agonist (GLP-1RA) exenatide improves glycaemic control and promotes satiety, leading to reductions in food intake and body weight. GLP-1RA actions on the brain may partly mediate satiety and weight effects. We hypothesised that exenatide reduces food intake by affecting CNS reward and satiety circuits.
Materials and methods: Normoglycaemic obese (n=11; mean± SD age 58±8 yrs, BMI 32±3 kg/m^2; 6 males) and gender and age-matched normoglycaemic healthy lean controls (n=11; age 57±9 yrs, BMI 24±2 kg/m^2) were studied in a randomised, cross-over, placebo-controlled trial. We determined the acute effect of iv infusion of exenatide (infusion duration approximately 120 min, spanning the entire test) on CNS reward and satiety responses to visual food-related stimuli, using functional magnetic resonance imaging (fMRI), after an overnight fast. Pictures of high calorie food, low calorie food and non-food objects were presented. To avoid the effects of metabolic and hormonal changes induced by exenatide, a somatostatin pituitary-pancreatic clamp (glucose 5 mmol/L) was performed, with replacement of basal insulin, glucagon and growth hormone. After the fMRI, subjects were presented a choice buffet to assess energy intake. Imaging data were analysed using SPM8. For each subject, activation contrasts were computed (food versus non-food).
Results: Obese versus lean subjects showed increased brain activation, measured as changes in blood oxygenation level dependent (BOLD) signal, in bilateral insula and right caudate nucleus, when watching food versus non-food pictures ($p<0.005$). Exenatide versus placebo blunted these activations in bilateral caudate nucleus, left insula and left thalamus in obese individuals ($p<0.005$), but in lean controls the effects of exenatide did not reach statistical significance. Exenatide effects were more pronounced in obese women than in men. Exenatide versus placebo reduced caloric intake by 25% in lean and by 21% in obese subjects.
Conclusion: Exenatide blunted hyperactivation in reward- and satiety-related brain regions, elicited by viewing food cues in obese subjects, thus restoring an activation pattern that resembled that of lean controls. These findings lend support to the hypothesis that GLP-1RA affects food-related CNS reward and satiety, which may contribute to treatment-related weight loss.

Liraglutide is applicable in elective perioperative patients with type 2 diabetes

I. Nakadaira[1], K. Hamano[1], N. Katagiri[2], Y. Tahara[2], Y. Sato[2], S. Kaneko[2];
[1]Diabetes and Endocrinology, Kanto Rosai Hospital, Kawasaki, [2]Diabetes/Endocrinology, Takatsuki Red Cross Hospital, Takatsuki, Japan.

Background and aims: Diabetic patients in sedentary states during perioperative periods tend to gain weight, and their glycemic control frequently deteriorates. There is substantial evidence linking hyperglycemia in surgical patients with worse outcomes. On the other hand, temporary insulin therapy needs frequent monitoring of blood glucose levels and carries a risk of hypoglycemia. The recent largest study NICE-SUGAR suggested intensive insulin therapy significantly increased the risk of hypoglycemia and resulted in no overall mortality benefit among critically ill patients. Analogues of incretins have been widely used to treat type 2 diabetes (T2DM), but data about the therapeutic applications of these drugs instead of insulin for perioperative glycemic control are scarce. To investigate the efficacy and safety of perioperative liraglutide (LGT) therapy as a non-insulin agent for perioperative glycemic control, we performed a retrospective case analysis on a total of 73 elective surgeries on 68 patients with T2DM in two separate hospitals.
Materials and methods: Informed consents were obtained, and LGT was introduced after cessations of OADs. Sixty-eight subjects with T2DM (male/female; 41/28, Age; 69.8±11.2 years old, HbA1c; 7.9±1.3 %, BMI; 26.9±4.0, Disease duration 12.9±11.7 years) were initiated with LGT therapy before elective operations, e.g. orthopedic operations (39 cases), cardiac catheterizations for ischemic heart disease (17), cataract (10), prostate cancer (2), uterus cancer (1), renal cancer (1), bladder cancer (1), breast cancer (1), plastic surgery (1). In case of hyperglycemia during perioperative period, regular insulin was added if needed. As LGT decreases gastrointestinal motility, surgical cases with gastrointestinal tracts were excluded. BMI change, glycemic level fluctuation, hypoglycemia, doses of insulin, if required, and perioperative complications were analyzed.
Results: LGT was continued through the entire period of hospital stay including the operation day (day 0). Meals were resumed on day1. The mean glucose levels on LGT initiation day, day 0, and day 1 were 194.5±52.5, 146.2±30.6 (*p<0.01*) and 162.2±35.1 (*p<0.01*) mg/dl, respectively. The BMI of almost all patients decreased (-1.1±1.4) with LGT therapy before operation. LGT achieved good glycemic control throughout the perioperative period. Additional regular insulin was not needed except in the case of 9 patients. HbA1c stayed within a good range (6.8±0.8 %) at 6th months after operation. There was an additional benefit of body weight loss enabling efficient rehabilitation. Adverse incidents such as hypoglycemic episodes, wound healing retardations, or other complications were not observed. Discussion: Insulin is a gold standard for treating hyperglycemia in surgical patients. It needs frequent glucose measurement and adjustment of dose by well-trained medical providers especially during perioperative periods when the caloric intake is variable. The present results showed the possible application of LGT in selected stable diabetic patients who are expected to consume meals at regular intervals without adjustment of dose.
Conclusion: LGT provides an effective and optional way as a perioperative non-insulin agent to safely achieve good glycemic control in perioperative subjects with T2DM, especially those with limited exercise ability and those at risks of hypoglycemia.

887

Pharmacokinetics (PK) and pharmacodynamics (PD) of the GPR40 agonist fasiglifam (TAK-875) and glimepiride following co-administration in type 2 diabetes subjects

P. Viswanathan, M. Tsai, R.D. Lee, M. Vakilynejad, W. Zhang, J. Marcinak, X. Peng;
Takeda Global Research and Development Center, Deerfield, USA.

Background and aims: This phase 1, single-blind, placebo-controlled, sequential, single-site study evaluated the effects of multiple oral doses of fasiglifam (TAK-875) on the PK of a single oral dose of glimepiride and effects of a single dose of glimepiride on steady-state PK and PD of fasiglifam in T2DM subjects.
Materials and methods: T2DM subjects (n=30) received a single dose of glimepiride 2 mg on Day 1 followed by fasiglifam 50 mg QD on Days 3-19. On Day 18, glimepiride was also given with fasiglifam. Serial plasma PK samples were collected on Days 1-3 & Days 18-20 for glimepiride and on Days 13-19 for fasiglifam & M-I. Serial PD samples for markers of fasting glucose, insulin, C-peptide, and glucagon were collected on Days 17-18. All PK & PD parameters were estimated using non-compartmental methods. PK interactions were assessed by point estimates and 90% confidence intervals (CIs) of the ratios of the central values for C_{max} and AUC values when treatments were coadministered relative to each treatment alone using paired t-test. The effects of glimepiride on fasiglifam PD response (AUEC) were similarly assessed for each marker.
Results: Glimepiride was absorbed (T_{max} ~ 3 hr) and eliminated ($T_{1/2}$ ~ 7.5 hr) following dosing of either glimepiride alone or with fasiglifam. Fasiglifam was absorbed (T_{max} ~ 4 hr) following dosing of either fasiglifam alone or with glimepiride. The 90% CIs for C_{max} and AUC of glimepiride, fasiglifam, and M-I fell within the no-effect range of 0.80 to 1.25. The mean AUEC values were lower for fasting glucose and higher for other PD markers after dosing of fasiglifam with glimepiride relative to fasiglifam alone; differences were statistically significant ($p<0.005$) for all markers.
Conclusion: Co-administration of fasiglifam with glimepiride was well-tolerated with no hypoglycemia and no effects on the PK of glimepiride, fasiglifam, or M-I. Changes in PD markers with coadministration of glimepiride suggest a potential synergistic effect between fasiglifam and glimepiride on insulin secretion mediated via different pathways.

Efficacy and safety of fasiglifam (TAK-875), a GPR40 selective agonist, in Japanese type 2 diabetes mellitus patients: a phase 3, double-blind, placebo controlled, comparative study

K. Kaku[1], K. Enya[2], R. Nakaya[2], T. Ohira[2], R. Matsuno[2];
[1]Division of Diabetes, Endocrinology and Metabolism, Kawasaki Medical School, Okayama, [2]Pharmaceutical Development Division, Takeda, Osaka, Japan.

Background and aims: G-protein-coupled receptor 40 (GPR40), which is highly expressed in pancreatic β-cells, functions as a receptor for free fatty acids and potentiates glucose-stimulated insulin secretion. Fasiglifam (TAK-875) is a potent and highly selective agonist of GPR40, and previous clinical data suggest that fasiglifam has the potential to be a safe and effective treatment for type 2 diabetes mellitus with glucose-lowering effect comparable with sulfonylureas and less risk of hypoglycemia. We aimed to evaluate the efficacy and safety of fasiglifam monotherapy in Japanese patients with type 2 diabetes mellitus.
Materials and methods: This randomized, double-blind, placebo-controlled, phase 3 study was designed to evaluate the efficacy and safety of fasiglifam 25 mg and 50 mg administered once daily before breakfast for 24 weeks in Japanese patients with type 2 diabetes inadequately controlled by diet and exercise. The primary endpoint was the change from baseline in HbA1c at Week 24. Secondary endpoints included proportions of patients with HbA1c < 6.9%, and changes in HbA1c and fasting blood glucose (FPG) at each assessment point.
Results: A total of 192 subjects were randomized to receive fasiglifam 25 mg (n=63), fasiglifam 50 mg (n=62), or placebo (n=67). Baseline characteristics were as follows: mean age of 60.4 years, mean BMI of 24.97 kg/m^2, mean HbA1c of 7.79%, and mean FPG of 155.6 mg/dL. There was no major difference among the treatment groups. At Week 24, all fasiglifam groups had statistically significant reductions in HbA1c compared with placebo ($p<0.0001$). Least-square mean HbA1c difference versus placebo was -0.75% (95% CI: -0.985 to -0.521) in the fasiglifam 25 mg group and -1.01% (95% CI: -1.244 to -0.777) in the fasiglifam 50 mg group. The mean change from baseline in HbA1c showed a time-dependent decrease from Weeks 2 to 24 in all fasiglifam groups and significant decreases versus placebo occurred as early as Week 4. The percentage of subject who achieved the HbA1c level of <6.9% at Week 24 was also significantly higher in the fasiglifam 25 mg (30.2%) and 50 mg (54.8%) groups than in the placebo group (13.8%). The mean change in FPG at Week 24 was -25.3 mg/dL, -25.5 mg/dL and -3.1 mg/dL in the fasiglifam 25 mg, 50 mg and the placebo groups, respectively, resulting in a significant decrease in all fasiglifam groups compared with the placebo group. There were no significant differences in incidence or types of adverse events between the fasiglifam groups and the placebo group. Hypoglycemia was reported only in 1 subject in the fasiglifam 50 mg. There were no changes in body weight in any groups.
Conclusion: Fasiglifam significantly improved glycemic control with minimum risk of hypoglycemia and was well tolerated in Japanese patients with type 2 diabetes inadequately controlled by diet and exercise.

PS 069 Incretin-based drugs: predictors of clinical outcomes

889

Markers of insulin resistance and beta cell function do not predict response to incretin based treatments in type 2 diabetes

A.G. Jones[1], A.V. Hill[1], J. Stewart[2], B.M. Shields[1], T.J. McDonald[1], B.A. Knight[1], A.T. Hattersley[1];
[1]NIHR Exeter Clinical Research Facility, University of Exeter Medical School, [2]Research and Development, Royal Devon and Exeter Hospital, Exeter, UK.

Background and aims: Glycaemic response to the incretin based agents (GLP-1 agonists (GLP-1A) and DPPIV inhibitors (DPPIVI)) is highly variable. Determining predictors of treatment response could potentially aid the selection of the most appropriate treatment for an individual. We aimed to determine whether markers of insulin resistance and beta cell function are associated with response to incretin based therapies in Type 2 diabetes.
Methods: We prospectively studied 530 predominantly white European participants with HbA1c >58mmol/mol (7.5%) commencing GLP-1A or DPPIVI therapy as part of their usual diabetes care. We assessed markers of insulin secretion (fasting C-peptide, post largest home meal urine c-peptide:creatinine ratio (UCPCR), HOMA2B, duration of diabetes) and insulin resistance (HOMA2IR, BMI, triglycerides) immediately prior to commencing therapy. We measured HbA1c at baseline and at 3 and 6 months on therapy: response was defined by 6 month HbA1c unless treatment was changed or stopped after 3 months. Participants who completed <3 months treatment, increased other treatment or stopped >1 OHA were excluded from analysis (number analysed 280 GLP-1A, 156 DPPIVI). We assessed the relationship between baseline markers and both absolute HbA1c change and achieving an HbA1c <7.5% (58mmol/mol) using linear and logistic regression respectively with adjustment for the following covariates: baseline HbA1c, discontinuation of OHA, number of baseline OHAs, insulin co-treatment and change in insulin dose (%). We assessed potential utility of predictors identified using Receiver Operating Characteristic (ROC) curve analysis.
Results: Participant characteristics were: GLP-1A - 51% male, 41% insulin treated, median (IQR) age 55 (48-62), diabetes duration 9 (5-13) years, BMI 38 (35-43)kg/m^2 baseline HbA1c 84 (72-96)mmol/mol, HbA1c change -14(-3 to -26)mmol/mol, DPPIVI - 60% male, 7% insulin treated, age 63 (56-70), diabetes duration 8 (5-13) years, BMI 32 (29-37)kg/m^2, HbA1c 75 (67-84)mmol/mol, HbA1c change -8.9 (-1 to -16)mmol/mol. In univariate analysis (Spearman's correlation) UCPCR and fasting C-peptide were weakly associate with GLP-1A response (absolute HbA1c fall over 6 months) with better response seen in those with higher insulin secretion: UCPCR r=0.13, p=0.04, fasting C-peptide r=0.18, p=0.04. No markers of insulin secretion or resistance were associated with DPPIV response. After adjusting for covariates no marker of insulin secretion or resistance was associated with absolute HbA1c fall for either therapy (p>0.12 for all). Both low fasting C-peptide and low HOMA2IR were associated with achieving an HbA1c <58mmol/mol (7.5%) for DPPIV inhibitors (C-peptide p=0.03, HOMA2IR p=0.02) but not for GLP-1 agonists (p=0.35 and 0.49 respectively), other markers were not associated with this outcome (p for all >0.11). In ROC analysis fasting C-peptide and HOMA2IR had low utility in predicting DPPIVI response (achieved HbA1c<58mmol/mol): C-peptide AUC ROC 0.63 (CI 0.52-0.78), HOMA2IR 0.68 (CI 0.55-0.81), no better than fasting glucose alone (AUC ROC 0.67 (0.57-0.77)).
Conclusion: Markers of insulin resistance and beta cell failure are not clinically useful predictors of response to incretin based treatments in Type 2 diabetes.

"Real-life" experience in use of dipeptidyl peptidase 4 inhibitors at a large Scottish teaching hospital

A.L. Brown, G. Jones, C. Sainsbury;
NHS Greater Glasgow and Clyde, Glasgow, UK.

Background and aims: Dipeptidyl Peptidase 4 Inhibitors (DPP4I) are a relatively new class of hypoglycaemic agent shown in clinical trials to improve HbA_{1c} whilst being weight neutral and well tolerated. There is little information however on real-life use and efficacy of these drugs. This study aimed to assess effect of DPP4I on glycaemic control and weight in a real-life clinical setting and review adherence to renal dosing guidance.
Materials and methods: Retrospective observational review of patients with type 2 diabetes attending the diabetes centre at Gartnavel General Hospital, Glasgow. Patients prescribed a DPP4I were identified using the Scottish Care Information - Diabetes Collaborative (SCI-DC) database. Electronic medical records were reviewed for initiation of DPP4I, concomitant hypoglycaemic drugs and the specific DPP4I and dose selected. HbA_{1c} (mmolmol^{-}1), weight (kg) and renal function as eGFR (ml/min/1.73m^2) were recorded at initiation and at the first follow-up appointment at least 3 months post initiation.
Results: 263 patients were identified as being initiated on DPP4I therapy between March 2008 and June 2012. Mean time between initiation and follow-up HbA_{1c} measurement was 207days (SD 81.5). Sitagliptin 100mg daily was the most commonly prescribed DPP4I (90.5%). In patients where DPP4I initiation was the only pharmacological intervention at initiation (n=195), mean change in HbA_{1c} at follow-up was -8.8mmolmol^{-1} (95%CI -10.8, -6.7; p-value 0.000). Largest mean change in HbA_{1c} was observed in patients with HbA_{1c} at initiation of 90-99molmol^{-1}, 100-109mmolmol^{-1} and 80-89mmolmol^{-1}: -17.2mmolmol^{1}(95%CI -26.2, -8.1; p-value 0.002). -13.6mmolmol^{-1}(95%CI -24.2, -2.98; p-value 0.016) and -9.6mmolmol^{-1}(95%CI -17.3, -1.99; p-value 0.0015) respectively. This is compared with initial HbA_{1c} 60-69mmolmol^{-1} and 70-79mmolmol^{-1}; -7.9mmolmol^{1}(95%CI -10-2, -5.5; p-value 0.000), -6.8mmolmol^{1}(95%CI -10.5, -3.1; p-value 0.000). Comparison of concomitant therapy showed significant changes in mean HbA_{1c} in DPP4I regimes including; metformin (-11.6mmolmol^{-1}, 95%CI -15.3, -7.8, p-value 0.000); metformin and sulphonylurea (SU) (-6.56mmolmol^{-1}, 95%CI -10.0, -3.0, p-value 0.000); metformin and thiazolidinedione (TZD) (-7.0mmolmol^{-1}, 95%CI -13.7, -0.26, p-value 0.043); metformin and insulin (9.2mmolmol^{-1}, 95%CI -15.1, -3.4, p-value 0.003); and metformin, SU and TZD(-14.5mmolmol^{-1}, 95%CI -20.6, -8.4, p-value 0.000). A reduction in weight was observed at follow-up; mean change: -0.79kg (95% CI -1.3, -0.3, p-value 0.001). Comparison of concomitant therapy showed significant weight changes in patients taking DPP4I with metformin and SU (mean change -1.6kg; 95%CI -2.3, -0.9; p-value 0.000), and metformin and insulin (mean change +1.3kg, 95% CI 0.02, 2.5, p-value 0.047). 87.7% of patients were initiated on a dose of DPP4I appropriate for degree of renal function. Examination of subdivisions of renal impairment found that 75% patients with moderate and 50% of patients with severe renal impairment were not prescribed doses in accordance with guidance.
Conclusion: DPP4I are effective in reducing HbA_{1c} in a "real-life" setting. Patients with higher initial HbA_{1c} values or on regimes including metformin exhibited larger mean reductions in HbA_{1c}. A small reduction in weight was observed at follow-up after at least three months. Dose adjustment of DPP4I in renal impairment was infrequent suggesting a lack of awareness.

891

INdividualised Treatment targets for ElderRly patients using Vildagliptin Add-on or Lone therapy (INTERVAL) study

W. David Strain[1], V. Lukashevich[2], W. Kothny[2], M.-J. Hoellinger[3], P. Paldánius[3];
[1]University of Exeter Medical School, UK, [2]Novartis Pharmaceuticals Corporation, East Hanover, USA, [3]Novartis Pharma AG, Basel, Switzerland.

Background and aims: Management of type 2 diabetes mellitus (T2DM) in elderly patients is challenging and complicated by multiple comorbidities, polypharmacy, high prevalence of renal impairment and increased risk of hypoglycaemia. Further, the benefit of aggressive glycaemic control has been questioned recently in the advent of outcome trials such as ACCORD, in which weight gain and hypoglycaemia were thought to contribute to the 25% increase in mortality. Guidelines are increasingly suggesting individualising treatment targets for vulnerable elderly adults, despite no evidence-base for such an approach. We evaluated the feasibility of such an approach. In order to achieve individualised targets, we used the DPP-4 inhibitor vildagliptin vs. placebo, in view of its weight neutrality and low risk of hypoglycaemia.
Materials and methods: We enrolled 278 drug-naïve or inadequately controlled (HbA1c ≥7.0% to ≤10.0%) T2DM patients aged ≥70 years in a multinational, double-blind, placebo-controlled 24-week study. Investigators were asked to set unique, individualised treatment targets for participants based on age, baseline HbA1c, comorbidities, polypharmacy, frailty status and local recommendations for glycaemic targets before 1:1 randomisation to vildagliptin (50 mg qd or bid as per label) or placebo.
Results: Mean age was 74.4 ± 4.0 and 75.1 ± 4.3 years with a maximum age of 89 and 97 years for the placebo and vildagliptin arms respectively; 76.6% of patients had mild or moderate renal failure and 9.4% were frail according to

the modified Fried definition. Baseline HbA1c was 7.9% for both groups. On average the target HbA1c reduction was set at 0·9% (range -4.4% to -0.1%). Simple advice and nursing intervention enabled 27% of elderly patients to achieve their target. After adjustment for baseline variables, patients treated with vildagliptin had a higher likelihood of achieving their individualised treatment targets (OR=3.16), accompanied by clinically relevant reductions in overall, conventional HbA1c assessment (Table). Change in FPG from baseline to endpoint was -1.34 and -0.47 mmol/L in the vildagliptin and placebo groups, respectively, and the between-group difference was statistically significant (p<0.001). Vildagliptin was well tolerated in this elderly cohort with low incidence of hypoglycaemia and no new safety signals emerging.
Conclusion: INTERVAL is the first study to introduce investigator-defined, individualised HbA1c targets as an endpoint in any T2DM population. It demonstrates the feasibility of evaluating individualised targets when exploring diabetes management in the growing elderly population. It also confirmed that individualised glycaemic target levels are achievable using vildagliptin without any tolerability issues.

Investigator-defined individualised HbA1c target (Full analysis set)

Treatment	N	Number of responders	Proportion of responders (%)	Treatment difference (Vildagliptin - Placebo)		
				Adjusted Odds ratio	96.2% CI	p-value

Efficacy and safety of linagliptin as add-on therapy to basal insulin and metformin in patients with type 2 diabetes
J. Lee[1], S. Durán-Garcia[2], H. Yki-Järvinen[3], J. Rosenstock[4], U. Hehnke[1], S. Thiemann[1], S. Patel[5], H.-J. Woerle[1];
[1]Boehringer Ingelheim, Germany, [2]Valme University Hospital Medical School, Seville, Spain, [3]Department of Medicine, University of Helsinki, Finland, [4]Dallas Diabetes and Endocrine Center at Medical City, Dallas, USA, [5]Boehringer Ingelheim, Bracknell, UK.

Background and aims: The combination of basal insulin and metformin (MET) is a common second-line treatment option for patients with type 2 diabetes mellitus (T2DM), potentially providing superior glycaemic control to either agent alone. Adding a dipeptidyl peptidase (DPP)-4 inhibitor to this combination may further improve glycaemic control without increasing risk of hypoglycaemia and weight gain. A Phase III study evaluated the efficacy and long-term safety of the DPP-4 inhibitor linagliptin (LINA), added to basal insulin alone or in combination with MET and/or pioglitazone. We performed a sub-analysis to evaluate the efficacy and safety of LINA in combination with insulin and MET which was the study's most common treatment.
Materials and methods: This sub-analysis of a global, placebo (PBO)-controlled, Phase III trial evaluated LINA 5 mg once daily in patients on background insulin and MET. Patients were randomised (1:1) to double-blind treatment with LINA or PBO for ≥52 weeks. The basal insulin dose was kept stable for 24 weeks but could be adjusted after this period. The primary endpoint was the change in HbA1c from baseline at Week 24.
Results: There were a total of 950 patients in this sub-analysis (LINA and PBO, n=475). Mean ± SD baseline characteristics were similar in the LINA vs PBO groups: age, 59.3 ± 9.9 vs 59.9 ± 9.8 yrs; BMI, 30.9 ± 5.4 vs 31.1 ± 4.9 kg/m^2; HbA1c, 8.3 ± 0.9% vs 8.3 ± 0.8%. At Week 24, adjusted mean ± SE changes from baseline in HbA1c were -0.63 ± 0.06% with LINA and +0.04 ± 0.06% with PBO (treatment difference -0.67 ± 0.06% [95% CI -0.78, -0.56; *P*<0.0001]). After 52 weeks, the adjusted mean ± SE change in HbA1c from baseline was -0.49 ± 0.06% with LINA and +0.10 ±0.06% with PBO (Figure). Fasting plasma glucose decreased only with LINA at Week 24 (adjusted mean ± SE: -0.5 ± 0.2 mmol/L vs +0.2 ± 0.2 mmol/L) and Week 52 (mean ± SE: -0.3 mmol/L vs +0.1 mmol/L). Although up-titration of basal insulin was allowed after 24 weeks, background insulin dose was only adjusted by +1.5 ± 0.7 IU/day with LINA vs +3.3 ± 0.7 IU/day with PBO (treatment difference -1.75 ± 0.6 [95% CI -2.95, -0.55; *P*<0.005]) at Week 52. The overall frequency of patients with ≥1 adverse event (LINA, 79.8%; PBO, 81.3%) and investigator-defined hypoglycaemia (LINA, 30.7%; PBO, 31.6%) appeared to be similar in both groups. The percentage of patients with severe hypoglycaemia was low (LINA, 1.7%; PBO, 0.8%). There were no relevant changes in mean ± SD body weight from baseline to Week 52 (LINA, -0.5 ± 3.2 kg; PBO, 0.0 ± 3.1 kg).
Conclusion: The addition of LINA to patients with T2DM inadequately controlled on basal insulin and MET significantly improved glycaemic control, with no additional risk of hypoglycaemia or weight gain.

Predictors of attaining a composite endpoint with exenatide once weekly (EQW): recursive partitioning analysis
V. Aroda[1,2], M. Zhou[3], L. Shen[3], L. MacConell[3], J. Han[3];
[1]MedStar Health Research Institute, Hyattsville, [2]Georgetown University School of Medicine, Washington, [3]Bristol-Myers Squibb, San Diego, USA.

Background and aims: Current treatment guidelines (ADA/EASD) advocate a patient-centered approach in the medical management of hyperglycemia. In addition to setting glycemic targets, individualized factors and goals should be considered in the choice of therapy, including minimizing risk of hypoglycemia and weight gain. Prediction of responders to specific therapies based on patient characteristics may further advance such a patient-centered approach. A recursive partitioning analysis was performed to identify patient characteristics that are potential predictors of response to EQW treatment, defined as attainment of the composite endpoint of HbA_{1C} <7%, without weight gain or hypoglycemia, following 24-30 weeks of treatment.
Materials and methods: Data from T2DM patients who received EQW for 24-30 weeks in 8 randomized, comparator-controlled clinical trials were pooled to identify predictors of attaining the composite endpoint using the recursive partitioning (classification tree) method. Potential predictors evaluated were age, gender, BMI, weight, ethnicity, HbA_{1C}, fasting glucose, concomitant antihyperglycemic use, diabetes duration, and renal function (creatinine clearance). Logistic regression with stepwise selection to find the best model to describe the current data, as opposed to predict future data, was explored.
Results: Among the 1522 patients (mean baseline age 55 yrs, HbA_{1C} 8.5%, weight 88 kg, BMI 31.4 kg/m^2, 45% with concomitant SU), 46% achieved the composite endpoint and the majority of patients attained at least one endpoint (HbA_{1C} <7%, 59%; no weight gain, 78%; no hypoglycemia, 93%). Baseline HbA_{1C} was the most important predictor of attaining the composite endpoint, with a 60% probability if baseline HbA_{1C} ≤8.1%, vs 34% if baseline HbA_{1C} >8.1% (*P*<0.001). The probability increased to 67% among patients who were not on SU if baseline HbA_{1C} ≤8.1% (*P*<0.001), vs 46% if baseline HbA_{1C} was >8.1% and ≤9.6% (*P*=0.007). For patients on SU, probabilities of attaining the composite endpoint were 50% and 32%, respectively. Among all patients, baseline HbA_{1C} >9.6% (*P*<0.001) conferred the least likelihood (22%) of achieving the composite endpoint, regardless of background concomitant antihyperglycemic use. No other significant predictors were identified for achieving the composite endpoint. Similar results were found in the logistic regression analysis.
Conclusion: A majority of patients reached glycemic target of HbA_{1C} <7% with the addition of EQW treatment, and 46% achieved a composite goal

that also included no weight gain or hypoglycemia. Among the 10 predictors examined, baseline HbA_{1C} and concomitant antihyperglycemic use were the most important predictors for attainment of the composite endpoint with EQW following 24-30 weeks of treatment. Results from such analysis may assist clinicians in patient-centered treatment approaches to hyperglycemia management in T2DM.

Diabetes duration and background diabetes therapies in predicting liraglutide treatment response: data from the post-marketing EVIDENCE study

A. Penfornis[1], P. Gourdy[2], L. Martinez[3], S. Madani[4], G. Charpentier[5], E. Eschwège[6], J.-F. Gautier[7];
[1]Endocrinology-Metabolism and Diabetology-Nutrition, University of Franche-Comté, Besançon, [2]Toulouse University Hospital, [3]Université Pierre & Marie Curie, Paris, [4]Novo Nordisk, Paris, [5]Centre Hospitalier Sud Francilien, Corbeil, [6]INSERM, Villejuif, [7]Saint Louis Hospital, Paris, France.

Background and aims: We used data from a post-marketing study in France to determine whether liraglutide treatment is more effective in lowering HbA_{1c} when used early in the course of type 2 diabetes.
Materials and methods: EVIDENCE is a multicentre, observational, post-marketing outpatient study requested by the French National Health Authority to evaluate the efficacy and safety of the human GLP-1 analogue liraglutide. Its primary objective is to determine the percentage of patients still taking liraglutide and at HbA_{1c} target (<7%) after 2 years. This analysis examined HbA_{1c} reductions 1 year after initiating liraglutide treatment, stratified according to diabetes duration (0-5 years; 6-10 years; >10 years) or extent of background diabetes therapy (1, 2, ≥3 oral anti-diabetes drugs or insulin [±OAD]). Statistical analyses: for quantitative variables a normality Kolmogorov-Smirnov test was used. For comparison of 2 independent groups the Mann-Whitney Wilcoxon test was used, and for >2 groups the Kruskal-Wallis test was used for quantitative variables. Comparisons of independent groups were performed by the Chi-square test with qualitative variables. The Wilcoxon signed rank test was used for paired quantitative variables, and the McNemar test for paired qualitative variables.
Results: The study included 3137 patients, 2433 (77.6%) of whom remained in the study at 1 year. Of these, diabetes duration was available for 2297 (94.4%) (duration 0-5 years, n=689; 6-10 years, n=800; >10 years, n=808) and background therapy was available for 2161 (88.8%) (1 OAD, n=413; 2 OADs, n=791; ≥3 OADs, n=640; insulin (±OAD), n=317). Mean±SD HbA_{1c} reductions for the 3 diabetes duration groups were: -1.22±1.73%, -1.01±1.39% and -0.76±1.33% (all p<0.0001) from baseline HbA_{1c} values of 8.53, 8.58 and 8.53%, respectively. Subjects with diabetes duration 0-5 years and 6-10 years achieved greater HbA_{1c} reductions than those with duration >10 years [between-treatment differences: -0.46% (p<0.001) and -0.25% (p=0.002), respectively]. HbA_{1c} reductions in the background treatment groups (1, 2, ≥3 OADs and insulin [±OAD]) were: -1.40±1.52%, -1.14±1.50%, -0.74±1.38% and -0.73±1.53% (all p<0.0001) from baseline HbA_{1c} values of 8.50, 8.55, 8.60 and 8.62%, respectively. Subjects taking 1 or 2 OADs achieved greater HbA_{1c} reductions than those treated with ≥3 OADs (-0.66% and -0.40%, respectively; both p<0.001) or insulin (±OAD) (-0.67% and -0.41%, respectively; both p<0.001). Increasing diabetes duration correlated with increasing number of background therapies; 6.3, 9.2, 10.9 and 12.5 years for 1, 2, ≥3 OADs and insulin (±OAD), respectively. Withdrawals were similar across diabetes duration groups (22-24%), but greater among patients receiving ≥3 OADs (25%) and insulin (±OADs) (30%) compared with patients on 1 or 2 OADs (19-21%). The most common reasons for withdrawal were gastrointestinal disorders experienced early in the study.
Conclusion: In this observational EVIDENCE study, treatment response to liraglutide was greater in patients with shorter duration of diabetes and fewer background treatments.

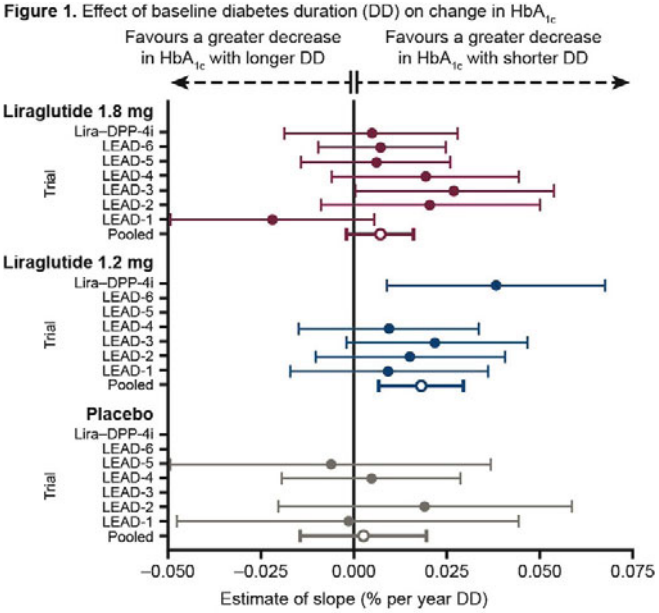
The effect of liraglutide on HbA_{1c} and body weight is largely independent of baseline diabetes duration

J.R. Seufert[1], T. Bailey[2], C. Svendsen[3], M. Donsmark[3], M.A. Nauck[4];
[1]Internal Medicine II, Universitätsklinikum Freiburg, Germany, [2]AMCR Institute, Escondido, USA, [3]Novo Nordisk, Søborg, Denmark, [4]Diabeteszentrum, Bad Lauterberg, Germany.

Background and aims: The LEAD phase 3 clinical programme demonstrated liraglutide's effectiveness across the continuum of type 2 diabetes (T2D); however, the effect of baseline diabetes duration is unclear. Using 26/28-week data from seven phase 3 trials, this post-hoc, pooled analysis evaluated the effect of diabetes duration on changes in HbA_{1c} and body weight from baseline with liraglutide 1.8 mg (n=1581), liraglutide 1.2 mg (n=1117) and placebo (n=524).
Materials and methods: The slope for change in HbA_{1c} or body weight vs. diabetes duration was determined by linear regression. The statistical model included the baseline value of the endpoint, diabetes duration, and age as continuous covariates. Previous treatment and country were categorical covariates.

Figure 1. Effect of baseline diabetes duration (DD) on change in HbA_{1c}



Data are modelled estimates with 95% confidence intervals, from ITT population, LOCF. The model included baseline endpoint value (HbA_{1c}/body weight; BW), diabetes duration and age as continuous covariates, previous treatment, and country as categorical covariates

Results: Across treatment arms, diabetes duration ranged from <1 to >40 years, with a mean of ~8 years for pooled groups. There was a trend towards

greater HbA_{1c} reduction with shorter diabetes duration with liraglutide but this was not clinically relevant (Figure 1); statistical significance was achieved for pooled liraglutide 1.2 mg group ($p<0.05$) but the difference only equated to -0.2% HbA_{1c}/10-year shorter diabetes duration. The effect of liraglutide on body weight was independent of diabetes duration.
Conclusion: The proven effectiveness of liraglutide to reduce HbA_{1c} and body weight is largely independent of diabetes duration. Therefore, liraglutide can be successfully used across the continuum of T2D.

Efficacy of lixisenatide in patients with different levels of beta cell function as assessed by C-peptide/glucose ratio

J.J. Meier[1], D. Yabe[2], E. Wang[3], J. Lin[4], J. Rosenstock[5], B. Ahrén[6];
[1]Department of Medicine I, St.Josef-Hospital, Bochum, Germany, [2]Division of Diabetes, Clinical Nutrition and Endocrinology, Kansai Electric Power Hospital, Osaka, Japan, [3]Sanofi-Aventis, Bridgewater, [4]Novosys Health, Flemington, [5]Dallas Diabetes and Endocrine Center, Dallas, USA, [6]Lund University, Sweden.

Background and aims: Over time, beta-cell mass declines progressively in type 2 diabetes and this decline is closely related to loss of glucose control. Previous studies have suggested that a fasting C-peptide/glucose ratio can predict pancreatic beta-cell mass in humans. Lixisenatide is a once-daily prandial GLP-1 receptor agonist that has been recently approved in Europe for the treatment of type 2 diabetes. Because lixisenatide is believed to act predominantly via delay of gastric emptying, we speculated that its glucose-lowering effect should be maintained even in patients with low beta-cell function. Therefore, the glucose-lowering efficacy was analysed in relation to beta-cell function at baseline.
Materials and methods: Data were extracted from two 24-week, randomized, double-blind, placebo-controlled trials from the lixisenatide Phase III clinical development programme: GetGoal-S (lixisenatide in patients insufficiently controlled on sulphonylurea ± metformin [MET]) and GetGoal-M (lixisenatide in patients insufficiently controlled on MET). Patients were grouped into four quartiles according to their baseline pre-prandial C-peptide/glucose ratios as a measure of beta-cell function (Table).
Results: C-peptide/glucose ratios were closely correlated with diabetes duration and degree of glucose control. HbA_{1c} and fasting blood glucose were reduced in all quartiles, with no correlation with C-peptide/glucose ratios. In contrast, reduction in postprandial glucose (PPG) was negatively correlated with C-peptide/glucose ratio, with a significant difference between quartile groups (p=0.0001). The greater PPG reduction with lixisenatide in patients with the lowest baseline beta-cell function suggests that most of the effect is probably driven by delaying gastric emptying. The relationship between the C-peptide/glucose ratios and PPG was similarly observed whether patients were receiving sulphonylureas or not. The incidence of symptomatic hypoglycaemia was low in all quartiles with no significant difference between groups.
Conclusion: Lixisenatide improves glycaemic control regardless of the baseline beta-cell function, presumably because of its effect on delaying gastric emptying. These data suggest that lixisenatide treatment is effective in reducing postprandial hyperglycaemia even in the more advanced stages of type 2 diabetes.

Effectiveness of prandial insulin and glucagon-like peptide-1 treatment regimens in patients with type 2 diabetes on basal insulin in a real-world setting in the United States

A. DiGenio[1], S. Karve[2], S.D. Candrilli[2], M.R. Dalal[1];
[1]Sanofi US, Inc., Bridgewater, [2]RTI Health Solutions, Research Triangle Park, USA.

Background and aims: Data from clinical trials suggest that glucagon-like peptide-1 (GLP-1) receptor agonists are attractive treatment options for certain populations of patients with type 2 diabetes mellitus (T2DM), either alone or in combination with other agents. However, availability of real-world data is limited. This study aims to document real-world demographic characteristics and outcomes of patients with T2DM, treated with basal inulin, who initiate add-on therapy with a GLP-1 analog or prandial insulin.
Materials and methods: Using electronic medical records (EMR), this retrospective study was conducted in T2DM patients aged ≥18 years old who initiated prandial insulin or a GLP-1 analog between January 2006 and January 2011, while on basal insulin therapy. Patients were required to have had EMR activity of ≥6 months prior to and ≥12 months after their prandial insulin or GLP-1 analog initiation date. Standardized differences were used to compare baseline characteristics and control for observed differences in baseline characteristics (including age, HbA_{1c}, and body mass index). Primary endpoints included change in HbA_{1c} and body weight at 6 and 12 months follow-up. Rates of hypoglycemia and adverse events, and utilization of health care resources were measured over 12 months' follow-up.
Results: After variable matching, the study group comprised 1,143 GLP-1 analog users and 5,557 prandial insulin users with the following mean baseline characteristics: age 56.0 and 56.6 years; HbA_{1c} of 8.5% and 8.6%; and body weight of 111.1 kg and 108.9 kg, respectively. Outcomes of the matched analysis are presented in the Table. At 6 and 12 months post-treatment initiation, reduction in HbA_{1c} levels was similar for the prandial insulin and GLP-1 analog users. GLP-1 analog users had a significantly greater reduction in body weight at both 6 and 12 months post-initiation. Throughout follow-up, significantly lower rates of hypoglycemia and utilization of health care resources were observed for patients adding GLP-1 analog therapy. The tolerability of both add-on therapies was similar (Table). Proportions achieving different composite endpoints favored the GLP-1 arm over the prandial insulin arm: HbA_{1c} goal <7.0% at 6 months was achieved by 28.8% vs 27.1% (34.9 vs 30.9% at 12 months), respectively. Also, 26.2% vs 22.6% (30.5% vs 25.2%) achieved this glycemic target without hypoglycemia, and 20.7% vs 13.7% (28.3% vs 20.3%) of patients did so without weight gain.
Conclusion: This study showed that, among real-world T2DM patients, the addition of a GLP-1 analog to basal insulin therapy was associated with similar glycemic control, but significantly greater reduction in body weight, lower incidence of hypoglycemia, and lower health care resource utilization compared with prandial insulin.

Primary efficacy endpoints	Prandial insulin (n=5,577)	GLP-1 analog (n=1,143)

Adding rapid-acting insulin or GLP-1 receptor agonist to basal insulin in patients with type 2 diabetes: real-world health care costs from a US managed care setting

M. Dalal[1], L. Xie[2], O. Baser[2,3], A. DiGenio[1];
[1]Sanofi US, Inc., Bridgewater, [2]STATinMED Research, Inc., Ann Arbor, [3]The University of Michigan, Ann Arbor, USA.

Background and aims: In patients with type 2 diabetes mellitus (T2DM) where basal insulin alone does not provide glycemic control, additional injections of rapid-acting insulin (RAI) or glucagon-like peptide-1 receptor agonists (GLP-1) may be an effective therapeutic approach. Few studies have evaluated the addition of GLP-1 or RAI to basal insulin. This study evaluated the real-world economic outcomes of basal insulin plus RAI (Basal+RAI) vs basal insulin plus GLP-1 (Basal+GLP1) among US patients with T2DM.
Materials and methods: This was a retrospective cohort study using data from a US managed care claims database (IMPACT) conducted in adult patients with T2DM on basal insulin (insulin glargine, insulin detemir, NPH) who added GLP-1 (exenatide, liraglutide) or RAI (insulin glulisine/aspart/lispro) between 1/07/07 and 31/12/11. Study index date was the first RAI/GLP-1 prescription. Included patients were prescribed basal insulin in the quarter before and the quarter after index date, and had continuous health plan coverage ≥6 months before (baseline) and 1 year after index date (follow-up). All baseline characteristics, clinical and economic outcomes were summarized and compared, with P values provided by *t* tests for continuous variables or X^2 tests for categorical variables. Propensity score matching (1 up to 3 ratio) was used to control for baseline demographics, clinical characteristics (including comorbidity score) and health resource utilization differences. Endpoints included 1 year follow-up, health care utilization and costs.
Results: Among the 11,338 patients identified, at baseline Basal+RAI patients were more often >65 years, had more comorbidities (except for hypertension, hyperlipidemia and obesity), higher hypoglycemia rates, and higher rates of hospitalizations and emergency room visits. For the outcomes analysis 6,718 matched patients were included: 5,013 Basal+RAI (7% insulin glulisine, 49% insulin aspart, 44% insulin lispro) and 1,705 Basal+GLP1 (82% exenatide, 18% liraglutide), with similar baseline characteristics (47% female; 54 years; 79% insulin glargine, 16% insulin detemir, 5% NPH). During follow-up, patients in both groups experienced a similar proportion of any type of hypoglycemic event (*P*=0.4079), but events leading to hospitalization were significantly higher for Basal+RAI (2.7% vs 1.8%, *P*=0.0444). The table shows health care utilization and costs in the follow-up period. Basal+RAI patients had a higher proportion of patients with a hospitalization and higher total health care costs, but lower pharmacy costs, than Basal+GLP1 patients.
Conclusion: This study demonstrates that in a real-world setting, the addition of RAI to basal insulin in T2DM patients is associated with a higher proportion of hospitalizations and higher total costs when compared to those patients who added GLP-1.

Efficacy of the human GLP-1 analogue liraglutide in patients with type 2 diabetes who switched from a DPP-4 inhibitor: 1-year data from the EVIDENCE study

G. Charpentier[1], L. Martinez[2], E. Eschwège[3], S. Madani[4], A. Penfornis[5], P. Gourdy[6], J.-F. Gautier[7];
[1]Service de Diabetologie, Centre Hospitalier Sud Francilien, Corbeil Essonne, [2]Université Pierre & Marie Curie, Paris, [3]INSERM, Villejuif, [4]Novo Nordisk, Paris,[5]University of Franche-Comté, Besançon, [6]Toulouse University Hospital, [7]Saint Louis Hospital, Paris, France.

Background and aims: Baseline and 1-year data from a post-marketing study in France were compared to assess the change in glycaemic control and body weight after 1 year's treatment with the human GLP-1 analogue liraglutide in patients who previously received a DPP-4 inhibitor (DPP-4i).
Materials and methods: EVIDENCE is a multicentre, observational, post-marketing outpatient study requested by the French National Health Authority to evaluate the efficacy and safety of liraglutide. Its primary objective is to determine the percentage of patients still taking liraglutide and at HbA_{1c} target (<7%) after 2 years. Statistical analyses: for quantitative variables a normality Kolmogorov-Smirnov test was used; comparisons of two independent groups were performed using the Mann-Whitney Wilcoxon test for quantitative variables and chi-square test for qualitative variables; for paired quantitative variables the Wilcoxon signed rank test was used; for paired qualitative variables the McNemar test was used.
Results: Data were collected from 3137 subjects of whom 1255 (40%) were receiving a DPP-4i prior to liraglutide initiation. A total of 1004 (32%) subjects switched from a DPP-4i to liraglutide at study start, while 251 (8%) added liraglutide to a DPP-4i. The table shows baseline characteristics of subjects who switched. Subjects who switched and continued liraglutide treatment for 1 year (n=734) achieved significant reductions from baseline in mean HbA_{1c} (-0.84%, p<0.0001), fasting plasma glucose (-0.27 g/L, p<0.0001) and body weight (-3.53 kg, p<0.0001). A greater percentage of subjects had HbA_{1c} <7% at 1 year (31.6%) vs. baseline (8.0%; p<0.0001). Withdrawals (30% in overall study cohort) were mostly due to gastrointestinal disorders experienced early in the study.

Baseline characteristics	
N	1004
Age, years	58 ± 10
Diabetes duration, years	9.8 ± 6.3
HbA_{1c}, %	8.5 ± 1.4
Proportion of patients with HbA_{1c} <7%	8%
Fasting plasma glucose, g/L	1.8 ± 0.6
Body weight, kg	95 ± 18
BMI, kg/m²	34 ± 6
Data are mean±SD	

Conclusion: In this observational study, significant improvements in glycaemic control and body weight from baseline were seen after 1 year of liraglutide treatment in a subgroup of patients who switched from a DPP-4i at study start. A limitation of this study is the lack of control arm, making it difficult to evaluate whether observed improvements are attributable to liraglutide alone. It was previously shown by Pratley *et al.* in 2012 that switching from the DPP-4i sitagliptin to liraglutide in a randomised controlled trial setting provided significant HbA_{1c} (-0.5%; p<0.0001) and body weight reductions

(-2.5 kg; $p<0.0001$). The cohort enrolled in EVIDENCE is more representative of patients routinely treated in the clinic; therefore results reported here may provide a better indication of the outcomes of liraglutide treatment in patients who switch from a DPP-4i in daily clinical practice.

A randomised trial comparing the addition of liraglutide to high dose intensive insulin therapy vs insulin up-titration in type 2 diabetes
J. Rappaport, W. Lane, S. Weinrib, C. Hale;
Mountain Diabetes and Endocrine Center, Asheville, USA.

Background and aims: Patients with type 2 diabetes may benefit from GLP-1 RA therapy in combination with basal insulin, which results in improved glycemic control, weight loss and lower insulin doses than addition of basal insulin alone . However, GLP-1 RA's have not been studied in combination with intensive insulin therapy (prandial plus basal insulin). This study compares the effects of the addition of the GLP-1 RA liraglutide to high dose basal/bolus insulin therapy vs. insulin up-titration alone in patients with type 2 diabetes requiring > 100 units of insulin per day.
Materials and methods: 30 subjects with type 2 diabetes and HbA1c > 6.5% using intensive insulin therapy of >100 units of insulin per day, either by MDI or CSII, with or without metformin, were randomized in a 1:1 fashion to receive either liraglutide with insulin (LIRA) or standard insulin up-titration (control). Liraglutide was initiated at 0.6 mg daily and increased to 1.2 or 1.8 mg. Subjects in each group were evaluated with HbA1c, weight, and 72 hour CGM (Medtronic iPro) at 0 and 6 months. The differences between groups in HbA1c, weight, total daily insulin dose (TDID), time spent in hypo-, hyper- and euglycemia by CGM, and glycemic variability as determined by average daily standard deviation (SD) of glucose by CGM were compared by ANOVA using XLSTAT2012 for Windows.
Results: Both treatment groups experienced a significant decrease in HbA1c at 6 months, from a mean baseline of 7.76% to 7.14% in the LIRA group ($p < 0.0001$) and from 7.88% to 7.38% in the control group ($p < 0.0001$). There was no significant difference in HbA1c between groups at 6 months. Subjects in the LIRA group experienced a weight loss of 12.25 lbs (5.57 kg) at 6 months ($p <0.001$) compared to a weight gain of 1.8 lbs (0.86 kg) (p=NS) in the control group ($p < 0.0001$ between groups). The TDID in the LIRA group decreased by 31%, from a mean baseline dose of 203 U to 140 U at 6 months ($p < 0.0001$), whereas the control group had an increase of 9% in TDID from 181 U to 198 U (p=NS). The LIRA group had an increase in time spent in the euglycemic range (BG 70 to 180 mg/dl) from 57% at baseline to 74% at 6 months (p=0.001), whereas the control group had no increase in time spent in the euglycemic range from baseline (68%) to 6 months (69%). The LIRA group reduced time in the hyperglycemic range (BG > 180 mg/dl), from 39% at baseline to 23% at 6 months (p=0.002); there was no change in time spent in the hyperglycemic range in the control group (29% at baseline and at 6 months). Neither group had any change in the amount of time spent in hypoglycemia (BG < 70 mg/dl) by CGM (LIRA group: 3.7% at baseline to 2.9% at 6 months; control group: 2.7% at baseline to 1.7% at 6 months; p=NS for both groups and between groups). Glycemic variability, expressed as the average daily SD of blood glucose, declined significantly by 25% in the LIRA group, from 40 mg/dl at baseline to 30 mg/dl at 6 months ($p < 0.0001$), whereas the control group had no reduction in glycemic variability (from a baseline of 38 mg/dl to 37 mg/dl at 6 months).
Conclusion: In obese subjects with type 2 diabetes on intensive insulin therapy with >100 units of insulin per day, the addition of liraglutide to insulin resulted in similar improvement in HbA1c to the current standard therapy of insulin up-titration alone, but with additional benefits of weight loss, reduction in TDID, increased percent of time in the euglycemic range and reduced glycemic variability by CGM.

A novel fixed-ratio combination of insulin degludec and liraglutide improves postprandial glycaemic control in patients with type 2 diabetes: results from a standardised meal test
J.J. Holst[1], J. Buse[2], S.C.L. Gough[3], H.W. Rodbard[4], V.C. Woo[5], S. Linjawi[6], P. Poulsen[7], L.H. Damgaard[7], B.W. Bode[8];
[1]The Panum Institute, University of Copenhagen, Denmark, [2]UNC, Chapel Hill, USA, [3]Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, UK, [4]Endocrine and Metabolic Consultants, Rockville, USA, [5]University of Manitoba, Winnipeg, Canada, [6]Coffs Endocrine & Diabetes Services, Coffs Harbour, Australia, [7]Novo Nordisk A/S, Søborg, Denmark, [8]Atlanta Diabetes Associates, Atlanta, USA.

Background and aims: Improvements in postprandial glycaemic control with the GLP-1 analogue, liraglutide (Lira), are in part attributed to the stimulation of postprandial insulin secretion. IDegLira is a novel fixed-ratio combination of the ultra-long-acting basal insulin, insulin degludec (IDeg), and Lira. Here we compare IDegLira vs IDeg or Lira given alone with respect to postprandial glycaemic control as assessed by a standardised 4-h mixed-meal test.
Materials and methods: In this 26-week randomised open-label trial in patients with type 2 diabetes inadequately controlled on metformin ± pioglitazone (n=1663; mean age: 55 yrs; diabetes duration: 6.6 yrs; HbA_{1c}: 8.3%; BMI: 31.2 kg/m^2), IDegLira was added once daily and compared to IDeg or Lira (1.8 mg) given alone. IDegLira and IDeg were titrated to achieve a similar pre-breakfast plasma glucose (PG) target of 4-5 mmol/l. A subgroup of patients (n=260) were randomised to a standardised 4-h liquid mixed-meal test (fasting ≥8 h) at baseline and after 26 weeks. PG, plasma glucagon and serum insulin were measured at timed intervals. For each parameter, mean incremental increase was calculated as the area under the curve (AUC) above the pre-meal value from t=0 to 4 h ($iAUC_{0-4h}$). Insulin secretion adjusted for postprandial glucose levels was expressed as $AUC_{insulin0-4h}/AUC_{glucose0-4h}$.
Results: After 26 weeks, IDegLira produced a significantly greater decrease from baseline in mean postprandial PG increment over the meal test ($iAUC_{0-4h}$) than IDeg (-0.87 vs. -0.17 mmol/l; estimated treatment difference (ETD): -0.71 mmol/l [-1.17; -0.26], p=0.0023). Similar reductions were observed for IDegLira and Lira (-0.87 vs -0.78 mmol/l; ETD: -0.09 mmol/l [-0.56; 0.37], p=0.70). Changes in postprandial insulin secretion ($iAUC_{0-4h}$) from baseline to week 26 were 20.6 vs -26.7 pmol/l for IDegLira vs IDeg (p=0.077), and 20.6 vs 64.8 pmol/l for IDegLira vs. Lira (p=0.083). Adjusting insulin secretion for postprandial glucose levels indicated that insulin secretion during the meal test was significantly higher for IDegLira than IDeg (33.8 vs 25.7 pM/mM; p=0.048), whereas insulin secretion was similar for IDegLira and Lira (33.8 vs 36.8 pM/mM; p=0.45). Postprandial glucagon ($iAUC_{0-4h}$) was suppressed similarly for IDegLira and IDeg (ETD: 0.00 pg/ml [-3.51; 3.50], p=0.998) but significantly more suppressed by IDegLira vs Lira (ETD: -5.38 pg/ml [-8.91; -1.86], p=0.0029).
Conclusion: IDegLira provides significantly better postprandial glycaemic control following a standardised mixed meal than IDeg. Because IDegLira and IDeg suppress glucagon secretion to a similar extent, the reduced postprandial PG increment associated with IDegLira may to some extent be explained by the higher endogenous insulin secretion associated with IDegLira compared to IDeg. The effect on postprandial glycaemic control and endogenous insulin secretion of the Lira component is maintained when used in a fixed-ratio combination with exogenous insulin (IDeg).

HARMONY 1 results at week 52 primary endpoint: once-weekly albiglutide vs placebo in patients with type 2 diabetes mellitus not controlled on pioglitazone ± metformin
J. Reusch[1], M. Stewart[2], C. Perkins[3], P. Ordronneau[2], J. Ye[4], C. Perry[2], R. Reinhardt[2], B. Bode[5];
[1]University of Colorado Anschutz Medical Center, Denver, [2]GlaxoSmithKline, Upper Merion, [3]PPD, Winston, [4]GlaxoSmithxKline, Research Triangle Park, [5]Atlanta Diabetes Association, Atlanta, USA.

Background and aims: The aim was to evaluate the efficacy and safety of the GLP-1 receptor agonist albiglutide administered subcutaneously once weekly vs placebo in patients with type 2 diabetes mellitus who had inadequately controlled haemoglobin A_{1c} (HbA_{1c}: 7–10%) on pioglitazone ± metformin.

Materials and methods: The trial was designed as a 3-year, randomised, double-blind, placebo-controlled, Phase III study. Patients on background pioglita zone ± metformin were randomised to receive either albiglutide 30 mg or placebo subcutaneously once weekly and were allowed to continue in the study if hyperglycaemic rescue was required.The primary objective was to evaluate HbA_{1c} change from baseline to Week 52 using an analysis of covari ance model adjusting for baseline HbA_{1c},region, prior myocardial infarc tion history, age, and background therapy.
Results: Baseline demographics were similar between the groups; mean HbA_{1c} 8.1%, mean age 55 years, BMI 34 kg/m^2, and duration of diabetes 8 years, Week 52 change from baseline HbA_{1c} was −0.05% for placebo and −0.81% for albiglutide, treatment difference [TD]: −0.75% (95% CI −0.95%, −0.56%), p <.0001. Fasting plasma glucose mirrored HbA_{1c} and showed a rapid improvement which was maintained out to 52 weeks (+0.35 mmol/l for placebo, −1.28 mmol/l for albiglutide [TD]: −1.64 mmol/l, p <.0001). There was a non-significant difference in weight change from baseline between the groups (+0.45 kg for placebo, +0.28 kg for albiglutide, TD: −0.1 8 kg). Adverse events (% participants including rescue) reported included nausea and vomiting, which was comparable between albiglutide and placebo (10.7%/11.3% and 4.0%/4.0%, respectively), diarrhoea, which was higher with albiglutide (11.3% vs 8.6%, respectively) and injection site reactions, which were also higher for albiglutide (11.3% vs 7.9%, respectively). The incidence of pre-rescue documented symptomatic (≤3.9 mmol/l) and severe hypoglycaemia was low: 1% and 0%, respectively, for placebo vs 3% and 1%, respectively, for albiglutide.
Conclusion: Albiglutide added on in combination therapy resulted in a robust and sustained glycaemic improvement with good tolerability in patients with type 2 diabetes mellitus.

HARMONY 2 results at week 52 primary endpoint: once-weekly albiglutide monotherapy for patients with type 2 diabetes mellitus inadequately controlled with diet and exercise

R. Reinhardt[1], M.A. Nauck[2], M. Stewart[1], C. Perkins[3], A. Jones-Leone[1], F. Yang[1], C. Perry[1], M. Rendell[4];
[1]GlaxoSmithKline, Upper Merion, USA, [2]Diabeteszentrum Bad Lauterberg, Harz, Germany, [3]PPD, Winston, [4]Creighton University, Omaha, USA.

Background and aims: The aim was to evaluate the efficacy and safety of 2 doses of the GLP-1 receptor agonist, albiglutide, compared to placebo in patients with type 2 diabetes mellitus who had inadequately controlled haemoglobin A_{1c} (HbA_{1c}: 7–10%) with diet and exercise alone.
Materials and methods: The trial was designed as a 3-year, randomised, double-blind, placebo-controlled, Phase III study. Patients on diet and exercise were randomised to receive either albiglutide 30 or 50 mg (all began at 30 mg, while those in the high-dose group uptitrated to 50 mg at Week 12) or placebo subcutaneously once weekly. Patients were allowed to continue in the study if hyperglycaemic rescue was required. The primary objective was to evaluate HbA_{1c} change from baseline at Week 52, using an analysis of covariance model adjusting for baseline HbA_{1c}, region, prior myocardial infarction history, age, and background therapy. Step-wise statistical analysis was first performed for high-dose albiglutide vs placebo followed by low-dose albiglutide vs placebo.
Results: Baseline demographics were similar across treatment groups; mean HbA_{1c} 8.1%; mean age 53 years; BMI 34 kg/m^2; and duration of diabetes 4 years. Week 52 change from baseline HbA_{1c} difference (albiglutide − placebo) was −0.84% (95% CI −1.11, −0.58) for albiglutide 30 mg and −1.04% (95% CI −1.31, −0.77) for albiglutide 50 mg; both p <.0001. Fasting plasma glucose decreased rapidly and the improvement mirrored HbA_{1c} out to 52 weeks (−1.89 mmol/l (95% CI −2.55, −1.22) for albiglutide 30 mg and −2.38 mmol/l (95% CI −3.05, −1.71) for albiglutide 50 mg, both p <.0001). Weight decreased in all groups: placebo, −0.7 kg; albiglutide 30 mg, −0.4 kg; and albiglutide 50 mg, −0.9 kg. Gastrointestinal adverse events (% participants including rescue) were low and comparable for placebo/albiglutide 30 mg/albiglutide 50 mg: nausea 8%/10%/9%; diarrhoea 12%/10%/13%; and vomiting 1%/3%/3%. Injection site reactions (% participants including rescue) were higher in the low-dose (18%) and high-dose (22%) albiglutide groups as compared to placebo (10%). The incidence of pre-rescue documented (≤3.9 mmol/l) symptomatic hypoglycaemia (%) for placebo/albiglutide 30 mg/albiglutide 50 mg were 2%/1%/0%; no severe events were reported in the study.
Conclusion: Once-weekly monotherapy with albiglutide in drug-naïve patients with type 2 diabetes mellitus resulted in a dose-dependent robust and durable glycaemic improvement out to 52 weeks of therapy.

HARMONY 4: 52-week efficacy of albiglutide vs insulin glargine in patients with type 2 diabetes mellitus

R. Pratley[1], M. Stewart[2], D. Cirkel[3], J. Ye[4], C. Perry[2], M.C. Carr[2];
[1]Florida Hospital Diabetes Institute, Sanford-Burnham Medical Research, Orlando, [2]GlaxoSmithKline, Upper Merion, USA, [3]GlaxoSmithKline, Stevenage, UK, [4]GlaxoSmithxKline, Research Triangle Park, USA.

Background and aims: To assess the efficacy and safety of the GLP-1 receptor agonist albiglutide administered once weekly vs daily glargine in patients with type 2 diabetes mellitus who had inadequately controlled haemoglobin A_{1c} (HbA_{1c}: 7–10%) on a regimen of metformin ± sulphonylurea therapy.
Materials and methods: The trial was a 3-year, randomised, open-label, parallel-group, multicentre, Phase III study. Albiglutide was administered at 30 mg once weekly vs glargine. Patients were treated to a target HbA_{1c} ≤7.0% and fasting plasma glucose (FPG) ≤5.6 mmol/l. If needed, patients could uptitrate to albiglutide 50 mg once weekly and glargine (per pre-specified criteria). Patients were allowed to continue hyperglycaemic rescue was required. The primary objective was to evaluate the HbA_{1c} change from baseline to Week 52 in albiglutide vs glargine.
Results: Baseline demographics were similar between groups; mean age 56 years, BMI 33 kg/m^2, HbA_{1c} 8.3%, duration of diabetes 8.8 years, 82% receiving metformin + sulphonylurea. HbA_{1c} decreased in both groups. The Week 52 treatment difference was 0.11% (95% CI: −0.04%, 0.27%). The upper bound of the CI was below the non-inferior margin of 0.3%, indicating non-inferiority of albiglutide to glargine. Change in FPG significantly favoured glargine, whereas change in weight significantly favoured albiglutide. Adverse

events through Week 52 for albgilutide/glargine were: nausea 9.9%/3.7%; diarrhoea 7.5%/4.1%;vomiting 3.8%/3.7%, respectively. Documented (≤3.9 mmol/l) symptomatic and severe hypoglycaemic events (prior to the addition of hyperglycaemia rescue medications) were fewer with albiglutide vs glargine (18%/0.4% and 27%/0.4%, respectively). Injection site reactions occurred in 13.9% of albiglutide and 8.7% of glargine patients.

Conclusion: Albiglutide treatment resulted in HbA_{1c} improvement at Week 52 that was non-inferior to glargine with modest weight loss. Both drugs were well tolerated.

Table. Week 52 Model-Adjusted Change From Baseline Least Square Mean for Key Efficacy Parameters

	Albiglutide (n = 496)	Glargine (n = 239)
HbA_{1c}, least square mean[a] (SE), %	−0.67 (0.04)	−0.79 (0.06)
p value (noninferiority)	.0086	
p value (superiority)	.1463	
FPG, least square mean (SE), mg/dl	−15.7 (2.30)	−37.1 (3.31)
p value	< .0001	
Weight, least square mean (SE), kg	−1.05 (0.17)	+1.56 (0.25)
p value	< .0001

52-week efficacy of albiglutide vs placebo and vs pioglitazone in triple therapy (background metformin and glimepiride) in patients with type 2 diabetes: HARMONY 5 study

M. Stewart[1], P. Home[2], F. Yang[1], C. Perry[1], M.C. Carr[1];
[1]GlaxoSmithKline, Upper Merion, USA, [2]Institute of Cellular Medicine, Newcastle University, Newcastle upon Tyne, UK.

Background and aims: To evaluate the efficacy and safety of the GLP-1 receptor agonist albiglutide (Albi) administered once weekly vs placebo (Pbo) and vs pioglitazone (Pio) in patients on dual therapy (all on background metformin and glimepiride) with baseline haemoglobin A_{1c}(HbA_{1c}) 7.0–10.0% (53–85 mmol/mol).

Materials and methods: The trial was designed as a randomised (N=685), double-blind, multicentre (234 centres) study. Dual-therapy dose stability (metformin >1500 mg, glimepiride 4 mg) was required after screening before randomisation. Uptitration of Albi 30 mg to 50 mg once weekly and Pio 30 mg to 45 mg once daily (both masked) was allowed if needed. Patients were allowed to continue if hyperglycaemic rescue was required. The primary objective was adjusted HbA_{1c} change from baseline at Week 52. Step-wise statistical analysis was first vs Pbo, then non-inferiority (margin: 0.30%) testingvs Pio.

Results: Baseline age w as 55.2 years (mean, SD 9.5), BMI 32.2 kg/m^2 (5.5), HbA_{1c} 8.2% (0.9%), duration of diabetes 8.9 years (6.2). Week 52 HbA_{1c} difference (Albi - Pbo) was −0.87% (95%CI: −1.07%, −0.68%) (−9.5 mmol/mol [−11.7, −7.4]; *p* <.0001)and vs Pio 0.25% (0.10%, 0.40%) (2.7 mmol/m ol [1.1, 4.4]) (non-inferiority *p* value .27, not shown non-inferior). Changes in fasting plasma glucose (FPG) mirrored those of HbA_{1c} (Table). Albi and Pio differed in weight change direction, difference −4.9 kg (−5.5, −4.2) (*p* <.0001) (Table). Adverse events included more gastrointestinal and injection site reaction reports with Albi vs Pbo and vs Pio, and more documented symptomatic hypoglycaemic events with Pio and Albi, with severe events being too infrequent to analyse (Table).

Conclusion: Albiglutide in triple therapy effectively lowers glucose with no unexpected side effects.

Table. Efficacy (Adjusted Mean Difference From Baseline [SE]) and Adverse Event (%) Findings at 52 Weeks

	Albiglutide	Pioglitazone	Placebo
Participants (n)	269	273	115
HbA_{1c} (%)	−0.55 (0.06)	−0.80 (0.06)[a]	+0.33 (0.08)[b]

HARMONY 8: once-weekly glucagon-like peptide 1 receptor agonist albiglutide vs sitagliptin for patients with type 2 diabetes with renal impairment: week 26 results

L. Leiter[1], M.C. Carr[2], M. Stewart[2], A. Jones-Leone[2], F. Yang[2], Y. Handelsman[3];
[1]University of Toronto, Ontario, Canada, [2]GlaxoSmithKline, Upper Merion, [3]Metabolic Institute of America, Tarzana, USA.

Background and aims: Therapies for patients with type 2 diabetes mellitus with renal impairment are limited and may require dose adjustment. This study evaluated the efficacy and safety of the GLP-1 receptor agonist albiglutide administered once weekly vs sitagliptin in patients with type 2 diabetes mellitus and renal impairment who had inadequately controlled haemoglobin A_{1c} (HbA_{1c}: 7–10%).

Materials and methods: Thistrial was designed as a 52-week, randomised, double-blind, active-controlled, Phase III parallel-group study. Once-weekly albiglutide 30 mg (uptitrated to 50 mg, if needed) vs daily sitagliptin was administered to patients with type 2diabetes mellitus and renal impairment (estimated glomerular filtration rate [eGFR] ≥15 and <90 ml/min per 1.73 m^2) on lifestyle only (11% of patients) or metformin, thiazolidinedione, sulphonylurea, or any combination (89% of patients). Sitagliptin was dosed by the degree of renal impariment per prescribing information; albiglutide dose did not require modification. Patients were allowed to continue if hyperglycaemic rescue was required. Primary endpoint wasHbA_{1c} change at Week 26 for albiglutide vs sitagliptin (non-in feriority with subsequent superiority analysis).

Results: Demographics matched between groups, including the degree of renal impairment; mean age 63 years, weight 83 kg, and HbA_{1c} 8.2%. HbA_{1c} decreased in both groups: −0.83% for albiglutide (n=246) and−0.52% for sitagliptin (n=240) at Week 26; treatment difference = −0.3 2% (95%CI: −0.49%, −0.15%). Albiglutide was superior to sitagliptin (*P* =.00 03). Mean HbA_{1c} change was greater with albiglutide vs sitagliptin regardless of degree of renal impairment. 35% of albiglutide patients uptitrated to 50 mg. HbA_{1c} <7% was achieved by 42.6% of albiglutide and 30.5% of sitagliptin patients. Fasting plasma glucose (−1.42 mmol/l vs −0.22mmol/l , *p* <.0001) and weight change (−0.8 kg vs −0.2 kg, *p* =.0281) favoured albiglutide. Adverse event rates for albiglutide/sitagliptin were low in both groups: nausea: 4.8%/2.8%,diarrhoea: 8.8%/6.1%, and vomiting:1.6%/0.8%. Documented (≤3.9 mmol/l) symptomatic hypoglycaemia rates (prior to the addition of hyperglycaemia rescue medications) were 10.4% (0 sev ere) for albiglutide v 5.7% (0.8% severe) for sitagliptin. Injection site reaction rate was 6.8% for albiglutide vs 2.8% for sitagliptin. Anti-albiglutide antibody rate was 2.8% (0% neutralising).

Conclusion: In patients with type 2 diabetes mellitus and renal impairment, once-weekly albiglutide had superior reductions of HbA_{1c} at Week 26 vs sitagliptin without requiring dose adjustment. Both agents were well tolerated.

Table. Change From Baseline in HbA_{1c} at Week 26 by Severity of Renal Impairment

	Albiglutide				Sitagliptin			
Renal impairment severity (eGFR range, ml/min/1.73 m²)	Mild (60–89) n=125	Moderate (30–59) n=98	Severe (15–29) n=19	Any (15–89) n=246	Mild (60–89) n=122	Moderate (30–59) n=99	Severe (15–29) n=15	Any (15–89) n=240

Meta-analysis of GLP-1 agonist lixisenatide use in patients insufficiently controlled with OADs

D. Raccah[1], A. Ceriello[2], P. Gourdy[3], L. Sagnard[4], J. Lin[5], J. Rosenstock[6];
[1]Department of Diabetology, University Hôpital Sainte Marguerite, Marseille, France, [2]Institut d'Investigacions biomèdiques August Pi i Sunyer (IDIBAPS), Barcelona, Spain, [3]Department of Diabetology, University Hospital Rangueil, Toulouse, [4]Sanofi, Paris, France, [5]Novosys Health, Flemington, [6]Dallas Diabetes and Endocrine Center, Dallas, USA.

Background and aims: Lixisenatide is a new once-daily prandial glucagon-like peptide-1 (GLP-1) receptor agonist, which was granted marketing authorization in Europe in February 2013 for the treatment of type 2 diabetes mellitus (T2DM).
Materials and methods: The safety and efficacy of lixisenatide was evaluated in combination with oral antidiabetic drugs (OADs) in patients with T2DM in five GetGoal Phase III studies (GetGoal-M, GetGoal-P, GetGoal-S, GetGoal-M-Asia and GetGoal-F1). The current meta-analysis reports composite efficacy and safety outcomes for lixisenatide compared with placebo.
Results: There were no significant differences in baseline characteristics between the lixisenatide and placebo groups (mean age: 55.5 years, mean BMI: 31.5 kg/m^2, duration of diabetes: 7.4 years, duration of OAD use: 4.5 years, metformin use: 92.3%, sulfonylurea use: 35.6%, thiazolidinedione use: 16.5%). The total patient population included n=1828 in the lixisenatide group and n=932 in the placebo group. A significantly greater proportion of patients treated with lixisenatide achieved HbA_{1c} <7% compared with placebo (odds ratio [95% confidence interval (CI)] 2.7 [2.1, 3.4], p<0.0001). Lixisenatide was also significantly better than placebo for the composite endpoints of HbA_{1c} <7% and no weight gain (odds ratio [95% CI]: 2.6 [2.0, 3.5], p<0.0001), HbA_{1c} <7% and no documented symptomatic hypoglycaemia (odds ratio [95% CI]: 2.6 [2.0, 3.2], p<0.0001) and HbA_{1c} <7%, no weight gain and no documented symptomatic hypoglycaemia (odds ratio [95% CI]: 2.5 [1.9, 3.3], p<0.0001) (Table). Only one patient reported documented severe hypoglycaemia (0.05%) (lixisenatide in combination with sulfonylurea).
Conclusion: Treatment with lixisenatide in patients with T2DM inadequately controlled on OADs significantly reduces HbA_{1c} (-0.9% vs -0.3%; p<0.0001) and is 2.5 times more likely than placebo to result in HbA_{1c} <7% with no documented symptomatic hypoglycaemia and/or no weight gain.

Meta-analysis of randomised controlled trials of lixisenatide as add-on to basal insulin and/or oral antidiabetic drugs in patients with type 2 diabetes mellitus

M.L. Puig Domingo[1], V. Fonseca[2], E. Wang[3], J. Lin[4], M. Davies[5], F.J. Tinahones[6], B. Charbonnel[7];
[1]Service of Endocrinology and Nutrition, Hospital Universitari Germans Trias i Pujol, Badalona, Spain, [2]Tulane University Health Sciences Center, New Orleans, [3]Sanofi-Aventis, Bridgewater, [4]Outcomes Research, Novosys Health, Flemington, USA, [5]University of Leicester, UK, [6]Departament of Endocrinology, Virgen de la Victoria University Hospital, Málaga, Spain, [7]Clinique d'Endocrinologie, University of Nantes, France.

Background and aims: Lixisenatide is a new once-daily prandial glucagon-like peptide-1 (GLP-1) receptor agonist, which was granted marketing authorization in Europe in February 2013 for the treatment of Type 2 diabetes mellitus (T2DM).
Materials and methods: The safety and efficacy of lixisenatide has been evaluated in combination with basal insulin with or without oral antidiabetic drugs in three Phase III, randomized, placebo-controlled trials (GetGoal-L, GetGoal-Duo-1 and GetGoal-L-Asia) in T2DM. Endpoints included HbA_{1c}, weight, insulin dose, fasting blood glucose, postprandial glucose and hypoglycaemia. A meta-analysis was performed on the safety and efficacy outcomes in 1198 patients (mean age: 57.2 years; diabetes duration: 11.7 years; BMI: 30.3 kg/m^2) using a random effects model (RevMan).
Results: Mean HbA_{1c} at baseline for lixisenatide compared with placebo-treated patients was 8.2% vs 8.1%, respectively. At endpoint, mean HbA_{1c} for lixisenatide, compared with placebo-treated patients, was 7.5% vs 7.9%, respectively. A significantly higher proportion of lixisenatide-treated patients achieved HbA_{1c} <7% compared with placebo (odds ratio [95% CI]: 3.7 [1.6, 8.2], p=0.0016). Furthermore, lixisenatide was more than three times more likely than placebo to result in HbA_{1c} <7% and no weight gain (odds ratio [95% CI]: 3.4 [1.7, 6.8], p=0.0008), and more than 2.5 times more likely than placebo to result in HbA_{1c} <7% together with no documented symptomatic hypoglycaemia (odds ratio [95% CI]: 2.7 [1.3, 5.4], p=0.0073). Lixisenatide was also more than 2.5 times as likely to result in HbA_{1c} <7% and no weight gain and no documented symptomatic hypoglycaemia (odds ratio [95% CI]: 2.6 [1.5, 4.7], p=0.0009) (Table).
Conclusion: In patients with T2DM, lixisenatide in combination with basal insulin with or without oral antidiabetic drugs is significantly more effective than placebo in combination with basal insulin with or without oral antidiabetic drugs in achieving HbA_{1c} <7%, and is more than 2.5 times as likely to result in HbA_{1c} <7% with no documented hypoglycaemia and no weight gain. Lixisenatide is a treatment option as add-on to treatment with basal insulin.

Effect of metformin on glycotoxic intermediate-methylglyoxal metabolism in patients with type 2 diabetes

Z. Kender[1], T. Fleming[2], P. Reismann[1], K. Rácz[1], P. Nawroth[2];
[1]2nd Department of Medicine, Semmelweis University, Budapest, Hungary, [2]Department of Medicine I and Clinical Chemistry, University of Heidelberg, Germany.

Background and aims: Hyperglycaemia increases the formation of intracellular reactive oxigen species and glycotoxic intermediates. Methylglyoxal (MG) is a highly potent glycatic agent that is throught to contribute to late diabetic complications either as a toxic agent or as a precursor for advanced glycation end products. Metformin, a biguanide is the most widely prescribed oral glucose-lowering agent for the treatment of type 2 diabetes. Its primary mechanism of action is to increase hepatic and peripherial tissue sensitivity to insulin. Metformin has also been proposed as a scavenger of MG. The effect of metformin on MG metabolism was studied with respect of its effects on MG levels, triosphosphate intermediates (TPINT) and intracellular activity of glyoxalase-1 (Glo1), the GSH dependent enzyme for MG detoxification in a prospective non-randomized 24 weeks trial of 12 patients with type 2 diabetes.
Materials and methods: Whole blood was sampled from newly diagnosed patients with type 2 diabetes in the fasting state at beginning and end of the 24 week trial period. The patients were educated for a low energy diet and treated with metformin (2000 mg/day). Glycaemic control was determined by blood glucose and HbA1C. Plasma MG was detected by HPLC. The glyoxalase system was measured by enzyme assays in peripherial blood mononuclear cells and red blood cells. TPINT was determined by endpoint enzymatic assays. Plasma N-Epsilon-(Carboxymethyl)-Lysine (CML) modified protein concentration was determined by ELISA.
Results: At baseline MG levels correlated with Glo1, but not glyoxalase 2 (Glo2) activity. Metformin treatment in addition to low energy diet reduced significantly fasting glucose from 7.7 to 6.3 mmol/l (p=0.04), HbA1c from 7.02 to 6.23% (p=0.02) while body weight and BMI was only marginally reduced during the 24 week trail. Treatment reduced significantly MG, from 653.3 to 451.1 nM (p=0.015) and subsequently also levels of CML, from 283.37 to 197.8 ng/ml (p=0.016). The reduction of MG was paralleled by a significant increase in the activity of Glo1 in peripherial blood mononuclear cells, from baseline 0.51 to 1.02 mM-1min-1mg-1 (p=0.002) and red blood cells from 0.22 to 0.39 mM-1min-1mg-1 (p=0.03), while no effect was observed on Glo2 activity. In addition no effect was found on triosephosphate intermediates such as glyceraldehyde-3-phosphate (GAP), dihydroxyacetonephosphate (DHAP), fructose-1,6-bisphosphate (FDP) or the TPI-pool. Most importantly multivariate analysis showed that the changes in MG were dependent upon the metformin treatment.
Conclusion: Metformin might beneficial influence on the glycotoxic intermediate-methylglyoxal-metabolism in type 2 diabetes. Our results supports previously findings that metformin can reduce plasma MG in type 2 diabetic patients. However, given the observed increase in Glo1 activity, this reduction is due not to the scavenging properties of metformin, but restoration of Glo1 activity.

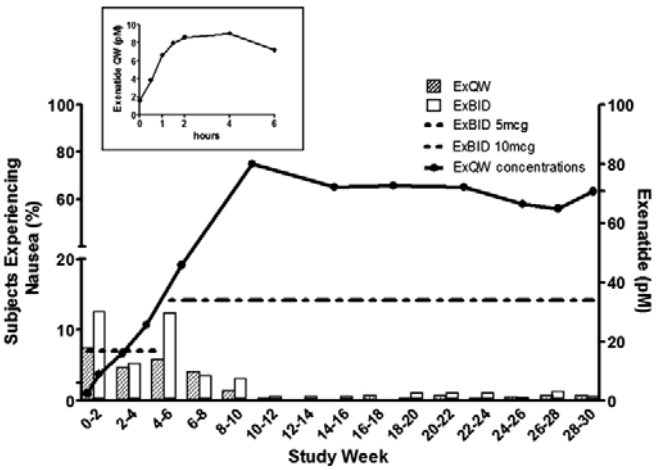
Gastrointestinal tolerability with twice-daily or once-weekly exenatide formulations was not predicted by concentration with long-term treatment

B. Cirincione, J. Edwards, M. Aisporna, L. MacConell;
Bristol-Myers Squibb, San Diego, USA.

Background and aims: The most frequent adverse events (AEs) associated with GLP-1 receptor agonists (GLP-1RA) are gastrointestinal (GI) eg nausea and vomiting. It has been hypothesized that GI AEs are related to GLP-1RA concentration (conc). To decrease GI AEs for exenatide (Ex) twice daily (EBID), a dose titration paradigm was employed (5 mcg for 4 weeks; 10 mcg maintenance dose). We examined Ex conc and GI AEs for the once-weekly 2 mg (EQW) sustained-release formulation (apparent $t_{1/2}$ = 15 d) and EBID immediate-release formulation ($t_{1/2}$ = 2.4 h).
Materials and methods: Ex conc and/or tolerability data from 2 clinical trials of EQW vs EBID (24 or 30 weeks) were evaluated, including extension data to 4 y. The conc of Ex (pM) in plasma was measured by ELISA and geometric means ± SE were calculated.
Results: With EQW there is an initial release of Ex within hours of injection (peak mean conc 9.0 pM at 4 hours; Figure inset), which is less than the 5 mcg dose of EBID (17 pM). The overall incidence of nausea was low on day 1 for EQW (1.8%) and EBID (4.9%). The lower incidence of nausea for EQW is consistent with lower peak conc. With repeated dosing $C_{steady\ state}$ for EQW (8 to 30 weeks) was 69.4 ± 2.9 pM (n = 217) and C_{max} for 10 mcg EBID was 34.0 ± 3.5 pM (n = 72). Despite the higher sustained conc of Ex with EQW, the incidence of nausea over all 30 weeks was lower for EQW than for EBID (22% vs 37%) and fewer patients discontinued due to GI AEs (1% vs 4%, respectively). Overall, the time course of GI AEs differed from the time course of Ex conc with both Ex formulations. For EQW, Ex conc gradually increased over time (steady state conc at 8-10 weeks), peak nausea occurred before week 6 and then declined markedly and remained low (only 1% reported between 3.5 and 4 y, n = 94). For EBID, the incidence of nausea decreased over time except for a transient increase at weeks 4-6, which coincides with dose titration from 5 to 10 mcg. The decreased incidence was not due to patient discontinuation for either formulation. In patients switched from EBID to EQW, no increase in GI AEs was apparent despite sustained and increased Ex conc; only 1 patient who switched withdrew due to nausea. Furthermore, there was no meaningful difference in steady-state Ex conc between patients who did and did not report nausea and/or vomiting with EQW (74.1 ± 6.5 pM [n = 31] vs 68.7 ± 3.2 pM [n = 186], respectively).
Conclusion: Ex conc was not an important predictor of GI AEs following the development of tolerance to Ex, which occurs within weeks of initiating Ex therapy, regardless of formulation. The lower incidence of GI AEs in subjects receiving EQW occurred despite higher sustained exenatide conc compared with EBID. For EQW, the gradual release of Ex from the microspheres results in a slow increase in exenatide conc over the first 6-8 weeks, to achieve optimal steady state levels of Ex for glycemic response, without the need for dose titration to mitigate GI AEs.



Clinical Trial Registration Number: NCT00308139, NCT00877890

Chronic palmitate excess results in reduced exendin-4 action and signalling via CREB and Akt in pancreatic beta cells

A. Natalicchio, G. Biondi, N. Marrano, F. Tortosa, R. Labarbuta, S. Perrini, L. Laviola, F. Giorgino;
Endocrinology & Metabolic Diseases, University of Bari, Italy.

Background and aims: The incretin effect is attenuated or markedly diminished in type 2 diabetic and obese subjects. The aim of this study was to investigate the mechanisms of incretin resistance induced by prolonged exposure to high concentrations of saturated fatty acids in pancreatic beta-cells.
Materials and methods: Studies were carried out in rat INS-1E cells treated with 0.5 mM palmitate for 24 h and in pancreatic islets from mice fed a high fat diet for 21 days. Mouse islets were isolated by bile duct perfusion and col-

lagenase digestion. Expression and phosphorylation levels of specific signaling molecules were assessed by immunoblotting techniques. Gene expression was evaluated by real-time RT-PCR. Insulin secretion was measured using an insulin ELISA.
Results: Prolonged exposure of INS-1E cells to palmitate reduced the ability of exendin-4 to augment insulin mRNA levels and to induce insulin release by 50% and 60%, respectively ($p<0.05$). In addition, palmitate markedly impaired exendin-4-stimulated CREB and Akt phosphorylation, whereas phosphorylation of MEK and Erk-1/2 was not altered; moreover, palmitate did not interfere with the ability of IGF-I to activate CREB and Akt, indicating that the inhibitory effects of palmitate are specific for exendin-4 signaling via CREB and Akt. Both islets from mice fed a high fat diet and INS-1E cells exposed to palmitate showed increased SREBP-1c mRNA (by 2-fold, $p<0.05$), reduced PDX-1 mRNA levels (by 45%; $p<0.05$), and reduced GLP-1 receptor mRNA and protein levels (by 30% and 50%, respectively; $p<0.05$) compared to control. Furthermore, in INS-1E cells, RNAi-mediated silencing of the GLP-1 receptor prevented exendin-4-induced CREB and Akt phosphorylation ($p<0.05$), but did not impair the ability to activate MEK and Erk-1/2. In addition, when INS-1E cells were pretreated with 1,10-phenanthroline, an inhibitor of SREBP-1c, the palmitate-induced reduction in PDX-1 and GLP-1 receptor levels was abrogated ($p<0.05$), and the ability of exendin-4 to stimulate CREB and Akt phosphorylation was restored ($p<0.05$). In contrast to palmitate, exposure of INS-1E cells to oleate for 24 h led to reduced SREBP-1c mRNA, and increased PDX-1 and GLP-1 receptor mRNA and protein levels. Consequently, oleate enhanced the ability of exendin-4 to stimulate CREB and Akt phosphorylation ($p<0.05$) and to induce insulin mRNA levels ($p<0.05$).
Conclusion: Prolonged exposure of pancreatic beta-cells to elevated concentrations of palmitate results in reduced exendin-4 action on insulin expression and secretion. The mechanisms underlying the resistance to the insulinotropic effect of exendin-4 appears to involve palmitate-mediated induction of SREBP-1c, which results in diminished GLP-1 receptor expression and specific reduction of signaling via CREB and Akt.

MK0626, a DPP-4 inhibitor for use in mice, in combination with low-dose systemic anti-CD3 stably reverses new-onset diabetes in non-obese diabetic mice

L. Ding, T. Takiishi, H. Korf, C. Gysemans, C. Mathieu;
Clinical and Experimental Endocrinology, Katholieke Universiteit Leuven, Belgium.

Background and aims: Immunotherapy can temporarily arrest loss of beta-cell function, but stable, permanent insulin independence is not achieved. Today, combining immune interventions with regenerative medicine or beta-cell replacement is considered as the way forward in type 1 diabetes cure. Dipeptidyl peptidase-4 (DPP-4) inhibitors increase circulating levels of incretin hormones, which can enhance insulin secretion and beta-cell function. We tested whether MK0626, a sitagliptin analog, enhances diabetes remission in new-onset diabetic non-obese diabetic (NOD) mice treated with low-dose systemic anti-CD3 and studied the effects of combination therapy (CT) on immune system as well as cellular and metabolic responses of beta-cells.
Materials and methods: Recent-onset diabetic NOD mice were given anti-CD3 for 5 consecutive days (clone 145-2C11, 2.5 μg/d, i.v.) together with MK0626 (3 mg/kg p.o.) for 3 weeks.
Results: Low-dose anti-CD3 plus MK0626 cured diabetes in 52% of animals (n=23), better than the anti-CD3 alone which cured diabetes in 35% (n=23), while MK0626 alone cured diabetes in 25% (n=4). Interestingly, anti-CD3 with MK0626 cured 69% of mice starting with glycaemia levels 350 mg/dl in contrast to 38% of mice treated with anti-CD3 alone. Anti-CD3 with MK0626 increased beta-cell volume as well as total insulin content in pancreas when compared to anti-CD3 alone. Moreover the CT induced recovery of GLUT-2 in beta-cells, although to the same extent as the anti-CD3 therapy alone. Splenic CD4+/CD8+ ratio for CT and anti-CD3 alone decreased temporarily compared to new-onset diabetic NOD mice; this normalised after 7 weeks of therapy discontinuation. CD4+CD25+FoxP3+ T-cell frequencies in pancreatic draining lymph nodes were significantly increased by CT and anti-CD3 alone compared to new-onset diabetic mice and this persisted long-term. As VEGF mRNA levels were clearly increased in pancreas of CT cured mice compared to anti-CD3 alone, we are investigating whether CT improved islet vasculature, which could increase the insulin content of recovered degranulated beta-cells.
Conclusions: MK0626 in combination with anti-CD3 modulates both the immune system and pancreatic beta-cells, which can lead to normalization of hyperglycaemia in diabetic NOD mice.

Renal safety and outcomes with linagliptin: meta-analysis of individual data for 5466 patients with type 2 diabetes

M. von Eynatten[1], M. Cooper[2], V. Perkovic[3], J. Rosenstock[4], C. Wanner[5], U. Hehnke[6], H.-J. Woerle[6];
[1]Boehringer Ingelheim, Ridgefield, USA, [2]The Baker IDI Heart and Diabetes Institute, Melbourne, [3]The George Institute for Global Health, Sydney, Australia, [4]Dallas Diabetes and Endocrine Center at Medical City, Dallas, USA, [5]University Hospital of Würzburg, [6]Boehringer Ingelheim, Germany.

Background and aims: Long-term glycaemic control in diabetes is associated with reduced risk of renal microvascular complications. Linagliptin has been associated with significantly reduced albuminuria in patients with type 2 diabetes mellitus (T2DM) and renal dysfunction. As this effect was not directly related to short-term glycaemic improvements, it has been speculated that linagliptin may have beneficial renal effects. The aim of this study was to evaluate renal outcomes with linagliptin in completed Phase 3, randomised, double-blind, placebo-controlled trials (≥12 wks).
Materials and methods: Predefined events from 13 trials were analysed using a composite primary endpoint: new onset of a) microalbuminuria, b) macroalbuminuria, c) new onset chronic kidney disease (CKD; serum creatinine increase ≥250 μmol/L), d) worsening CKD (loss in estimated glomerular filtration rate [eGFR] >50% vs. baseline), e) acute renal failure (standardised Medical Dictionary for Regulatory Activities query), and f) death by any cause. Statistical analyses included hazard ratio (HR) using cox regression.
Results: Of 5466 participants (mean baseline HbA1c, 8.2%; eGFR, 91.5 mL/min/1.73 m^2), 3505 received linagliptin 5 mg qd and 1961 received placebo. Cumulative exposure was 1756 and 1057 person years, respectively. Events in the composite endpoint occurred in 448 (12.8%) patients receiving linagliptin vs. 306 (15.6%) with placebo, resulting in an HR in favour of linagliptin of 0.84 (95% confidence interval [CI]: 0.72, 0.97; $P<0.05$). For white patients and Asian patients, HRs (95% CI) were 0.82 (0.68, 0.98) and 0.89 (0.68, 1.15), respectively. Among patients <65 years and ≥65 years, HRs (95% CI) were 0.77 (0.64, 0.92) and 1.04 (0.80, 1.35), respectively. HRs (95% CI) for individual renal endpoints were: microalbuminuria, 0.82 (0.69, 0.98); macroalbuminuria, 0.86 (0.61, 1.20); new onset of CKD, 0.32 (0.10, 1.01); worsening of CKD, 1.42 (0.24, 8.52); acute renal failure, 0.94 (0.61, 1.45); and death by any cause, 1.09 (0.29, 4.09).
Conclusion: This large meta-analysis of the linagliptin global Phase 3 development programme supplements the overall safety evidence for linagliptin and supports its potentially favourable renal safety profile. These combined findings support the hypothesis of a potential direct effect of linagliptin on the onset and progression of renal disease in T2DM.

Linagliptin versus placebo followed by glimepiride in type 2 diabetes patients with moderate to severe renal impairment

P.-H. Groop[1], M. Laakso[2], J. Rosenstock[3], U. Hehnke[4], I. Tamminen[5], S. Patel[6], M. von Eynatten[4], H.-J. Woerle[4];
[1]Helsinki University Central Hospital, Department of Medicine, Division of Nephrology, Helsinki, Finland and Folkhälsan Institute of Genetics, Folkhälsan Research Center, Biomedicum Helsinki, [2]Department of Medicine, University of Eastern Finland and Kuopio University Hospital, Kuopio, Finland, [3]Dallas Diabetes and Endocrine Center at Medical City, Dallas, USA, [4]Boehringer Ingelheim, Germany, [5]Boehringer Ingelheim, Helsinki, Finland, [6]Boehringer Ingelheim, Bracknell, UK.

Background and aims: Renal impairment is a serious complication of type 2 diabetes mellitus (T2DM) that restricts options for managing hyperglycaemia and associated increased cardiovascular risk.

Materials and methods: This randomised double-blind trial evaluated the efficacy and tolerability of the dipeptidyl peptidase-4 inhibitor linagliptin in T2DM patients (HbA1c 7-10%) with moderate to severe renal impairment (estimated glomerular filtration rate [eGFR] <60 mL/min/1.73m^2; not on dialysis). Patients received linagliptin 5 mg once daily (qd) (n=113) or placebo (n=122) for 12 weeks, then placebo patients were switched to glimepiride 1-4 mg qd and treatment continued to week 52. The primary endpoint was HbA1c change from baseline at week 12.
Results: At baseline, 63.4% were male, mean±SD age 67±9 years, HbA1c 8.1±0.9% and eGFR 37±13 mL/min/1.73 m^2. Most patients had T2DM for >10 years (76.4%) and were on insulin (85.8%). At week 12, adjusted mean±SE HbA1c change with linagliptin was -0.50±0.06% (change with placebo -0.08±0.07%: difference -0.42%, 95% CI -0.60 to -0.24; *P*<0.0001). In the 40-week extension, HbA1c was lower with linagliptin than glimepiride (Figure). The incidence of drug-related adverse events was similar in the first 12 weeks (linagliptin 23.9%, placebo 24.6%), and lower with linagliptin in the extension (linagliptin 38.3%, glimepiride 46.5%). Hypoglycaemia was less frequent with linagliptin (linagliptin 57.9%, glimepiride 69.3%). Mean adjusted weight increase after 52 weeks was 0.06 kg (linagliptin) and 1.74 kg (placebo/glimepiride).
Conclusion: Linagliptin was efficacious and well tolerated in T2DM patients with moderate to severe renal impairment, with less hypoglycaemia and relative weight loss compared with glimepiride.

Efficacy and safety of alogliptin in subjects with type 2 diabetes: a randomised, double-blind, placebo-controlled, phase 3 study in mainland China, Taiwan and Hong Kong

Q. Ji[1], P. Han[2], C. Li[3], J. Lu[4], J. Yang[5], W. Li[6], J. Zeng[7], A.-T. Hsieh[8], J. Chan[9], C. Pan[10];
[1]The First Affiliated Hospital of the Fourth Military Medical University, Xi'an, [2]Shengjing Hospital of China Medical University, Shenyang, [3]First Affiliated Hospital Zhejiang University College of Medicine, Hangzhou, [4]The General Hospital of the People's Liberation Army, Beijing, [5]Beijing Tongren Hospital, Beijing, [6]Peking Union Medical College Hospital, Beijing, [7]Affiliated Jingzhou Hospital Tongji Medical School, Wuhan, China, [8]Taipei Medical University Shuang Ho Hospital, Taipei, Taiwan, [9]Hong Kong Prince of Wales Hospital, Sha Tin, Hong Kong, [10]The General Hospital of the People's Liberatino Army, Beijing, China.

Background and aims: This multicenter clinical trial in Mainland China, Taiwan and Hong Kong was done to determine the efficacy and safety of once-daily oral Alogliptin (ALO) as monotherapy, add-on to ongoing metformin (MET) therapy, and add-on to pioglitazone (PIO) therapy (with or without MET) in patients with type 2 diabetes.
Materials and methods: A total of 506 subjects (185 in the monotherapy group, 197 in the add-on to MET therapy group, and 124 in the add-on to PIO group) were randomized to receive ALO 25mg QD or placebo (PBO) QD for 16 weeks. The primary endpoint was change from baseline in HbA1c at week 16. The secondary endpoints were change in fasting plasma glucose (FPG), incidence of marked hyperglycemia, clinical HbA1c response, and change in body weight from baseline.
Results: For monotherapy, the decrease of HbA1C from baseline to week 16 in the ALO and PBO arms were 0.99% and 0.42%, respectively (P <0.001). For the add-on to MET group, ALO decreased HbA1c by 0.91 % compared to PBO 0.22% (P<0.001). For add-on to PIO group, ALO decreased HbA1c by 0.76% vs PBO 0.25% (P<0.001). The decreases in FPG were greater in the ALO arms than in the PBO arms. The percentage of subjects able to achieve an HbA1c target of ≤ 6.5%, ≤7.0% and ≤7.5% were all significantly higher (P<0.001) in the ALO arms than in the PBO arms. ALO treatment showed lower incidence of hyperglycemia than PBO in all groups. No weight gain was observed in either the ALO or PBO arms. Pooled analysis showed that the percentage of subjects who experienced hypoglycemia was 1.6% in the ALO arm vs 0.8% in PBO arm. All episodes of hypoglycemia were considered mild or moderate. The percent of subjects who experienced at least one drug related treatment-emergent adverse events was 9.1% in the ALO arm vs. 8.7% in the PBO arm. The percentage of subjects who experienced treatment-emergent AEs leading to discontinuation of study drugs was1.6% in ALO arm vs. 2.0% in the PBO arm. No significant changes were observed between the ALO and PBO arms in laboratory parameters compared with baseline.
Conclusion: ALO 25mg QD significantly reduced HbA1c and FPG, and enhanced clinical HbA1c response compared to PBO when used as monotherapy, add-on to MET, and add-on to PIO. ALO 25mg QD showed a safety profile comparable to PBO.

Continuous infusion of lixisenatide or exenatide in mice stimulates calcitonin and GLP-1 receptor gene expression but does not induce thyroid C-cell proliferation

G. Dietert[1], X. Palazzi[2], M. Borne[3], M. Dorau[1], G. Hadour[3], F. Levai[1], S. Nellen[1], S. Ratering[1], T. Kissner[1];
[1]Sanofi-Aventis Deutschland GmbH, Frankfurt am Main, Germany, [2]Sanofi, Paris, [3]Sanofi, Montpellier, France.

Background and aims: Lixisenatide is a novel once-daily glucagon-like peptide-1 (GLP-1) receptor agonist, recently approved in Europe for the treatment of adults with type 2 diabetes mellitus. Long-term exposure to GLP-1 receptor agonists has been associated with the development of thyroid C-cell hyperplasia and tumours in rodents. Because calcitonin is synthesized in large amounts by thyroid C-cell tumours, it is frequently used as a marker for C-cell neoplasia. The current study evaluated the effect of a 3-month continuous infusion of lixisenatide or exenatide on thyroid C-cell proliferation in mice.
Materials and methods: CD1 mice were administered aqueous solution of lixisenatide or exenatide at 75 µg/animal/day or vehicle (control) by continuous infusion with subcutaneous mini-pump implants for 12 weeks. Blood samples were collected on Day 10 and/or Day 84 for evaluation of drug exposure and plasma calcitonin. At study end, histomorphometry analysis of C-cell numbers and/or volume was performed on standardized thyroid cross-sections stained for calcitonin by immunohistochemistry. Statistical comparisons between treated and control groups were conducted using pairwise two-sided Wilcoxon's tests. Gene expression of proliferative markers *Ccnd1, Ccnd2, Ccnd3, C-myc, Bcl-xl, p21* and *p27* was evaluated with quantitative real-time transcription polymerase chain reaction, as was gene expression for the *calcitonin* and *GLP-1 receptor* genes.
Results: Pharmacokinetic evaluation indicated good systemic drug exposure in both lixisenatide- and exenatide-treated mice (Table). Plasma calcitonin on Day 84 was elevated in both treatment groups vs controls (p≤0.05 for both, Table). Elevated gene expression for *calcitonin* and *GLP-1 receptor* was recorded in both treatment groups vs controls (Table). Changes in expression of other proliferative markers were minimal and generally not considered to be treatment-related or biologically relevant. No macroscopic or microscopic treatment-related changes were observed in the thyroid glands and the histomorphometric analysis of C-cells failed to demonstrate any difference in the volume and number of C-cells between either treatment group and negative controls.

Conclusion: In CD1 mice, a 3-month continuous subcutaneous infusion of lixisenatide stimulated calcitonin and GLP-1 receptor expression but did not induce C-cell proliferation.

Drug exposure, calcitonin and gene expression: 12 weeks of sc infusion with lixisenatide/exenatide

GLP-1 receptor expression in human C-cell carcinomas and human thyroid glands without C-cell pathology

T. Kissner[1], M. Dorau[1], A. Perren[2], A. Blank[2], M. Heinrichs[1], G. Dietert[1]; [1]Sanofi, Frankfurt am Main, Germany, [2]Institute of Pathology, Berne, Switzerland.

Background and aims: In C-cells isolated from human thyroid gland tissue, only marginal glucagon-like peptide-1 (GLP-1) receptor expression has been observed. This study assessed the expression of the GLP-1 receptor in human thyroid tissue with proliferative C-cell findings compared with tissue without C-cell pathology.
Materials and methods: A total of 49 tissue samples were examined in three separate studies: human thyroid tissue without C-cell pathology (n=19; Group A), C-cell carcinoma (sporadic; n=10; Group B), C-cell carcinoma (multiple endocrine neoplasia; n=10; Group C), and non-neoplastic and neoplastic C-cell hyperplasia (Groups D1 [n=5] and D2 [n=5]). C-cells and follicular cells were evaluated separately for GLP-1 receptor expression after laser capture microdissection, with calcitonin expression levels determined to ensure proper separation of cell fractions.
Results: Calcitonin expression levels in the follicular cells were low or undetectable in Groups A (cycle time [CT]=32.1) and D (CT=28.4), and were higher in Groups B (CT=20.1) and C (CT=23.9). In the C-cell fractions, the calcitonin expression levels were consistently higher than in follicular cell fractions, with CT values of 21.5-26.6 for Group A, 23.7 for Group B, 25.0 for Group C, and 29.2 for Group D1 and 27.0 for Group D2. In both C-cell and follicular cell samples, GLP-1 receptor expression levels were low or undetectable in all groups. Calcitonin RNA was expressed in the C-cell fractions and, to a much lower extent, in the follicular cell samples, demonstrating that they had been successfully separated.
Conclusion: No difference in GLP-1 receptor expression was observed between thyroid tissue samples with or without proliferative C-cell findings, neither in follicular nor C-cell fractions.

Occurrence of spontaneous pancreatic lesions in normal and diabetic rats may confound the non-clinical assessment of glucagon-like peptide (GLP)-1-elevating therapies

K.D. Chadwick[1], D. Roy[2], A. Fletcher[1], C. Parrula[1], A.-M. Bergholm[3], N. Neef[1], R. Mangipudy[1], E. Janovitz[4], M. Graziano[5], T.P. Reilly[5]; [1]Drug Safety Evaluation, Bristol-Myers Squibb, New Brunswick, [2]Nonclinical Drug Safety, Amylin, LLC, San Diego, USA, [3]Global Safety Assessment, AstraZeneca, Mölndal, Sweden, [4]Discovery Toxicology, Bristol-Myers Squibb, Hopewell, [5]Drug Safety Evaluation, Bristol-Myers Squibb, Lawrenceville, USA.

Background and aims: GLP-1 therapeutics, including GLP-1 receptor agonists and dipeptidyl peptidase (DPP) 4 inhibitors, have glycemic and potential non-glycemic benefits for Type 2 diabetes, but recent literature reports raise concern for a potentially increased risk of pancreatitis and pancreatic cancer with these new therapies. Preclinical reports have attributed a variety of findings (including ductular metaplasia, exocrine pancreas degeneration and pancreatic duct abnormalities) to GLP-1 therapeutics in normal rats and rodent models of diabetes and/or pancreatitis. However, extensive non-clinical toxicology experience with the saxagliptin (DPP4 inhibitor) and exenatide (GLP-1 analog) has not demonstrated drug-related exacerbation of pancreatitis or neoplasia in any species (mouse, rat, dog, or monkey) compared to controls, with hundreds of animals being dosed for up to 2 years at exposure multiples up to 2300x therapeutic levels.
Materials and methods: We hypothesized that the lesions attributed to GLP-1 therapeutics in previous studies are commonly observed in the absence of drug treatment, similar to those observed in control groups in our studies. Therefore, we endeavored to characterize the incidence of spontaneous pancreatic lesions in 3 rat strains (Sprague-Dawley [SD], Zucker diabetic fatty [ZDF] and HIP rats [rats expressing human islet amyloid polypeptide]; n=36/group) under different feeding conditions (standard [std] or high fat [HF] diet) over a 4-month period.

Results: Pancreatic findings in all groups included focal exocrine degeneration, atrophy, inflammation, ductular cell proliferation and/or observations in large pancreatic ducts similar to those described in the literature with an incidence of exocrine atrophy/inflammation in SD (42% [HF]-72% [std] of rats) > HIP (39%) > ZDF (6%).
Conclusion: These data indicate that "pancreatitis" is a common background finding in rats that is independent of diet or glycemic status. Thus, many of the preclinical pancreatic lesions that are described as resulting from GLP-1 elevating therapies occur regularly in untreated normal and diabetic animals.

Efficacy and safety of dulaglutide versus placebo and exenatide in type 2 diabetes (AWARD-1)

C. Wysham[1], T. Blevins[2], R. Arakaki[3], G. Colon[4], P. Garcia[5], C. Atisso[6], D. Kuhstoss[6], J. Scism-Bacon[6], M. Lakshmanan[6];
[1]Rockwood Clinic, Spokane, [2]Texas Diabetes and Endocinology, Austin, [3]University of Hawaii at Manoa, Honolulu, USA, [4]American Telemedicine Center of Puerto Rico, San Juan, Puerto Rico, [5]Endocrinology Service at Hospital Universitario, Monterrey, Mexico, [6]Eli Lilly and Company, Indianapolis, USA.

Background and aims: This Phase 3, randomised, parallel-arm study compared efficacy and safety of 2 doses of dulaglutide (DU), a long-acting GLP-1 receptor agonist, with exenatide (EX) or placebo (PL) in patients (pts) with type 2 diabetes treated with metformin (1500-3000 mg) and pioglitazone (30-45 mg).
Materials and methods: Pts (N=976; mean baseline [BL] characteristics: age, 55.7 years; HbA_{1c}, 8.1%; weight, 96.0 kg) were randomised (2:2:2:1 ratio) openly to twice-daily EX 10 µg or in a double-blind fashion to once-weekly DU 1.5 mg, DU 0.75 mg, or PL. After 26 weeks (wks), pts on PL were randomly assigned to either DU 1.5 mg or 0.75 mg for 26 additional wks. All others continued in originally assigned treatments for the study duration (52 wks). Primary hypothesis was that DU 1.5 mg is superior to PL for change in HbA_{1c} from BL to 26 wks.
Results: Both DU doses were superior to PL at 26 wks and to EX at 26 and 52 wks as measured by HbA_{1c} change. Incidence of serious adverse events (AEs) was similar among PL and DU groups. The rank order of incidence of gastrointestinal-related AEs among groups was: EX ~ DU 1.5 mg > DU 0.75 mg > PL. Documented symptomatic hypoglycaemia (<3.9 mmol/L) incidence was 3.2%, 4.3%, 12.3%, and 1.4% for DU 1.5 mg, DU 0.75 mg, EX, and PL, respectively.
Conclusion: Both once-weekly DU doses demonstrated superior glycaemic control compared to PL or EX and were well tolerated.

Safety and efficacy of dulaglutide vs sitagliptin after 104 weeks in type 2 diabetes (AWARD-5)

B. Guerci[1], R.S. Weinstock[2], G. Umpierrez[3], M.A. Nauck[4], K. Boleyn[5], Z. Skrivanek[5], Z. Milicevic[6];
[1]Diabetology, Metabolic Diseases and Nutrition & CIC Inserm ILCV, University of Nancy I, Vandoeuvre les Nancy, France, [2]SUNY Upstate Medical University, Syracuse, [3]Emory University, Atlanta, USA, [4]Diabetes Centre, Bad Lauterberg im Harz, Germany, [5]Eli Lilly and Company, Indianapolis, USA, [6]Eli Lilly and Company, Vienna, Austria.

Background and aims: This Phase 3, adaptive, double-blind, parallel arm trial compared dulaglutide (DU), a once-weekly, long-acting glucagon-like

peptide 1 receptor agonist, with sitagliptin (sita) and placebo (PL) in metformin-treated type 2 diabetes patients.
Materials and methods: Primary time point was 52 weeks (wks); final time point was 104 wks. Patients (N=1098; mean baseline age 54 years; HbA_{1c} 8.1%; weight 86.4 kg; diabetes duration 7 years) were randomized to DU 1.5 mg or 0.75 mg, sita 100 mg, or PL (up to 26 wks).
Results: Similar proportions of DU and sita patients completed 104 wks. Adverse event (AE) was the most common reason for discontinuation. Both DU doses reported higher incidence of treatment-emergent AEs vs sita due to gastrointestinal (GI) events. The incidence of the most common GI treatment-emergent AEs for DU 1.5 mg, DU 0.75 mg and sita 100 mg, respectively, were nausea (17%, 15%, 7%), vomiting (14%, 8%, 4%) and diarrhoea (16%, 12%, 6%). Incidence of GI AEs peaked during the first 12 wks, with no difference after 26 wks. Both DU doses were superior vs sita for change in HbA_{1c} (Table 1).
Conclusion: The AE profile and superior HbA_{1c} vs sita after 104 wks indicate an acceptable benefit/risk profile of DU over a longer time.

Table 1: Summary of Efficacy Measures at 104 Weeks

Final Time Point Measures (104 Weeks, ITT, LOCF)	DU 1.5 mg (N=304)	DU 0.75 mg (N=302)	Sita 100 mg (N=315)

Efficacy and safety of dulaglutide vs sitagliptin after 52 weeks in type 2 diabetes (AWARD5)
M.A. Nauck[1], R.S. Weinstock[2], G. Umpierrez[3], B. Guerci[4], K. Boleyn[5], Z. Skrivanek[5], Z. Milicevic[6];
[1]Diabetes Centre, Bad Lauterberg im Harz, Germany, [2]SUNY Upstate Medical University, Syracuse, [3]Emory University, Atlanta, USA, [4]Diabetology, Metabolic Diseases and Nutrition & CIC Inserm ILCV, University of Nancy I, Vandoeuvre les Nancy, France, [5]Eli Lilly and Company, Indianapolis, USA, [6]Eli Lilly and Company, Vienna, Austria.

Background and aims: This Phase 3, adaptive, double-blind, parallel-arm trial compared dulaglutide (DU), a once-weekly, long-acting glucagon-like peptide-1 receptor agonist, with sitagliptin (sita) and placebo (PL) in poorly-controlled metformin-treated patients with type 2 diabetes. The primary objective was to show noninferiority of DU 1.5 mg vs sita on change in HbA_{1c} at 52 weeks.
Materials and methods: Patients (N=1098, mean baseline age 54 years, HbA_{1c} 8.1% [65 mmol/mol], weight 86.4 kg, diabetes duration 7 years) were randomised to DU 1.5 mg, DU 0.75 mg, sita 100 mg, or PL (replaced with sita after 26 weeks) in a 2:2:2:1 ratio. The statistical analysis plan allowed for subsequent superiority testing once the noninferiority criterion for each of the doses relative to sita had been met. The study continued until 104 weeks.
Results: Both DU doses were superior to sita in reducing HbA_{1c} after 52 weeks (Table 1, Summary of Efficacy Measures at 26 Weeks and 52 Weeks). Rates of self-monitored hypoglycaemia (plasma glucose ≤3.9 mmol/L and/or symptoms; events/patient/year) were 1.6 (DU 1.5 mg), 1.7 (DU 0.75 mg), 1.6 (sita), and 1.2 (PL). No severe hypoglycaemia was reported. The most common gastrointestinal treatment-emergent adverse events for DU 1.5 mg and 0.75 mg, respectively, were nausea (17.4%, 13.9%), vomiting (12.8%, 7.6%), and diarrhoea (14.5%, 9.9%). Incidence of discontinuations due to adverse event or death was 11.2% (DU 1.5 mg), 7.6% (DU 0.75 mg), 10.2% (sita), and 16.4% (PL), most commonly due to hyperglycaemia.
Conclusion: In conclusion, both once-weekly DU doses demonstrated superior glycaemic control vs sita after 52 weeks with an acceptable tolerability and safety profile.

Table 1: Summary of Efficacy Measures at 26 Weeks and 52 Weeks

Placebo-Controlled Period (26 Weeks, ITT, LOCF)	DU 1.5 mg (N=304)	DU 0.75 mg (N=302)	Sita 100 mg (N=315)	PL (N=177)
HbA_{1c} change (%), LS Mean (SE)	-1.22 (0.05)‡‡,#	-1.01 (0.06)‡‡,#	-0.61 (0.05)*	0.03 (0.07)
% of patients with HbA_{1c} <7%	60.9*,#	55.2*,#	37.8*	21.0
Weight change (kg), LS Mean (SE)	-3.18 (0.18)*,#	-2.63 (0.19)*,#	-1.46 (0.18)	-1.47 (0.24)
Primary Time Point (52 Weeks, ITT, LOCF)				
HbA_{1c} change (%), LS Mean (SE)	-1.10 (0.06)††	-0.87 (0.06)††	-0.39 (0.06)	NA
% of patients with HbA_{1c} <7%	57.6#	48.8#	33.0	NA
Weight change (kg), LS Mean (SE)	-3.03 (0.22)#	-2.60 (0.23)#	-1.53 (0.22)	NA

ITT = Intent-to-treat, LOCF = last observation carried forward, LS = least squares, N = number of patients in a specified category, NA = not applicable, SE = standard error.
†† and ‡‡ multiplicity adjusted (based on tree-gatekeeping) 1-sided p<0.001 for superiority vs sita at 52 weeks or PL at 26 weeks, respectively, for HbA_{1c} change only.

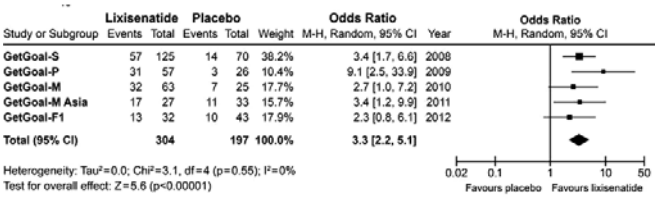
Efficacy and safety of lixisenatide in elderly type 2 diabetes mellitus patients: subanalysis from the GetGoal programme
M. Hanefeld[1], R. Berria[2], J. Lin[3], R. Aronson[4], P. Darmon[5], M. Evans[6], L. Van Gaal[7];
[1]Center for Clinical Studies, GWT-TUD GmbH, Dresden, Germany, [2]Sanofi, Bridgewater, [3]Novosys Health, Flemington, USA, [4]LMC Diabetes and Endocrinology, Toronto, Canada, [5]Department of Nutrition, Metabolic Diseases and Endocrinology, Sainte-Marguerite Hospital, Marseille, France, [6]University Hospital Llandough, UK, [7]Antwerp University Hospital, Belgium.

Background and aims: The number of elderly people with Type 2 diabetes mellitus (T2DM) is increasing. Therefore, the efficacy and safety of antidiabetic drugs for vulnerable patients is a key question for individualized treatment. Lixisenatide is a novel once-daily prandial glucagon-like peptide-1 (GLP-1) receptor agonist, which was granted marketing authorization in Europe in February 2013 for the treatment of T2DM.
Materials and methods: This meta-analysis of five Phase III lixisenatide randomized controlled trials (GetGoal-M, -P, -S, -M-Asia and -F1) evaluated lixisenatide as add-on to oral antidiabetic drugs compared with placebo in 501 elderly patients (≥65 years) with T2DM.
Results: At baseline, patients were aged 69.4 years; had BMI of 29.4 kg/m^2; mean diabetes duration of 10.6 years; HbA_{1c} of 8.0% (lixisenatide) and 7.9% (placebo); 90.0% of patients were treated with metformin, 44.7% with sulfonylurea and 16.6% with thiazolidinediones. After 24 weeks, lixisenatide significantly reduced HbA_{1c} compared with placebo (odds ratio [95% CI]: -0.5% [-0.7, -0.4], p<0.00001) and was statistically better than placebo in each of the following composite endpoints: proportion of patients achieving HbA_{1c} <7% (49.3 vs 22.8%, p<0.0001); HbA_{1c} <7% and no weight gain (41.8 vs 18.8%, p<0.0001); HbA_{1c} <7% and no documented symptomatic hypoglycaemia (44.4 vs 22.3%, p<0.0001); HbA_{1c} <7%, no documented symptomatic hypoglycaemia and no weight gain (37.2 vs 18.8%, p<0.0001). A higher trend for more frequent documented symptomatic hypoglycaemia was seen with lixisenatide compared with placebo (odds ratio [95% CI]: 2.1 [0.9, 5.0] p=0.09), mainly driven by sulfonylurea as background medication. There were no cases of severe hypoglycaemia in either group.
Conclusion: This *post hoc* analysis suggests that, in elderly patients with long-term T2DM inadequately controlled on oral antidiabetic drugs, lixisenatide significantly improved glycaemic control, particularly in composite assessments that indicate limited risk of weight gain or hypoglycaemia.

Figure. Meta-analysis of composite endpoints

A. HbA_{1C} <7%



B. HbA_{1C} <7% and no weight gain

923

Effectiveness and tolerability with liraglutide among patients with type 2 diabetes. 1-year data from EVIDENCE: a 2-year, prospective, follow-up, post-marketing study

P. Gourdy[1], A. Penfornis[2], G. Charpentier[3], S. Madani[4], L. Martinez[5], E. Eschwège[6], J.-F. Gautier[7];
[1]Institut de Recherche sur les Maladies Métaboliques et Cardiovasculaires, Toulouse, [2]University of Franche-Comté, Besançon, [3]Centre Hospitalier Sud Francilien, Corbeil, [4]Novo Nordisk, Paris, [5]Université Pierre & Marie Curie, Paris, [6]INSERM, Villejuif, [7]Saint Louis Hospital, Paris, France.

Background and aims: Here we report 1-year data on the effectiveness and tolerability of the GLP-1 analogue liraglutide in the EVIDENCE observational, post-marketing study.
Materials and methods: EVIDENCE is a 2-year multicentre, observational, post-marketing outpatient study requested by the French National Health Authority in order to evaluate the efficacy and safety of liraglutide in routine clinical practice. The primary objective is to determine the percentage of patients still taking liraglutide and at HbA_{1c} target (<7%) after 2 years. EVIDENCE will also record data on characteristics of patients treated with liraglutide, how closely physicians follow instructions for use, treatment adherence, reasons for treatment discontinuation, change in HbA_{1c} and weight from baseline and long-term safety (over 2 years). Diabetologists and general practitioners in France recruited patients starting treatment with liraglutide. Patients and physicians completed questionnaires at study entry, 3 months and 6 months, then at 6-month intervals for a further 18 months. Statistical analyses were performed by Wilcoxon test on rank for paired quantitative variables. For quantitative variables a normality Kolmogorov-Smirnov test was used. For paired qualitative variables the McNemar test was used.
Results: Baseline data (mean±SD) were collected from 3137 patients (53% male, age 59±11 years, BMI 34±7 kg/m², duration of diabetes 10±6 years, HbA_{1c} 8.5±1.5%); 2433 (77.6%) patients were still in the study at 1 year. HbA_{1c} levels exceeded 7.0% (ADA/EASD target) in the majority of patients (n=2761, 88%) at baseline. The proportion of patients with HbA_{1c} <7% was significantly higher after 1 year's liraglutide treatment (n=850, 36.5%) vs. baseline (n=303, 9.8%; p<0.001). Following 1 year of liraglutide treatment, significant reductions in mean±SD HbA_{1c} (-1.04±0.98%, p<0.001), fasting plasma glucose (-0.36±0.60 g/L, p<0.001) and body weight (-3.56±5.78 kg, p<0.001) were observed from baseline. Gastrointestinal disorders (nausea, vomiting and diarrhoea) were the most frequent adverse events, reported by 247 patients (7.9%) treated with liraglutide; they were also the most common reason for withdrawal.
Conclusion: These results suggest that the efficacy of liraglutide in real world clinical practice is similar to that observed in randomised clinical trials (RCTs) (up to -1.5% HbA_{1c} reductions and -3.24 kg weight loss). However, the absence of a control arm makes it difficult to evaluate whether observed improvements are attributable to liraglutide alone. The slightly lower mean HbA_{1c} in this study may be due to differences in background therapies: in contrast with the RCTs there was no washout period prior to switching from an existing therapy to liraglutide in EVIDENCE. The incidence of gastrointestinal events was considerably lower than that reported in RCTs (up to 26.5%). In summary, 1-year results from the EVIDENCE study suggest that clinical trial data for liraglutide translate into therapeutic benefits in routine clinical practice.

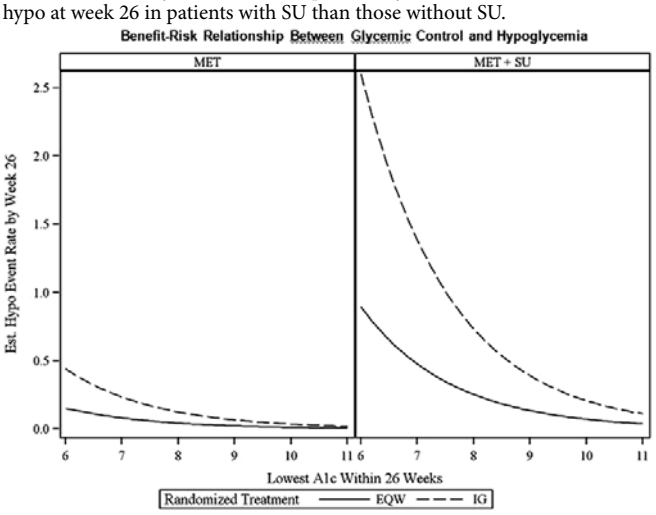
Quantification of the benefit-risk relationship between glycaemic control and hypoglycaemia: a comparison of exenatide once weekly with titrated insulin glargine

J. Han, M. Zhou, J. Malloy, L. Shen;
Bristol-Myers Squibb, San Diego, USA.

Background and aims: The DURATION-3 trial reported significantly greater HbA_{1c} reduction and lower risk of hypoglycemia (hypo) with the GLP-1 receptor agonist exenatide once weekly (EQW) compared with titrated once daily insulin glargine (IG) over 3 years. As the risk of hypo typically increases when better glucose control is achieved, these analyses further quantify the benefit-risk relationship between reduction in HbA_{1c} and incidence of hypo, as well as the impact of baseline characteristics.
Materials and methods: Exposure-adjusted event rates (EAER) of hypo were evaluated in relation to both the lowest and the weighted average HbA_{1c} over 26 weeks by Poisson regression models. Time to first hypo episode with EQW compared with IG, adjusted for end point HbA_{1c} (last observation carried forward), was evaluated by the Cox proportional hazard model. Baseline characteristics including age, gender, race, duration of diabetes, BMI, concomitant oral antihyperglycemic (OAH) use, and creatinine clearance, were examined as continuous covariates or categorical factors. Data beyond 26 weeks and up to 3 years were explored.
Results: The intent-to-treat (ITT) population comprised 233 EQW and 223 IG patients (mean baseline age 58 yrs, BMI 32.3 kg/m², duration of diabetes 7.9 yrs, HbA_{1c} 8.3%, OAH 70% metformin (MET) and 30% MET+sulfonylurea (SU). Results from the regression model showed that treatment (EQW or IG), concomitant OAH use (±SU), BMI, duration of diabetes, and HbA_{1c} (lowest or weighted average HbA_{1c} over 26 weeks) were statistically significant (P<0.05) factors for hypo EAER estimation. The EAER of hypo by week 26 with EQW, adjusted for the lowest HbA_{1c}, was 0.37 of that observed with IG. The same between-treatment risk ratio of hypo was reduced to 0.34 when OAH use was examined concurrently, with a 5.9 times hypo EAER in patients with SU compared with those without SU (figure). The risk of hypo in EQW to IG was 0.36 when BMI and duration of diabetes were further adjusted in the statistical model independently with higher risk in patients with lower BMI (1.38, <30 kg/m² vs ≥30 kg/m²) or longer duration of diabetes (1.35, ≥10 yrs of diabetes duration vs <10 yrs). Results from the hazard model showed that treatment, OAH use, and end point HbA_{1c} were statistically significant factors to predict the onset of the first hypo at week 26. The hazard ratio of first hypo between EQW and IG, adjusted for end point HbA_{1c}, was 0.33. The same hazard ratio was reduced slightly to 0.32 when OAH use was evaluated simultaneously with a 3.5 times probability on the occurrence of the first hypo at week 26 in patients with SU than those without SU.



Conclusion: Although the risk of hypo increased with the benefit of decreased HbA_{1c}, such risk was significantly reduced with EQW compared with IG. Further, regardless of EQW or IG, the EAER of hypo by week 26 was significantly higher in patients with concomitant SU use, lower BMI, or longer duration of diabetes, while incidence of hypo was significantly higher in patients with concomitant SU use.

Efficacy and safety of low-dose sitagliptin (25 mg) in elderly (≥70 years old) Japanese patients with type 2 diabetes

H. Ikeda[1], K. Ida[1], M. Usami[1], H. Koshiyama[2], M. Ikeda[1];
[1]The Seimeikai Ikeda Hospital, Amagasaki-City, [2]Center for Diabetes & Endocrinology, The Tazuke Kofukai Foundation Medical Research Institute Kitano Hospital, Osaka-City, Japan.

Background and aims: The standard dose of sitagliptin is 50 mg, but lower doses of 25 mg or 12.5 mg can be used in patients with decreased renal function. Low-dose administration of sitagliptin may be appropriate to improve blood glucose control in the elderly patients, who generally tend to have decreased renal function, but this approach has not been widely examined. Therefore, in this study, we examined the efficacy and safety of 25-mg sitagliptin in elderly patients with type 2 diabetes.
Materials and methods: The subjects were 39 Japanese outpatients (male: 23, female: 16) with type 2 diabetes who received administration of 25-mg sitagliptin for the first time at our hospital. All patients were aged ≥70 years old and their mean age was 78.5±4.82 years. The subjects included 13 patients who received 25-mg sitagliptin monotherapy and 26 who received 25-mg sitagliptin combination therapy with other anti-diabetic drugs. The control group included 39 younger Japanese outpatients (male: 27, female: 12) with type 2 diabetes who were matched for baseline HbA1c and BMI to those of the elderly subjects and received administration of 50-mg sitagliptin for the first time. All controls were aged ≤65 years old and their mean age was 54.9±6.99 years old. Among the 39 controls, 8 received 50-mg sitagliptin monotherapy and 31 received 50-mg sitagliptin combination therapy with other anti-diabetic drugs. Improvement of HbA1c from before to after 3 months of sitagliptin treatment and the incidence of adverse effects were compared between the two groups.
Results: HbA1c values before and after 3 months of sitagliptin treatment were 7.68% and 7.00%, respectively, in the 25-mg group, and 7.70% and 6.89%, respectively, in the 50-mg group, with both groups showing a significant improvement. There was no significant difference in improvement of HbA1c between the two groups. No serious hypoglycemia occurred in either group, but mild hypoglycemia occurred in 7 patients in the 25-mg group and 2 patients in the 50-mg group, with no significant difference between the groups. There were no changes in body weight in each group, no significant difference in digestive symptoms between the groups, and no changes in hepatic and renal functions in either group.
Conclusion: Administration of 25-mg sitagliptin in elderly Japanese patients (≥70 years old) with type 2 diabetes showed a similar effect on improvement of blood glucose control to that of 50-mg sitagliptin in patients aged ≤65 years old. There was a slight tendency for increased mild hypoglycemia in the elderly patients, but no significant difference in other side effects between the elderly and younger patients. Therefore, these results suggest that administration of 25-mg sitagliptin is effective and safe in elderly patients with type 2 diabetes. This low dosage may also be beneficial from a standpoint of medical costs.

926

Renal safety of linagliptin in elderly patients with type 2 diabetes: analysis of pooled patient data from 7 phase 3 clinical trials

S. Patel[1], G. Schernthaner[2], A.H. Barnett[3], U. Hehnke[4], M. von Eynatten[5], H.-J. Woerle[4];
[1]Boehringer Ingelheim, Bracknell, UK, [2]Rudolfstiftung Hospital, Vienna, Austria, [3]University of Birmingham and Heart of England NHS Foundation Trust, Birmingham, UK, [4]Boehringer Ingelheim, Germany, [5]Boehringer Ingelheim, Ridgefield, USA.

Background and aims: Renal impairment (RI) is common in elderly patients with type 2 diabetes mellitus (T2DM), and progression of kidney disease is associated with increased morbidity and mortality. Renal safety is therefore an important consideration in the selection of appropriate treatments for this population. As several drugs are either contraindicated or require dose adjustment in patients with RI, it is important to identify well-tolerated treatments for elderly T2DM patients with or at risk of declining renal function. This analysis of pooled data from a large clinical trials programme investigated the efficacy and renal and overall safety of the DPP-4 inhibitor linagliptin in elderly patients with T2DM.
Materials and methods: This post hoc analysis evaluated data from 7 randomised, placebo-controlled Phase 3 trials of linagliptin 5 mg once daily as monotherapy or add-on to common glucose-lowering therapies for ≥24 weeks (including all subjects ≥65 years not receiving pioglitazone background therapy). Renal function was assessed by estimated glomerular filtration rate (eGFR) using the Modification of Diet in Renal Disease formula.
Results: The pooled population comprised 1293 elderly patients randomised to either linagliptin (n=823) or placebo (n=470). Baseline characteristics (mean ± SD) were similar between the linagliptin and placebo groups: age, 71.1 ± 4.6 vs. 70.9 ± 4.7 years; HbA1c, 8.0 ± 0.8 vs. 8.1 ± 0.8%. In the linagliptin group, 56.4%, 14.8%, and 4.5% of patients had mild (eGFR 60 to <90 mL/min), moderate (eGFR 30 to <60 mL/min), and severe RI (eGFR <30 mL/min) with similar proportions found in the placebo group (51.3%, 18.7%, and 5.1%, respectively). Overall renal function was not significantly altered by treatment with linagliptin from baseline to Week 24 (adjusted mean ± SE eGFR [−1.8 ± 0.7 mL/min] vs. placebo [−1.1 ± 0.9 mL/min], resulting in a placebo-corrected difference of −0.7 ± 1.0 mL/min [95% CI: −2.6, 1.2; *P*=0.4912]). Changes in urine albumin-to-creatinine ratio trended toward improvement with linagliptin. In total, 71.3% and 72.8% of patients who received linagliptin or placebo, respectively, experienced adverse events (AEs). Drug-related AEs were less frequent with linagliptin (18.1%) than with placebo (20.0%). Renal and urinary AEs were experienced by 5.5% and 4.3% of linagliptin and placebo patients, respectively. Acute renal failure was a rare event and occurred in 0.5% and 0.2% of patients, respectively. Incidence of investigator-defined hypoglycaemia was lower in patients who received linagliptin (21.3%) compared with placebo (24.7%), with most events occurring in the trials that included a sulphonylurea or basal insulin as background therapy. Severe hypoglycaemic events were experienced by 1.0% and 1.7% of linagliptin and placebo patients, respectively. Linagliptin achieved placebo-corrected adjusted mean ± SE changes from baseline to Week 24 of −0.6 ± 0.1% (95% CI: −0.7, −0.5; *P*<0.0001) for HbA1c, and −0.8 ± 0.2 mmol/L (95% CI: −1.2, −0.5; *P*<0.0001) for fasting plasma glucose.
Conclusions: In an elderly patient population with renal function ranging from normal to severe RI, linagliptin was well tolerated, providing meaningful efficacy with a reassuring renal safety profile.
Clinical Trial Registration Number: NCT00621140; NCT00601250; NCT00602472; NCT00954447; NCT00800683; NCT00798161; NCT01084005

Clinical experience with vildagliptin in patients ≥ 75 years with type 2 diabetes mellitus and moderate or severe renal impairment

A. Schweizer[1], S. Dejager[2];
[1]Novartis Pharma AG, Basel, Switzerland, [2]Novartis Pharma S.A.S., Rueil-Malmaison, France.

Background and aims: Patients with type 2 diabetes (T2DM) are at increased risk for renal impairment (RI), and in addition there is an age-related decline in renal function. At the same time, T2DM treatment is more complex and treatment options are more limited in elderly patients as well as patients with RI, with the patient population ≥ 75 years with moderate or severe RI posing unique challenges, in particular the high risk and more severe consequences of hypoglycaemia. It was therefore of interest to assess the efficacy and tolerability of the dipeptidyl peptidase-4 (DPP-4) inhibitor vildagliptin in patients with T2DM ≥ 75 years who also have moderate or severe RI.
Materials and methods: This was a sub-analysis of data derived from a previously described randomised, double-blind, parallel-group, 24-week study (N=515) that included 105 patients (50 randomised to vildagliptin 50 mg qd and 55 to placebo) ≥ 75 years (mean age ~78 years) with T2DM and moderate or severe RI (baseline eGFR ~35 ml/min/1.73 m^2). Patients were treated mainly with either insulin (~55%) or OAD (~25%) monotherapy or a combination of insulin and OAD (~13%), and had long-standing disease (mean T2DM duration ~16 years).
Results: The adjusted mean change in HbA1c with vildagliptin was -1.0% from a baseline (BL) of 7.8% (between-group difference -0.8%; p<0.001). This improvement in glycaemic control was not associated with an increased risk

of hypoglycaemia; the rate of confirmed hypoglycaemia was 0.49 events per patient-year with vildagliptin and 0.96 events per patient-year with placebo (p=0.970). Weight remained stable with vildagliptin treatment (adjusted mean change from BL (81 kg) = 0.4 kg vs. -1.0 kg with placebo, p=0.015). Adverse events (AEs) (58.0 vs. 72.7%), serious AEs (14.0 vs. 16.4%), discontinuations due to AEs (4.0 vs. 9.1%) and deaths (0 vs. 5.5%) were reported at a comparable or lower frequency in patients receiving vildagliptin versus patients receiving placebo.
Conclusion: In this uniquely fragile elderly population ≥ 75 years with T2DM and moderate or severe renal impairment, vildagliptin was well tolerated and efficacious, with no increase in the rate of hypoglycaemia compared to placebo despite the marked improvement in glycaemic control.

Treat 4 Ramadan trial: a randomised control trial comparing liraglutide vs a sulphonylurea as add-on to metformin in patients with established type 2 diabetes
E.M. Brady[1], M.J. Davies[2], L.J. Gray[3], M.A. Saeed[4], W. Hanif[4], K. Khunti[2];
[1]Leicester Diabetes Centre, [2]Diabetes Research Unit, [3]Health Sciences, University of Leicester, [4]Diabetes and Endocrinology, University Hospitals of Birmingham, Leicester, UK.

Background and aims: Treat 4 Ramadan was a randomised control trial comparing a sulphonylurea (SU) or Liraglutide (Lira) in combination with Metformin in patients on either mono or dual oral therapy with established Type 2 diabetes.
Materials and methods: 100 adults (50% male, mean age 52 years and BMI 32 Kg/m^2) were recruited from two UK sites (Leicester and Birmingham). Baseline data were collected ≥14 days prior to commencing their fast and follow-up at 4 (FU1) and 12 weeks (FU2) following Ramadan.
Results: Significantly more patients in the Lira compared to the SU group (FU1:37% vs. 7%, p=0.001; FU2:27% vs. 8%, p=0.03) achieved a composite endpoint of HbA1c <7%, weight reduction of ≥1 kg and no severe hypoglycaemia, defined as leading to hospitalisation. From a baseline of 7.7% there was no change in HbA1c at FU2 in the SU (+0.02%) compared to a 0.3% reduction in the Lira group (p=0.17). No significant differences in HbA1c were observed between prior mono (p=0.43) or dual therapy (p=0.14). Significant reductions were observed in body weight (-4.9 vs. +0.3kg, p=0.02) and diastolic BP (-6.2 vs. -0.06 mmHg, p=0.01) in the Lira compared to the SU group at FU2. More patients in the Lira group achieved the composites of weight reduction and improved HbA1c (p=0.04) and weight reduction and no severe hypoglycaemia (p=0.002) compared to SU. No severe hypoglycaemia was observed in any group.
Conclusion: Lira compared to SU appears to be a safe and well tolerated therapy in combination with Metformin during Ramadan with evidence of weight loss, no increase in severe hypoglycaemia and a trend towards improved HbA1c.

Verification of the efficacy and safety of tofogliflozin, a novel SGLT2 inhibitor, in Japanese patients with type 2 diabetes mellitus: results from a phase 2/3 clinical study
E. Araki[1], K. Kaku[2], H. Watada[3], Y. Iwamoto[4], K. Utsunomiya[5], Y. Terauchi[6], K. Tobe[7], Y. Tanizawa[8], for the Tofogliflozin 003 Study group;
[1]Kumamoto University, [2]Kawasaki Medical School, Kurashiki, [3]Juntendo University, Tokyo, [4]Tokyo Women's Medical University, [5]Jikei University, Tokyo, [6]Yokohama City University, [7]University of Toyama, [8]Yamaguchi University, Ube, Japan.

Background and aims: Tofogliflozin, a highly selective sodium-glucose cotransporter 2 (SGLT2) inhibitor, reduces blood glucose and body weight by inhibiting renal glucose reabsorption and promoting urinary excretion of excess blood glucose in type 2 diabetes mellitus (T2DM) patients. The characteristics of tofogliflozin, which include high selectivity toward SGLT2, a short half-life and an insulin-independent mode of action, mean that it exerts sustained efficacy with low hypoglycemic risk and can be used in combination with any existing T2DM therapy. This study was undertaken to verify the efficacy and safety of tofogliflozin in Japanese patients with T2DM with inadequate glycemic control on diet/exercise therapy.
Materials and methods: The study was designed as a randomized, double-blind, placebo-controlled, parallel-group comparison. Tofogliflozin 10, 20 or 40 mg (n=58 for each dose) or placebo (n=56) was orally administered once daily for 24 weeks to a total of 230 patients. The primary endpoint was the change from baseline in HbA1c.
Results: Tofogliflozin caused a statistically significant decrease in HbA1c at all doses tested (changes from baseline of 0.0%, −0.8%, −1.0%, and −0.9% in the placebo, 10 mg, 20 mg, and 40 mg groups, respectively; P<0.0001 vs. placebo). In addition, statistically significant decreases in fasting blood glucose (changes from baseline of -0.48, -1.77, -1.99, -1.80 mmol/L in the placebo, 10 mg, 20 mg, and 40 mg groups, respectively; P<0.0001 vs. placebo) and body weight (changes from baseline of −0.4, −2.2, −2.9, and −3.0 kg in the placebo, 10 mg, 20 mg, and 40 mg groups, respectively; P<0.0001 vs. placebo) were observed in the tofogliflozin groups, compared with the placebo group. Moreover, decreased blood pressure, improved HOMA-R and Matsuda index, reduced abdominal circumference, increased adiponectin and HDL-cholesterol levels, and decreased levels of uric acid, alanine aminotransferase and γ-glutamyl transferase were secondarily observed. Regarding safety, the incidences of adverse events were 44.6%, 60.3%, 53.4%, and 53.4% in the placebo, 10 mg, 20 mg, and 40 mg groups, respectively. Adverse drug reactions occurring at an incidence ≥5% higher than those in the placebo group included increased blood ketone bodies accompanying ketonuria, and pollakiuria. One patient (1.7%) in each of the 10 mg and 40 mg groups experienced symptoms suggesting hypoglycemia, while no patient in the placebo group and no patient in the 20 mg group experienced this adverse event. Tofogliflozin was well tolerated up to a dose of 40 mg.
Conclusion: In Japanese patients with T2DM with inadequate glycemic control on diet/exercise therapy, tofogliflozin, orally administered once daily for 24 weeks, exhibits significant blood glucose- and body weight-lowering effects and was well tolerated. Thus, the efficacy and safety of tofogliflozin has been verified.

Safety and efficacy of empagliflozin monotherapy in a 52-week study in Japanese patients with type 2 diabetes mellitus
H.J. Woerle[1], T. Kadowaki[2], M. Haneda[3], N. Inagaki[4], A. Taniguchi[5], M. Sakamoto[5], K. Koiwai[5], H. Rattunde[1], U.C. Broedl[1];
[1]Boehringer Ingelheim, Germany, [2]Graduate School of Medicine, University of Tokyo, [3]Asahikawa Medical University, Hokkaido [4]Kyoto University Graduate School of Medicine, [5]Nippon Boehringer Ingelheim, Tokyo, Japan.

Background and aims: Empagliflozin (EMPA) is a potent and selective sodium glucose cotransporter 2 inhibitor in development for the treatment of type 2 diabetes mellitus (T2DM). A Phase II trial investigated the safety and efficacy of EMPA as monotherapy over 52 weeks in Japanese patients with T2DM.
Materials and methods: The study comprised a 12-week dose-finding period and a 40-week extension period. In the dose-finding period, patients (mean

age 57.5 [SD 9.9] years; mean BMI 25.5 [SD 3.9] kg/m^2) were randomised double-blind and treated with EMPA 5 mg (n=110), 10 mg (n=109), 25 mg (n=109) or 50 mg (n=110) qd or placebo (n=109) for 12 weeks. In the 40-week double-blind extension period, patients treated with EMPA 10 mg or 25 mg continued the same treatment and patients originally assigned placebo, EMPA 5 mg or 50 mg were re-allocated to EMPA 10 mg or 25 mg. Efficacy is reported for patients who took EMPA 10 mg or 25 mg in both treatment periods (i.e. for 52 weeks; n=109 each). Safety is reported for all patients who took at least one dose of EMPA 10 mg (n=267) or 25 mg (n=265) during the 52-week study.

Results: Treatment with EMPA for 52 weeks led to sustained reductions from baseline in HbA_{1c} and fasting plasma glucose (FPG) that were dose dependent, and in body weight, systolic BP (SBP) and diastolic BP (DBP) (Table). Adverse events (AEs) were reported in 70.8% of patients on EMPA 10 mg and 66.8% on EMPA 25 mg. Confirmed hypoglycaemic AEs (≤3.9 mmol/l and/or requiring assistance) was rare (1 patient in each of the EMPA 10 mg and 25 mg groups) and no patients required assistance. AEs consistent with urinary tract infection were reported in 7 patients (2.6%) on EMPA 10 mg and 3 patients (1.1%) on EMPA 25 mg. AEs consistent with genital infection were reported in 8 patients (3.0%) on EMPA 10 mg and 2 patients (0.8%) on EMPA 25 mg. AEs consistent with volume depletion were reported in 3 patients (1.1%) on EMPA 10 mg and 3 patients (1.1%) on EMPA 25 mg.

Conclusion: EMPA monotherapy led to sustained reductions in HbA_{1c}, FPG, body weight, SBP and DBP over 52 weeks in Japanese patients with T2DM, and was well tolerated.

Table. Efficacy (Adjusted Mean Difference From Baseline [SE]) and Adverse Event (%) Findings at 52 Weeks

	Albiglutide	Pioglitazone	Placebo

Empagliflozin as add-on to basal insulin for 78 weeks improves glycaemic control with weight loss in insulin-treated type 2 diabetes mellitus

J. Rosenstock[1], A. Jelaska[2], F. Wang[2], G. Kim[3], U.C. Broedl[3], H.J. Woerle[3];
[1]Dallas Diabetes and Endocrine Center at Medical City, Dallas, [2]Boehringer Ingelheim Pharmaceuticals, Inc., Ridgefield, USA, [3]Boehringer Ingelheim, Germany.

Background and aims: Empagliflozin (EMPA) is a selective SGLT2 inhibitor in development for the treatment of T2DM. We assessed the efficacy and safety of EMPA added-on to basal insulin in patients with T2DM.

Materials and methods: Patients with T2DM (mean age 58.8 yrs; HbA_{1c} 8.2%; BMI 32.2 kg/m^2) were randomized double-blind to receive EMPA 10 mg (n=169) or 25 mg qd (n=155) or placebo (PBO; n=170) for 78 weeks. Basal insulin dose remained constant for the first 18 weeks, then adjustments were allowed at investigator discretion. Primary endpoint was change from baseline in HbA_{1c} at week 18. Key secondary endpoints were changes from baseline in insulin dose and HbA_{1c} at week 78.

Results: EMPA significantly reduced HbA_{1c} at week 18 and 78, and insulin dose at week 78, vs PBO (Table). Further analyses showed reductions in FPG, body weight, and systolic BP (Table). Hypoglycemia (glucose ≤70 mg/dL and/or requiring assistance) was reported similarly in 36.1% of patients on EMPA 10 mg and 25 mg and 35.3% on PBO; 2 patients on EMPA 25 mg required assistance. AEs consistent with urinary tract infection were reported in 14.8%, 11.6% and 8.8% on EMPA 10 mg, EMPA 25 mg and PBO, respectively. AEs consistent with genital infection were reported in 7.7%, 5.2% and 1.8% on EMPA 10 mg, EMPA 25 mg and PBO, respectively.

Conclusion: EMPA 10 mg and 25 mg for 78 weeks as add-on to basal insulin improved glycemic control, led to reductions in body weight without increase in hypoglycemia risk, and were well tolerated except for increased genitourinary infections.

Metabolic response to sodium-glucose transporter 2 (SGLT2) inhibition with empagliflozin in patients with type 2 diabetes

E. Ferrannini[1], E. Muscelli[1], S. Frascerra[1], S. Baldi[1], A. Mari[2], T. Heise[3], U.C. Broedl[4], H.-J. Woerle[4];
[1]Department of Internal Medicine, University of Pisa, [2]CNR Institute of Biomedical Engineering, Padova, Italy, [3]Profil Institute, Neuss, [4]Boehringer Ingelheim, Germany.

Background and aims: SGLT2 inhibitors lower plasma glucose by enhancing urinary glucose excretion. The physiologic response to pharmacologically-induced glycosuria has not been investigated.

Materials and methods: We studied 66 T2D patients (62 ± 7 years, BMI = 31.6 ± 4.5 kg/m^2, HbA_{1c} = 7.2 ± 0.2%, mean ± SD) at baseline, after a single dose (25 mg, Study I), and following 4 weeks of treatment with empagliflozin (25 mg/day, Study II). For each study, patients received a mixed meal coupled with double-tracer glucose administration and indirect calorimetry.

Results: Compared to baseline, Study I caused glycosuria (7.8 [4.4] g over 3 hrs of fasting, median [IQR]), which led to an increase in endogenous glucose production (EGP, 13.8 [5.2] to 17.6 [4.8] $\mu mol \cdot kg_{FFM}^{-1} \cdot min^{-1}$, p<0.0001) matching the glycosuria. These fasting-state changes were maintained in Study II. Postmeal glycosuria rose to 29.0 [12.5] and 28.2 [15.4] g over 5 hrs in Study I and Study II, respectively. Correspondingly, postmeal glucose AUC (51 [11] and 51 [10] *vs* 57 [16] g/dL) and insulin AUC (80 [59] and 76 [59] *vs* 93 [68] nmol/L) dropped, whereas the glucagon response rose (6.5 [2.1] and 5.6 [1.8] *vs* 5.2 [1.6] nmol/L) (all p<0.001). While appearance of oral glucose was unchanged, postmeal EGP was increased (AUC = 40 [14] and 37 [11] *vs* 34 [11] g, both p<0.01). Tissue glucose disposal (= total glucose disposal minus glycosuria) was reduced (75 [16] and 70 [21] *vs* 93 [18] g, p<0.0001) due to a decrease in both glucose oxidation and non-oxidative glucose disposal, with a concomitant rise in lipid oxidation (all p<0.01). ß-cell glucose sensitivity improved (55 [35] and 55 [39] *vs* 44 [32] $pmol \cdot min^{-1} \cdot m^{-2} \cdot mM^{-1}$, p<0.0001), while insulin sensitivity was unchanged (9.1 [6.7] and 8.6 [8.0] *vs* 8.2[5.8] $ml \cdot kg_{FFM}^{-1} \cdot min^{-1} \cdot nM^{-1}$, p=ns).

Conclusion: In T2D patients empagliflozin lowers fasting and postprandial glycaemia by (a) increasing total glucose removal despite a compensatory in-

crease in endogenous glucose production, (b) improving ß-cell function, and (c) shifting substrate utilization from glucose to lipid.

Canagliflozin added on to dipeptidyl peptidase-4 inhibitors or glucagon-like peptide-1 agonists with or without other antihyperglycaemic agents in type 2 diabetes mellitus

G. Meininger[1], C. Wysham[2], V. Woo[3], C. Mathieu[4], G. Capuano[1], M. Alba[1], M. Desai[1];
[1]Janssen Research & Development, LLC, Raritan, [2]Washington State University, Spokane, USA, [3]University of Manitoba, Winnipeg, Canada, [4]KU Leuven, Belgium.

Background and aims: Canagliflozin (CANA) is a sodium glucose co-transporter 2 (SGLT2) inhibitor developed for the treatment of patients with type 2 diabetes mellitus (T2DM). The efficacy and safety of CANA were evaluated in subjects with T2DM who were on dipeptidyl peptidase-4 inhibitors (DPP-4i) or glucagon-like peptide-1 (GLP-1) agonists as monotherapy or in combination with other antihyperglycaemic agents (AHAs).
Materials and methods: This post hoc analysis of data from the CANagliflozin cardioVascular Assessment Study (CANVAS; subjects with T2DM who had a history or high risk of cardiovascular disease) evaluated CANA 100 and 300 mg compared with placebo (PBO) in subsets of subjects who were on DPP-4i (N = 316; mean age, 63 years; HbA_{1c}, 8.1%; body mass index [BMI], 32.3 kg/m^2) or GLP-1 agonists (N = 95; mean age, 61 years; HbA_{1c}, 8.1%; BMI, 37.4 kg/m^2) over 18 weeks of therapy.
Results: At Week 18, CANA 100 and 300 mg reduced HbA_{1c} and body weight compared with PBO in both the DPP-4i and GLP-1 agonist subsets (Table). The overall incidence of adverse events (AEs) was higher with CANA than with PBO in the DPP-4i subset, and comparable or lower with CANA relative to PBO in the GLP-1 agonist subset. Rates of serious AEs were generally higher with CANA than with PBO in both subsets. The proportion of subjects with documented hypoglycaemia episodes was higher with CANA 100 and 300 mg than PBO among those who were on insulin, sulphonylurea, or meglitinide in the DPP-4i subset (17/70, 29/87, and 12/74, respectively) and the GLP-1 agonist subset (11/29, 11/22, and 4/26, respectively); only 2 and 1 CANA-treated subjects who were not on these concomitant agents reported documented hypoglycaemia episodes in the DPP-4i and GLP-1 agonist subsets, respectively.
Conclusion: CANA added on to DPP-4i or GLP-1 agonists (with or without other AHAs) lowered HbA_{1c}, reduced body weight, and was generally well tolerated in subjects with T2DM at 18 weeks.

Efficacy and safety of canagliflozin in subjects with type 2 diabetes mellitus inadequately controlled with metformin plus sulphonylurea over 52 weeks

F. Vercruysse[1], G. Charpentier[2], J. Wilding[3], P. Hollander[4], G. González Gálvez[5], C. Mathieu[6], K. Usiskin[7], U. Vijapurkar[7], S. Black[7], W. Canovatchel[7], G. Meininger[7];
[1]Janssen Research & Development, Beerse, Belgium, [2]Sud-Francilien Hospital, Corbeil-Essonnes, France, [3]University of Liverpool, UK, [4]Baylor University Medical Center, Dallas, USA, [5]Instituto Jalisciense de Investigacion en Diabetes y Obesidad, Guadalajara, Mexico, [6]KU Leuven, Belgium, [7]Janssen Research & Development, LLC, Raritan, USA.

Background and aims: Canagliflozin (CANA) is a sodium glucose co-transporter 2 inhibitor developed for the treatment of patients with type 2 diabetes mellitus (T2DM). This 52-week study assessed the efficacy and safety of CANA in subjects with T2DM on background metformin (MET) plus sulphonylurea (SU) therapy.
Materials and methods: In this randomised, double-blind, placebo (PBO)-controlled, Phase 3 study, subjects with T2DM on MET + SU (N = 469) received CANA 100 or 300 mg or PBO once daily during a 26-week core period followed by a 26-week extension (n = 353). Changes from baseline in glycaemic and other efficacy parameters at Week 52 are reported. Adverse events (AEs) were recorded throughout the study.
Results: Mean baseline characteristics were similar across groups (age, 56.8 y; HbA_{1c}, 8.1%; fasting plasma glucose [FPG], 9.5 mmol/L; body mass index, 33.1 kg/m^2). Over 52 weeks, CANA 100 and 300 mg reduced HbA_{1c} and FPG compared with PBO (Table). More PBO-treated subjects received rescue therapy (24.4%) than those treated with CANA 100 or 300 mg (8.9% and 5.1%). Both CANA doses reduced body weight and systolic blood pressure (BP) and increased high-density lipoprotein cholesterol (HDL-C) compared with PBO; increases in low-density lipoprotein cholesterol (LDL-C) and non-HDL-C were seen with CANA 300 mg versus PBO. Overall incidence of AEs was slightly lower with CANA 100 mg than CANA 300 mg and PBO (67.5%, 73.1%, 71.2%). Serious AE rates were lower with CANA 100 mg (4.5%) and 300 mg (5.1%) than PBO (8.3%). Rates of AE-related discontinuations were higher with CANA 100 mg (7.0%) and 300 mg (7.7%) than PBO (4.5%). CANA 100 and 300 mg were associated with higher rates than PBO of genital mycotic infections in women (18.5%, 18.8%, 5.0%) and men (7.9%, 5.7%, 1.3%). Incidences of osmotic diuresis-related AEs (eg, pollakiuria, polyuria) were higher with CANA 100 and 300 mg than PBO (5.7%, 7.1%, 1.9%); none led to study discontinuation. Urinary tract infection rates were slightly higher with CANA 100 and 300 mg than PBO (8.3%, 8.3%, 7.7%). Incidences of AEs related to reduced intravascular volume (eg, postural dizziness, orthostatic hypotension) were 0.6%, 3.8%, and 1.9% with CANA 100 and 300 mg and PBO. Rates of documented hypoglycaemia were higher with CANA 100 and 300 mg than PBO (33.8%, 36.5%, 17.9%); the number of subjects with severe hypoglycaemia episodes was small (1 [0.6%] per group).
Conclusion: CANA 100 and 300 mg improved glycaemic control, reduced body weight, and were generally well tolerated in subjects with T2DM inadequately controlled with MET + SU over 52 weeks.

Efficacy and safety of canagliflozin monotherapy in subjects with type 2 diabetes mellitus inadequately controlled with diet and exercise over 52 weeks

K. Stenlöf[1], W.T. Cefalu[2], K.-A. Kim[3], E. Jodar[4], M. Alba[5], R. Edwards[5], C. Tong[5], W. Canovatchel[5], G. Meininger[5];
[1]Clinical Trial Center, Sahlgrenska University Hospital, Gothenburg, Sweden, [2]Pennington Biomedical Research Center and LSUHSC School of Medicine, Baton Rouge and New Orleans, USA, [3]Dongguk University Ilsan Hospital, Dongguk University School of Medicine, Goyang, Republic of Korea, [4]Hospital Quiron, Madrid, Spain, [5]Janssen Research & Development, LLC, Raritan, USA.

Background and aims: Canagliflozin (CANA) is an SGLT2 inhibitor developed for the treatment of type 2 diabetes mellitus (T2DM). This study assessed the efficacy and safety of CANA in subjects with T2DM who have inadequate glycaemic control with diet and exercise over 52 weeks.
Materials and methods: In this randomised, double-blind, Phase 3 study, subjects with T2DM (N = 584) received CANA 100 or 300 mg or PBO once daily during a PBO-controlled, 26-week core period followed by a 26-week extension (n = 451; blinded switch of PBO group to sitagliptin 100 mg [PBO/SITA; n = 119]). Changes from baseline in efficacy parameters at Week 52 are reported for CANA 100 and 300 mg (SITA was used only to maintain the double-blind and control group, not as an efficacy comparator). Safety data are reported for CANA and PBO/SITA at 52 weeks.
Results: Mean baseline characteristics were similar across groups (age, 55.4 y; HbA_{1c}, 8.0%; fasting plasma glucose [FPG], 9.5 mmol/L; body mass index, 31.6 kg/m^2). At Week 52, CANA showed numerical, dose-related reductions from baseline in HbA_{1c}, FPG, and body weight (Table). Both CANA doses were associated with decreases in systolic blood pressure (BP) and triglycerides, and increases in high-density lipoprotein cholesterol (HDL-C) and low-density lipoprotein cholesterol (LDL-C). From Weeks 26 to 52, changes in HbA_{1c}, body weight, and HDL-C with CANA were generally stable, with small increases observed in LDL-C. Over 52 weeks, overall AE rates with CANA 100 and 300 mg and PBO/SITA were 67.2%, 66.0%, and 64.1%, respectively. Serious AE rates were lower with CANA 300 mg than CANA 100 mg and PBO/SITA (2.5%, 5.6%, 5.7%). Rates of AE-related discontinuations were higher with CANA 100 and 300 mg than PBO/SITA (3.1%, 2.0%, 1.0%). CANA 100 and 300 mg were associated with higher rates than PBO/SITA of genital mycotic infections in women (11.4%, 9.3%, 4.8%) and men (6.2%, 9.0%, 0%). Urinary tract infection rates were slightly higher with CANA 100 and 300 mg than PBO/SITA (8.2%, 7.1%, 6.3%). Incidences of osmotic diuresis-related AEs (eg, pollakiuria, polyuria; 4.6%, 7.6%, 2.1%) and AEs related to reduced intravascular volume (eg, postural dizziness, orthostatic hypotension; 1.5%, 2.0%, 0.5%) were higher with CANA 100 and 300 mg than PBO/SITA, but generally did not lead to discontinuation. Hypoglycaemia rates were low across groups (CANA 100 mg, 5.1%; CANA 300 mg, 3.6%; PBO/SITA, 3.6%).
Conclusion: CANA 100 and 300 mg provided improvement in glycaemic control and body weight reduction, and were generally well tolerated in subjects with T2DM inadequately controlled with diet and exercise over 52 weeks.

Table. Summary of Efficacy Endpoints at Week 52 (Extension mITT*, LOCF)

Parameter†	CANA 100 mg	CANA 300 mg
HbA_{1c} change, %	–0.81 (0.07)	–1.11 (0.07)
% of subjects reaching HbA_{1c} <7.0%	52.4 (3.9)	64.5 (3.7)
FPG change, mmol/L	–1.5 (0.1)	–2.2 (0.1)
Body weight % change	–3.3 (0.3)	–4.4 (0.3)
Systolic BP change, mmHg	–1.4 (0.8)	–3.9 (0.8)
Diastolic BP change, mmHg	–0.4 (0.6)	–0.7 (0.6)
Triglycerides % change	–2.0 (3.0)	–2.1 (3.0)
HDL-C % change	11.1 (1.5)	14.7 (1.5)
LDL-C % change	6.3 (2.1)	11.2 (2.1)
LDL-C/HDL-C % change	–3.1 (2.1)	–0.1 (2.1)
Non–HDL-C % change	1.8 (1.7)	5.6 (1.7)

mITT, modified intent to treat; LOCF, last observation carried forward; ANCOVA, analysis of covariance; SE, standard error. *Including all subjects who were randomised to a treatment group on Day 1, took ≥1 dose of study drug, did not receive rescue medication in the core period, and entered the extension period; †Least squares mean (SE) change from baseline using ANCOVA for all parameters except for % of subjects reaching HbA_{1c} <7.0%.

Durability of dapagliflozin vs glipizide as add-on therapies in type 2 diabetes inadequately controlled on metformin: 4-year data

A. Langkilde[1], M.A. Nauck[2], S. Del Prato[3], S. Durán-Garcia[4], K. Rohwedder[5], A. Theuerkauf[6], S.J. Parikh[7];
[1]AstraZeneca, Mölndal, Sweden, [2]Diabeteszentrum Bad Lauterberg, Bad Lauterberg im Harz, Germany, [3]University of Pisa, Italy, [4]Hospital Nestra Señora de Valme, Sevilla, Spain, [5]AstraZeneca, Wedel, [6]Aptiv Solutions, Köln, Germany, [7]AstraZeneca, Wilmington, USA.

Background and aims: Dapagliflozin (DAPA), a selective SGLT2 inhibitor, lowers blood glucose by increasing urinary glucose excretion in an insulin-independent manner. Results from a randomised, double-blind trial of DAPA (≤10 mg/d, n=406) vs glipizide (GLIP; ≤20 mg/d, n=408) as add-on to metformin (MET; median 2000 mg/d) in T2DM, have been previously reported. DAPA was non-inferior to GLIP in HbA1c change at 52 weeks (primary endpoint; both −0.52%), with the added benefits of weight loss and reduced hypoglycaemia (hypo). Here we report 4-year data from this study, the longest duration of therapy studied for any SGLT2 inhibitor to date.
Materials and methods: In the double-blind extension of this study, patients continued to receive DAPA (n=204) and GLIP (n=188) added to MET. In Year 2, one up-titration was allowed if HbA1c ≥7%. In Years 3 and 4, one up-titration was allowed before rescue (DPP4-inhibitor, insulin and pioglitazone [only South Africa]); rescue may occur if HbA1c 7.0-<8.0% and must occur if HbA1c ≥8.0%. Efficacy was analyzed by a repeated measures mixed model, excludes data after rescue and are reported as adjusted mean changes (95% CI). Safety was assessed throughout and includes data after rescue.
Results: Mean baseline HbA1c was 7.72%. Of the 814 patients entering the study, 161 (39.7%) DAPA and 141 (34.6%) GLIP patients completed Year 4. Effect of therapy on HbA1c attenuated over time in both groups, but DAPA showed more persistent metabolic benefits vs GLIP up to Year 4 (change from baseline in HbA1c of −0.10 vs +0.20%): treatment difference of −0.30% (95% CI: −0.51, −0.09). Sustained and stable weight loss was seen with DAPA vs weight gain with GLIP (−3.95 vs +1.12 kg): difference of −5.07 kg (95% CI: −6.21, −3.93). More DAPA vs GLIP patients achieved a ≥5% weight loss (10.2% vs 1.8%) at Year 4. Mean systolic BP was reduced with DAPA but not with GLIP: difference of −3.7 mmHg (95% CI: −5.9, −1.4). Rate of patients with hypo was ~10-fold less with DAPA (5.4%) vs GLIP (51.5%); most patients first presented during Year 1. All major hypos (n=3) were with GLIP. There were no discontinuations due to hypo with DAPA. Overall frequencies of AEs and SAEs were similar between groups; 87.7% and 18.5% for DAPA vs 87.0% and 19.9% for GLIP. Discontinuation due to AEs was 13.3% for DAPA vs 11.3% for GLIP. Proportion of patients reporting urinary tract infections (UTI) was 13.5% for DAPA (8.8% male; 19.4% female) vs 9.3% for GLIP (5.8% male; 13.5% female). Upper UTI occurred in 1 patient receiving DAPA vs 3 patients receiving GLIP. Genital infections (GenI) occurred in 14.3% of DAPA patients (7.5% male; 22.8% female) vs 2.9% of GLIP patients (0.4% male; 5.9% female). The majority of patients with GenI and UTI first presented during Year 1. The majority of events were of mild/moderate intensity and resolved with standard treatment. There were no signs of deteriorating renal function as measured by eGFR over 4 years.
Conclusion: DAPA demonstrated sustained metabolic benefits, including stable weight loss and BP reductions with low rates of hypo, compared with GLIP over 4 years of treatment. DAPA was well-tolerated throughout, with no new safety signals identified.

Dapagliflozin improves glycaemic control and reduces body weight as add-on therapy to metformin plus sulphonylurea

S. Matthaei[1], K. Rohwedder[2], A. Grohl[3], E. Johnsson[4];
[1]Diabetes-Zentrum Quakenbrück, [2]AstraZeneca, Wedel, [3]Aptiv Solutions, Koeln, Germany, [4]AstraZeneca, Mölndal, Sweden.

Background and aims: Dapagliflozin (DAPA) is a highly selective inhibitor of sodium glucose co-transporter 2 (SGLT2), the primary transporter responsible for mediating renal glucose reabsorption. DAPA has been shown to be well tolerated and effective in improving glycaemic control and promoting body weight loss in patients with type 2 diabetes (T2DM) both as monotherapy and in combination with other anti-hyperglycaemic medications. The aim of this 24 week randomised, double-blind, parallel-group phase III study, with

an on-going 28 week blinded extension period, was to evaluate the efficacy and safety of DAPA in patients with T2DM inadequately controlled with the combination of metformin (MET) plus sulphonylurea (SU).

Materials and methods: Men and women aged ≥18 years, receiving a maximum tolerated dose of SU (≥ half maximum dose) and MET (≥1500 mg QD), were randomised to receive double-blind DAPA 10 mg/d (N=108) or placebo (PBO, N=108) for 24 weeks.

Results: Demographic and baseline characteristics were generally balanced between DAPA and PBO groups: 55.6% and 42.6% were men, mean patient age was 61.1 and 60.9 years and mean T2DM duration was 9.28 and 9.62 years. At week 24, glycaemic measures (mean HbA1c and mean fasting plasma glucose [FPG]) were significantly improved with DAPA versus PBO (Table). In addition, a greater proportion of patients achieved a therapeutic glycaemic response, defined as the achievement of HbA1c <7.0%, following treatment for 24 weeks with DAPA (31.8%) versus PBO (11.1%). Total body weight was significantly reduced over 24 weeks with DAPA versus PBO. A significant reduction in seated systolic blood pressure (SBP) was observed at week 8 in patients treated with DAPA versus PBO. This change in SBP was maintained out to week 24. Overall, 48.6% of patients treated with DAPA and 51.4% with PBO experienced ≥1 adverse event that were mostly mild or moderate in intensity and unrelated to study treatment. Hypoglycaemic events were experienced by 12.8% of patients in the DAPA group versus 3.7% with PBO. In patients receiving DAPA, 6.4% had a down-titration of SU compared to 3.7% with PBO. Events of genital infection were experienced by 5.5% of patients receiving DAPA and none with PBO. Over 24 weeks, events of urinary tract infection were reported by 6.4% of patients in both groups. One event of pyelonephritis was observed in the DAPA group.

Conclusion: DAPA was well tolerated and effective over 24 weeks when administered as an add-on to MET therapy in the presence of SU.

Dapagliflozin helps reduce HbA_{1c} and body weight in patients with type 2 diabetes as part of triple combination therapy: a subanalysis of four clinical studies

S. Jabbour[1], E. Hardy[2], T.W. de Bruin[2], I. Gause-Nilsson[3], K. Rohwedder[4], P. Martin[2], S. Parikh[2];
[1]Division of Endocrinology, Diabetes & Metabolic Diseases, Jefferson Medical College of Thomas Jefferson University, Philadelphia, [2]AstraZeneca, Wilmington, USA, [3]AstraZeneca, Mölndal, Sweden, [4]AstraZeneca, Wedel, Germany.

Background and aims: Dapagliflozin (DAPA) is a highly selective inhibitor of sodium-glucose co-transporter 2, the primary transporter involved in mediating renal glucose re-uptake. DAPA has been shown to reduce hyperglycaemia in patients with type 2 diabetes mellitus (T2DM) through the urinary excretion of glucose. Due to an accompanying loss of calories, DAPA is also associated with a reduction in body weight (BW). DAPA has demonstrated efficacy as monotherapy in treatment-naïve patients and in those inadequately controlled with single oral antidiabetic drugs (OADs) or insulin (INS) (+/- OADs). In the progression of T2DM, second and even third agents are often needed to intensify therapy. To investigate the efficacy of DAPA when added to 2 stable medications, we performed subgroup analyses of four 24-week studies. The primary results from the full populations of these studies have been presented previously.

Materials and methods: Patients in the subgroups received placebo (PBO) or DAPA 10 mg for 24 weeks in the presence of either sitagliptin (SITA) plus metformin (MET) (prespecified stratification), or sulphonylurea (SU) plus MET (HbA1c analysis prespecified, BW analysis post hoc), or INS plus MET (analysis post hoc).

Results: DAPA reduced HbA1c compared with PBO at 24 weeks in each of the 4 subgroups (Table). A consistent clinically beneficial reduction in HbA1c was observed with DAPA when added to 2 prior antidiabetic therapies, including INS. BW was likewise reduced to a greater extent in the DAPA group compared with PBO across each of the studies.

Conclusion: DAPA is effective in reducing glycaemia and BW in patients with T2DM who are inadequately controlled on 2 different background antidiabetic medications. This observation is consistent with an INS-independent mechanism of action that works regardless of residual β-cell function.

Table

PS 074 SGLT-2 inhibitors: influence on cardiovascular risk factors

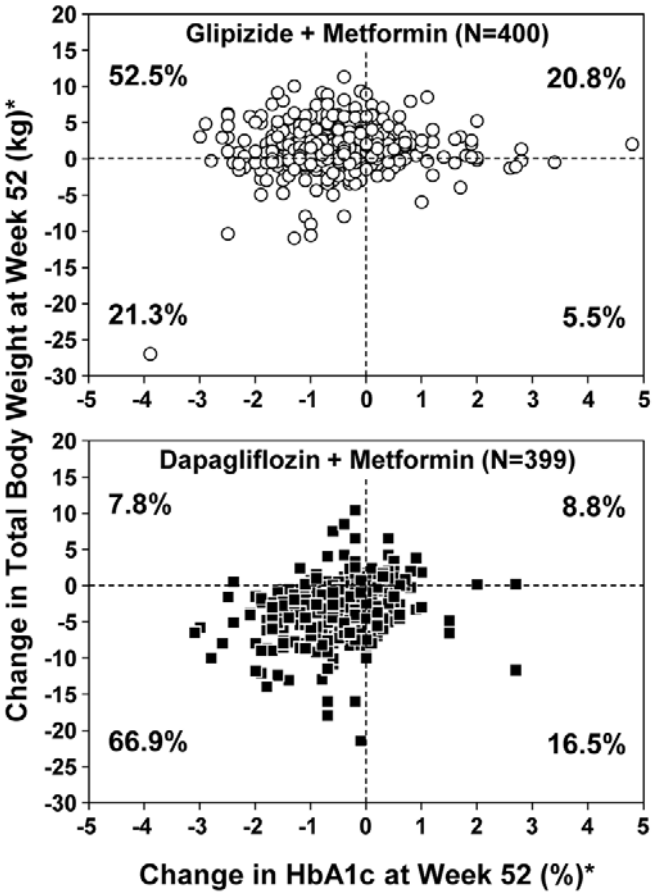
939

Combined HbA_{1c} and weight reduction is more frequent with dapagliflozin vs glipizide add-on treatment in patients with type 2 diabetes inadequately controlled on metformin

K. Rohwedder[1], M.A. Nauck[2], S. Duran-Garcia[3], M. Hashemi[4], S.J. Parikh[5]; [1]AstraZeneca, Wedel, [2]Diabeteszentrum Bad Lauterberg, Germany, [3]Hospital Nestra Señora de Valme, Sevilla, Spain, [4]AstraZeneca, Mölndal, Sweden, [5]AstraZeneca, Wilmington, USA.

Background and aims: Sulfonylureas are often used as add-on therapy in type 2 diabetes when metformin fails to maintain glycaemic control, but risks include weight gain and hypoglycaemia. Dapagliflozin (DAPA), a sodium-glucose cotransporter 2 inhibitor, increases urinary glucose excretion and reduces hyperglycaemia independently of insulin secretion or action. The aim of this analysis was to compare the proportion of patients who had combined reduction in HbA1c and weight with DAPA therapy compared with glipizide (GLIP) after inadequate control on metformin alone.

Materials and methods: This 52-week, double-blind, active-controlled, non-inferiority trial randomised patients inadequately controlled on metformin (mean baseline HbA1c, 7.7%) to add-on DAPA (n=406, ≤10 mg/d) or GLIP (n=408, ≤20 mg/d) and maintained to Week 52 unless hypoglycaemia warranted down-titration. HbA1c non-inferiority at Week 52 has been reported previously. Here, we report the proportion of patients achieving combined HbA1c and weight reduction, and rates of hypoglycaemia. Combined HbA1c and body weight reduction was defined as any decrease in HbA1c of >0 % and any decrease in weight of >0 kg.



Results: At Week 52, three-fold more DAPA-treated patients achieved combined HbA1c and weight reduction (66.9%) vs 21.3% of GLIP-treated patients. Proportions achieving HbA1c reduction were 74.7% vs 73.8% and weight reduction were 83.5% vs 26.8% with DAPA vs GLIP, respectively. The distribution of these proportions was significantly different between treatments ($Chi^2 = 268.6$, df = 3, $p<0.0001$). Hypoglycaemic events were less frequent with DAPA (3.5%) vs GLIP (40.8%).

Conclusion: DAPA produced similar glycaemic efficacy to GLIP, but with the benefits of weight loss and low rates of hypoglycaemia.

Dapagliflozin a glucose-regulating drug with diuretic properties in subjects with type 2 diabetes

H.J. Lambers Heerspink[1], D. de Zeeuw[1], L. Wei[2], J.F. List[3]; [1]University of Groningen, Netherlands, [2]Bristol-Myers Squibb, Hopewell, [3]Bristol-Myers Squibb, Princeton, USA.

Background and aims: Sodium-glucose co-transporter 2 (SGLT2) reabsorbs glucose and sodium in the renal proximal tubule. Dapagliflozin (DAPA), an SGLT2 transporter inhibitor, targets hyperglycaemia in type 2 diabetes mellitus (T2DM) by increasing renal glucose excretion. To investigate whether the parallel occurring sodium loss would have diuretic-like physiological effects, we compared DAPA and hydrochlorothiazide (HCTZ) effects on 24-h blood pressure (BP), body weight, plasma volume and glomerular filtration rate.

Materials and methods: In this randomised, placebo-controlled, double-blind trial, 75 subjects with T2DM aged 18-70 years, HbA1c 6.6%-9.5%, seated systolic/diastolic BP (130-165)/(80-105) mm Hg, on a stable dose of angiotensin-converting enzyme inhibitor or angiotensin receptor blockers and no other antihypertensive medications were randomly assigned to placebo (PBO), DAPA 10 mg/d, or HCTZ 25 mg/d. Changes from baseline in 24-h ambulatory BP, body weight, glomerular filtration rate measured by iohexol plasma clearance, and plasma volume measured by ^{125}I-labeled human serum albumin, were compared after 12 weeks of treatment.

Results: Patients' mean age was 56 years, T2DM duration was 6.3 years, and HbA1c was 7.5%. Treatment with PBO, DAPA, or HCTZ resulted in changes from baseline in 24-h ambulatory mean systolic BP of -0.9 (95% CI -4.2, +2.4), -3.3 (95% CI -6.8, +0.2), and -6.6 (95% CI -9.9, -3.2) mm Hg, respectively at week 12, adjusted for baseline systolic BP. Body weight decreased with DAPA and HCTZ. In a sub-study plasma volume appeared to decrease with DAPA but did not change with PBO or HCTZ treatment. DAPA was associated with a small reduction in glomerular filtration rate (-10.8%; 95% CI -14.6, -6.7) relative to PBO (-2.9%; 95% CI -6.9, +1.2) or HCTZ (-3.4%; 95% CI -7.3, +0.6).

Conclusion: DAPA-mediated SGLT2 inhibition is associated with reductions in 24-h BP, body weight and possibly plasma volume. Cumulatively, these effects suggest that DAPA may have a diuretic-like capacity to lower BP in addition to beneficial effects on glycaemic control.

Weight loss related quality of life among type 2 diabetes mellitus patients treated with dapagliflozin

S.J. Parikh[1], A. Ingelgard[2], A.-M. Langkilde[2], J. Sugg[1], S. Grandy[1]; [1]AstraZeneca LP, Wilmington, USA, [2]AstraZeneca LP, Molndal, Sweden.

Background and aims: Data related to the impact on health-related quality of life (HRQOL) from oral antidiabetic therapy-induced weight loss in T2DM patients are scarce. Dapagliflozin, a novel sodium-glucose cotransporter 2 (SGLT2) inhibitor, lowers blood glucose by increasing urinary glucose excretion and is associated with body weight reductions. This study evaluated HRQOL associated with weight change among T2DM patients treated with dapagliflozin.

Materials and methods: Patients with T2DM (BMI ≥25 kg/m^2; 56% men; mean age, 61 years) who had inadequate glycemic control on metformin (MET) alone were enrolled in a 24-week, international, double-blind, randomized, placebo-controlled study with an additional 78-week extension to evaluate the effect of dapagliflozin + MET. Primary end point was total body weight change at week 24, and weight loss was -2.96 kg for dapagliflozin and -0.88 kg for placebo ($p<0.0001$). Patients completed the SHIELD WQ-9, a weight change-related HRQOL survey, at baseline and week 102. Difference

of proportions for patients treated with dapagliflozin 10 mg + MET (n=89) or placebo + MET (n = 91) who reported improvement in each HRQOL domain and weight loss was analyzed with Fisher's exact test.

Results: Among patients with reported weight loss at week 102 (31.5% in dapagliflozin group; 29.7% in placebo group), baseline HRQOL (% reporting improvement in each of 9 domains) was similar for dapagliflozin and placebo groups (p>0.05). At week 102, among those who reported weight loss, more dapagliflozin-treated patients reported improvement in 8 of 9 HRQOL domains (14.3%-57.1%), compared with patients who received placebo (7.4%-37.0%). Significantly greater proportion of dapagliflozin patients than placebo patients with reported weight loss reported improvement in overall quality of life (57.1% vs. 22.2%, p=0.013) and self-esteem (57.1% vs. 25.9%, p=0.029).

Conclusion: Weight loss-related HRQOL was maintained or improved during 2 years of treatment with dapagliflozin, a novel mechanism for treatment of T2DM.

Empagliflozin improves blood pressure in patients with type 2 diabetes (T2DM) and hypertension

I. Tikkanen[1], K. Narko[2], C. Zeller[3], A. Green[4], A. Salsali[5], U.C. Broedl[5], H.J. Woerle[5];
[1]Department of Medicine, Helsinki University Central Hospital, Minerva Institute for Medical Research, Helsinki, [2]Boehringer Ingelheim Finland Ky, Helsinki, Finland, [3]Boehringer Ingelheim, Biberach, Germany, [4]inVentiv Health Clinical, Maidenhead, UK, [5]Boehringer Ingelheim, Germany.

Background and aims: A Phase III randomized placebo-controlled trial was conducted to investigate the efficacy, safety and tolerability of the SGLT2 inhibitor empagliflozin (EMPA) compared with placebo in patients with T2DM and hypertension.

Materials and methods: Patients with T2DM (mean [SD] age 60.2 [9.0] years and BMI 32.6 [5.1] kg/m^2) and hypertension (mean seated systolic blood pressure [SBP] 130-159 mmHg and diastolic blood pressure [DBP] 80-99 mmHg) were randomized double-blind and received EMPA 10 mg (n=276), EMPA 25 mg (n=276) or placebo (PBO; n=271) qd for 12 weeks. Co-primary endpoints were changes from baseline in HbA_{1c} and mean 24-hour SBP (ambulatory blood pressure monitoring [ABPM]) at week 12. The key secondary endpoint was change from baseline in mean 24-hour DBP (ABPM) at week 12. Other secondary endpoints included changes from baseline in office SBP and DBP, and the proportion of patients reaching controlled BP (<130/80 mmHg) at week 12.

Results: EMPA 10 and 25 mg significantly reduced HbA_{1c} and mean 24-hour SBP and DBP compared with placebo (Table). Changes in office SBP and DBP were consistent with the changes in ABPM results. More patients receiving EMPA 10 mg and 25 mg who had uncontrolled BP at baseline had controlled BP (<130/80 mmHg) at week 12 vs PBO (18% and 16% vs 8%, respectively; p<0.01). Adverse events (AEs) were reported by 48.9%, 51.4%, and 52.6% of patients on EMPA 10 mg, 25 mg, and PBO, respectively. Events consistent with volume depletion were reported in 1 patient (0.4%) on EMPA 10 mg, no patients on EMPA 25 mg and 1 patient (0.4%) on PBO. AEs consistent with urinary tract infection were reported in 4.0% of patients on EMPA 10 mg, 4.7% on EMPA 25 mg and 3.7% on PBO. AEs consistent with genital infection were reported in 5.1% of patients on EMPA 10 mg, 5.4% on EMPA 25 mg and 0.4% on PBO.

Conclusion: EMPA 10 mg and 25 mg qd were associated with significant and clinically meaningful reductions in BP compared with PBO, and were well tolerated in patients with T2DM and hypertension.

Change from baseline in mean seated office DBP, mmHg (SE)	-1.13 (0.39)	-3.06 (0.39)***	-3.02 (0.39)***

Adjusted means based on ANCOVA in full analysis set with last observation carried forward (LOCF) imputation. For blood pressure parameters, values following a change in antihypertensive therapy were set to missing and imputed via LOCF. Values after start of antidiabetic rescue medication were set to missing and imputed via LOCF for all parameters. For each dose group, statistical testing of primary and key secondary endpoints was hierarchical at alpha = 0.05. Further endpoints were called statistically significant if p-values were smaller than nominal alpha = 0.05. *p<0.05 vs. placebo; **p<0.01 vs. placebo; ***p<0.001 vs. placebo.

Empagliflozin improves glycaemic parameters and cardiovascular risk factors in patients with type 2 diabetes: pooled data from four pivotal phase III trials

T. Hach[1], J. Gerich[2], A. Salsali[1], G. Kim[1], S. Hantel[3], H.J. Woerle[1], U.C. Broedl[1];
[1]Boehringer Ingelheim, Germany, [2]University of Rochester School of Medicine, Rochester, USA, [3]Boehringer Ingelheim, Biberach, Germany.

Background and aims: We analysed pooled data from 2477 patients with T2DM (mean [SD] age 55.6 [10.2] years, HbA_{1c} 7.99 [0.85], BMI 28.7 [5.5]) from four randomized, placebo-controlled Phase III trials that investigated empagliflozin (EMPA) 10 mg or 25 mg given for 24 weeks as monotherapy, add-on to metformin (MET), add-on to MET + SU, or add-on to pioglitazone ± MET.

Materials and methods: Effects on HbA_{1c}, fasting plasma glucose (FPG), weight, systolic and diastolic blood pressure (SBP and DBP) were evaluated in the full analysis set (placebo [PBO]: n=825, EMPA 10 mg: n=831, EMPA 25 mg: n=821). Effects on lipids and uric acid were evaluated in all treated patients (PBO: n=825, EMPA 10 mg: n=830, EMPA 25 mg: n=822). Effects on SBP and DBP were also evaluated in patients with uncontrolled BP (SBP ≥130 mmHg or DBP ≥80 mmHg) at baseline (PBO: n=501, EMPA 10 mg: n=517, EMPA 25 mg: n=506).

Results: EMPA significantly reduced HbA_{1c}, FPG, weight, SBP, DBP and uric acid at week 24 vs PBO. Reductions in SBP and DBP were more pronounced in patients with uncontrolled BP at baseline. Small increases in HDL- and LDL-cholesterol and small decreases in triglyceride levels were observed with EMPA vs PBO.

	Placebo	Empagliflozin 10 mg	Empagliflozin 25 mg

Design of the empagliflozin cardiovascular outcome event trial in type 2 diabetes mellitus

S.E. Inzucchi[1], B. Zinman[2,3], J.M. Lachin[4], C. Wanner[5], R. Ferrari[6], E. Bluhmki[7], S. Hantel[7], O. Johansen[8], H.-J. Woerle[8], U.C. Broedl[8]; [1]Section of Endocrinology, Yale University School of Medicine, New Haven, USA, [2]Samuel Lunenfeld Research Institute,, Mount Sinai Hospital, Toronto, [3]Division of Endocrinology, University of Toronto, Canada, [4]The Biostatistics Center, The George Washington University, Rockville, USA, [5]Department of Medicine, Division of Nephrology, Würzburg University Clinic, Germany, [6]Section of Cardiology, University of Ferrara, Italy, [7]Boehringer-Ingelheim, Biberach, [8]Boehringer-Ingelheim, Germany.

Background and aims: A large number of diabetes drug classes are available for the management of type 2 diabetes mellitus (T2DM), but the impact of different glucose-lowering therapies on cardiovascular (CV) disease remains unclear.

Materials and methods: The empagliflozin CV outcome event trial is an ongoing multi-center, randomized, double blind, placebo-controlled trial designed to assess the impact of the SGLT-2 inhibitor empagliflozin 10 or 25 mg, compared with placebo (1:1:1), on CV events.

Results: 7000 patients with T2DM being treatment naive or receiving any glucose lowering therapy (≥18 years, body mass index ≤45 kg/m^2, estimated glomerular filtration rate (eGFR) ≥30 mL/min/1.73m^2) at elevated CV risk will be studied (TABLE). First patient was randomized September 2010 and the primary outcome is time-to-first occurrence of CV death, nonfatal myocardial infarction or nonfatal stroke. 691 events will be required to provide 90% power to yield the upper limit of the adjusted 95% confidence interval for hazard ratio <1.3 at a one-sided α level of 0.025, assuming equal risks. Hierarchical testing for superiority will follow for the primary and key secondary (time-to-first occurrence of CV death, nonfatal myocardial infarction, nonfatal stroke or hospitalization for unstable angina pectoris) outcomes where non-inferiority is achieved for the pooled doses vs. placebo. Other outcomes include a microvascular composite (laser therapy for retinopathy, vitreous hemorrhage, blindness, new/worsening nephropathy [macroalbuminuria, doubling of serum-creatinine and eGFR ≤ 45 mL/min/1.73m^2, renal replacement therapy, death due to renal disease]) and efficacy (glycaemia, weight, blood pressure).

Conclusion: The empagliflozin CV outcome event trial will complete its recruitment in 2013 and is powered to show CV safety with the option to demonstrate CV superiority for the SGLT-2 inhibitor empagliflozin in patients with T2DM at elevated risk for CV complications.

Table. Glycaemic and CV entry criteria for the empagliflozin CV outcome event trial

Glycemic entry criterion (HbA1c):	Drug-naive patients: 7.0 – 9.0%
	Stable pharmacological therapy: 7.0 – 10.0%
CV entry criteria - any of the following:	History of MI (>2 months prior to enrollment)
	Evidence of CAD* in ≥2 major vessels or left main coronary artery
	Evidence of single-vessel CAD* with no scheduled revasc./previously unsuccessful revasc. and: a) positive non-invasive, functional stress test for ischemia (ECG, echo or nuclear), or b) hospital-discharge due to unstable angina pectoris ≤12 months before enrollment
	Hospital-discharge due to unstable angina pectoris >2 months before enrollment with evidence of CAD* according to any of the following: a) left main coronary artery b) ≥2 major vessels c) single vessel with positive non-invasive, functional stress test for ischemia (ECG, echo or nuclear) and no scheduled revasc./previously unsuccessful revasc.
	History of stroke (>2 months prior to enrollment)
	Peripheral occlusive arterial disease according to any of the following: a) previous limb angioplasty, stenting or bypass surgery b) previous limb or foot amputation due to circulatory insufficiency c) significant peripheral artery stenosis (> 50%) in at least one limb (angiography or non-invasive) d) ankle brachial index < 0.9 in at least one limb

Abbreviations: CAD – coronary artery disease; revasc – revascularization. *CAD defined as ≥ 50% luminal narrowing detected on invasive coronary angiography or multi-sliced computed tomography angiography

Effects of canagliflozin on blood pressure and adverse events related to osmotic diuresis and reduced intravascular volume in subjects with type 2 diabetes mellitus

M. Weir[1], A. Januszewicz[2], R. Gilbert[3], U. Vijapurkar[4], G. Meininger[4]; [1]University of Maryland Medical Center, Baltimore, USA, [2]Institute of Cardiology, Warsaw, Poland, [3]University of Toronto, St. Michael's Hospital, Canada, [4]Janssen Research & Development, LLC, Raritan, USA.

Background and aims: Hypertension is a common comorbidity of T2DM. The blood pressure (BP)-lowering effects of canagliflozin (CANA), a sodium glucose co-transporter 2 (SGLT2) inhibitor developed for the treatment of type 2 diabetes mellitus (T2DM), were evaluated in Phase 3 studies.

Materials and methods: BP changes were assessed based on pooled analyses of data from 4 randomised, double-blind, placebo (PBO)-controlled studies in subjects with T2DM at Week 26 (N = 2,313; mean age, 56.0 y; HbA_{1c}, 8.0%; BMI, 32.1 kg/m^2; estimated glomerular filtration rate [eGFR], 88.1 mL/min/1.73 m^2).

Results: Relative to PBO, CANA 100 and 300 mg were associated with reductions in systolic BP (SBP; -4.0 and -4.7 mmHg) and diastolic BP (DBP; -1.9 and -1.9 mmHg) (**Table**). No notable changes in heart rate were seen with CANA 100 and 300 mg versus PBO (-0.6, -0.4, and 0.0 beats/min). In subjects with baseline SBP ≥140 mmHg (n = 453), SBP was reduced with CANA 100 and 300 mg and PBO (-12.8, -14.2, and -6.8 mmHg); PBO-subtracted decreases were -6.0 and -7.4 mmHg with CANA 100 and 300 mg (P <0.001). In subjects with baseline DBP ≥90 mmHg (n = 171), decreases in DBP were observed with CANA 100 and 300 mg and PBO (-5.9, -9.0, and -7.4 mmHg); a PBO-subtracted reduction was seen with CANA 300 mg (-1.6 mmHg) and a slight increase was seen with CANA 100 mg (1.5 mmHg). Absolute decreases in BP were larger in subjects with higher baseline BP, but PBO-subtracted decreases were generally similar across groups. PBO-subtracted decreases in BP with CANA 100 and 300 mg were similar among subjects on antihypertensives (n = 1,332; SBP, -4.4 and -4.6 mmHg; DBP, -1.8 and -1.7 mmHg) and those not on these agents (n = 981; SBP, -3.5 and -4.7 mmHg; DBP, -2.1 and -2.0 mmHg). Consistent with CANA's osmotic diuretic effect, an increase in related AEs was seen with CANA 100 and 300 mg compared with PBO (6.7%, 5.6%, 0.8%), the most common being pollakiuria (4.2%, 3.1%, 0.6%), thirst (1.3%, 1.9%, 0.2%), and polyuria (0.7%, 1.4%, 0%). Similar rates of AEs related to reduced intravascular volume were observed with CANA 100 and 300 mg and PBO (1.2%, 1.3%, 1.1%), including hypotension (0.7%, 0.2%, 0.6%), postural dizziness (0.4%, 0.5%, 0.3%), and orthostatic hypotension (0%, 0.5%, 0.2%). AEs related to osmotic diuresis and reduced intravascular volume were generally mild or moderate in severity and led to few discontinuations.

Conclusion: CANA was associated with BP lowering compared with PBO in subjects across a range of baseline BP; absolute reductions were greater in subjects with higher BP, but PBO-subtracted decreases were generally similar across groups. In this pooled analysis, CANA was associated with an increased incidence of AEs related to osmotic diuresis but the rates of AEs related to reduced intravascular volume were similar across groups.

Canagliflozin lowers HbA_{1c} and blood pressure through weight loss-independent and weight loss-associated mechanisms

J. Wilding[1], L. Blonde[2], J.-L. Chiasson[3], D. Polidori[4], G. Meininger[5], P. Stein[5];
[1]Department of Obesity and Endocrinology, University of Liverpool, UK, [2]Department of Endocrinology, Diabetes, and Metabolic Diseases, Ochsner Medical Center, New Orleans, USA, [3]University of Montreal, Canada, [4]Janssen Research & Development, LLC, San Diego, [5]Janssen Research & Development, LLC, Raritan, USA.

Background and aims: Canagliflozin (CANA) is a sodium glucose co-transporter 2 (SGLT2) inhibitor that increases urinary glucose excretion (UGE), leading to decreased plasma glucose and HbA_{1c} and weight loss (WL) in subjects with type 2 diabetes mellitus (T2DM). Systolic blood pressure (SBP) also decreases, possibly due in part to the osmotic diuresis with increased glucose excretion. Since WL can improve glycaemic control and lower BP, this analysis examined the WL-independent (WL-I) and WL-associated (WL-A) effects of CANA on HbA_{1c} and SBP in subjects with T2DM enrolled in Phase 3 studies.
Materials and methods: WL-I and WL-A effects of CANA were evaluated based on a pooled analysis of 4 previously reported, randomised, double-blind, 26-week, Phase 3 studies (N = 2,250). Each study had 3 groups: placebo (PBO), CANA 100 mg, CANA 300 mg. Mean baseline values of HbA_{1c} = 8.0%, body weight (BW) = 89 kg, and SBP = 128 mmHg were similar across groups. Within each group, mean changes in HbA_{1c} and SBP were calculated for each decile of WL, and ANCOVA analysis was done with ΔHbA_{1c} or ΔSBP as response and ΔBW (%) as covariate. Plots of ΔHbA_{1c} and ΔSBP versus ΔBW were generated to illustrate the changes observed over the different deciles of weight loss and the relationships obtained from the ANCOVA models. WL-I effects were defined as the vertical distance between lines (ie, difference in response observed when WL is the same in each group) and WL-A effects were determined as the total difference in group means minus the WL-I effects.
Results: Greater reductions in HbA_{1c} and SBP were seen with greater WL, with similar slopes in each group (Figure). Total PBO-subtracted mean reduction in HbA_{1c} was 0.72% with CANA 100 mg (0.60% [85%] of the effect was WL-I) and 0.90% with CANA 300 mg (0.75% [85%] of the effect was WL-I). Total PBO-subtracted reduction in SBP was 3.5 mmHg with CANA 100 mg (2.0 mmHg [57%] WL-I) and 4.7 mmHg with CANA 300 mg (2.7 mmHg [59%] WL-I).
Conclusion: CANA lowers both HbA_{1c} and BP through WL-I and WL-A mechanisms; a greater proportion of the reduction in HbA_{1c} is WL-I compared to SBP.

Changes in lipid profiles of patients with type 2 diabetes mellitus on dapagliflozin therapy

E. Hardy[1], A. Ptaszynska[2], T.W.A. de Bruin[1], E. Johnsson[3], S.J. Parikh[1], J.F. List[2];
[1]AstraZeneca, Wilmington, [2]Bristol-Myers Squibb, Princeton, USA, [3]AstraZeneca, Mölndal, Sweden.

Background and aims: Dapagliflozin (DAPA), a sodium-glucose cotransporter 2 inhibitor, increases urinary glucose excretion, and improves hyperglycaemia in patients with type 2 diabetes mellitus (T2DM). DAPA also favourably affects cardiovascular risk factors by reducing weight, blood pressure and uric acid in these patients. The effects of DAPA on lipids in patients with T2DM are reported here.
Materials and methods: Data from 3731 patients in 12 phase 2b/3 double-blind controlled trials receiving DAPA 5 or 10 mg or placebo (PBO) for up to 24 weeks were analysed. Changes in the plasma lipid profile were pre-specified for analysis in these studies. Adjustments in concomitant lipid-lowering medications were permitted.
Results: Demographic and baseline characteristics were balanced between DAPA and PBO groups. Improved glycaemic control with DAPA versus PBO has been previously reported in these studies. Changes in lipid parameters from individual trials showed variability across studies. In a 24-week pooled analysis, changes from baseline in HDL-C were +6.5% and +5.5% for DAPA 5 and 10 mg, respectively and +3.8% for PBO; LDL-C were +0.6% and +2.7% for DAPA 5 and 10 mg, respectively, and −1.9% for PBO; total cholesterol were +1.1% and +1.4% for DAPA 5 and 10 mg, respectively, and −0.4% for PBO. Changes from baseline to Week 24 in LDL-C/HDL-C ratio were −5.4% and −2.8% for DAPA 5 and 10 mg respectively, and −5.4% for PBO.
Conclusion: DAPA is associated with small mean changes in fasting lipid parameters versus PBO at 24 weeks.

LX4211, a dual inhibitor of sodium glucose transporters SGLT1 and SGLT2, reduces blood pressure in patients with type 2 diabetes

P. Lapuerta[1], J. Neutel[2], B. Zambrowicz[1], I. Ogbaa[1], P. Banks[1], K. Frazier[1], A. Sands[1];
[1]Lexicon Pharmaceuticals, Inc., The Woodlands, [2]Orange County Research Center, Tustin, USA.

Background and aims: Dual inhibition of sodium glucose transporter 1 (SGLT1) and SGLT2 by LX4211 is being evaluated as a potential treatment of diabetes. Since SGLT1 in the gastrointestinal tract is involved in sodium absorption and SGLT2 in the kidney is involved in urinary sodium excretion, we evaluated the impact of LX4211 on several measures of glycemic control and blood pressure (BP) in a dose-ranging study of 299 patients with type 2 diabetes mellitus.
Materials and methods: Patients with inadequately controlled type 2 diabetes mellitus on metformin were randomly assigned to receive LX4211 (doses of 75 mg qd, 200 mg qd, 200 mg bid, or 400 mg qd) or placebo for 12 weeks. Changes in trough sitting systolic and diastolic blood pressure (SBP and DBP) were secondary endpoints. Patients were allowed in the study both with and without hypertension, and there were no restrictions on the prescribing or adjustment of antihypertensive medications.
Results: At entry, mean age was 55.9 years, A1C was 8.1%, body mass index was 33.1 kg/m^2, and BP was 125/79 mmHg. At Week 12, LX4211 reduced both A1C and BP in a dose-dependent manner. SBP reductions were 0, 4, 4, 6, and 0 mmHg with LX4211 75 mg qd, 200 mg qd, 200 mg bid, 400 mg qd, and placebo, respectively ($p<0.05$ vs. placebo for LX4211 200 mg bid and 400 mg qd). Corresponding DBP reductions were 1, 3, 2, 2, and 0 mmHg (p=NS vs. placebo for all dose arms). In those with baseline SBP ≥130 mmHg, placebo-subtracted SBP reductions for LX4211 400 mg were 14 mmHg (p=0.002) as compared to 1 mmHg (p=0.6) for those with baseline SBP <130 mmHg. Placebo-subtracted DBP reductions for LX4211 400 mg were 3 mmHg (p=0.2) and 0 mmHg (p=0.9) in those with baseline DBP ≥80 mmHg and DBP <80 mmHg, respectively.
Conclusion: Dual inhibition of SGLT1 and SGLT2 by LX4211 was associated with marked BP reductions among hypertensive patients.

Urinary tract infection with canagliflozin in subjects with type 2 diabetes mellitus

K. Usiskin[1], L. Nicolle[2], G. Capuano[1], A. Fung[1], G. Meininger[1];
[1]Janssen Research & Development, LLC, Raritan, USA, [2]Univeristy of Manitoba, Winnipeg, Canada.

Background and aims: Canagliflozin (CANA), a sodium glucose co-transporter 2 (SGLT2) inhibitor developed for the treatment of type 2 diabetes mellitus (T2DM), inhibits renal glucose reabsorption, resulting in increased glucosuria. The impact of this on urinary tract infection (UTI) was assessed in subjects with T2DM enrolled in placebo (PBO)-controlled, Phase 3 studies of CANA.
Materials and methods: UTIs were evaluated using a UTI case report form to characterise the presentation and severity of events. Findings are reported based on pooled analyses of subjects from four 26-week studies (DS1; N = 2,313) and subjects with moderate renal impairment (eGFR ≥30 and <60 mL/min/1.73 m^2) from four 18- or 26-week studies (DS2; N = 1,085), and for the CANagliflozin cardioVascular Assessment Study (CANVAS; 52-week interim safety analysis) in subjects with a history or high risk of cardiovascular disease (N = 4,327). Subjects with a history of UTI were not excluded from these studies.
Results: Across all datasets analysed, the proportion of subjects with UTI adverse events (AEs) was slightly higher with CANA than PBO, with no increase in recurrent or serious events or in UTI-related discontinuations (Table). Incidences of upper UTIs were low and similar across groups. The majority of UTI AEs were considered to be mild or moderate in severity, as assessed by the investigator. UTI was more common in women than men, but the increased incidence with CANA was consistent between genders. UTIs generally occurred within 26 weeks of initiating CANA therapy, with a subsequent attenuation in incidences. Median time to first symptomatic UTI tended to be earlier with CANA relative to PBO, but median duration and severity of symptoms of UTIs were similar with CANA and PBO.
Conclusion: Treatment with CANA was associated with a slight increase in UTI rates, with no increase in serious or upper UTIs, in subjects with T2DM.

Table. Summary of UTI Adverse Events

	Subjects,* n (%)

Genital mycotic infections with canagliflozin in subjects with type 2 diabetes mellitus

K. Ways[1], P. Nyirjesy[2], J.D. Sobel[3], A. Fung[1], C. Gassmann-Mayer[4], K. Usiskin[1];
[1]Janssen Research & Development, LLC, Raritan, [2]Department of Obstetrics and Gynecology, Drexel University College of Medicine, Philadelphia, [3]Division of Infectious Diseases, Wayne State University School of Medicine, Detroit, [4]Janssen Research & Development, LLC, Titusville, USA.

Background and aims: Canagliflozin (CANA), a sodium glucose co-transporter 2 (SGLT2) inhibitor developed for the treatment of type 2 diabetes mellitus (T2DM), lowers plasma glucose by increasing urinary glucose excretion. Genital mycotic infections (GMIs) associated with CANA were assessed in subjects with T2DM.
Materials and methods: GMIs were characterised based on pooled analyses of data from 4 randomised, double-blind, 26-week, placebo (PBO)-controlled studies in subjects with T2DM (N = 2,313; mean age, 56.0 y; HbA_{1c}, 8.0%; body mass index, 32.1 kg/m^2).
Results: The incidence of GMIs was 11% versus 3% (women) and 4% versus 1% (men) with CANA relative to PBO (**Table**). GMIs were generally considered mild or moderate in severity by investigators, none were serious, and few led to discontinuation; most events with CANA were treated with antifungal agents (women, 82%; men, 83%). CANA-treated women with GMIs were more likely to have a history of vulvovaginitis (29% vs 12%), be premenopausal (35% vs 27%), and reside in North America (60% vs 42%) than those without GMIs. CANA-treated men with GMIs were more likely to have a history of balanitis/balanoposthitis (25% vs 2%), have a slightly longer mean T2DM duration (9 vs 7 years), and to reside in Europe (44% vs 26%) than men without GMIs. With CANA treatment, 2% and 1% of females and males, respectively, had >1 GMI. In a larger dataset (N = 9,439) from 8 studies with longer mean exposure (CANA, 68 weeks; control, 64 weeks), a higher rate of male GMIs was seen (n = 5,493; 8% and 2% for CANA [n = 3,569] and control [n = 1,924]), more commonly in uncircumcised than circumcised men (11% vs 3%) and infrequently associated with phimosis or the need for circumcision.
Conclusion: Treatment with CANA was associated with modestly higher rates of GMIs relative to PBO that were generally manageable with standard treatments.

Table. Summary of Genital Mycotic Infection Adverse Events (AEs)

Efficacy and safety of canagliflozin in subjects with type 2 diabetes mellitus and chronic kidney disease over 52 weeks

J. Nieto[1], J.-F. Yale[2], G. Bakris[3], B. Cariou[4], E. Wajs[5], K. Figueroa[6], J. Jiang[6], K. Usiskin[6], G. Meininger[6];
[1]Hospital General Universitario, Ciudad Real, Spain, [2]Royal Victoria Hospital and McGill University, Montreal, Canada, [3]The University of Chicago, Medicine, Chicago, USA, [4]Nantes University Hospital, France, [5]Janssen Research & Development, Beerse, Belgium, [6]Janssen Research & Development, LLC, Raritan, USA.

Background and aims: Canagliflozin (CANA), an SGLT2 inhibitor developed for the treatment of type 2 diabetes mellitus (T2DM), lowers plasma glucose by increasing urinary glucose excretion. This randomised, double-blind, Phase 3 study assessed the efficacy and safety of CANA in subjects with T2DM and chronic kidney disease (CKD) over 52 weeks.
Materials and methods: Subjects (N = 269) with T2DM and Stage 3 CKD (estimated glomerular filtration rate [eGFR] ≥30 and <50 mL/min/1.73 m^2) received CANA 100 or 300 mg or placebo (PBO) added to current therapy (96.3% on insulin and/or sulphonylurea [SU]) during a 26-week core period followed by a 26-week extension (n = 207). Changes from baseline in efficacy parameters at Week 52 are reported. Adverse events (AEs) were recorded throughout the study. Renal safety parameters were also evaluated.
Results: Mean baseline characteristics were similar across groups (age, 68.5 y; HbA_{1c}, 8.0%; fasting plasma glucose [FPG], 9.1 mmol/L; BMI, 33.0 kg/m^2; eGFR, 39.4 mL/min/1.73 m^2; median albumin/creatinine ratio [ACR], 30.0 µg/mg). At 52 weeks, CANA 100 and 300 mg reduced HbA_{1c}, FPG, body weight, and systolic BP relative to PBO; small increases in high-density lipoprotein cholesterol (HDL-C) and decreases in low-density lipoprotein cholesterol (LDL-C) were seen with both CANA doses versus PBO (**Table**).

Table. Summary of Efficacy Endpoints at Week 52 (mITT, LOCF)

Parameter*	CANA 100 mg	CANA 300 mg	PBO
HbA_{1c} change, %	–0.19 (0.10)	–0.33 (0.10)	0.07 (0.10)

% of subjects reaching HbA_{1c} <7.0%†	23.6 (4.5)	28.1 (4.8)	18.4 (4.2)
Difference vs PBO	5.2 (–7.9, 18.3)	9.7 (–3.8, 23.2)	
FPG change, mmol/L	–0.1 (0.3)	–0.3 (0.3)	0.5 (0.3)
Difference vs PBO	–0.7 (–1.5, 0.2)	–0.8 (–1.7, 0.1)	
Body weight % change	–1.3 (0.4)	–1.0 (0.4)	0.1 (0.4)
Difference vs PBO	–1.5 (–2.6, –0.4)	–1.1 (–2.2, 0.0)	
Systolic BP change, mmHg	–5.5 (1.5)	–6.7 (1.5)	–0.01 (1.5)
Difference vs PBO	–5.5 (–9.3, –1.7)	–6.7 (–10.5, –2.9)	
Diastolic BP change, mmHg	–2.0 (1.0)	–2.4 (1.0)	–1.4 (1.0)
Difference vs PBO	–0.7 (–3.1, 1.8)	–1.0 (–3.5, 1.5)	
Triglycerides % change	12.4 (4.8)	9.1 (4.7)	9.9 (4.9)
Difference vs PBO	2.5 (–9.9, 14.9)	–0.8 (–13.0, 11.4)	
HDL-C % change	3.3 (1.9)	4.1 (1.8)	1.3 (1.9)
Difference vs PBO	1.9 (–2.9, 6.8)	2.8 (–1.9, 7.6)	
LDL-C % change	6.4 (3.8)	2.5 (3.7)	9.4 (3.9)
Difference vs PBO	–3.0 (–12.7, 6.8)	–6.9 (–16.6, 2.8)	
LDL-C/HDL-C % change	4.7 (4.1)	–1.2 (4.0)	9.0 (4.2)
Difference vs PBO	–4.3 (–14.9, 6.3)	–10.2 (–20.7, 0.4)	
Non–HDL-C % change	6.1 (2.9)	3.5 (2.8)	6.4 (3.0)
Difference vs PBO	–0.3 (–7.9, 7.3)	–2.9 (–10.3, 4.6)	

mITT, modified intent to treat; LOCF, last observation carried forward; LS, least squares; SE, standard error; ANCOVA, analysis of covariance; CI, confidence interval. *LS mean (SE) change from baseline using ANCOVA and PBO-subtracted LS mean (95% CI) for all parameters except for % of subjects reaching HbA_{1c} <7.0%; †% (SE) and PBO-subtracted % (95% CI) of subjects reaching HbA_{1c} <7.0%.

Overall AE rates were slightly higher with PBO (86.7%) than CANA 100 and 300 mg (85.6%, 80.9%). Serious AE rates were lower with CANA 100 and 300 mg than PBO (20.0%, 23.6%, 26.7%); AE-related discontinuation rates were low across groups. Rates of osmotic diuresis-related AEs (eg, pollakiuria, thirst) were higher with CANA 100 and 300 mg than PBO (3.3%, 6.7%, 2.2%). Higher rates were seen with CANA 300 mg than CANA 100 mg and PBO for urinary tract infections (14.6%, 5.6%, 10.0%) and AEs related to reduced intravascular volume (eg, postural dizziness, orthostatic hypotension; 12.4%, 5.6%, 5.6%). Genital mycotic infection rates were low in women and men (n ≤2 per group). Among subjects on background therapy associated with hypoglycaemia (insulin/SU), documented hypoglycaemia rates were higher with CANA 100 and 300 mg than PBO (61.2%, 57.0%, 43.2%); severe hypoglycaemia rates were low, but higher with CANA 100 and 300 mg than PBO (5.9%, 2.3%, 1.1%). No hypoglycaemia was reported in subjects not on insulin/SU. Increases in blood urea nitrogen (12.0%, 17.3%, 5.4%) and decreases in eGFR (-4.3%, -9.4%, -2.8%) were seen with CANA 100 and 300 mg versus PBO. Median ACR was decreased with CANA 100 and 300 mg versus PBO (-16.4%, -28.0%, 19.7%).
Conclusion: CANA 100 and 300 mg improved glycaemic control and were generally well tolerated in subjects with T2DM and Stage 3 CKD over 52 weeks.

Empagliflozin in patients with type 2 diabetes mellitus and stage 3A, 3B and 4 chronic kidney disease (CKD)

A. Mithal[1], A.H. Barnett[2], J. Manassie[3], R. Jones[3], H. Rattunde[4], H.J. Woerle[4], U.C. Broedl[4];
[1]Medanta - The Medicity, Gurgaon, Delhi NCR, India, [2]Diabetes Centre, Heart of England NHS Foundation Trust and University of Birmingham, [3]Boehringer Ingelheim UK Ltd, Berkshire, UK, [4]Boehringer Ingelheim, Germany.

Background and aims: A Phase III trial investigated the efficacy and safety of empagliflozin (EMPA) as add-on to existing therapy for 52 weeks in patients with T2DM and CKD stage 3A, 3B and 4.
Materials and methods: Patients with CKD stage 3A (eGFR [MDRD equation] ≥45 to <60 ml/min/1.73 m^2; n=180; mean [SD] age 64.5 [8.0] years; mean [SD] BMI 30.5 [5.2] kg/m^2), CKD stage 3B (eGFR ≥30 to <45 ml/min/1.73 m^2; n=194; mean [SD] age 65.2 [9.0] years; mean [SD] BMI 30.0 [5.4] kg/m^2) or CKD stage 4 (eGFR ≥15 to <30 ml/min/1.73 m^2; n=74; mean [SD] age 64.1 [11.1] years; mean [SD] BMI 30.4 [5.6] kg/m^2) received EMPA 25 mg qd or PBO for 52 weeks. In exploratory analyses, we assessed the long-term efficacy and safety of EMPA, including changes from baseline in HbA_{1c}, fasting plasma glucose (FPG), weight and systolic and diastolic blood pressure (SBP and DBP) at week 52.
Results: EMPA 25 mg significantly reduced HbA_{1c} vs PBO at week 52 in patients with CKD stage 3A and 3B (Table). EMPA 25 mg did not reduce HbA_{1c} in patients with CKD stage 4 (Table). EMPA significantly reduced FPG, weight, SBP and DBP in patients with CKD stage 3A, and significantly reduced FPG and weight in patients with CKD stage 3B (Table). Reductions in FPG, weight and BP were observed in patients with CKD stage 4 (Table). During 52 weeks' treatment, adverse events (AEs) were reported by 86.8% and 79.8% of patients with CKD stage 3A on EMPA 25 mg and PBO, respectively, by 80.2% and 86.7% of patients with CKD stage 3B on EMPA 25 mg and PBO, respectively, and by 91.9% and 83.8% of patients with CKD stage 4 on EMPA 25 mg and PBO, respectively. AEs consistent with volume depletion were reported by 4.4% and 2.2% of patients with CKD stage 3A on EMPA 25 mg and PBO, respectively, by 3.1% of patients with CKD stage 3B on EMPA 25 mg or PBO, and by 5.4% patients with CKD stage 4 on EMPA 25 mg or PBO. AEs consistent with urinary tract infection were reported by 16.5% and 18.0% of patients with CKD stage 3A on EMPA 25 mg and PBO, respectively, by 16.7% and 13.3% of patients with CKD stage 3B on EMPA 25 mg and PBO, respectively, and by 18.9% and 8.1% of patients with CKD stage 4 on EMPA 25 mg and PBO, respectively. Treatment with EMPA for 52 weeks resulted in small decreases in eGFR in each group; eGFR returned to near baseline values within 3 weeks of last drug intake.
Conclusion: EMPA 25 mg for 52 weeks was associated with significant and clinically meaningful reductions in HbA_{1c} compared with placebo in patients with T2DM and CKD stage 3A or 3B. EMPA led to favourable reductions in body weight and BP in patients with T2DM and CKD stage 3A, 3B or 4. EMPA was well tolerated, and showed small changes in eGFR that were reversible after the end of treatment.

Canagliflozin is effective and generally well tolerated in subjects with type 2 diabetes mellitus and Stage 3 chronic kidney disease

V. Woo[1], M. Davies[2], D. de Zeeuw[3], G. Bakris[4], V. Perkovic[5], C. Gassmann-Mayer[6], U. Vijapurkar[7], K. Usiskin[7], G. Meininger[7];
[1]University of Manitoba, Winnipeg, Canada, [2]University of Leicester, UK, [3]University Medical Centre Groningen, Netherlands, [4]The University of Chicago Medicine, USA, [5]George Institute for Global Health, Sydney, Australia, [6]Janssen Research & Development, LLC, Titusville, [7]Janssen Research & Development, LLC, Raritan, USA.

Background and aims: The efficacy and safety of the sodium glucose co-transporter 2 (SGLT2) inhibitor, canagliflozin (CANA), were evaluated in subjects with type 2 diabetes mellitus (T2DM) and Stage 3 chronic kidney disease (CKD) using a pooled analysis of data from four Phase 3 clinical studies.
Materials and methods: Data were pooled from subjects with T2DM from 4 randomised, placebo (PBO)-controlled studies (at Week 18 [1 study] and Week 26 [3 studies]) who had a baseline estimated glomerular filtration rate (eGFR) ≥30 and <60 mL/min/1.73 m^2 (N = 1,085), and in subgroups of subjects with baseline eGFR ≥45 and <60 mL/min/1.73 m^2 (n = 721) or ≥30 and <45 mL/min/1.73 m^2 (n = 364).
Results: CANA 100 and 300 mg reduced HbA_{1c}, body weight, and systolic blood pressure compared with PBO in the overall population and in subjects with eGFR ≥45 or <45 mL/min/1.73 m^2 (Table); HbA_{1c} and body weight changes with CANA relative to PBO were larger in subjects with eGFR ≥45 mL/min/1.73 m^2 than in those with eGFR <45 mL/min/1.73 m^2. For the pooled CANA group, the incidence of overall AEs was higher than with PBO across populations (eGFR ≥30 to <60: 74.7% vs 70.4%; ≥45: 71.0% vs 66.9%; <45: 81.5% vs 78.4%); serious AE rates were higher with PBO than CANA and AE-related discontinuation rates were low across populations. Incidences of osmotic diuresis-related AEs (eg, pollakiuria [increased urine frequency], polyuria [increased urine volume]) were higher with CANA than PBO in subjects with eGFR ≥30 and <60 mL/min/1.73 m^2 (4.0% vs 3.7%) and in those with eGFR <45 mL/min/1.73 m^2 (4.8% vs 2.6%). Incidences of AEs related to reduced intravascular volume (eg, orthostatic hypotension, postural dizziness) were higher with CANA than PBO across populations (eGFR ≥30 to <60: 6.8% vs 2.6%; ≥45: 5.9% vs 3.4%; <45: 8.9% vs 1.7%). Rates of serious renal-related AEs were low and similar across groups.
Conclusion: In subjects with T2DM and Stage 3 CKD, CANA reduced HbA_{1c}, with a greater effect in subjects with eGFR ≥45 than <45 mL/min/1.73 m^2, and was generally well tolerated.

Safety and efficacy of the SGLT2 inhibitor dapagliflozin in older patients with type 2 diabetes

P. Fioretto[1], T.W. de Bruin[2], E. Johnsson[3], A. Ptaszynska[4], S. Parikh[2], J.F. List[4]; [1]University of Padova Medical School, Italy, [2]AstraZeneca, Wilmington, USA, [3]AstraZeneca, MoIndal, Sweden, [4]Bristol-Myers Squibb, Princeton, USA.

Background and aims: Given the high prevalence of type 2 diabetes (T2DM) and its co-morbid conditions in the elderly, this report summarises efficacy and safety observations in patients aged ≥65 years treated with dapagliflozin (DAPA) 10 mg daily. DAPA, a first-in-class inhibitor of the sodium–glucose co-transporter 2 (SGLT2), reduces renal glucose reabsorption and increases glucuresis, resulting in improved glycaemic control and weight loss. DAPA efficacy is dependent on the filtered glucose load, a function of the plasma glucose concentration and the glomerular filtration rate (GFR).
Materials and methods: Efficacy variables were analysed using pooled data from 9 phase 3 studies of DAPA (n=4047; placebo [PBO]=1257, DAPA=2790) up to 24 weeks. Safety variables were analysed using pooled data from 12 phase 2b/3 studies of DAPA (n=4684; PBO=1393, DAPA=3291), including studies as monotherapy or in combination with metformin, pioglitazone, sulphonylurea, or insulin.
Results: Approximately 20% of patients in both efficacy (776/4047) and safety (907/4684) analyses were aged ≥65 years, with equal gender distribution. Treatment with DAPA was associated with HbA1c reductions across baseline age subgroups (<65 years and ≥65 years). PBO-corrected reductions in HbA1c appeared to be greater in patients aged <65 years (-0.62% [95% CI -0.71, -0.54]) than in patients aged ≥65 years (-0.41% [-0.58, -0.22]). Efficacy was assessed in different estimated GFR (eGFR) categories and did not appear to be age dependent in patients with eGFR ≥60 mL/min/1.72 m^2. After controlling for eGFR, no conclusive evidence was found that age affects efficacy as an independent factor (interaction *P*-value=0.2903). PBO-corrected reductions in body weight were similar in patients aged <65 years (-1.77 kg [-2.05, -1.48]) and ≥65 years (-1.73 kg [-2.32, -1.41]). Overall, the proportions of patients with adverse events (AEs) were similar in both age populations. Events of special interest are presented in Table 1. Hypoglycaemia, volume depletion, and renal AEs occurred more often in patients aged ≥65 years. Orthostatic hypotension occurred infrequently in both age groups (<0.1%). The majority of renal AEs were patients reaching pre-defined thresholds of serum creatinine. AEs of urinary tract and genital infection were similar for both DAPA-treated age groups.
Conclusion: These results demonstrate that DAPA is efficacious and safe as monotherapy or combination therapy in patients aged ≥65 years when compared with placebo. Findings of somewhat reduced efficacy and slightly increased renal AEs in patients aged ≥65 years reflect the lower eGFR in this population. DAPA's efficacy and safety observations indicate a practical, new approach to the treatment of T2DM patients aged ≥65 years.

Table 1

	Patients aged <65 years		Patients aged =65 years

Efficacy and safety of canagliflozin in older subjects with type 2 diabetes mellitus

A. Sinclair[1], B. Bode[2], S. Harris[3], U. Vijapurkar[4], C. Gassmann-Mayer[5], A. Fung[4], W. Shaw[4], K. Usiskin[4], M. Desai[4], G. Meininger[4]; [1]Luton & Dunstable University Hospital, Luton, UK, [2]Atlanta Diabetes Associates, USA, [3]University of Western Ontario, London, Canada, [4]Janssen Research & Development, LLC, Raritan, [5]Janssen Research & Development, LLC, Titusville, USA.

Background and aims: The efficacy and safety of canagliflozin (CANA), a sodium glucose co-transporter 2 (SGLT2) inhibitor, were evaluated in older subjects with type 2 diabetes mellitus (T2DM) using a pooled analysis of data from four Phase 3 clinical studies.
Materials and methods: Data from subjects with T2DM were pooled from 4 randomised, placebo (PBO)-controlled, 26-week studies (N = 2,313) and were analysed by age: <65 years (n = 1,868; male, 49.1%; mean age, 52.8 years; HbA_{1c}, 8.0%; body weight, 90.1 kg; estimated glomerular filtration rate [eGFR], 90.8 mL/min/1.73 m^2) or ≥65 years (n = 445; male, 51.5%; mean age, 69.3 years; HbA_{1c}, 7.9%; body weight, 85.1 kg; eGFR, 76.9 mL/min/1.73 m^2).
Results: CANA 100 and 300 mg reduced HbA_{1c}, body weight, and systolic blood pressure compared with PBO in subjects <65 and ≥65 years of age (Table); similar lipid changes were seen in both age groups. The incidence of overall adverse events (AEs) was similar with CANA 100 and 300 mg and PBO in subjects <65 years (59.9%, 59.0%, 58.9%) and those ≥65 years (61.0%, 60.4%, 61.3%). Rates of serious AEs and AE-related discontinuations were similar with CANA 100 and 300 mg and PBO in subjects <65 years (serious AEs: 2.5%, 2.5%, 3.3%; AE-related discontinuations: 3.3%, 3.2%, 2.8%), and higher with CANA 100 mg than CANA 300 mg or PBO in subjects ≥65 years (serious AEs: 6.9%, 3.4%, 3.6%; AE-related discontinuations: 8.8%, 5.4%, 4.4%). As in subjects <65 years, those ≥65 years who received CANA had higher rates than PBO of genital mycotic infections in women and men and osmotic diuresis-related AEs (Table); the incidence of AEs related to reduced intravascular volume was low across treatment groups in both age groups. Incidences of urinary tract infections and renal-related AEs were similar across groups in subjects ≥65 years.
Conclusion: CANA 100 and 300 mg provided reductions in HbA_{1c} and body weight and were generally well tolerated in older subjects with T2DM.

Luseogliflozin, a SGLT2 inhibitor, improves glycaemic control and reduces body weight as monotherapy up to 52 weeks in Japanese patients with type 2 diabetes mellitus

Y. Seino[1], T. Sasaki[2], A. Fukatsu[3], M. Ubukata[4], T. Sasaki[4], Y. Kasai[4], S. Sakai[4], Y. Samukawa[4];
[1]Kansai Electric Power Hospital, Osaka, [2]Jikei University School of Medicine, Tokyo, [3]Yachiyo Hospital, Aichi, [4]Taisho Pharmaceutical Co., LTD., Tokyo, Japan.

Background and aims: Luseogliflozin is a highly selective sodium glucose co-transporter 2 (SGLT2) inhibitor. In a previous 12-weeks confirmatory dose finding study, 2.5 mg or higher doses of luseogliflozin showed amelioration of glycemic control in Japanese patients with type 2 diabetes mellitus (T2DM). The aims were to evaluate the efficacy and safety of luseogliflozin monotherapy compared with placebo over 24 weeks (Study-1, N = 158), and to evaluate the long-term efficacy and safety of luseogliflozin as monotherapy up to 52 weeks (Study-2, N = 299), in Japanese T2DM patients inadequately controlled with diet and exercise.
Materials and methods: In Study-1, a double-blind, placebo-controlled confirmatory study, a total of 158 Japanese patients with T2DM (HbA1c 6.9-10.4%) were randomized to receive luseogliflozin 2.5 mg (N = 79) or placebo (N = 79) once daily for 24 weeks. Change from baseline and difference versus placebo in HbA1c and other efficacy parameters were assessed at week 24 using last observation carried forward (LOCF). In Study-2, an open-label study, Japanese patients with T2DM (HbA1c 6.9-10.4%) received luseogliflozin 2.5 mg (N = 299) once daily for 52 weeks. The starting dose of luseogliflozin was 2.5 mg. Patients whose glycemic control was insufficient could be titrated from 2.5 mg to 5 mg at week 24. Change from baseline in HbA1c and other efficacy parameters were assessed at week 52. In both studies, adverse events, clinical laboratory tests, vital signs and 12-lead ECGs were recorded throughout the study.
Results: Luseogliflozin significantly reduced HbA1c, fasting plasma glucose (FPG), 2-hour postprandial plasma glucose (PPG), body weight and abdominal circumstance (Table). In addition, luseogliflozin reduced systolic blood pressure (difference versus placebo; -5.6 mmHg) and diastolic blood pressure (difference versus placebo; -2.5 mmHg) without relevant change in heart rate and showed trends toward improvement in plasma lipids (triglyceride and HDL-cholesterol) in both studies. Frequencies of adverse events were similar across groups (Luseogliflozin 2.5mg, 59.5%; placebo, 57.0%) in Study-1 and 75.3% in Study-2. Most adverse events were mild in severity. There were no major changes in clinical laboratory tests. Luseogliflozin was well tolerated throughout both studies.
Conclusion: Once daily treatment of luseogliflozin as monotherapy for 24 weeks significantly improved glycemic control and reduced body weight, with amelioration of abdominal circumstance compared with placebo. Glycemic control and body weight reduction were sustained for up to 52-weeks. Luseogliflozin showed trend toward improvement in blood pressures and plasma lipids, and was well tolerated in Japanese patients with T2DM.

Table. Summary efficacy endpoints

Study-1 (24 weeks, Double-blind, N = 158)

Luseogliflozin, a SGLT2 inhibitor, as add-on therapy to 5 types of oral antidiabetic drugs improves glycaemic control and reduces body weight in Japanese patients with type 2 diabetes mellitus

M. Haneda[1], Y. Seino[2], T. Sasaki[3], A. Fukatsu[4], M. Ubukata[5], Y. Sato[5], S. Sakai[5], Y. Samukawa[5];
[1]Asahikawa Medical University, Hokkaido, [2]Kansai Electric Power Hospital, Osaka, [3]Tokyo Jikei University School Of Medicine Hospital, Tokyo, [4]Yachiyo Hospital, Aichi, [5]Taisho Pharmaceutical Co., Ltd., Tokyo, Japan.

Background and aims: Luseogliflozin increases urinary glucose excretion by inhibiting renal sodium glucose co-tanspoter 2 (SGLT2). In a previous 12 weeks monotherapy study, once daily administration of luseogliflozin 2.5 mg or higher doses significantly improved glycemic control and showed a favorable safety profile in patients with type 2 diabetes mellitus (T2DM). In drug-drug interaction studies of luseogliflozin with other oral antidiabetic drugs (OADs), no significant pharmacokinetic interactions between luseogliflozin and OADs were observed. This study examined the long-term efficacy and safety of luseogliflozin added-on to OADs [metformin (MET), dipeptidyl peptidase-4 inhibitor (DPP4i), pioglitazone (PIO), Glinide, or alpha-glucosidase inhibitor (α-GI)] for 52 weeks in Japanese patients with T2DM inadequately controlled with OADs monotherapy. The effects of add-on luseogliflozin on glimepiride was examined in another study.
Materials and methods: In this phase 3, multicenter study, patients exhibiting insufficient glycemic control (HbA1c 6.9-10.4%), who had received OADs monotherapy with fixed dose over 12 weeks, were administered 2.5 mg luseogliflozin as starting dose [Total (N = 487); MET (N = 117), DPP4i (N = 111), PIO (N = 95), Glinide (N = 59), α-GI (N = 105)]. Patients received luseogliflozin once daily for 52 weeks. If their glycemic control was insufficient, dose of luseogliflozin could be increased to 5 mg at week 24. Changes from baseline in glycemic and other efficacy endpoints were assessed. Adverse events (AEs), clinical laboratory tests, vital signs and 12-lead ECGs were recorded throughout the study.
Results: Mean baseline characteristics in each group were 7.8-8.0% in HbA1c, 142-152 mg/dL in fasting plasma glucose (FPG), and 25.1-26.9 kg/m^2 in BMI. HbA1c, FPG, and body weight were significantly decreased from baseline at week 52 in all groups (shown in Table). Luseogliflozin decreased blood pressure and showed trends toward improvement in plasma lipids (triglyceride and HDL-cholesterol) at week 52 compared with baseline in all groups. The frequency of AEs, serious AEs, AEs leading to discontinuation were comparable across treatment groups. In AEs of special interest, hypoglycemia, pollakiuria or urine output increase and events suggestive of urinary tract/genital infection were observed in all groups, but most of these events were mild in severity. Luseogliflozin was well tolerated throughout the study.
Conclusion: Luseogliflozin combination therapy with other OADs improved glycemic control and showed a favorable safety profile without dose adjustments. Luseogliflozin may provide a new treatment option in patients with T2DM inadequately controlled with currently available OADs.

PS 076 Metformin: old agent - novel perspectives

958

Metformin and berberine promote glucose metabolism via inhibiting mitochondrial respiratory chain complex I independently of AMPK activation

J. Yin, M. Xu, L. Wei, W. Jia;
Shanghai Clinical Center for Diabetes, Department of Endocrinology and Metabolism, Shanghai Key Labo, Shanghai Jiao Tong University Affiliated Sixth People's Hospital, China.

Background and aims: Metformin is a well-known hypoglycemic agent for treatment of type 2 diabetes. Berberine, a plant alkaloid, has also been found to possess anti-diabetic action. The mechanisms of both medicines were proposed to activate AMP-activated protein kinase (AMPK) pathway. This study aimed to examine whether AMPK activation was necessary for their glucose-lowering effect, and tried to explore the exact mechanism.
Materials and methods: Glucose consumption was used to evaluate the glucose-lowering effect of metformin and berberine on HepG2 hepatocytes and C2C12 myotubes. Compound C, an AMPK inhibitor, or small interference RNA (siRNA) was administrated to block the activity or expression of AMPKα in the cells. AMPK phosphorylation and ACC phosphorylation were measured with western blot to assess the activity of AMPK pathway. Anaerobic glycolysis was evaluated through determining lactate concentration in the medium. Oxygen consumption rate of C2C12 myotubes was determined in Seahorse XF24 analyzer to estimate the mitochondrial respiratory function.
Results: In this study, we found that in HepG2 hepatocyte and C2C12 myotubes, metformin and berberine significantly increased glucose consumption in a dose-dependent manner. Meanwhile, AMPK and ACC phosphorylation was stimulated by 10 mmol/L metformin or 20 μmol/L berberine. Nevertheless, the inhibition of AMPK activity by Compound C, or suppression of AMPKα expression by siRNA, failed to diminish the promotion in glucose utilization of both medicines. On the other hand, the lactate production was largely enhanced by metformin or berberine in the cells in the same way that they affect glucose consumption. Both drugs deeply inhibited the mitochondrial respiratory function in C2C12 myotubes. The activity of respiratory chain complex I was significantly reduced. All these changes could not be blocked by Compound C.
Conclusion: These results suggest that metformin and berberine promote glucose metabolism by stimulation of glycolysis, which is probably resulted from inhibition of mitochondrial respiratory chain complex I, independent of AMPK activation.

Early phase of metformin action in dietary-obese mice: lack of involvement of AMPK and possible interaction with *n-3* fatty acids

P. Kucharikova, O. Horakova, M. Rossmeisl, J. Kopecky;
Department of Adipose Tissue, Institute of Physiology Academy of Sciences, Prague, Czech Republic.

Background and aims: Long-chain *n*-3 polyunsaturated fatty acids (omega-3) act as natural hypolipidaemics and prevent development of cardiovascular disease in humans. We have shown that omega-3 could prevent impairement of hepatic insulin resistance in mice fed high-fat diet (HFD), depending on functional AMP-activated protein kinase (AMPK). Metformin is a first-line oral antidiabetic drug with blood glucose-lowering effect and beneficial impact on lipid metabolism. The precise mechanism of metformin action still remains unknown. Existing data suggest that metformin lowers glycaemia via mild suppression of mitochondrial complex I activity, leading to a suppression of hepatic glucose production and concomitant AMPK activation. However, AMPK-independent mechanisms of metformin action may also exist. We sought to learn whether pre-treatment of dietary-obese mice with omega-3 could enhance early phase of metformin action, and whether AMPK is involved.
Materials and methods: Adult male B6 mice were fed a corn oil-based HFD (35 % lipids wt/wt) for 6 weeks. Mice were then randomly divided into two groups and fed for 2 weeks either the HFD or HFD-based diet containing omega-3 concentrate replacing 15 % (wt/wt) of dietary lipids (HFD-F). At the end of dietary intervention, mice were treated with a single dose of metformin (400 mg/kg body weight) or NaCl (placebo) administered by oral gavage, and 30 min later some mice were subjected to oral glucose tolerance test (OGTT), while the remaining mice were killed in order to collect liver and skeletal muscle for the AMPK activity assay and western blot analysis. A similar experimental setup, with a lower metformin dose (60 mg/kg), was used to investigate the involvement of AMPK in metformin action using transgenic mice with a whole-body inactivation of α2 subunit of AMPK (AMPKα2-KO).
Results: Glucose levels at 30th and 60th minute after glucose administration during OGTT, as well as an incremental area under the glycaemic curve (AUC; marker of glucose intolerance), were decreased (1.7-fold, 2.0-fold and 2.9-fold, respectively; $p<0.05$) after the single dose of metformin as compared to the saline-treated mice. Two-week consumption of HFD-F diet lowered AUC as compared to the HFD diet-fed mice (1.5-fold, $p<0.05$), the omega-3 treatment tended to augment effect of metformin, but the effect of the interaction between omega-3 and metformin was not statistically significant (3.2-fold vs. the HFD group; 1.1-fold vs. the HFD + metformin group). No differences in AMPK activity between the subgroups were detected. There were no significant differences in the OGTT in the response to metformin between wild type and AMPKα2-KO mice.
Conclusion: We demonstrated acute dose-dependent hypoglycaemic effect of metformin during OGTT in dietary-obese mice. Although two-week-supplementation by omega-3 lowered the response to glucose challenge, significant synergistic effect of omega-3 and metformin was not found in this experimental setup. There was also no difference between wild type and AMPKα2 deficient mice suggesting that AMPK was not essential for the acute blood glucose-lowering effect of metformin. Possible AMPK-independent interaction between omega-3 and metformin in their effects on glucose homeostasis is likely and requires further characterization.

Metformin extended release compared to metformin immediate release on glycaemic control and patients' satisfaction in type 2 diabetic patients

A. Bonaventura[1], P. Maffioli[1], A. D'Angelo[1], L. Bianchi[1], D. Romano[1], G. Derosa[2];
[1]Department of Internal Medicine and Therapeutics, University of Pavia, Fondazione IRCCS Policlinico S. Matteo, [2]Department of Internal Medicine and Therapeutics, University of Pavia, Fondazione IRCCS Policlinico S. Matteo and Center for the Study of Endocrine-Metabolic Pathophysiology and Clinical Research, Pavia, Italy.

Background and aims: Metformin is usually the first line therapy for the treatment of type 2 diabetes mellitus; metformin is available in two formulations: immediate release (IR) as tablets, and extended release (XR) in powder form. The aim of this study was to evaluate, using international questionnaires, validated in Italian, if metformin XR formulation can be more effective than metformin IR in improving patients' quality of life and satisfaction towards treatment in a self-controlled clinical trial.
Materials and methods: Two hundred patients were enrolled. All patients were taking metformin IR at different dosages, and they were instructed to take metformin XR at the same dosage for 6 months. The following questionnaires were self-administered to each patient at the baseline and after 6 months since the beginning of treatment: the SF-36 Health Survey, the Diabetes Quality Of Life Modified questionnaire (DQOL/Mod) and the Diabetes Treatment Satisfaction Questionnaire (DTSQ). In particular the DTSQ was developed to assess the total diabetes treatment satisfaction and can be used in patients with type 2 diabetes mellitus. It consists of eight items; six of them (item 1: satisfaction with current treatment; item 4: treatment convenience; item 5: flexibility of treatment; item 6: understanding of diabetes; item 7: continuity of treatment, and item 8: recommending treatment to others with diabetes), are summed to get treatment satisfaction score with a possible range of 0 (very dissatisfied) to 36 (very satisfied). Item 2 evaluates perceived frequency of hyperglycemia and item 3 perceived frequency of hypoglycemia. All items are rated on a seven point scale (0-6). We also evaluated the following parameters, at the baseline and after 3, and 6 months: fasting plasma glucose (FPG), post-prandial glucose (PPG), glycated hemoglobin (HbA_{1c}), fasting plasma insulin (FPI), HOMA-index (HOMA-IR).
Results: We did not record any significant differences between metformin IR and metformin XR on glycemic control. We did not observe any differences in SF-36 Health Survey and the DQOL/Mod questionnaires scores between the two treatments. However, there was a greater satisfaction towards met-

formin XR according to the DTSQ questionnaire, in particular there was a greater score at the DTSQ in items 1, 4-8 with metformin XR compared to metformin IR. No differences in items regarding "Perceived Hyperglycemia, and "Perceived Hypoglycemia" were recorded.
Conclusion: Metformin XR showed to be as effective as metformin IR in maintaining glycemic control, and to be more effective in improving patients satisfaction toward anti-diabetic treatment.

961

Association between metformin therapy and quantity and quality of sleep in type 2 diabetic patients referred for potential sleep disorders

J.-D. Lalau[1], F. Kajbaf[1], A. Basille-Fantinato[2], M. Diouf[3], D. Rose[2], S. Fendri[1];
[1]Endocrinology-Nutrition, [2]Pneumology, [3]Clinical Research, University Hospital, Amiens, France.

Background and aims: Since sleep disorders are linked with insulin resistance, and since metformin bears favorable effects on insulin resistance and also exerts direct effect on ventilator drive in non-obese rats, we tested the hypothesis of a favorable impact of metformin therapy on sleep parameters (in quality and quantity) in type 2 diabetic patients.
Materials and methods: We systematically searched in our university hospital's database for patients referred for potential sleep disorders. From the selected patients, we compared metformin-treated patients with those not treated with this drug. All study patients underwent the same procedure of polysomnography. Multivariate analysis was conducted to establish whether there was, or not, an independent relationship between metformin use and sleep parameters when controlling for age, gender, body mass index, neck circumference, cumulated risk factors, and insulin use.
Results: We studied 387 patients (58.4 ± 10.8 yr, sex ratio M/F 0.64), of whom 314 were treated with metformin. The metformin user and non-user groups did not differ significantly in terms of the main demographic characteristics and the use of hypnotic and sedative drugs. Total sleep time and sleep efficiency (total sleep time/total recording time) were higher in metformin-treated patients (6 hrs 39 min *vs.* 6 hrs 03 min, p = 0.002; and 77.9±12.3 % *vs.* 71.5±17.2 %, p = 0.003, respectively). These differences were persisting after control for study variables (p =0.0002 for both). Patients with or without metformin did not differ significantly in terms of sleep apnea syndrome (although BMI tended to be higher in metformin-treated patients: 38.4±7.9 *vs*. 36.7±8.2 kg/m^2, NS).
Conclusion: We showed for the first time that metformin therapy was associated with longer sleep duration and better sleep efficiency. Prospective studies are needed for confirming such a favourable effect of metformin on sleep disorders.

962

Metformin therapy improves pregnancy outcome in women with polycystic ovary syndrome

M.V. Macesic[1,2], A. Jotic[1], T. Milicic[1], L. Lukic[1], M. Gojnic Dugalic[2], K. Lalic[1], N. Rajkovic[1], J. Seferovic Mitrovic[1], J. Stanarcic Gajovic[1], N.M. Lalic[1];
[1]Clinic for Endocrinology, Belgrade, [2]Clinic for Gynecology and Obstetrics, Clinical Center of Serbia, Belgrade, Serbia.

Background and aim: Previous studies have shown that many risk factors associated with polycystic ovary syndrome (PCOS) such as obesity, insulin resistance, hyperandrogenemia and polycystic ovaries may predict more frequent poor pregnancy outcomes and congenital malformations. Since when insulin resistance and hyperinsulinemia may play a critical role in the pathogenesis of PCOS, metformin, the insulin-sensitizing drug, has been introduced as a therapeutic option in PCOS, stirring a better control of glucose uptake. However, the role of metformin therapy on pregnancy outcome in women with PCOS is still controversial. This study was aimed to evaluate the effect of metformin on (a) the rate of first trimester spontaneous abortion (SA), (b) incidence of gestational diabetes (GD) and (c) outcome of pregnancies in women with the PCOS.
Materials and methods: The study included 83 oligo-amenorrheic women with PCOS conceived on metformin 1500 mg/day+lifestyle changes therapy. 43 of them continued metformin+lifestyle changes therapy throughout pregnancy (group A: BMI: 30,12 +/- 0.78 kg/m^2, age: 27,32+/-2,54 years) and 40 were treated without metformin and with lifestyle changes only (group B: BMI: 27,83 +/- 0.96 kg/m^2, age: 28,13+/-2,24 years). Insulin resistance was estimated using homeostatic model assessment, HOMA-IR, calculated from basal insulinemia and glycaemia. Outcome measures included number of first trimester SA, GD, live births, congenital defects (CD), gestational age, birthweight, height and APGAR score.
Results: HOMA-IR was significantly higher in metformin group then in group B before conception (A: 4,65 +/- 0.78 vs B: 3,08+/- 0.57, p< 0.05). SA rate was practically the same in both groups (A: 4.67% vs B: 5.03%, p=ns). The incidence of GD was significantly lower in group A vs group B (A: 6,8% vs B: 24% (p<0.01). Simultaneously, there was no significant difference in gestational age at the delivery in the two groups (A: 37,45+/- 0.64 vs B: 37,23+/- 0.58, p=ns). In addition the percent of live births was the same in women on or without metformin therapy. However, average birthweight was higher in the group without metformin (A: 3,025+/- 0.14 vs B: 3,197+/- 0.213, p< 0.05), while the height and APGAR score were not significantly differ between the groups. No congenital anomaly was found in either group, as well.
Conclusion: Our results have demonstrated that metformin therapy during pregnancy was associated with more favorable results in pregnancy outcome in women with PCOS by its insulin-lowering effect. These results also imply that use of metformin throughout pregnancy is responsible for a fourfold reduction of gestational diabetes.

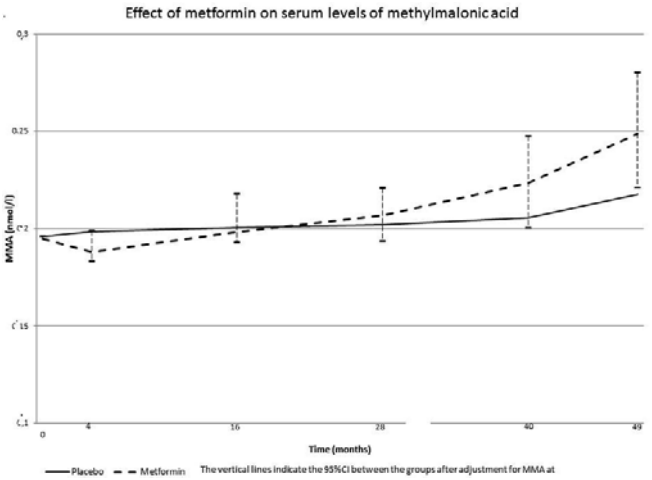
Metformin treatment is associated with increased serum levels of methylmalonic acid in patients with type 2 diabetes treated with insulin: a placebo-controlled 4-year trial

A. Kooy[1], M. Out[2], P. Lehert[3], C.G. Schalkwijk[4], C.D.A. Stehouwer[5];
[1]Bethesda Diabetes Research Center, Hoogeveen, [2]Internal Medicin, Bethesda Hospital, Hoogeveen, Netherlands, [3]Louvain Academy, Belgium, [4]Faculty of Health, Medicine and Life Sciences, [5]Internal Medicine, Maastricht University Medical Centre, Netherlands.

Background and aims: Metformin is a key treatment option in type 2 diabetes (T2D), but is associated with lowering of vitamin B12 (B12) levels. Although it is commonly assumed that lower B12 levels reflect biological B12 deficiency, this is in fact not certain. Accumulation of methylmalonic acid (MMA) may reflect a biologically important B12 deficit. We investigated whether treatment with metformin during 52 months affects serum levels of MMA.
Materials and methods: In this placebo-controlled trial, 390 patients with T2D were randomized to metformin or placebo added to insulin therapy. Baseline characteristics have been described previously (BMJ 2010). MMA levels were measured by ultra performance liquid chromatography tandem mass spectrometry (UPLCMSMS).
Results: Multivariate regression showed that metformin treatment significantly raised MMA serum concentrations. Compared to placebo, metformin increased MMA by 0.03 nmol/l (95% Confidence Interval 0.003 to 0.063; p=0.03; after adjustment for MMA at baseline). Renal function and age did not affect this increase. In addition, this effect appeared to be dose-related (P<0.001).
Conclusion: This long-term placebo controlled trial is the first study to show that in patients with T2D metformin not only reduces serum levels of B12, but also increases serum MMA, thus supporting the view that metformin-associated lowering of B12 levels reflects biological B12 deficiency.



Clinical Trial Registration Number: NCT00375388

Metformin use in diabetics with reduced kidney function: prescription pattern in 4,414 subjects with type 2 diabetes and different eGFR levels

A. Cignarelli, L. Laviola, G. Stefanelli, G. Garruti, F. Logoluso, N. Morea, S. Perrini, A. Natalicchio, R. Giorgino, F. Giorgino;
Endocrinology & Metabolic Diseases, University of Bari, taly.

Background and aims: Evaluation of eGFR is important to guide drug prescription, because most hypoglycaemic medications require dose adjustment and/or are contraindicated according to the degree of kidney dysfunction. Metformin is traditionally considered to be contraindicated when eGFR falls below 60 ml/min; however, recent guidelines and expert recommendations propose to extend metformin use to lower eGFR classes, with specific cautions. Therefore, the objective of this cross-sectional study was to evaluate the distribution of eGFR, calculated by the abbreviated MDRD equation, in a cohort of type 2 diabetic patients, and to investigate the use of diabetes medications and specifically metformin in patients with different eGFR.
Materials and methods: A total of 4,414 type 2 diabetic patients (2,330 M; 2,084 F) were sub-grouped according to eGFR values >60 ml/min (n=3,357; 76%), 30-60 ml/min (n=967; 22%), or <30 ml/min (n=88; 2%), respectively.
Results: Mean ± SE BMI and waist were progressively higher in subjects with decreasing kidney function, from eGFR >60 (29.3 ± 0.1 kg/m^2; 101.9 ± 0.3 cm) to eGFR <30 (31.5 ± 0.7 kg/m^2; 109.6 ± 2.2 cm) (p<0.05). HbA1c was higher in the intermediate kidney function patients (7.5 ± 0.1%) as compared to the eGFR >60 (7.3 ± 0.1%) and eGFR <30 groups (7.4 ± 0.1%) (p<0.05). The proportion of patients with CKD using oral diabetes medications was lower as kidney disease progressed, and decreased from 55.3% in the eGFR >60 group to 43.5% in the eGFR 30-60 group and to 19.3% in the eGFR <30 group (p<0.05). Conversely, the proportion of patients using insulin alone was 13.2% in the eGFR >60 group, 21.7% in the eGFR 30-60 group, and 54.4% in the eGFR <30 group (p<0.001). The proportion of patients using association of oral diabetes medications and insulin was higher in the eGFR 30-60 group (21.4%) compared to the eGFR >60 (15.5%) and eGFR <30 groups (12.5%) (p<0.05). The proportion of drug-naive patients was comparable among groups (~15.0%). Metformin resulted to be prescribed in 43.4% of the eGFR 30-60 group and in 4.5% of the eGFR <30 group. In the eGFR 30-60 group, patients using metformin showed significant differences compared to patients not on metformin, in terms of age (70.1 ± 0.4 vs 73.9 ± 0.4 yrs), BMI (30.8 ± 0.3 vs 29.9 ± 0.3 kg/m^2), and eGFR (51.0 ± 0.3 vs 47.1 ± 0.3 ml/min) (p<0.05).
Conclusion: Almost 25% of patients with type 2 diabetes in this cohort show some degree of CKD. Use of oral medications declines and insulin prescription increases as eGFR falls. Metformin appears to be widely prescribed also in patients with eGFR between 30-60 ml/min. Younger age, higher BMI and eGFR in the upper half of the 30-60 ml/min range appear to be indicators of a more liberal use of metformin in type 2 diabetic patients with moderate kidney dysfunction.

965

Metformin reduces serum CA199 levels in type 2 diabetic patients with time-effect and gender difference

D.D. Zhang, F. Liu, W. Jia;
Dept of Endocrinology & Metabolism, Shanghai Jiaotong University Affiliated Sixth People's Hospital, Shanghai, China.

Background and aims: The antineoplastic effect of metformin has been reported. This study was to clarify the influence of metformin on serum carbohydrate antigen 199 (CA199) levels and its associated factors in Chinese type 2 diabetic patients with normal renal and hepatic function.
Materials and methods: Serum CA199 levels was measured and compared in 1253 Type 2 diabetic patients with or without metformin treatment. Non-metformin group consists of 616 patients (male : female=347:269) and metformin-treated group has 637 patients (male : female=332:305). The latter was further divided into short-term metformin group (n=325, male: female=163:162), and long-term metformin group (n=312, male : female=169:143) based on whether the treatment duration exceeds two years. Association between CA199 and other variables were assessed with Spearman or Pearson correlation and multiple stepwise regression analysis.
Results: In overall patients, CA199 levels in females was significantly higher than that of males [(22.89 &plusmn 15.03 *vs* 15.97&plusmn18.89) U/ml, *P*=0.001]. The correlation and multiple stepwise regression analysis revealed that HbA1c, metformin, gender, TC and FSH were independent risk factors of CA199 concentrations (all *P*& it0.05). Serum CA199 levels in the short-term metformin group (17.62&plusmn10.87 U/ml) was lower than that in the non-metformin group (25.60&plusmn13.68 U/ml, *P*=0.000), and the long-term metformin group showed the lowest concentration of CA199 (10.54&plusmn8.14 U/ml) (*P*& it0.01). After 1-year of follow-up, CA199 in the long-term metformin group was decreased to the greatest extent compared with short-term and non-metformin controls (-17% *vs* -4.9% *vs* 3%,*P*=0.000). The change in females was more apparent than that of males (-18% *vs* -5%, *P*=0.000). Binary logistic regression revealed that the risk of abnormal CA199 concentrations of short-term metformin group and long-term metformin group decreased 11% (OR=0.89, 95%CI 0.87-0.92, *P*& it0.01) and 30% (OR=0.70, 95%CI 0.65-0.75,*P*& it0.01) respectively after adjusting for HbA1c, TC and sex.
Conclusion: Metformin therapy reduced serum CA199 levels of T2DM patients, and its greater decline range occurred in women with longer therapeutic time.

Improved resistance to exercise in mice treated with metformin

I. Terruzzi[1], P. Senesi[2], A. Montesano[2], R. Codella[2], S. Benedini[2,3], L. Luzi[2,3];
[1]Nutrition-Metabolism Unit, San Raffaele Scientific Institute, [2]Department of Biomedical Sciences for Health, University of Milan, [3]Research Centre, San Donato Hospital and Scientific Institute, Milan, Italy.

Background and aims: Skeletal muscle insulin resistance is a key development in diabetes pathogenesis and induces functional, metabolic and structural changes leading to muscle weakness and muscle atrophy. Metformin (MET) is a first-line anti-diabetic therapy exhibiting potent antihyperglycemic and insulin-sensitizing properties. Its ability to regulate blood glucose has been attributed to a suppression of hepatic gluconeogenesis and increased glucose uptake in peripheral tissues such as skeletal muscle. Its action mechanism in skeletal muscle still remains unclear, although a number of studies have suggested that MET may act to stimulate glucose uptake independently of insulin or may potentiate insulin-stimulated glucose uptake. Skeletal muscle differentiation is a process in which proliferative myoblasts break free from the cell cycle and fuse to form multinucleated myotubes. These events are orchestrated by early Myogenic Regulator Factors (MRFs: MyoD, Myf-5, myogenin and Myf-6) and late myogenic protein MyHC (Myosin Heavy Chain), through p38 MAP kinase/ERK pathway modulation. Our previous data suggested that MET induces ERK pathway activation and MyHC synthesis in *vitro* muscle model (C2C12). Aim of this work is to confirm in C2C12 in vitro model and to study *in vivo,* in a rodent model, the action of MET during myogenesis process and in hypertrophy genesis.
Materials and methods: We studied muscle proteosynthesis and morphological features in the late differentiation. After 72 h of differentiation, cells were treated with 400 μM MET for 4, 8 and 24 h. We used a positive control with 0.1 nM insulin added to medium and a negative control in which MET and insulin were not added. MRFs protein expression levels and morphological characteristics were evaluated by Western Blot and Immunofluorescence. We investigated *in vivo* the action of MET on exercise performance in adult C57BL6 mice through an endurance performance treadmill running test. Mice were injected intra abdominally with MET (250 mg/kg) and the control mice with 0.9% saline for 30 days.
Results: During late differentiation, MRFs, cytoskeletal and muscle marker protein expression levels were higher in cells treated with MET in respect to control. Furthermore, MET treatment is able to increase cell mass and fusion competence indicating that MET may regulate myogenesis progression and hypertrophy genesis. Endurance performance treadmill running test, made at the beginning and at the end of this study, revealed that MET treated mice exhibit an enhanced performance respect to the control mice. Statistical evaluation was performed using an unpaired *t*-test. Data are presented as means ± SD. Results were considered statistically significant if p≤0.05.
Conclusion: Data shown the role of MET in myogenesis promotion and in neo-formed myotubes hypertrophy induction. Our findings revealed a novel therapeutic indication of MET for muscle hypotrophy conditions in chronic muscle impairment (diabetic sarcopenia and cachexia) and a new potential role as integrator in exercise performance.

Effect of acarbose compared with metformin on incretins of GIP, PYY, Ghrelin in patients of newly diagnosed type 2 diabetes mellitus

H. Ma, Y. Ren, S.F. Liu, H.M. Tian;
Endocrinology and Metabolism, West China Hospital of Sichuan University, Chengdu, China.

Background and aims: Compare the effect of Acarbose and Metformin on serum incretins of GIP, PYY, Ghrelin levels in patients of newly diagnosed T2DM for 1 year.
Materials and methods: 70 T2DM patients were randomized into two groups and received treatment of Acarbose or Metformin respectively for 1 year. Diet style, BMI, waist circumferences, hip circumferences, plasma glucose, lipids, serum GIP, PYY, Ghrelin were followed up after 6 and 12 months treatment.
Results: 1. The 0h, 1/2h, 2h serum PYY levels in standard meal test and the mean area under the curve (AUC) of PYY(PYY_{AUC}) in T2DM group were lower than those in NC group(P <0.05). The 0h, 1/2h, 2h serum Ghrelin levels in standard meal test and $Ghrelin_{AUC}$ in T2DM group were higher than those in NC group(P<0.05). The fasting serum GIP level was positively correlated with 2-hour postprandial plasma glucose (2hPG)(P <0.05) in NC group. In T2DM group the fasting serum GIP level was correlated positively with BMI (P <0.05), PYY_{AUC} and triglycerides (TG) were negatively correlated(P <0.05), the fasting serum Ghrelin level and total cholesterol (TC) were negatively correlated(P <0.05), $Ghrelin_{AUC}$ was correlated negativly with the low-density lipoprotein cholesterol (LDL-C) and fasting plasma glucose (FPG) (P <0.05). 2. In Acarbose group, after treatment of 6 months, FPG, 2hPG, BMI, waist circumference and hip circumference were lower than those at baseline (P<0.05), the 0h, 1/2h, 2h serum PYY levels and PYY_{AUC} increased comparing with those at baseline (P<0.05), the 2h serum Ghrelin level in standard meal test was lower than that at baseline (P<0.05). After reatment of 1 year, high-density lipoprotein cholesterol (HDL-C) was higher than that at baseline (P <0.05), waist circumference and HDL-C increased and 2hPG decreased comparing with those after treatment of 6 months(P<0.05). In Metformin group, after treatment for of 6 months and 1 year, FPG, 2hPG, BMI, waist circumference, hip circumference, WHR, TC and LDL-C were lower than those at baseline (P<0.05), HDL-C, the 0h, 1/2h, 2h serum PYY levels in standard meal test, and PYY_{AUC} were higher than those at baseline (P<0.05). No significant differences were found in these indicators between treatment of 6 months and treatment of 1 year.3. After treatment for 6 months and 1 year, no significant differences of the changes of PYY, PYY_{AUC}, plasma glucose, BMI between Acarbose group and Metformin group were found.
Conclusion: Patients of T2DM had decreased fasting and postprandial PYY levels and increased levels of Ghrelin. Both Acarbose and Metformin can comparably increase serum PYY levels in newly diagnosed T2DM, which may play a role in glucose control. In addition, Acarbose can reduce the 2h Ghrelin level, and Metformin had no effect on Ghrelin.

SLC47A1 gene rs2289669 G>A variant influences the hypoglycaemic effect of metformin in type 2 diabetes patients

F. Liu, D. Zhang, Y. Shen, T.S. Zheng, W. Lu, W.P. Jia;
Endocrinology and Metabolism, Shanghai Clinical Medical Center of Diabetes, Shanghai, China.

Background and aims: The SLC47A1 gene encodes for multidrug and toxin extrusion 1(MATE1) which plays a pivotal role in the metabolism and excretion of metformin. The present study is to investigate whether the SLC47A1 gene polymorphism influence the therapeutic effect of metformin in Chinese Hans who suffered from type 2 diabetes mellitus (T2DM).
Materials and methods: The SLC47A1 single nucleotide polymorphism (SNP) rs2289669 G/A was genotyped in 497 T2DM patients, including a metformin treated group (n = 224) and a non-metformin-treated group (n = 288) with PCR-restriction fragment length polymorphism method. HbA1c was followed up for 6 months after metformin treatment.
Results: Three SLC47A1 genotypes, GA, GG and AA were found and the frequency of the SLC47A1 rs2289669 G/A and A allele was 46.99% in T2DM patients with the similar frequency in metformin group(47.1%) and non-metformin group(46.9%). The plasma lactate levels was significantly higher in AA carrier patients(1.18±0.47mmol/L) than that in patients who carried GA (1.04±0.39mmol/L) and GG (1.04±0.34mmol/L, *P*=0.008), and the incidence of hyperlactatemia increased significantly in patients with SLC47A1 rs2289669 AA genotype (5.9%) compared to GA (3.4%) and GG genotype (1.5%, *P*<0.01). The 6-month follow-up of 250 patients revealed that there was greatest reduction of HbA1c in patients with SLC47A1 rs2289669 AA genotype than that of GA and GG genotype (ΔHbA1c -2.3% in AA genotype vs. -1.3% in GA, and -1.1% in GG genotype, *P*<0.01).
Conclusion: The SLC47A1 gene rs2289669 G>A variant influences the hypoglycemic effect of metfotmin in Chinese T2DM patients, and the patients with AA genotype got better HbA1c reduction.

SNPs related to the glucose lowering effect of metformin: do they affect plasma concentrations of metformin and their effects on insulin requirements?

M. Out[1], A. Kooy[1], M.L. Becker[2], R.H.N. van Schaik[3], P. Lehert[4], C.D.A. Stehouwer[5];
[1]Bethesda Hospital, Hoogeveen, [2]Epidemiology & Biostatistics, [3]Clinical Chemistry, Erasmus MC, Rotterdam, Netherlands, [4]Faculty of Economics, Louvain Academy, Belgium, [5]Internal Medicine, Maastricht University Medical Centre, Netherlands.

Background and aims: Several genes involved in the pharmacokinetics and pharmacodynamics of metformin may influence the glucose lowering effect of metformin. However, the clinical importance is yet unknown. In the population of the HOME trial (a placebo-controlled, randomised trial with patients with type 2 diabetes, treated with insulin) we genotyped four single nucletide polymorphisms (SNPs) of such genes to detect their potential influence on metformin plasma concentrations. Furthermore, we studied the potential of these SNPs and the metformin plasma concentrations to predict the reduction of the daily dose of insulin (DDI), an important action of metformin in insulin therapy.
Materials and methods: We genotyped 164 metformin users of the HOME trial for polymorphisms in the genes coding for organic cation transporter 1 (OCT1, rs12208357 and rs622342), multidrug and toxin extrusion 1 transporter (MATE1, rs2289669) and Ataxia Telangiectasia Mutated (ATM, rs11212617). The daily dose of metformin and DDI have been reported previously (Arch Int Med 2009). Metformin plasma concentrations were measured using HPLC-UV.
Results: Stepwise linear analysis showed that the SNP rs11212617 (ATM) had a significant effect on metformin plasma concentrations (p < 0.001), but not on DDI. Other SNPs studied did not affect metformin plasma concentrations or DDI (P values ranging between 0.30-0.92 and 0.40-0.72, respectively). Overall, we found a significant relationship between metformin plasma concentrations and DDI (most pronounced after adjustment for renal clearance): an increase of metformin plasma concentrations with 1mg/ml was associ-

ated with a decrease of DDI with 3.51 IU (95% CI: -6.70 to -0.32; p=0.01). The daily dose of metformin predicted the metformin plasma concentrations (p<0.001) and was strongly correlated with a reduction of DDI: an increase of the daily dose of metformin with 1 gram/day was associated with a mean decrease of DDI with 10.57 IU (95% CI: -17.20 to -3.94; p<0.001).
Conclusion: Of the SNPs studied, only the ATM SNP has an effect on metformin plasma concentrations, but its clinical relevance is unclear, since this SNP has no effect on DDI. The daily dose of metformin is a strong predictor of the effect of metformin on DDI, independent of all SNPs studied.

Efficacy and safety of acarbose plus metformin fixed-dose combination versus acarbose monotherapy for type 2 diabetes: a randomised, double-blind, parallel-group study

J.-S. Wang[1], C.-N. Huang[2], Y.-J. Hung[3], C.-F. Kwok[4], J.-H. Sun[5], D. Pei[6], C.-Y. Yang[7], C.-C. Chen[8], C.-L. Lin[9], W.-H. Sheu[1];
[1]Department of Internal Medicine, Taichung Veterans General Hospital, [2]Department of Internal Medicine, Chung Shan Medical University Hospital, Taichung, [3]Division of Endocrinology and Metabolism, Tri-Service General Hospital, Taipei, [4]Division of Endocrinology and Metabolism, Taipei Veterans General Hospital, [5]Department of Internal Medicine, Linkou and Taipei Chang Gung Memorial Hospital, Taipei, [6]Department of Internal Medicine, Cardinal Tien Hospital, Taipei, [7]Division of Endocrinology and Metabolism, Chi Mei Medical Center, Tainan, [8]Division of Endocrinology and Metabolism, China Medical University Hospital, Taichung, [9]Department of Internal Medicine, Cathay General Hospital, Taipei, Taiwan.

Background and aims: To compare the efficacy and safety of acarbose plus metformin fixed-dose combination (FDC) versus acarbose monotherapy for type 2 diabetes (T2D).
Materials and methods: Subjects were T2D patients aged 20-80 years, with body mass index <35 kg/m2, glycosylated haemoglobin (HbA1c) 7.0-10.0%, and being treated with diet control only or oral antidiabetic medications. Eligible patients were run-in with acarbose 50 mg thrice-daily for 4 weeks, then randomised either to acarbose 50 mg plus metformin hydrochloride 500 mg FDC (acarbose/metformin FDC), or to acarbose 50 mg monotherapy, both thrice-daily for 16 weeks. The primary endpoint was HbA1c change from baseline.
Results: Acarbose/metformin FDC therapy significantly reduced HbA1c, fasting plasma glucose (FPG), and 2-hour postprandial plasma glucose (PPG) relative to baseline (all p<0.0001) with antihyperglycaemic efficacy superior to acarbose monotherapy (between-group differences HbA1c -1.35%, FPG -29.5 mg/dl, 2-hour PPG -41.6 mg/dl, all p<0.0001). A greater proportion of patients treated with acarbose/metformin FDC (47.8% vs. 10.7%, p<0.0001) achieved HbA1c target (<7.0%). Both treatments reduced bodyweight from baseline (both p<0.0001), with a significant between-group difference (-0.6 kg, p<0.01) favouring acarbose/metformin FDC. Hypoglycaemia was not reported in either treatment group, and incidences of other adverse events did not differ significantly between them.
Conclusion: Compared with acarbose monotherapy, acarbose/metformin FDC has superior antihyperglycaemic efficacy, enables proportionally more T2D patients with inadequate glycaemic control to achieve HbA1c goal, and further reduces bodyweight. Acarbose/metformin FDC is well-tolerated without significant risk of hypoglycaemia. Collectively, these attributes make acarbose/metformin FDC a potentially advantageous combination therapy for T2D.

Sulfonylureas use among US veterans with type 2 diabetes mellitus at high risk for cardiovascular disease (CVD) or existing CVD-CREST study: comparison to current treatment guidelines

L. Shi[1,2], S. Kachroo[3], H. Kawabata[4], S.A. Colilla[5], J. Mukherjee[6], U. Iloeje[6], V. Fonseca[7];
[1]Global Health Systems and Development, Tulane University, New Orleans, [2]Southeast Louisiana Veterans Health Care System, New Orleans, [3]Bristol-Myers Squibb, Nassau Park, [4]Bristol-Myers Squibb, Hopewell, [5]Bristol-Myers Squibb, Hopewell, [6]Bristol-Myers Squibb, Wallingford, [7]Section of Endocrinology, Tulane University, New Orleans, USA.

Aims: Increased risk of cardiovascular disease (CVD) and all-cause mortality is associated with sulfonylureas (SUs). This retrospective cohort study examined the treatment patterns of SUs in US veterans with different levels of cardiovascular risk or existing CVD.
Materials and methods: Electronic medical and pharmacy records were obtained for 149,053 patients with at least 2 records of T2DM diagnosis from the Veterans Integrated Service Network (VISN) 16 data warehouse from 01/01/2004 to 06/30/2010. All patients were required to be ≥ 18 years and have their first diagnosis of T2DM (ICD-9-CM codes: 250.x0 and 250.x2) after 01/01/2005 to ensure the one-year baseline information. Patients (n=18,099) with type 1 diabetes were excluded (ICD-9-CM codes: 250.x1 and 250.x3). Group 1: Patients with existing CVD (n=16,913) were defined by at least one of the following, ischemic heart disease, peripheral vascular disease, and ischemic stroke; Group 2: Patient with multiple CVD risk factors (n=30,348) were defined by, age ≥ 55 (male) or 60 (female), plus at least 1 additional risk factor (treated or non-treated): dyslipidemia or hypertension. Group 3: The remaining patients were considered as low risk patients (n=13,014). Frequency of SU use was reported as use rate per 1,000 patient years and by percentages (%). Chi-square tests were used to test the cross-cohort difference (Group 1 vs. 3 and Group 2 vs. 3) in the % of SU use. The results of SU use were further adjusted by within age-group comparisons to address the age differences resulting from the study cohort definition. Logistic regression models were used to explore the associations between baseline characteristics and use of SUs in adjusted odds ratio with 95% confidence interval (aOR [95% CI]) within each of the study groups.
Results: Across the three cohorts, approximately one quarter of patients reported the use of SUs in the study period (Group 1: 24.9%, Group 2: 25.4%, Group 3: 26.3%). The SU use over the study period was 104.8/1,000 person-year for Group 1, 106.5/1,000 person-year for Group 2, and 114.6/1000 person-year for Group 3. The adjustment of within-age-group comparisons further showed that the use frequencies of SUs for Group 1 or 2 were significantly higher (p<0.05) than Group 3 within most of age groups: 18-54, 55-64, 65-74, and >75 years old. Logistic regression models found statistically significant factors associated with the current use of SUs (aOR[95%CI]): Group 1: chronic kidney disease (CKD) (1.24 [1.05-1.47]), congestive heart failure (CHF) (1.14 [1.02-1.27]), and depression (0.87 [0.79-0.97]); Group 2: CHF (1.45, [1.25-1.67]), hypertension (1.10 [1.04-1.17]), and osteoporosis (0.68 [0.49-0.96]); Group 3: hypertension (1.17 [1.07-1.27]), obesity (0.90 [0.82-0.99]), and arthritis (0.81 [0.72-0.91]).
Conclusion: The use of SUs among veterans with either a history of cardiovascular disease or multiple risk factors for cardiovascular disease were still quite prevalent and similar to those at low risk for CVD, despite recommendations against such use in the ADA/EASD guidelines.

Change in body weight after 24 weeks of vildagliptin therapy as a function of baseline fasting plasma glucose levels in patients with type 2 diabetes

J.E. Foley[1], G. Bader[2], A. Schweizer[2];
[1]Novartis Pharmaceuticals Corporation, East Hanover, USA, [2]Novartis Pharma AG, Basel, Switzerland.

Background and aims: Overall, treatment with DPP-4 inhibitors is weight neutral. However, from lower baseline levels of glycaemia it was reported that vildagliptin therapy results in >1 kg weight loss over a 2-year treatment period. Reducing glucose levels from above the renal threshold to below the renal threshold with any therapy can lead to increased caloric balance by less calories lost in the urine. We hypothesise that when weight change is correlated with baseline fasting plasma glucose (FPG), patients with FPG predicted

to be above the renal threshold would be associated with positive caloric balance and those predicted to be below the renal threshold would be associated with negative caloric balance.
Materials and methods: Utilising the vildagliptin (50 mg bid and qd) database of clinical monotherapy studies, we used a linear regression model to analyse the body weight changes from baseline to week 24 as a function of baseline FPG.
Results: We included 2863 vildagliptin-treated patients of which 55% were male, average age was 54±11 years, BMI was 30±5 kg/m^2 and mean duration of type 2 diabetes was 2±3 years. The analysis confirms that there is a positive slope of 0.0085 kg/mg (95% CI: 0.005, 0.011; p<0.001). Neutral caloric balance (no weight change) was observed at FPG of 230 mg/dL. Baseline FPG values below and above this threshold were associated with weight loss and weight gain, respectively.
Conclusion: Extra-pancreatic effects of vildagliptin to reduce fat absorption and increase energy expenditure during meals may explain this negative caloric balance when glycosuria is considered. Overall the data support the conclusion that when loss of glycosuria is taken into consideration, treatment with vildagliptin results in negative caloric balance. This may explain why vildagliptin is associated with a modest reduction in fasting lipids and blood pressure.

Saxagliptin improves glycaemic control and is well tolerated in adult diabetes patients with glutamic acid decarboxylase antibodies
R. Buzzetti[1], P. Pozzilli[2], R. Frederich[3], N. Iqbal[3], B. Hirshberg[4];
[1]Clinical Sciences Department, Sapienza, University of Rome, [2]Department of Endocrinology and Diabetology, Policlinico Universitario Campus Bio-Medico, Rome, Italy, [3]Bristol-Myers Squibb, Princeton, USA, [4]AstraZeneca, Wilmington, USA.

Background and aims: Latent autoimmune diabetes in adults (LADA) is recognized by the presence of glutamic acid decarboxylase (GAD) antibodies, and there is a need for effective therapies for these patients.
Materials and methods: Patients from 5 placebo-controlled studies from the saxagliptin phase 3 program were pooled and classified by GAD status (GAD-positive: values ≥ lower limit of quantitation [LLOQ]; GAD-negative: values <LLOQ). To assess similarity in saxagliptin efficacy by GAD status, we analyzed treatment effects (HbA_{1c}, fasting plasma glucose [FPG], 120-min postprandial glucose [PPG], adverse events [AEs], serious AEs, hypoglycemia) using analysis of covariance, with test for treatment by subgroup interaction.
Results: The GAD-positive group included 98 saxagliptin patients and 35 placebo patients; the GAD-negative group included 1849 saxagliptin and 727 placebo patients. Age, sex, and race were balanced across subgroups. For GAD-positive and GAD-negative patients, baseline mean HbA_{1c} was 8.2% in both subgroups, mean FPG was 177 and 170 mg/dL, and mean C-peptide was 3.3 and 3.4 nmol/L. Saxagliptin showed greater decreases from baseline than placebo, with consistent treatment effects in GAD-positive and GAD-negative patients: mean change from baseline HbA_{1c} was −0.64% and −0.62%, respectively (P=0.93) and PPG was −39.1 and −39.7 mg/dL, respectively (P=0.97). Differences in achieving HbA_{1c} <7% were also consistent between GAD-positive and GAD-negative patients. There was a larger treatment effect for FPG for GAD-positive vs GAD-negative patients (−33.9 vs. −13.8 mg/dL; P<0.01). General similarity was shown with saxagliptin vs placebo for both GAD categories for incidence of AEs (65% vs 80% for GAD-positive; 73% vs 70% for GAD-negative), serious AEs (2.0% vs 5.7% and 3.5% vs 3.4%, respectively), and hypoglycemic events (5.1% vs 5.7% and 7.4% vs 6.5%, respectively).
Conclusion: SAXA was effective and generally well tolerated in patients with type 2 diabetes, regardless of GAD status. These data suggest that SAXA is an effective glycemic treatment in patients with LADA

Use of pioglitazone and risk of bladder cancer among diabetic patients in Korea: a multicentre retrospective cohort study supported by a nested case-control analysis
S.-M. Jin[1], B.-S. Cha[2], C. Jung[3], S. Suh[4], C.-Y. Park[5], J. Kim[1], J. Cho[6], B.-W. Lee[2];
[1]Division of Endocrinology and Metabolism, Department of Medicine, Samsung Medical Center, Seoul, [2]Division of Endocrinology and Metabolism, Department of Internal Medicine, Yonsei University College of Medicine, Seoul, [3]Division of Endocrinology and Metabolism, Department of Internal Medicine, Asan Medical Center, Seoul, [4]Division of Endocrinology and Metabolism, Department of Internal Medicine, Dong-A University Medical Center, Busan, [5]Division of Endocrinology and Metabolism, Department of Internal Medicine, Kangbuk Samsung Hospital, Seoul, [6]Department of Endocrinology and Metabolism, The Catholic University of Korea, Seoul, Republic of Korea.

Background and aims: Although an increased risk of bladder cancer with pioglitazone exposure has been suggested, it has not been determined whether chronic exposure to low dose of pioglitazone also exhibits such risk. We aimed to assess the risk of bladder cancer associated with pioglitazone in Korea, where the approved dosage of pioglitazone is 15mg per day.
Materials and methods: Using electronic medical record of the four tertiary referral hospitals in Korea, we extracted a clinical database of diabetic patients with ≥2 visit to the clinic during November 2005 and June 2011. Cox regression-generated age-, sex-adjusted hazard ratios (HRs) compared the incidence rate of bladder cancer between never- and ever-user of pioglitazone. A nested case-control study was followed to further adjust other confounders.
Results: After exclusion of patients who had diagnosis of bladder cancer before onset of diabetes, 113,193 patients were included. Among these patients, 11,240 patients was ever-user of pioglitazone. We found 237 and 30 cases of incident bladder cancer (rate 64.9 and 54.9 per 100000 person years) in never-users and ever-users of pioglitazone. Ever-use of pioglitazone was not significantly associated with bladder cancer incidence (adjusted HR 1.135, 95% confidence interval [CI] 0.769-1.677). In the nested case-control analysis, use of pioglitazone with observed duration of >6 months was associated with an increased rate of bladder cancer (rate ratio 2.143, 95% CI 1.041-4.414).
Conclusion: Ever-use of pioglitazone was not significantly associated with incidence of bladder cancer. However, association between longer-term use of pioglitazone and risk of bladder cancer could be suggested.

Pioglitazone increases bone marrow fat content
I. Lingvay[1], Q. Yuan[2], M. Poduri[1], B. Adams-Huet[3], X. Li[3], N. Maalouf[4];
[1]Endocrinology, [2]Radiology, [3]Clinical Sciences, [4]Mineral Metabolism, University of Texas Southwestern Medical Center, Dallas, USA.

Background and aims: Use of the thiazolidinedione pioglitazone is associated with an increased risk of fractures. Proposed mechanisms based on animal studies include increased bone marrow adiposity, decreased bone formation, and/or accelerated bone resorption, although the exact impact of pioglitazone on these parameters in humans remains unclear.
Materials and methods: In this double-blind placebo-controlled clinical trial, we randomized 30 obese volunteers with the metabolic syndrome to pioglitazone (PIO, 45 mg/day) or matching Placebo (PLA) for 1 year. Liver and femoral neck bone marrow fat content was measured by ^{1}H-magnetic reso-

nance spectroscopy at baseline, 6 and 12 months. The bone turnover markers serum C-telopeptide (CTX, bone resorption) and bone-specific alkaline phosphatase (BSAP, bone formation), and beta-cell function and insulin sensitivity (SI, by an insulin-modified frequently sampled intravenous glucose tolerance test) were measured at baseline, 1, 2, 6 and 12 months.
Results: Subjects included 13 women and 17 men, with mean age of 52.2 years, mean weight of 94.5 Kg, and mean BMI of 33.3 Kg/m^2. PIO use was associated with a significant decline in liver fat content and a significant increase in bone marrow fat content and insulin sensitivity (SI) at 6 and 12 months (Table). The change in bone marrow fat content was inversely and significantly associated with the change in liver fat at 12 months (Spearman R= -0.41, p=0.026). There was a trend towards increased bone resorption based on serum CTX elevation at 6 months vs. baseline in the pioglitazone group.
Conclusion: PIO use is associated with a significant increase in bone marrow fat content at the femoral neck. This increase in bone marrow fat was significantly correlated with the decrease in liver fat content, a finding compatible with the proposed model of fat redistribution from liver (and other ectopic tissues) to the bone marrow compartment.

Table:

Group	ΔLiver Fat (Month 6 vs. 0)	ΔLiver Fat (Month 12 vs. 0)	ΔBone Fat (Month 6 vs. 0)	ΔBone Fat (Month 12 vs. 0)	ΔSI (Month 6 vs. 0)	ΔSI (Month 12 vs. 0)	ΔCTX (Month 6 vs. 0)

Effect of pioglitazone on thyroid stimulating hormone and insulin resistance in hypothyroid patients
K.A. Moskva[1], L.J. Lapovets[2], O.P. Kikhtyak[3];
[1]Diabetology, Lviv Regional Endocrine Hospital, [2]Clinical Laboratory, [3]Endocrinology, Lviv National Medical University named Daniel Galician, Lviv, Ukraine.

Background and aims: Mechanism of insulin resistance in hypothyroidism is still not fully understood. Thyroid hormone receptor and PPAR-gamma are members of the same nuclear receptors superfamily and it is speculated that it could be a crosstalk between PPAR-gamma and thyroid hormone signaling pathways. Accordingly, it has been reported that intracerebral injection of PPAR-gamma agonists modify transcription of thyroid release hormone in the hypothalamus and increase serum thyroxine levels. The aim of this study is to estimate if PPAR-gamma agonist pioglitazone has an influence on thyroid stimulating hormone (TSH) and its relationship with insulin resistance parameters in hypothyroid patients treated with levothyroxine.
Materials and methods: 17 women and 8 men with overt hypothyroidism and insulin resistance without diabetes were included in the crossover study. After three months period when patients received levothyroxine (first line approach), treatment was changed to combination of levothyroxine and pioglitazone for next three months (second line approach). We measured: TSH, free triiodothyronine (fT3), free thyroxine (fT4), fasting glucose, fasting insulin, homeostasis model assessment of insulin resistance index (HOMA-IR), HOMA-B%, glycated hemoglobin (HbA1c) lipid profile at baseline and after each treatment approach.
Results: We observed significant decrease of TSH level following combining levothyroxine with pioglitazone in comparison with levothyroxine treatment alone (1.57±0.15 vs. 3.52±0.28 μIU/ml, p<0.001). Significant difference of fT3 and fT4 levels were observed between two treatment approaches (3.17±0.09 vs. 2.81±0.08 pg/ml, P<0.001 and 1.65±0.08 vs. 1.23±0.09 ng/dl, P<0.001 respectively). HbA1c decreased after second line treatment approach in comparison to the first one (5.44±0.05 vs. 5.85±0.06, P<0.001). Significant change in glucose (from 6.07±0.08 to 4.91±0.08 mmol/l (P<0.001) and insulin (from 15.94±0.57 to 8.57±0.15 μIU/ml (P<0.001) between first and second treatment lines was also established. HOMA-IR improved from 4.29±0.16 to 1.87±0.04 (P<0.001) after course with pioglitazone in comparison to levothyroxine treatment alone. Our investigation shows significant increase of high density lipoproteins (1.42±0.06 to 1.62±0.06 mmol/l, P<0.05) and significant decrease of atherogenic index (3.42±0.33 to 2.42±0.20, P<0.05) after second line approach in comparison to baseline. There was no significant difference between two treatment approaches in HOMA-B%, total cholesterol, triglycerides, high-density lipoproteins, low-density lipoproteins, very-low-density lipoproteins.
Conclusion: To our knowledge, it was discovered for the first time that pioglitazone administration is characterized by elevation of thyroid hormone and by diminishing of thyroid stimulating hormone. We also present novel data indicating pioglitazone as a drug with ability to decrease HbA1c, to improve HOMA-IR index by lowering insulin and glucose without influence on HOMA-B% in hypothyroid patients. Therefore our study suggests that PPAR-gamma receptors play a role in pathogenesis of hypothyroidism and PPAR-gamma agonist pioglitazone may have new indication to be used.

The glucagon receptor antagonist LY2409021 significantly lowers HbA_{1c} and is well tolerated in patients with type 2 diabetes mellitus: a 24-week phase 2 study
C.M. Kazda[1], S.A. Headlee[2], Y. Ding[2], R.P. Kelly[3], P. Garhyan[2], T.A. Hardy[2], A.J. Lewin[4];
[1]Lilly France, Vagnas, France, [2]Lilly, Indianapolis, USA, [3]Lilly, Singapore, [4]National Research Institute, Los Angeles, USA.

Background and aims: LY2409021 (LY), a potent, selective antagonist of the human glucagon receptor (GRA), is being investigated as a treatment for type 2 diabetes mellitus (T2DM). This phase 2, multicenter, double-blind, placebo-controlled, parallel-group study examined the efficacy of once-daily LY, compared with placebo, as measured by the mean change in HbA1c from baseline to the end of the 24-week active treatment period.
Materials and methods: A total of 254 participants (aged 18-70 years) with T2DM (HbA1c 7.0% to 10.5%) who were naive to antidiabetic medications or taking stable doses of metformin were randomized to LY 2.5 mg (n=63), 10 mg (n=64), 20 mg (n=64), or placebo (n=63), each administered once daily.
Results: Once-daily doses of 10-mg and 20-mg LY were associated with statistically and clinically significant reductions in HbA1c. The least squares mean differences for HbA1c change from baseline to the 24-week endpoint were −0.15%, −0.45%, −0.78%, and −0.92% for the placebo, LY 2.5-mg, LY 10-mg, and LY 20-mg groups, respectively (p<.001 vs placebo for the LY 10-mg and LY 20-mg groups) (Figure). The frequency of hypoglycemia was low: 17 subjects (7%) reported a total of 20 events (none was severe or required hospitalization), and the overall incidence did not differ significantly between placebo and active treatment groups. The LY fasting glucose response relative to placebo was dose-dependent and was statistically significant versus placebo (p=.035) in the 20-mg group. The safety and efficacy findings were consistent with those from previous studies of LY in subjects with T2DM. There were no dose-dependent effects of LY on lipids, weight, or blood pressure. Small increases in hepatic aminotransferases (mean alanine aminotransferase elevation of about 10 U/L from baseline for the 10-mg and 20-mg groups) were observed and reversed during treatment or following cessation of treatment. Dose-dependent increases in fasting glucagon were observed; they returned to pre-LY levels after cessation of treatment.
Conclusion: GRA treatment significantly lowered HbA1c with good overall tolerability and a low frequency of hypoglycemia. Small increases in hepatic aminotransferases that were observed were reversible.

Effects of pioglitazone vs glyburide on endothelial function in type 2 diabetic patients with vascular complications: the SPLENDOR study

M. Garofolo[1], L. Pucci[2], D. Lucchesi[1], R. Bruno[3], E. Russo[1], V. Sancho Bornez[1], R. Russo[2], L. Giusti[1], A. Dardano[1], A. Avogaro[4], L. Ghiadoni[3], R. Miccoli[1], C. Di Pietro[5], G. Penno[1], S. Del Prato[1];
[1]Endocrinology and Metabolism, University of Pisa, [2]Institute of Agricultural Biology and Biotechnology, CNR, Pisa, [3]Internal Medicine, University of Pisa, [4]Department of Medicine and Venetian Institute of Molecular Medicine, University of Padua, [5]Takeda Italia, Rome, Italy.

Background and aims: In patients with type 2 diabetes mellitus (T2DM), pioglitazone treatment has been shown to reduce the risk for cardiovascular disease (CVD). This effect is most likely due to improved insulin sensitivity and the beneficial effects on lipids, blood pressure, and inflammation. We now report results of a double-blind, randomized 24-week trial examining the effect of pioglitazone (PIO) vs. glyburide (GLY) as add-on to metformin on the endothelial function of T2DM patients with CV disease.
Materials and methods: T2DM patients were randomized to 30 mg/day PIO (n=18; age 62±6 years, BMI 30.1±3.4 kg/m2, HbA1c 8.0±0.4%) or 10 mg/day GLY (n=17; age 60±9 years, BMI 31.5±4.1 kg/m2, HbA1c 7.9±0.5%). All randomized patients completed the study with a mean exposure to study drug of 184.5±8.0 days (range 167-197) for PIO and 184.6±10.2 days (range 172-211) for GLY and with a compliance rate of 96.9±2.7% and 96.3±5.4% for the two treatments, respectively. Before randomization and at end of treatment, brachial artery endothelium dependent flow-mediated dilation (FMD) and non-endothelium dependent glyceryl trinitrate-mediated dilation (GTN) were determined by high-resolution ultrasound and computerized edge detection system along with measurement of markers of lipid metabolism and inflammatory response and insulin sensitivity (OGIS).
Results: Glycemic control improved to a similar extent with no difference in HbA1c reduction at week 24 between PIO (-0.76±0.19%) and GLY (-0.77±0.18%). Basal brachial artery diameter (BAD; 4.3±0.2 vs. 4.3±0.3 mm) increased by week 24 with PIO (+0.19±0.10 mm) compared to no changes in GLY (-0.04±0.10 mm, p=0.098). Maximal BAD in response to reactive hyperemia was greater with PIO than with GLY (+0.22±0.10 vs. -0.05±0.10 mm, p=0.034). Consensually, FMD increase from baseline (4.04±0.63 vs. 3.65±0.60%) was greater with PIO (+0.72±0.88 vs. +0.32±0.77%; p=0.574) though not statistically different. There was no difference between groups as far as GTN% was concerned. With PIO, insulin sensitivity improved (OGIS, +36±12 vs. +5±7; p=0.04) and adiponectin levels increased (+2.5±1.0 vs. +0.2±0.4 ng/ml; p=0.0005) along with a greater reduction in serum levels of triglycerides (-60±20 vs. +3±14 mg/dl; p=0.008) and an increase in HDL-cholesterol (+6±2 vs. -3±1 mg/dl; p=0.0002) and Apo-A1 (+0.11±0.04 vs. -0.05±0.05 g/l; p=0.029). No differences were apparent for other lipid parameters as well as ox-LDL levels. Compared to GLY, PIO treatment was associated with a slight reduction in serum levels of hs-CRP (-21±11 vs. +2.74±10 mg/l; p=0.084), PAI-1 (-16.3±9.2 vs. +4.4±18.1 ng/ml; p=0.056), with no differences for IL-6, sICAM-1, sVCAM-1, and MCP-1.
Conclusion: In T2DM with CVD already on metformin failure, 24 week addition of pioglitazone as compared to glyburide, was not associated with significant changes in endothelial function in spite of improved insulin sensitivity, better lipid profile, and marginal improvement in inflammatory response.

The comparative safety and effectiveness of sitagliptin in patients with type 2 diabetes and heart failure

D.L. Weir, F.A. McAlister, A. Senthilselvan, J.R. Dyck, J.K. Sandhu-Minhas, D.T. Eurich;
University of Alberta, Edmonton, Canada.

Background and aims: Sitagliptin belongs to a new class of antidiabetic agents called incretins, which are hypothesized to have pleiotropic effects on the cardiovascular system as well as heart failure specific effects. The objective of this study was to determine if the use of sitagliptin was associated with any

benefit or risk on clinical outcomes in a population-based cohort of patients with type 2 diabetes and incident heart failure.
Materials and methods: Using a large commercially insured US claims and integrated laboratory database, 11,967 subjects with type 2 diabetes and incident heart failure were identified through physician claims, hospital discharge abstracts, and/or ambulatory care visits based on ICD-9 CM codes. Our population-based cohort was followed from January 1, 2004 until death, termination of medical insurance, or December 31, 2010. Time-varying multivariable Cox proportional hazards models were used to asses differences in all-cause mortality.
Results: Average age of subjects was 56 years, 39.6% were female, and median duration of follow-up was 1.94 years. In total, 653 subjects died (5.5%). No association between all-cause death and sitaglitpin use was observed compared to other glucose lowering agents. After adjustment for demographics, clinical & laboratory data, pharmacy claims, health care utilization and time-varying propensity scores, any sitagliptin use was not associated with a statistically significant increase in mortality (adjusted HR 0.64, 95% CI 0.37-1.12) compared to no sitagliptin use. Similarly, compared to metformin/sulfonylurea combination therapy, sitagliptin combination therapy was not associated with an increase in mortality (adjusted HR 1.01, 95% CI 0.40-2.56).
Conclusion: Sitagliptin therapy was not associated with excess risk of all-cause death among patients with type 2 diabetes and heart failure.

Efficacy and safety of exenatide once weekly over 5 years
L. MacConell[1], D. Maggs[1], Y. Li[1], P. Griffin[1], C. Wysham[2];
[1]Bristol-Myers Squibb, San Diego, [2]Rockwood Clinic, Spokane, USA.

Background and aims: In the 30-week controlled DURATION-1 trial patients with T2DM on a range of background therapies treated with the once weekly formulation of the GLP-1 receptor agonist (GLP-1 RA) exenatide (EQW) exhibited a greater reduction in HbA_{1c} compared with the twice daily (BID) formulation of exenatide (ΔHbA_{1c} -1.9% vs -1.5%). The controlled period of the trial was followed by an open-ended, open-label period in which all patients either continued EQW or switched from exenatide BID to EQW. The current analyses examined the safety and efficacy of treatment with EQW over 5 years, the longest assessment of a GLP-1RA reported to date.
Materials and methods: Study end points included change in HbA_{1c}, fasting plasma glucose (FPG), weight, lipid profile, and systolic blood pressure. Efficacy data are reported for the completer population. Safety data are reported for the intent-to-treat (ITT) population comprised of individuals who received at least one dose of exenatide.
Results: Approximately 54% (n=158) of the 295 ITT patients completed 5 years of treatment. Completer baseline characteristics (mean±SD) were HbA_{1c} 8.2±0.9%; FPG 9.18±2.24 mmol/l; weight 100±18 kg; duration of diabetes 7±6 years. Significant HbA_{1c} improvement (LS mean [95%CI]: 1.6% [-1.8, -1.3]) was observed with long term EQW treatment. The mean±SE HbA_{1c} was 7.1±1.0% at the 5 year end point, with 32% achieving $HbA_{1c} \leq 6.5\%$. Significant improvements in FPG (LS mean 1.66 mmol/l [-2.04, -1.27]) and weight (2.8kg [-4.3, -1.2]) were also observed. At 5 years of treatment the following changes in fasting metabolic markers were observed: total cholesterol (0.31 mmol/l [0.47, -0.14]), HDL cholesterol (+0.06 mmol/l [+0.02, +0.10]), LDL cholesterol (0.25 mmol/l [-0.38, -0.11]), and triglycerides (geometric LS mean [95%CI]: -13% [-20%, -5%]). Change (LS mean [95%CI]) in systolic blood pressure was +0.63 mmHg [-2.29, 3.56]. Within the ITT population nausea (predominantly mild) was the most common adverse event with EQW during the initial controlled period with a treatment exposure-adjusted annual event rate of 0.85 which notably decreased over time (0.08 from week 30 to year 5). The exposure-adjusted annual event rates of injection site pruritus and erythema lessened considerably from the controlled period compared with the open-ended period (0.51 and 0.14 vs 0.02 and 0.01, respectively). Treatment-emergent adverse events leading to withdrawal from week 30 to year 5 were also infrequent (5.8%). One case of pancreatitis and 3 cases of acute renal failure were reported during the 5 year treatment period. No severe hypoglycemia was observed; minor hypoglycemia in this treatment period occurred predominantly with concomitant sulfonylurea use.
Conclusion: Greater than 50% of patients continued treatment with EQW for 5 years. Long-term treatment with EQW was well-tolerated and associated with sustained improvement in glycemic control in patients with T2DM on an array of oral therapies with no unexpected safety findings. This outcome was associated with improvements in broader metabolic measures, including body weight and lipids.
Clinical Trial Registration Number: NCT00308139

981

Long-term cardiovascular outcomes with exenatide twice daily compared to insulin: a retrospective observational study
K. Klein[1], J.H. Best[2,3], S.P. Marso[4], D. Maggs[3], S.K. Paul[1];
[1]University of Queensland, Brisbane, Australia, [2]University of Washington, Seattle, [3]Amylin Pharmaceuticals, LLC, San Diego, [4]Saint Luke's Mid America Heart Institute, Kansas City, USA.

Background and aims: Treatment with exenatide has shown some beneficial effects on cardiovascular (CV) risk factors, including weight loss, in patients with T2DM. However, data on the long-term CV outcomes of treating T2DM patients with glucagon-like peptide-1 (GLP-1) receptor agonists remain limited. Using the GE Healthcare database, we evaluated the risk of heart failure (HF), myocardial infarction (MI) and stroke in patients initiating exenatide twice daily (EBID; n=2795) or any insulin (INS; n=51,547) in routine clinical practice.
Materials and methods: A cohort of 54,342 patients who received a first prescription of EBID or INS between June 2005 and May 2009, combined with oral antidiabetes agents (OADs), was selected for this retrospective study under the following conditions: a minimum follow-up period of 3 years, a minimum of 6 months under the same drug regimen, no crossover between EBID and INS during the follow-up, no cardiovascular event within 6 months of start of the follow-up period, and age-matched between the two drug regimens. The possible effects of EBID vs INS on CV events in this age-matched cohort were evaluated using a stratified Cox regression model, adjusted for age, sex, race, history of CV disease, OADs, and cardio-protective medications.
Results: Demographics of the EBID and INS-treated patients were: 39% vs 47% men; 56 vs 59 years of age, 54% vs 48% white, 11% vs 12% with a history of CV disease, 39 vs 34 kg/m^2 BMI, respectively). Medication use for the two groups differed for some drug classes (Metformin: 89% vs 61%; SFU: 55% vs 46%; TZDs: 47% vs 33%; ACE-ARB: 74% vs 82%; β blocker: 43% vs 56%; statins: 85% vs 84% for EBID vs INS, respectively). During a median follow-up of 4.3 years for EBID and 4.2 years for INS, the rate of CV events were 2.1% vs 5.8% for HF, 0.5% vs 0.9% for MI, and 0.9% vs 2.1% for stroke, respectively. CV event rates per 1000 person-years were significantly lower among patients treated with EBID vs INS (HF: 4.8 vs 13.6, MI: 1.1 vs 2.1, stroke: 2.0 vs 4.9). Compared to INS, patients treated with EBID had significantly lower risk of HF by 53% (HR CI: 0.36, 0.61) and MI or stroke by 48% (HR CI: 0.38, 0.72). Patients with a history of CV disease had a 47% (HR CI: 1.35, 1.60) increased risk of HF and 70% (HR CI: 1.50, 1.91) increased risk of MI or stroke compared to patients without a history of CV disease. Potential limitations of this analysis include misclassification of outcome and residual confounding.
Conclusion: In this retrospective database study, treatment with EBID was associated with significantly lower risk of HF and MI or stroke during 4 years of follow-up compared with INS.

Impact on cardiovascular risk factors of exenatide BID vs insulin lispro TID added to titrated insulin glargine QD in metformin-treated type 2 diabetes mellitus patients: the 4B trial
M. Diamant[1], M.A. Nauck[2], R. Shaginian[3], J. Malone[4], S. Cleall[5], D. de Vries[3], B. Hoogwerf[3], L. MacConell[6], B.H.R. Wolffenbuttel[7];
[1]VU Univ Medical Centre, Amsterdam, Netherlands, [2]Diabeteszentrum Bad Lauterberg, Harz, Germany, [3]Eli Lilly, Houten, Netherlands, [4]Eli Lilly, Indianapolis, USA, [5]Eli Lilly, Windlesham, UK, [6]Bristol-Myers Squibb, San Diego, USA, [7]University of Groningen, Netherlands.

Background and aims: Many patients with type 2 diabetes mellitus (T2DM) who fail to achieve adequate glycaemic control on oral antidiabetic agents plus insulin have elevated cardiovascular (CV) risk factors including excess weight, hypertension and hyperlipidaemia. Therefore, add-on therapies should be evaluated for their effect on these and related characteristics. The 4B Trial prospectively assessed the effect of Basal insulin glargine (IG) + Exenatide BID Treatment (BET) versus Basal IG + mealtime Bolus insulin lispro (IL) 3 times daily (TID) Treatment (BBT) in patients (pts) with insufficient glycaemic control despite intensified IG. Secondary outcomes included the evaluation of CV risk factors.
Materials and methods: After a 2-wk screening period and 12-wk basal insulin optimization (BIO) phase to titrate IG dose (INITIATE algorithm) to achieve the lowest possible FBG (target of 5.6 mmol/L) without hypo, pts

unable to achieve HbA_{1c} ≤7% (53 mmol/mol) despite IG intensification were randomised in the 30-wk intervention phase comparing BET to BBT. Secondary outcomes assessed change from randomisation to 30-wk endpoint of body weight, BMI, waist circumference, blood pressure (BP), pulse rate, fasting lipids (total-, HDL- and LDL-cholesterol, TG), high sensitivity C-reactive protein (hs-CRP), adiponectin and urinary albumin excretion (UACR).

Results: 1036 pts were screened and 917 pts entered the 12-wk BIO phase. 637 pts (concomitant medications: statins 53%, fibrates 11%, antihypertensives 76%) were randomised 1:1 to BET (n=316, PP n=247) or BBT (n=321, PP n=263). HbA_{1c} reduction with BET was non-inferior to BBT for mean change in HbA_{1c} from randomisation to wk 30. Body weight decreased significantly in the BET arm from randomisation to wk 30 and increased significantly in the BBT arm (BET vs BBT treatment difference -4.6 kg [95% CI, -5.2 to -3.9], *P*<.0001). LS mean change in waist circumference for BET was -1.98 cm and for BBT was 0.72 cm (between group comparison *P*<.0001). In the BET arm LS mean change for SBP was -4.1 mm Hg, in the BBT arm the LS mean change was +0.4 mm Hg (between group comparison *P* = .0004). LS mean changes in DBP were -0.6 for BET and -0.1 mm Hg for BBT. Analyses did not identify significant treatment group differences in hs-CRP, adiponectin and UACR.

Conclusion: There was a significant difference between treatment groups for weight change, and changes in waist circumference and systolic BP. Other changes in both groups were not significant.

Cardiovascular effects of antidiabetic drugs: exendin-4 and liraglutide

B. Faricelli[1,2], M. Salomonsson[2], A. Consoli[3], T. Engstroem[4], M. Treiman[2];
[1]Department of Medicine and Aging Sciences, Università G.d'Annunzio, Pescara, Italy, [2]Faculty of Health Sciences, Department of Biomedical Science, Copenhagen University, Denmark, [3]Department of Medicine and Aging Sciences, Università G.d'Annunzio, Chieti, Italy, [4]Rigshospitalet - Copenhagen University Hospital, Denmark.

Background and aims: Exendin-4 (exe4) postconditioning has been shown to limit reperfusion injury (RI) in experimental [1], [2], [3] and clinical settings [4]. Left ventricle hypertrophy (LVH) may be associated with increased RI. Our objective was to study exe4 and liraglutide postconditioning (PostC) in hearts with LVH, isolated from hypertensive SHR-SP (hypertensive LVH) rats.

Materials and methods: Hearts isolated from WKY (control) and SHR-SP rats (11-15 weeks old) were subjected to 35 min LAD occlusion-2 hrs reperfusion, with exe4 0.3 nM or liraglutide 0.3 nM present during the first 15 min in treated hearts. Evans blue/TTC method was used to determine area-at-risk (AAR) and infarct size (% of AAR). Akt phosphorylation (Akt-P) was measured on western blots after 3 min of reperfusion. Arterial blood pressure (BP) was measured in conscious animals by tail cuff method.

Results: BP and heart/body weight ratio were increased in SHR-SP compared to WKY rats (p<0.0001 for both parameters). Infarcts were larger in SHR-SP than in WKY (65.7 +/-3.2, N=7 vs 37.1 +/-3.4, N=12 respectively; P<0.05). Exe-4 and liraglutide PostC decreased infarct size (IS) after 35 min ischemia in WKY (p<0.05). Liraglutide and preconditioning, but not Exe-4, decreased IS after 35 min in SHR-SP (p<0.05). Exe4 PostC decreased IS after 15 min ischemia in SHR-SP (p<0.05). In WKY hearts, exe4 treatment significantly decreased diastolic contracture and increased left ventricle developed pressure. Liraglutide, but not exe4, decreased diastolic pressure in SHR hearts. Degree of Akt phosphorylation was smaller in LVH hearts compared to normal hearts.

Conclusion: These data suggest that 0.3 nM liraglutide was more effective than 0.3 nM exe4 in limiting reperfusion injury in both WKY and SHR-SP. In both WKY and SHR-SP hearts there was a loss of response to PostC by exe4 with increasing ischemia time and infarct size. This loss of response to PostC occurs earlier in hypertrophy hearts.

Effects of lixisenatide on survival and cardiac function in a mouse model of chronic myocardial infarction

P. Wohlfart, K. Hiss, D. Hein, T. Hübschle, H. Ruetten, U. Werner;
Sanofi R&D Diabetes Division, Translational Medicine, Frankfurt am Main, Germany.

Background and aims: Cardioprotection by the GLP-1 receptor agonist lixisenatide (LIXI) has recently been described in *ex vivo* and *in vivo* ischaemia/reperfusion rat studies. Here, we assessed the cardioprotective activity of LIXI in a more severe mouse model of myocardial infarction (MI), induced by permanent ligation of the left anterior descending coronary artery.

Materials and methods: The protective effects of once-daily treatment with LIXI for 4 weeks were compared with placebo and to sham-operated controls without MI. The ACE inhibitor ramipril served as reference. Treatment was started 3 days prior to induction of ischaemia. Male C57BL/6 mice (6-7 weeks of age) were randomized into 5 groups: Sham, MI-control (placebo injection QD); MI-LIXI 10 (10 µg/kg s.c. QD), MI-LIXI 150 (150 µg/kg s.c. QD) and MI-ramipril (2.5 mg/kg*day in drinking water). Post-MI survival was monitored throughout the study and cardiac function was assessed by pressure-volume loop analysis at study end.

Results: Four weeks after infarct induction, MI-control animals showed dramatically reduced global cardiac parameters with significantly depressed systolic and diastolic function. This resulted in a significantly increased mortality (survival <60%). The survival rate with ramipril was, however, ~90%. Chronic daily injection with LIXI (at 10 and 150 µg/kg) significantly improved (40 and 47%) cardiac function, as indicated by an increase in ejection fraction, stroke volume and cardiac output compared with MI-control, translating into an increased survival rate of >70% (see figure).

Conclusion: Cardioprotection by LIXI following ischaemia/reperfusion has already been demonstrated in previous studies in the rat. With the present study, we could confirm and even extended the cardioprotective effects of LIXI towards a more aggravated MI-induced heart failure mouse model with permanent coronary artery occlusion.

Cardioprotective effects of lixisenatide treatment in mice*

Patient-reported outcomes with dulaglutide, exenatide, or placebo (AWARD-1)

K. Van Brunt[1], M. Reaney[1], M. Yu[2], M. Lakshmanan[3], B. Curtis[3], B. Mitchell[3];
[1]Eli Lilly, Surrey, UK, [2]Eli Lilly, Toronto, Canada, [3]Eli Lilly, Indianapolis, USA.

Background and aims: Patient-reported Outcomes (PRO) were secondary objectives in this study designed to compare the safety and efficacy of a long acting GLP-1 receptor agonist dulaglutide (DU) to exenatide (EX) and placebo (PL) in patients with type 2 diabetes.

Materials and methods: This was a 52-week (wk), Phase 3, randomised study where patients received once-weekly DU 1.5 mg or 0.75 mg, twice daily EX, or PL (26 wks only). PRO measures for treatment satisfaction (DTSQ), weight-related self-perception (IW-SP), ability to perform physical activities of daily living (APPADL), and health status (EQ-5D) were administered at baseline (BL), 26, and 52 wks.

Results: Both DU doses were superior to PL (26 wks) and EX (26 and 52 wks) in HbA_{1C} change from baseline (BL; p<0.001). Weight reductions were observed in DU 1.5 mg and EX. Significant (p<0.05) improvements from BL were observed in IW-SP (26 and 52 wks, all groups) and total DTSQ scores

(26 wks, both DU doses and EX; 52 wks, both DU doses). A decrease in frequency of perceived hyperglycaemia (all groups) was observed at 26 and 52 wks, but an increase in perceived hypoglycaemia was observed with EX at 26 and 52 wks. EQ-5D visual analog scale (VAS) score showed significant improvements for both DU doses and EX at 26 and 52 wks. No significant changes were observed in APPADL and EQ-5D index scores for any group. Some significant between group differences were observed (Table 1).

Conclusion: Both once weekly DU doses and EX showed improvements from BL for IW-SP, total DTSQ, perceived hyperglycaemia, and EQ-5D VAS scores. Improvement in total DTSQ and perceived hyperglycaemia scores were greater in both DU doses vs EX.

Safety and tolerability of linagliptin in 7400 patients with type 2 diabetes: a pooled comprehensive analysis of prospective safety reporting in placebo-controlled studies

M. Lehrke[1], N. Marx[1], S. Patel[2], T. Seck[3], S. Crowe[3], M. von Eynatten[4], O. Johansen[3];
[1]Department of Internal Medicine I, University Hospital Aachen, Germany, [2]Boehringer-Ingelheim, Bracknell, UK, [3]Boehringer-Ingelheim, Ingelheim, Germany, [4]Department of Metabolic Medicine, Boehringer-Ingelheim, Ridgefield, USA.

Background and aims: A large number of diabetes drugs are available for the management of type 2 diabetes (T2D) and drug safety is a key consideration. We aimed to assess the safety and tolerability of the dipeptidyl peptidase-4 inhibitor linagliptin involving patients with T2D in a large global development program.

Materials and methods: Safety data were pooled from a comprehensive trial data base comprising all available randomized, double-blind, placebo controlled, clinical trials with linagliptin lasting up to 52 weeks. Incidences of predefined adverse events (AE) were calculated with descriptive statistics and results are summarized by treatment group (linagliptin, placebo) overall and by age category (≤ 65 years, 65-74 years, ≥ 75 years). Hypoglycaemia was assessed descriptively and with an exploratory analysis based on the risk ratio, the respective 95% confidence interval (CI) and Fisher's exact test.

Results: In total, 22 trials were included in the analysis involving 7400 patients (age ≥ 65 years: 69.7%) whereof 4810 received linagliptin 5 mg once daily or placebo (n= 2590). The overall incidence of AE or serious AE (SAE) by various system organ classes including cardiac disorders, vascular disorders, infections and infestations, gastrointestinal disorders (including pancreatitis) with linagliptin was similar to placebo (AE 56.5% vs. 61.2%; SAEs 4.8% vs. 6.3%, respectively). As expected, with advancing age, aggregated incidence of AE and SAE numerically increased, but the incidences comparing linagliptin to placebo remained similar (TABLE). Overall hypoglycaemia incidence was significantly lower for linagliptin (11.5%) as compared to placebo (14.0%) with a risk ratio of 0.82 (95% CI: 0.73 - 0.93; p=0.0021). A low hypoglycaemia risk with linagliptin was seen in all three subgroups of advancing age.

Conclusion: This pooled comprehensive safety analysis supports previous evidence that linagliptin is well tolerated overall and across all age groups, with a low incidence of hypoglycaemic events. Ongoing large outcome trials will provide further insights into the long-term safety profile of linagliptin.

Table. Frequency of investigator reported AEs, SAEs and hypoglycaemic events for linagliptin vs. placebo in 7400 patients included in a global clinical development program.

Metformin safety in the very elderly

L. Czupryniak, N. Szyłło, E. Szymańska-Garbacz, M. Pawłowski, M. Saryusz-Wolska, J. Loba;
Metabolic Diseases Dept., Medical University of Lodz, Poland.

Background and aims: With the increasing life expectancy more and more subjects with type 2 diabetes are aged over 80, and they often have a high quality of life. According to DECODE study, over 40% of octogenarians suffer from diabetes. However, there are no specific guidelines for the treatment of this group of the very elderly patients, and metformin use in this population is controversial. The aim of our study was to assess metformin use, with a special reference to its safety, in the very elderly individuals with type 2 diabetes mellitus.

Materials and methods: We have assessed cross-sectionally modes of type 2 diabetes therapy used in randomly selected subjects aged 80-90 (n=158) - and retrospectively analyzed 3-year safety of thereof. The comparative group comprised gender- and BMI-matched type 2 diabetes subjects aged 60-70 years (n=112).

Results: The treatment modes and cardiovascular risk factors distribution is presented in the table (mean±SD or %). Symptomatic hypoglycemia was recorded in 21% of the very elderly and 45% of the controls (p<0.01) in the 3-year period preceding the cross-sectional analysis. No case of ketoacidosis or lactic acidosis was noted in the studied subjects.

Conclusion: Majority of the very elderly type 2 diabetes patients are treated safely with metformin. Moreover, glucose control and cardiovascular risk profile is more favorable in these subjects than in the younger ones, suggesting the effective use of available therapies. The very elderly subjects with type 2 diabetes, despite differing at many instances from the over-a-decade younger patients, can be effectively and safely treated with traditional therapies, including metformin.

Metabolic effects of cell therapy based GLP-1 treatment in streptozotocin diabetic mice

N. Irwin[1], S. Vasu[1], R.C. Moffett[1], J.T. McCluskey[1], M.H. Hamid[2], P.R. Flatt[1];
[1]School of Biomedical Sciences, University of Ulster, Coleraine, UK,
[2]Department of Microbiology and Biochemistry, University of Putra, Kuala Lumpur, Malaysia.

Background and aims: The use of long-acting glucagon-like peptide-1 (GLP-1) mimetics has generated significant therapeutic interest for diabetes. Despite their obvious attractiveness, timing of injections and circulating drug levels remain an issue. As such, *in situ* production of GLP-1 by cellular delivery could circumvent these problems. We have investigated the effects of GLP-1 delivery by cell therapy using subscapular implantation of the GLP-1 secreting cell line, GLUTag, in streptozotocin-induced diabetic mice.
Materials and methods: Diabetes was induced in female severe combined immunodeficient mice (15-28 g) by intraperitoneal injection of streptozotocin (150 mg/kg bw). GLUTag cells were suspended at a density of 50 x 10^6 cells/ml and 100 µl injected subcutaneously at the subscapular region of diabetic mice. Control mice received 100 µl vehicle (cell culture media alone). All diabetic mice were given insulin (15 U/kg bw) from days 7 to 29 after streptozotocin treatment. Food intake, water intake, body weight and blood glucose were monitored every 2-3 days. In addition a glucose tolerance test (18 mmol/kg bw) was carried out 30 days post transplantation. At termination, plasma insulin, glucagon and GLP-1 levels were assessed. Additional terminal analyses included assessment of GLP-1 intestinal content, pancreatic morphology and Ki-67 and TUNEL staining of beta-cells.
Results: Cell implantation was well tolerated and over the 30 day study period, transplantation gave rise to encapsulated and well vascularised growths which contained immunoreactive GLP-1. These weighed between 0.21 g to 0.81 g with cell mass sizes between 9 x 8 mm^2 to 21 x 19 mm^2. Transplantation significantly (P<0.001) countered excessive food and fluid intake in diabetic mice and maintained normal control body weight. Circulating glucose was significantly (P<0.01) lowered from day 9 post-implantation onwards, and plasma insulin was 1.9 ± 0.7 ng/ml on day 30, compared with undetectable levels of insulin in diabetic controls. In addition, glucagon levels were significantly (3.7-fold; P<0.05) reduced and GLP-1 (6.2-fold; P<0.05) increased in transplanted mice compared to controls. This was associated with significantly (P<0.05 to P<0.01) lower blood glucose levels in GLUTag cell implanted mice following exogenous glucose administration. The improvement of glucose tolerance was corroborated by significantly (1.5-fold; P<0.01) decreased AUC values when compared to controls. GLP-1 content of intestines of implanted mice was substantially (8.7-fold; P<0.05) higher than controls. Histological examination of the pancreata of transplanted mice revealed significant elevations in islet (2.0-fold; P<0.001) and beta-cell (2.3-fold; P<0.001) area, with reduced (1.5-fold; P<0.001) alpha-cell area. Ki-67 and TUNEL staining demonstrating that increased beta-cell mass was due to enhanced proliferation relative to apoptosis, with approximate 2:1 ratio favouring enhanced beta-cell mass.
Conclusion: GLP-1 delivery by cell therapy has significant beneficial effects on metabolic control in streptozotocin-induced diabetic mice. The positive effects in diabetes were associated with enhanced beta-cell mass expansion and insulin-secretion. The results represent proof of concept that GLP-1 delivery by cell therapy affords a possible means of improving metabolic control in diabetes.

989

Molecular mechanism of protective effect by pioglitazone and/or liraglutide on beta cell damage with the progression of diabetic morbidity

T. Kimura, M. Shimoda, H. Hirukawa, S. Hamamoto, K. Tawaramoto, M. Hashiramoto, K. Kaku;
Diabetes, Endocrinology and Metabolism, Kawasaki Medical School, Kurashiki, Japan.

Background and aims: We previously reported that pioglitazone(PIO) and liraglutide(LIRA) preserved pancreatic beta-cell mass and function in obese

diabetic *db/db* mice. The aim of this study is to examine the molecular mechanism of protective effects of these drugs on beta-cell damage with the progression of diabetic morbidity.
Materials and methods: Seven week-old male *db/db* mice, as early stage model, and 16 week-old male *db/db* mice, as advanced stage model, received PIO (25mg/kg QD, PO), LIRA (0.2mg/kg BID, *s.c.*), PIO and LIRA combination, or vehicle for 2 days (*study 1*: for acute effect) or 2 weeks (*study 2*: for chronic effect) (n=5 for each group). Body weight, fasted blood glucose (FBG), plasma insulin (FIRI), and plasma triglyceride (TG) levels were measured before and after the intervention. The beta-cell mass was assessed after 2weeks intervention. Gene expressions specific for the core area of pancreatic islet were analyzed by LCM method and real time RT-PCR. Primer pairs encoding genes associated with pancreatic hormones, cell differentiation/proliferation, cell cycle, apoptosis, oxidative/endoplasmic reticulum(ER) stress, inflammation and fibrosis were prepared, and real-time RT-PCR with Sybr Green was applied. Each genes expression was relatively quantified by the comparative Ct method with each result in the 18 SrRNA as a control.
Results: Study 1: After 2-days intervention, when the deranged biochemical markers did not ameliorate completely, gene expressions of *NeuroD*, *PDX-1*, and *ERK1* in early stage model were significantly up-regulated by PIO and/or LIRA treatment, and the most significant effect was observed in the combination group, but those effects were not demonstrated in advanced stage. The *bcl-2* gene expression was increased, and *caspase8* and *caspase3* gene expressions were decreased by PIO and/or LIRA in both models. The combination treatment showed more significant effect on those gene expressions. The short-term intervention did not alter the oxidative/ ER stress and inflammation related gene expressions in both early and advanced model of mice. Study 2: In early stage, LIRA significantly lowered FBG with an increment of insulin level. PIO also decreased FBG compared with the control. FBG reduction was further enhanced by combination treatment. In advanced stage, FBG was lowered only in combination group. The beta-cell mass was greater in LIRA and/or PIO groups than in the control in early stage, and the most significant effect was observed in combination group. All drug groups preserved the beta-cell mass also in advanced stage, but effects were not so much significant compared with those in early stage model. Gene expression profiles related with cell proliferation and apoptosis were not different from those shown in *Study 1* (2 days intervention) in both early and advanced stage models. Furthermore, the long-term treatment with PIO and/or LIRA down-regulated gene expressions associated with fibrosis. The combination of 2 drugs also showed the most significant effect.
Conclusion: Both PIO and LIRA protect beta-cell damage directly through promotion of cell differentiation/proliferation and inhibition of apoptosis in early stage, but those effects attenuate in advanced stage. The present results also suggest that action mechanisms of PIO and LIRA on beta-cell survival differ each other.

GLP-1 attenuates the acceleration of gastric emptying induced by hypoglycaemia in healthy subjects

M.P. Plummer[1], T.D. Crowhurst[1], C.E. Annink[1], C.E. Cousins[1], R.R. Sardana[2], J.J. Meier[3], M.J. Chapman[1], M. Horowitz[2], K.L. Jones[2], A.M. Deane[1];
[1]Discipline of Acute Care Medicine, University of Adelaide, [2]Discipline of Medicine, University of Adelaide, Australia, [3]Department of Medicine I, Ruhr-University, Bochum, Germany.

Background and aims: Acute administration of glucagon-like peptide-1 (GLP-1) and 'short acting' GLP-1 agonists markedly slow gastric emptying in health and type 2 diabetes, which is likely the major mechanism responsible for the reduction in postprandial glycaemic excursions. Acute changes in glycaemia also modulate gastric emptying, such that gastric emptying is slower during hyperglycaemia and markedly accelerated by insulin-induced hypoglycaemia. The latter is likely to be an important mechanism underlying the counter-regulation of hypoglycaemia by increasing nutrient availability. The aim of this study was to determine whether GLP-1 attenuates the acceleration of gastric emptying induced by hypoglycaemia in healthy subjects.
Materials and methods: Ten healthy subjects (5M:5F, age 69±1.7y, BMI 26±1 kg/m^2), were studied on 4 days in a randomised double-blind fashion. Following an overnight fast, blood glucose was stabilised using a glucose/insulin clamp at either hypoglycaemia (hypo; blood glucose 2.6mmol/L) or euglycaemia (eu; 6.0mmol/L) between T=-15 to 45min before clamping at 6.0mmol/L until 180min. During hypoglycaemia and euglycaemia each subject received intravenous GLP-1 (1.2pmolkg/min) or placebo between T=-60 to 180min. At T=0min subjects ingested 100g of minced beef (25g protein, 21g fat, ~270Kcal), labelled with 20MBq ^{99m}Technetium-sulphur-colloid. Gastric emptying was measured scintigraphically with 1 min images acquired until T=180min. The area under the curve (AUC) for gastric emptying (T=0-180min) was analysed using one-way RM-ANOVA with Bonferroni-Holm adjusted posthoc tests.
Results: Results are shown in the figure as mean ± SE. The studies were well tolerated and blood glucose concentrations were stabilised at the proposed levels. Gastric emptying was accelerated during hypoglycaemia (hypo/placebo vs eu/placebo; P<0.001), and administration of exogenous GLP-1 markedly slowed gastric emptying during euglycaemia (eu/placebo vs eu/GLP-1; P<0.001). During GLP-1 infusion gastric emptying was faster during hypoglycaemia than euglycaemia (hypo/GLP-1 vs eu/GLP-1; P<0.008). However, the hypoglycemia-induced acceleration of gastric emptying on placebo was attenuated by GLP-1 (hypo/placebo vs hypo/GLP-1; P<0.008) and there was no significant difference between gastric emptying during euglycaemia on placebo compared with hypoglycaemia after administration of GLP-1 (eu/placebo vs hypo/GLP-1; P = 0.52).
Conclusion: In health the acceleration of gastric emptying induced by hypoglycaemia is attenuated by exogenous GLP-1. This observation may be of particular relevance to the counter-regulatory response to hypoglycaemia with the combined use of GLP-1 agonists and basal insulin.

GLP-1 and liraglutide increase the platelet inhibitory effects of nitric oxide

I. Russo, C. Barale, L. Mattiello, F. Cavalot, M. Trovati;
Internal Medicine and Metabolic Disease Unit, Department of Clinical and Biological Sciences, University of Turin, Orbassano - Turin, Italy.

Background and aims: Glucagon-like peptide-1 (GLP-1) exerts metabolic and cardiovascular actions. After its secretion, GLP-1(7-36) amide is rapidly truncated by dipeptidyl peptidase-4 to GLP-1(9-36) amide, the major circulating form of GLP-1, unable to interplay with GLP-1 receptor (GLP-1R). Defective GLP-1 synthesis and action occur in type 2 diabetic patients and incretin drugs are increasingly used in their therapy. GLP-1 exerts beneficial effects on heart and endothelium: its effects on platelets -which play a major role in diabetes vascular complications- are unknown. Aim of the study is to investigate the effects of GLP-1(7-36), GLP-1(9-36) amides and GLP-1 analogue Liraglutide on platelet sensitivity to agonists and to the anti-aggregating pathway nitric oxide (NO)/cGMP/Vasodilator-Stimulated Phosphoprotein (VASP).
Materials and methods: In platelet-rich plasma and washed platelets from 38 healthy subjects (M/F 23/15; age: 22.7±6.6 years; body mass index: 21.6±2.3 kg/m2) we measured the effects of a 10-min pre-incubation with 100 nmol/l GLP-1(7-36), or GLP-1(9-36) or Liraglutide on: i) platelet aggregation to ADP (10 micromol/l) and to collagen (4 mg/l), ii) cGMP synthesis (ELISA), and iii) expression of VASP phosphorylated (pVASP) at ser-239 (western blot), in the absence or in the presence of the NO donor sodium nitroprusside (SNP) (1-5 micromol/l, 5min). Experiments were repeated with GLP-1R antagonist Exendin (9-39) (100 nmol/l).
Results: GLP-1(7-36), GLP-1(9-36) and Liraglutide did not influence platelet aggregation to agonists, cGMP synthesis and pVASP ser-239 expression.

They increased, however, the inhibitory effects of SNP. In particular, the percent inhibition of the ADP-induced aggregation in the presence of SNP alone, SNP+GLP-1(7-36), SNP+GLP-1(9-36) and SNP+Liraglutide were 34.7±10.3, 56.1±11.9, 55.6±11.6 and 53.6±13.0, respectively (p<0.0001 vs SNP alone for all the incretin preparations); the percent inhibition of the collagen-induced aggregation in the presence of SNP alone, SNP+GLP-1(7-36), SNP+GLP-1(9-36) and SNP+Liraglutide was 35.1±12.6, 62.1±13.6, 60.7±12.4 and 50.7±21 (p<0.0001 vs SNP alone for all the incretin preparations). The increased platelet response to SNP was attributable, at least in part, to the increased cGMP synthesis/action: actually, i) the percent increase of cGMP concentrations with SNP alone, SNP+GLP-1(7-36), and SNP+GLP-1(9-36) were 92.6±42.8, 171.1±80.2 (p<0.01 vs SNP alone) and 197.3±92.9 (p<0.04 vs SNP alone); ii) the percent increase of SNP-induced pVASP ser-239 expression with SNP alone, SNP+GLP-1(7-36), SNP+GLP-1(9-36) and SNP+Liraglutide were 198.6±74.5, 371.1±94.4 (p<0.001 vs SNP alone), 423±93.9 (p<0.0001 vs SNP alone), and 398.6±75.7 (p<0.005 vs SNP alone), respectively. Pre-incubation with Exendin(9-39) did not modify GLP-1(7-36), GLP-1 (9-36) and Liraglutide influence on the platelet inhibitory effects exerted by SNP.

Conclusion: In platelets from healthy subjects GLP-1 increases platelet sensitivity to NO via GLP-1R-independent mechanisms. This beneficial effect of GLP-1 induces to hypothesize that its defective synthesis/action play a role in the impairment of platelet sensitivity to NO observed in type 2 diabetes, and that this impairment could be attenuated by incretin therapy.

Exploring the potential of dapagliflozin in type 1 diabetes: phase 2a pilot study

R.R. Henry[1], J. Rosenstock[2], A.-G. Chalamandaris[3], S. Kasichayanula[4], A. Bogle[4], S. Griffen[4];
[1]University of California, San Diego, La Jolla, [2]Dallas Diabetes and Endocrine Center, Dallas, USA, [3]Bristol-Myers Squibb, Braine-l'Alleud, Belgium, [4]Bristol-Myers Squibb, Princeton, USA.

Background and aims: Intensive insulin therapy for type 1 diabetes (T1D) is associated with weight gain and is often insufficient in maintaining glycaemic control. Dapagliflozin (DAPA), an insulin-independent sodium glucose cotransporter 2 inhibitor that increases urinary glucose excretion, has shown antihyperglycaemic efficacy in type 2 diabetes. This 2-week randomised, double-blind, placebo-controlled, Phase 2a study evaluated DAPA added to insulin in patients with suboptimally controlled T1D.

Materials and methods: Adult patients on stable insulin ≥12 months with HbA_{1c} 7-10% (baseline mean 8.5%) were randomised to receive DAPA (1, 2.5, 5, or 10 mg) or placebo once daily for 14 days (Days -3 to 7 as inpatients). DAPA pharmacokinetics/pharmacodynamics, including continuous glucose monitoring (CGM) and 24-hour urine glucose, was assessed at Day 7.

Results: Seventy patients were randomised to treatment; 62 (88.6%) completed the trial. As expected, there was a dose-dependent increase in urine glucose with DAPA. CGM data suggested a potential for reduced glycaemic levels and diminished glycaemic variability with DAPA. Marked reductions in total daily insulin dosing at Day 7 were reported for DAPA 5 mg (-19%) and 10 mg (-16%). Hypoglycaemia was common in all treatment groups; 1 event (DAPA 10 mg) was major and led to discontinuation. The incidence of adverse events (AEs) was 38.5% to 61.5%; there was 1 non-treatment-related serious AE (DAPA 5 mg) and no deaths.

		Placebo + insulin (n=10 to 13)	DAPA 1 mg + insulin (n=10 to 13)	DAPA 2.5 mg + insulin (n=11 to 15)	DAPA 5 mg + insulin (n=13 to 14)	DAPA 10 mg + insulin (n=9 to 15)
Hypoglycaemia (%)	No. pts (%) with =1 event	8 (61.5)	12 (92.3)	9 (60.0)	11 (78.6)	10 (66.7)
24 h urine glucose excretion	Baseline, g/24h ± SD	30.7 ± 52.0	6.6 ± 6.5	12.1 ± 12.3	11.2 ± 10.9	11.9 ± 14.3
	Day 7, g/24h ± SD	9.0 ± 7.5	48.5 ± 20.8	60.8 ± 38.2	83.6 ± 47.9	99.7 ± 58
	Mean change from baseline, g/24h (95% CI)	-21.6 (-54.4, 11.1)	41.9 (27.6, 56.1)	48.5 (28.1, 69.0)	72.4 (47.0, 97.9)	88.8 (55.2, 122.5)
24 h glucose/CGM daily average	Baseline, mmol/L ± SD	9.6 ± 2.4	9.0 ± 1.7	9.7 ± 2.3	9.6 ± 1.8	9.7 ± 2.5
	Day 7, mmol/L ± SD	8.5 ± 2.3	8.1 ± 1.1	9.1 ± 2.1	8.0 ± 2.8	7.7 ± 1.9
	Mean change from baseline, mmol/L (95% CI)	-1.1 (-3.6, 1.4)	-0.9 (-2.1, 0.4)	-0.8 (-2.6, 1.1)	-1.6 (-2.6, -0.7)	-2.3 (-3.7, -0.9)

Conclusion: DAPA was generally well tolerated in this T1D population. Further studies to determine the potential benefit of DAPA as treatment of T1D are warranted.

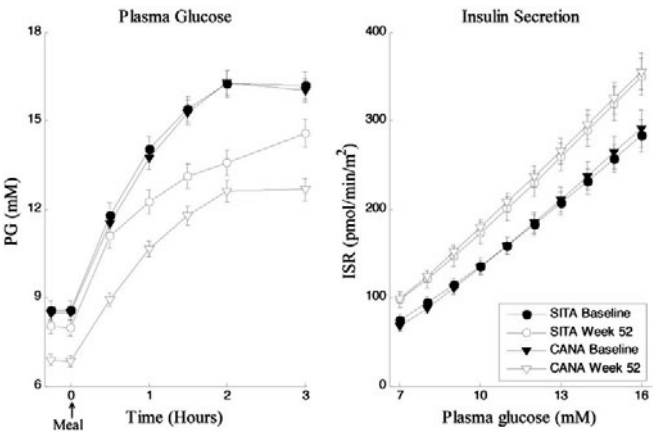
Effects of one-year treatment with canagliflozin or sitagliptin on glycaemic control and beta cell function measures in subjects with type 2 diabetes on metformin + sulfonylurea

G. Schernthaner[1], E. Ferrannini[2], A. Mari[3], C. Tong[4], M. Kawaguchi[4], G. Meininger[4], D. Polidori[4];
[1]Rudolfstiftung Hospital-Vienna, Austria, [2]University of Pisa School of Medicine, [3]National Research Council Institute of Biomedical Engineering, Padova, Italy, [4]Janssen R&D, LLC, Raritan, USA.

Background and aims: Canagliflozin (CANA), an SGLT2 inhibitor, and sitagliptin (SITA), a DPP-4 inhibitor, lower plasma glucose (PG) by different mechanisms. CANA lowers PG by increasing urinary glucose excretion, whereas SITA increases active concentrations of the incretin hormones GLP-1 and GIP. The aim of this analysis was to compare the effects of CANA and SITA treatment on fasting and postprandial glucose (PPG) control and measures of β-cell function (βCF) in subjects with type 2 diabetes mellitus (T2DM) with inadequate glycaemic control on metformin + sulfonylurea (MET + SU).

Materials and methods: Data were obtained during a 52-week Phase 3 study comparing the effects of CANA 300 mg and SITA 100 mg as add-on therapy in subjects with T2DM with inadequate glycaemic control on MET + SU (mean baseline characteristics: age = 57 y; HbA_{1c} = 8.1%; body weight = 88 kg; BMI = 32 kg/m^2). A subset of subjects (n = 249) in the study underwent a 3-hr frequently-sampled mixed-meal tolerance test (FS-MMTT), scheduled at baseline and Week 52. During the FS-MMTT, PG, insulin, and C-peptide were measured at several time points. PG control was assessed using fasting PG (FPG), mean PG during the FS-MMTT (MPG; calculated over t = 0-3 hr), and mean incremental (above fasting) PG during the FS-MMTT (MiPG). βCF was assessed using a model-based approach that calculates the insulin secretion rate (ISR) from deconvolution of measured C-peptide and relates ISR to PG. Calculated βCF parameters included ISR at 9 mM glucose and β-cell glucose sensitivity (the slope of the ISR vs PG relationship). Subjects with FS-MMTT data at both visits (n = 135) were included in the analysis. Statistical comparisons were made using ANCOVA with baseline value as a covariate.

Results: Both CANA and SITA reduced FPG and PPG compared to baseline (Figure). Greater reductions in both FPG (mean [SE] ΔFPG = -1.6 [0.2] mM with CANA vs -0.6 [0.3] mM with SITA; p<0.001) and MPG (ΔMPG = -3.1 [0.3] mM with CANA vs -1.8 [0.4] mM with SITA; p<0.001) were observed with CANA than with SITA, whereas both treatments had generally similar reductions in incremental PG excursions (ΔMiPG = -1.5 [0.2] mM with CANA vs -1.2 [0.2] mM with SITA; p=0.2). Both treatments shifted the ISR vs PG relationship (Figure) and provided similar increases in ISR at 9 mM (ΔISR at 9 mM = 41 [7] pmol/min/m^2 with CANA vs 31 [11] pmol/min/m^2 with SITA; p=0.4). Small numerical increases in mean β-cell glucose sensitivity were observed with both treatments, but these changes were not statistically significant.



Conclusion: After one year of treatment with CANA or SITA in subjects with T2DM who have inadequate glucose control with MET + SU, CANA provided greater reductions in FPG and MPG than observed with SITA. Both treatments provided similar improvements in measures of βCF.

Synergistic glucose-lowering effects of SGLT1- and ASBT-inhibitor combinations in ZDF rats
A.A. Young, Y. Liu, J. McNulty, D. Cowan, J. Collins, B. Dobbins, M. Bishop, L. Chen;
GlaxoSmithKline, RTP, USA.

Background and aims: The profound, rapid, and weight-independent antidiabetic effects of bariatric surgery affirm the promise of modulating gastrointestinal function for therapeutic purposes. We have previously demonstrated separate glucose-lowering effects of inhibitors of the sodium-glucose cotransporter 1 (SGLT1) and the apical sodium-dependent bile acid transporter (ASBT) in human and/or animal studies.
Materials and methods: A potential synergy between SGLT1 inhibition and ASBT inhibition was tested in male Zucker-fatty diabetic rats using a novel dose-ratio scanning method. First, equi-effective (ED30) glucose-lowering doses of an SGLT1 inhibitor (KGA2727; 0.5 mg/kg bid) and an ASBT inhibitor (GSK2299027; 0.14 mg/kg bid) were determined by dose-response analysis of each agent.
Results: At high doses, both KGA2727 and GSK2299027 significantly decreased blood glucose. In subsequent studies, a maximally effective dose of an ASBT inhibitor (264W94) reduced plasma [glucose] to 196 ± 33 mg/dL versus 341 ± 24 mg/dL in vehicle controls. A series of 9 combination treatments in ZDF rats (n=16 rats each), the subtraction of one agent was made up by the addition of the other, were conducted at the same time. With a 50%-of-ED30 + 50%-of-ED30 mixture (KGA2727, 0.25 mg/kg; GSK2299027, 0.07 mg/kg), maximal effect was attained (plasma [glucose] 192 ± 29 mg/dL) without evidence of correlated increases in cecum weight, fecal water content, or fecal bile acid excretion.
Conclusion: In summary, we demonstrate synergy of the glucose-lowering, but not the adverse effects of distinct gastrointestinal mechanisms (ASBT and SGLT1 inhibition), each capable of being invoked by agents restricted to the gut lumen.

LX2761, an SGLT1 inhibitor restricted to the intestine, improves glycaemic control in mice
D.R. Powell[1], M. Smith[1], D. Doree[1], A. Harris[1], J. Greer[1], C. DaCosta[1], A. Thompson[1], S. Jeter-Jones[1], N. Goodwin[2], B. Harrison[2], E. Strobel[2], F. Mseeh[1], A. Sands[1], B. Zambrowicz[1], Z.-M. Ding[1];
[1]Lexicon Pharmaceuticals, Inc., The Woodlands, [2]Lexicon Pharmaceuticals, Inc., Princeton, USA.

Background and aims: LX2761, an orally available small molecule with IC50 = 2 nM vs both hSGLT1 and hSGLT2, was designed to improve glycemic control by remaining in the intestine (Int) to inhibit SGLT1-mediated glucose (G) absorption and to trigger release of glucagon-like peptide 1 (GLP1). Studies were performed to test the ability of LX2761 to achieve these endpoints.
Materials and methods: Study 1 asked if LX2761 is absorbed by the Int, by measuring 24-hr urine G excretion (UGE) in healthy wild type (WT) mice after 1 oral dose of LX2761. Studies 2-5 asked how multiple once-daily oral doses of LX2761 affect glycemic control: study 2 asked if a meal challenge containing 9.2 g G raises cecal G and serum GLP1 in WT mice 7 hr after their 4th LX2761 dose; study 3 asked if G tolerance (GT) during an oral GT test (oGTT; 4 g/kg G) is improved in WT mice 15 hr after their 4th LX2761 dose; study 4 asked if GT (2 g/kg G) and HbA1c are improved in KKA^y diabetic mice after 30 days of LX2761; and study 5 asked if GT (2 g/kg G) and HbA1c are improved, and if an oral G bolus raises cecal G and serum GLP1, in STZ diabetic mice treated with LX2761 for 7 weeks.
Results: Data from studies 1-4 are shown in the Table below. Study 5 found that STZ diabetic mice receiving 3 mg/kg/day LX2761: 1) showed improved GT (G AUC of 38 ± 10 g/dL•min vs vehicle G AUC of 65 ± 3 g/dL•min, p<0.001); 2) had lower HbA1c (decrease from baseline of 0.9 ±1.6 % vs vehicle increase from baseline of 0.9 ±1.4 %, p<0.05); and 3) showed, 2 hours after a 2 g/kg oral G bolus, higher postprandial cecal G (1.4 ± 0.8 mg vs vehicle 0.2 ± 0.1 mg, p<0.01) and higher postprandial serum tGLP1 (103 ± 28 pM vs vehicle 66 ± 5 pM, p<0.05).
Conclusion: 1) In LX2761-treated WT mice, low UGE suggests that Int absorption of LX2761 is trivial; 2) In LX2761-treated WT and STZ diabetic mice, oral G raises cecal G and serum GLP-1 levels, and improves GT, suggesting that LX2761 inhibits Int SGLT1; and 3) In LX2761-treated KKA^y and STZ diabetic mice, improved GT and lower HbA1c suggest that LX2761 significantly improves glycemic control. Overall, these data demonstrate that LX2761 significantly improves glycemic control via local inhibition of Int SGLT1.

LX4211, a dual SGLT1/SGLT2 inhibitor, decreases body weight and triglycerides in patients with type 2 diabetes mellitus and elevated baseline values
B. Zambrowicz, P. Lapuerta, I. Ogbaa, P. Banks, K. Frazier, K.A. Boehm, M. Kelly, A. Sands;
Lexicon Pharmaceuticals, Inc., The Woodlands, USA.

Background and aims: LX4211 reduced intestinal glucose absorption and enhances GLP-1 and PYY release in the gastrointestinal tract through inhibition of SGLT1. In addition, LX4211 increases urinary glucose excretion through inhibition of SGLT2 in the kidney.
Materials and methods: In this dose-ranging study, 299 patients with type 2 diabetes mellitus (T2DM) and inadequate glycemic control on stable dose metformin monotherapy were treated with LX4211 (75 mg qd, 200 mg qd, 200 mg bid or 400 mg qd) or placebo for 12 weeks. The primary endpoint was hemoglobin A1C (A1C). Secondary endpoints included body weight (BW) and triglycerides (TG). LX4211 produced significant decreases in A1C, fasting plasma glucose, blood pressure, and BW. Patients were subgrouped based on baseline BW and TG to further explore the effect of LX4211 on these parameters.
Results: For patients with a baseline BMI (body mass index) of ≥30 kg/m^2, LX4211 produced a significant reduction in BW at Week 12 relative to baseline (-0.91 kg, -1.84 kg, -2.89 kg, -1.97 kg, and -0.44 kg for 75 mg qd, 200 mg qd, 200 mg bid, 400 mg qd, and placebo arms, respectively; p<0.001 for the top 3 dose arms vs. placebo). For subjects with elevated baseline TG (≥2.26 and <5.65 mmol/L), LX4211 treatment resulted in significant reductions in TG relative to baseline in 3 of the treatment arms (-0.76 mmol/L -0.55 mmol/L, and -0.92 mmol/L for 75 mg qd, 200 mg bid, and 400 mg qd arms, respectively; p<0.05 for all 3 arms). A reduction of -0.41 mmol/L (NS) was observed in the placebo arm.
Conclusion: Treatment with LX4211 reduced BW and TG in T2DM patients with elevated baseline values, and these results merit further investigation in future trials.
Clinical Trial Registration Number: NCT01376557

The effect of ipragliflozin on the total glucose turnover after OGTT in healthy subjects and patients with type 2 diabetes mellitus
R.A. Smulders[1], S. Leeflang[1], F. Schliess[2], T. Jax[2], E. Kurosaki[3], T. Kadokura[3];
[1]Astellas Pharma Europe BV, Leiden, Netherlands, [2]Profil, Neuss, Germany, [3]Astellas Pharma Inc., Tokyo, Japan.

Background and aims: Sodium Glucose co-Transporter 2 (SGLT2) accounts for about 90% of renal of glucose reabsorption. Ipragliflozin is a novel selective SGLT2 inhibitor, which increases urinary glucose excretion (UGE), thereby reducing plasma glucose levels in patients with Type 2 diabetes mellitus (T2DM). This study investigated the effect of ipragliflozin on the total glucose turnover in healthy subjects (HS) and patients with T2DM.
Materials and methods: Twelve HS (age 46.1 yrs (sd 8.69)) and 12 T2DM patients (age 59.0 (6.16)) received ipragliflozin 100 mg or placebo once daily for 6 days in a 2 period crossover design. In each period an OGTT with a

double-tracer methodology (oral administration of [$_{13}C_6$]-labeled glucose during a [6,6-$^2H_2$]-glucose intravenous infusion) was performed at baseline (Day -1) and on Day 6. The amounts of glucose absorbed from the gut and disappearing from the circulation, as well as the UGE and the endogenous glucose production (EGP) were determined.
Results: Baseline EGP (EGP_{basal}) was lower in HS compared to T2DM patients (11.2 (1.0) vs 12.7 (1.6) µmol/min/kg). The baseline EGP increased after ipragliflozin compared to placebo in HS and in T2DM patients (P<0.05; +0.68 (1.5) and +0.91 (1.4) µmol/min/kg, respectively). During the OGTT the mean $EGP_{0\text{-}6h}$ in HS and in T2DM patients was 6.0 (1.2) and 4.1 (0.5) µmol/min/kg, respectively. The OGTT-related decrease from baseline was less with ipragliflozin than with placebo (P< 0.01) without any difference between the subject groups. At baseline in HS the total amount of glucose appearing in the circulation in 6 hours after the OGTT was 107.2 g of which 80.6 g resulting from the uptake via the gut and 26.7 g resulting from EGP. During the same time period 107.1 g disappeared from the circulation. There was no relevant UGE. In T2DM patients 107.1 g appeared in the circulation of with 88.6 g resulting from uptake from the gut, and 18.4 g from EGP. 107.5 g of glucose disappeared from the circulation of which 99 g was distributed into tissues and only a small portion excreted via urine (8.5 g). After 6 days of ipragliflozin treatment, in HS the total amount of glucose appearing in the circulation in 6 hours after the OGTT was 110 g, with 81.4 g resulting from the uptake via gut and 28.6 g from EGP. During the same time period, 108.1 g of glucose disappeared from the circulation. The majority of disappearing glucose (92.3 g) was distributed into the tissues while a smaller portion (15.8 g) was excreted via urine. In T2DM patients, the total amount of glucose appearing in the circulation in 6 hours after the OGTT was 110.7 g, with 87.9g resulting from the uptake via gut and 22.7g from EGP. During the same time period, 111.4 g of glucose disappeared from circulation. The majority of disappearing glucose (78.5 g) was distributed into the tissues and a considerable portion (32.9 g) was excreted via urine.
Conclusion: Ipragliflozin increased EGP_{basal} both in HS and patients with T2DM as a result of an increased UGE. After an OGTT the total amount of glucose absorbed from the gut and the EGP did not change through ipragliflozin, neither in HS nor in T2DM patients. Ipragliflozin increased UGE-which led to a reduced tissue glucose distribution.

A novel GLP-1/glucagon co-agonist peptide exhibits improved glucose-lowering and insulinotropic actions in diet induced obese diabetic mice
V.A. Gault, V.K. Bhat, P.R. Flatt;
School of Biomedical Sciences, University of Ulster, Coleraine, UK.

Background and aims: Patients with type 2 diabetes frequently require a range of anti-hyperglycaemic agents to successfully maintain glycaemic control and thus there is demand to develop novel and effective combination strategies. One approach is to generate incretin-glucagon co-agonist peptides combined within a single molecule to improve stability and maximise therapeutic efficacy. In this study we developed a novel GLP-1/glucagon peptide based on [DA^2]GLP-1 comprising mid-chain substitution with human glucagon at residues S^{12}-F^{22}. Biological properties of [DA^2]GLP-1/GcG were assessed *in vitro* and in a mouse model of diet induced obesity-diabetes.
Materials and methods: GLP-1, glucagon, exendin-4 and [DA^2]GLP-1/GcG (95% purity) were incubated (0, 2, 4 and 8 h; 5 g) with DPP-IV (5 mU; n=3) to determine enzyme stability and with BRIN-BD11 cells to evaluate insulin secretion and intracellular Ca^{2+} (20 min; n=8). cAMP production (n=4) was examined using GLP-1-R and glucagon-R transfected cells. Acute and persistent effects of peptides (25 nmol/kg bw; *ip*) on plasma glucose and insulin concentrations were examined in NIH *Swiss* high-fat fed (HFF) and GLP-1-R and GIP-R knockout mice (n=8). For longer-term studies, groups of HFF mice (n=8) received twice-daily injections (09:00 and 16:00 hr) of saline vehicle (0.9% w/v NaCl), exendin-4 or [DA^2]GLP-1/GcG (each at 25 nmol/kg bw; *ip*) for 21 days. Food intake, body weight, non-fasting plasma glucose and insulin concentrations were monitored every 2 to 4 days. Glucose tolerance (18 mmol/kg bw; *po*) and insulin sensitivity (25 U insulin/kg bw; *ip*) tests were performed at the end of the study.
Results: Native peptides were rapidly degraded by DPP-IV, however [DA^2] GLP-1/GcG remained intact during the incubation (half-life > 8h). [DA^2] GLP-1/GcG concentration-dependently (10^{-12} to 10^{-6}M) stimulated insulin secretion (1.2 to 1.7 fold; P<0.001), intracellular Ca^{2+} (1.5-fold; P<0.05) and cAMP production. Acute administration of [DA^2]GLP-1/GcG significantly lowered plasma glucose (14% reduction; P<0.05) and increased plasma insulin concentrations (1.4-fold; P<0.05) in HFF mice. Furthermore, [DA^2] GLP-1/GcG elicited a significantly protracted glucose-lowering effect (29% reduction; P<0.05) and insulinotropic response (1.4 to 1.8-fold; P<0.001) when administered 8 hours prior to a glucose load in HFF mice. Twice-daily administration of [DA^2]GLP-1/GcG for 21 days decreased body weight (4% reduction; P>0.05), non-fasting plasma glucose (40% reduction; P<0.05) and increased non-fasting plasma insulin concentrations (1.2 to 1.3-fold; P<0.05 to P<0.001) compared to saline-treated controls. Furthermore, [DA^2]GLP-1/GcG improved oral glucose tolerance (21% reduction; P<0.05), glucose-mediated insulin secretion (1.2-fold; P<0.01) and insulin sensitivity (46% reduction; P<0.001). Food intake remained unchanged during the study. Interestingly, [DA^2]GLP-1/GcG treatment resulted in significantly improved insulinotropic responses (1.2-fold; P<0.05) compared to exendin-4. Studies in GLP-1R and GIP-R knockout mice confirmed primary action of [DA^2] GLP-1/GcG via the GLP-1-R.
Conclusions: Ability of [DA^2]GLP-1/GcG to improve glucose homeostasis and insulin secretion in HFF mice suggests significant promise for novel GLP-1/glucagon hybrid peptides as therapies in obesity-diabetes.

Apical sodium-dependent bile acid transport inhibitors (ASBTi) exhibit potent antidiabetic activity in ZDF rats
B. Gedulin, S. Nikoulina, G. Gedulin, N. Nazarenkov, B. Keller;
Lumena Pharmaceuticals Inc., San Diego, USA.

Background and aims: Bile acids (BAs) are recognized as important regulators of metabolism. Free BAs in the distal gut bind TGR5 and stimulate secretion of GLP-1 and other active peptides from enteroendocrine L-cells. One approach to increase free BAs in the distal gut is to block BA recycling with an ASBT inhibitor. In the present study, we used the Zucker Diabetic Fatty (ZDF) rat model of Type 2 diabetes to test the hypothesis that ASBTi treatment will

increase BAs in the large intestine, stimulate GLP-1 release and elicit an anti-diabetic response as measured by markers of glucose metabolism.

Materials and methods: Two structurally distinct, minimally-absorbed ASBTi's, LUM002 and SC-435 (in vitro IC50 =0.6 nm and 12.2 nm respectively), were administered to 8-wk old ZDF rats by twice daily oral gavage at doses of 0, 0.1, 1, 10 and 30 mg/kg. The rats (n=3-8/group) were initially randomized by plasma HbA1c and glucose values. Feces were collected (24 hr) on day 10 for fecal BA analysis and weekly blood samples were drawn for analysis of plasma markers. At 3 wks, OGTTs were performed on fasted animals in the 0, 0.1 and 10 mg/kg groups.

Results: Oral dosing of LUM002 and SC-435 increased 24hr fecal BA concentrations up to 4-fold (P<0.01) and decreased total plasma BAs by 30-60% (P<0.05) across all doses compared to the vehicle group. Steady-state non-fasting plasma total GLP-1 was increased up to 50% by LUM002 (P<0.05); SC-435 showed a trend for increases in GLP-1 that did not attain statistical significance. During the 3-wk study, vehicle-treated rats developed progressive hyperglycemia with increases in both plasma glucose (55.6±5.03%) and HbA1c (1.70±0.27%). Treatment with both ASBTi's caused dose-dependent reductions in plasma glucose up to 57.6% (P<0.01). The compounds also significantly attenuated the increase in percent HbA1c observed in the vehicle animals (see figure). Insulin secretion stimulated during OGTT was enhanced 3- and 2-fold with LUM002 and SC-435, respectively (P<0.05 for both) and resulted in up to 57% reduction in glucose excursion vs. vehicle when calculated as AUC. (P<0.05 for 0.1 and 10 mg/kg doses of LUM002; P<0.05 for 10 mg/kg SC-435.) Both in vitro and in vivo data suggest that LUM002 is about 10-fold more potent than SC-435.

Conclusion: Our results confirm that two distinct structural classes of ASBT's increase BA flux into the distal gut, promote GLP-1 release and improve glycemic control in ZDF rats. Thus, ASBTi may offer a new therapeutic approach for treating diabetes/metabolic disease.

HM11260C, a new generation long acting GLP-1R agonist with a unique pharmacokinetic profile improves glucose control and GI tolerability; a phase IIa clinical trial in type 2 diabetes mellitus

J. Kang[1], S. Choi[1], I. Choi[2], S. Kwon[2], M. Trautmann[3], K. Yoon[4], J. Son[1]; [1]Hanmi Pharmaceuticals Co., Ltd, Seoul, [2]Hanmi Pharmaceuticals Co., Ltd, Hwaseong-si, Republic of Korea, [3]Profil Institute, Chula Vista, USA, [4]The Catholic University of Medicine, Seoul, Republic of Korea.

Background and aims: A very long T1/2(~ 180 hrs) and no burst absorption (Tmax:: ~144 hrs) of HM11260C, a novel long acting GLP-1R agonist, was confirmed in previous single ascending dose study in T2DM. The aim of study is to investigate safety, tolerability, PK and PD of Langlenatide when treated with multiple doses.

Materials and methods: Patients with T2DM who participate in this double-blinded, randomized, placebo controlled trial are on stable Metformin monotherapy at study start. Subjects were randomized 3:1 to HM11260C or placebo injections. HM11260C was administered subcutaneously over an 8-week for weekly regimens or a 9-week for monthly regimens. PK was assessed up to 35 days after the last dose. PD endpoints include the markers of metabolic control, and changes in body weight (BW). Tolerability and safety are determined with AEs, vital signs, laboratory and ECG.

Results: Data through Day 57 from 48 patients in W1 (1 mg/wk), W2 (2 mg/wk), W3 (4 mg/wk), M1 (8 mg/mo) and M2 (12 mg/mo) are reported. Key demographics were (active vs placebo; mean [SD]): age, 53.3 [7.0] vs 52.9 [8.7] years; HbA1c, 8.4 [1.0] vs 8.1 [0.9] %. At Day 57, patients treated with weekly regimens or monthly regimens experienced clinical significant improvements from baseline HbA1c, fasting plasma glucose, body weight compared with placebo. Most common AEs were nausea, vomiting and diarrhea and were mild or moderate. Weekly regimen showed fewer GI AEs and most events were reported after first injection. No notable safety signal was apparent for laboratory parameters, vital sign or ECG. At weekly cohorts, absorption rate was indicated by a T_{max} of 109 ~ 128 hrs and elimination rate was indicated by a $T_{1/2}$ of 153~ 156 hrs. The accumulation ratio (around 3.5) was consistent with elimination kinetics and did not show relevant differences between the cohorts. The peak-to-trough ratio was 1.4. At M1 cohort, the T_{max} was 129 hrs and the $T_{1/2}$ was 162 hrs. The accumulation ratio was 1.1 and the peak-to-trough ratio was 10.4.

Conclusion: From this study, with the demonstrated unique pharmacokinetic profiles, HM11260C shows meaningful improvements in blood glucose control and good tolerability after repeated treatment in all weekly and monthly cohorts. Further development of HM11260C is warranted to explore its full potential as mono and combination therapy in patients with T2DM.

Sitagliptin improves blood glucose control by suppressing glucagon secretion in insulin-treated type 2 diabetic patients

Y. Otsuka, M. Kosuda, N. Ueno, S. Yamaguchi, M. Nakazaki, H. Ishihara; Division of Diabetes and Metabolic Diseases,Nihon University School of Medicine, Tokyo, Japan.

Background and aims: Amelioration of blood glucose control by DPP-4 inhibitors is reportedly accompanied by increased insulin release and suppressed glucagon secretion in drug naïve diabetic patients and patients treated with oral hypoglycemic agents. DPP-4 inhibitors are also demonstrated to improve blood glucose control in patients supplemented with insulin by multiple daily insulin injection. However, islet hormone changes in response

to DPP-4 inhibitors and thus glucose lowering mechanisms of DPP-4 inhibitors are not fully examined in insulin-treated patients.
Materials and methods: Sixteen patients with type 2 diabetes (age: 61.4 ± 10.9 years old, duration of diabetes 18.7 ± 8.1 years, BMI 23.8 ± 3.2 kg/m^2, HbA1c:8.35 ± 0.74%) treated with multiple daily injections of insulin (total daily dose of insulin: 33.8 ± 12.2 units) without any hypoglycemic reagents were randomly assigned to 750 mg metformin or 50 mg sitagliptin addition. Insulin dose would be fixed unless hypoglycemia occurred and other drugs, such as antihypertensive and antilipidemic agents, were not changes throughout the study. At 0, 4, 8 and 12 weeks of the study, patients were subjected to meal (450 Kcal, 17.2 g protein, 16.6 g fat, 57.6 g carbohydrate)-tolerance tests (MTT). Blood glucose, C-peptide and glucagon levels were determined at 0,15, 30, 60, 90 and 120 min after the meal loads.
Results: Dose of insulin has not changed since there was no hypoglycemia event during the study. Both sitagliptin and metformin reduced HbA1c levels after the 12-week treatment (sitagliptin: -0.81% (95% CI -0.35 ~ -1.28%), metformin: -0.86% (-0.40 ~ -1.33), P < 0.001 for both). After 12 weeks, fasting glucose, C-peptide and glucagon levels were unaltered in both groups. Glucose excursion during MTT was reduced in both groups: AUC of plasma glucose was lowered from 620.8 mg*h/dl to 491.0 for sitagliptin (P < 0.05) and 497.4 to 446.0 for metformin (P < 0.05). C-peptide responses were unaltered by sitagliptin addition but slightly increased by 12.9% (P = 0.035) in insulin-treated patients with additional metformin. AUC for glucagon responses were reduced by -15.34% (P <0.001) after 12 weeks in the sitagliptin group but showed minimal changes in the metformin group (-6.3%, P = 0.07). When data from patients of the two groups were combined, analysis of covariance revealed that suppression of glucagon secretion was a determinant of reduced HbA1c levels. There were no changes in body weight in both groups.
Conclusion: Our findings indicate that sitagliptin and metformin achieve blood glucose control though different effects on islet function in type 2 diabetes patients treated with multiple daily insulin injections: sitagliptin suppresses glucagon secretion while metformin exerts minimal effects on islet function. Our data also suggest that reduction of glucagon secretion is one of factors contributing plasma glucose control in insulin-treated patients, highlighting glucagon secretion as a therapeutic target of diabetes mellitus.

Exenatide suspension, a novel exenatide formulation, improves insulin sensitivity 28 days after a single injection in diabetic fatty Zucker rats
P. Smith, J. Hoyt, J. Athanacio, C. Villescaz, C. Jodka, D. Parkes;
Bristol-Myers Squibb, San Diego, USA.

Background and aims: Extended release (once-weekly) exenatide (EQW) is approved for the treatment of T2DM. Exenatide suspension uses the same extended-release microspheres as EQW but is reformulated with a medium chain triglyceride vehicle with a history of safe use in humans. This formulation was developed to 1) yield a presuspended product not requiring reconstitution of microspheres just prior to injection as with EQW, 2) be compatible with an easier-to-use pen device. The present study assessed the pharmacodynamic effects of a single SC injection of exenatide suspension (ExS) in diabetic fatty Zucker (ZDF) rats, a model of type 2 diabetes.
Materials and methods: 10-week-old male ZDF rats with matched initial HbA1c values (n=8-9/group) received a single SC injection of ExS (0, 0.003, 0.03, 0.3, 1 and 3 mg/rat) or 1mg/rat EQW. Food intake was measured daily; body weight, HbA1c and PK exposure were measured on days 0, 10, 20 and 28; overnight fasting glucose on days 0, 10 and 28; glomerular filtration rate, creatinine and glucose excretion on day 20; insulin sensitivity, assessed as the glucose infusion rate required to maintain euglycemia during a hyperinsulinemic-euglycemic clamp, and glucose-stimulated β-cell secretion, assessed by changes in plasma C-peptide after an IVGTT, on day 28.
Results: Single injections of ExS evoked dose-dependent reductions in total food intake (756±40, 757±74, 733±49, 667±61, 578±34, 534±36, 526±39 g; *P*<0.0001 ANOVA) and weight gain (101±16, 94±23, 92±13, 68±15, 57±9, 49±9, 50±13 g; *P*<0.0001 ANOVA) for up to 28 days after administration when compared to vehicle controls. The effect of ExS treatment to improve glycemic endpoints was dose-dependent, despite very slight progression of diabetes in most rats, but did not achieve significance in this study. Glomerular filtration rate, plasma creatinine, urine volume or urine creatinine remained unchanged from controls with long term exposure to ExS. Plasma exenatide concentrations were sustained for at least 28 days (1.4±0.7, 42±29, 290±182, 1099±327, 3993±1278, 1787±486 pM) and increased with time in all but the 0.003 mg dose. During the euglycemic-hyperinsulinemic clamp, dose-dependent and significant increases in insulin sensitivity were observed with ExS at 0.3 mg and above (glucose infusion rate required to maintain euglycemia over 60-180 min: 7.5±0.8, 7.6±2.4, 7.4±1.8, 9.9±1.5, 10.4±1.8, 11.4±1.6, 11.7±1.2 mg/kg/min; *P*<0.0001 ANOVA). ExS at doses of 0.03 mg and above significantly decreased C-peptide responses compared to controls (485±196, 369±244, 263±164, 73±87, 4.6±3.9, 5.1±8.9, 4.9±5.3 pM; *P*<0.001 ANOVA), reflecting a decrease in insulin demand due to improved insulin action. Importantly, these changes were comparable to the responses observed with EQW treatment in this model.
Conclusion: The significant metabolic improvements seen in diabetic ZDF rats with exenatide suspension further elucidate the mechanism of action and prolonged duration of action of this novel exenatide formulation. Together with the beneficial glycemic actions observed with once-weekly injection of ExS in a clinical trial, these data lend further support to the ongoing development of exenatide suspension for the treatment of Type 2 diabetes, administered as both weekly and monthly regimens.

Dose-finding results in an adaptive trial of dulaglutide combined with metformin in type 2 diabetes (AWARD-5)
Z. Skrivanek[1], J.Y. Chien[1], B. Gaydos[1], M. Heathman[1], M. Geiger[2], Z. Milicevic[3];
[1]Eli Lilly, Indianapolis, [2]Relypsa, Inc, Redwood City, USA, [3]Eli Lilly, Vienna, Austria.

Background and aims: The AWARD-5 study was an adaptive, double-blind, placebo (PL)- and sitagliptin (sita)-controlled Phase 3 trial with dose-finding, efficacy, and safety objectives to assess dulaglutide (DU), a long-acting glucagon-like peptide-1 receptor agonist, in type 2 diabetes mellitus (T2DM). We present the dose-finding results from this study that selected doses for the DU clinical development plan.
Materials and methods: Patients with T2DM (HbA_{1c} ≥7.0% to ≤9.5%), treated with diet and exercise only, oral antihyperglycaemic medication (OAM) monotherapy, or metformin (MET) combination with OAM, were randomised 1:1:3 to PL, sita 100 milligrams (mg) once daily, or 1 of 7 once-weekly DU doses (0.25, 0.5, 0.75, 1.0, 1.5, 2.0, 3.0 mg) after stabilisation on MET monotherapy. A Bayesian algorithm was used to adaptively randomise patients to the DU doses based on accumulated data (updated bi-weekly) on HbA_{1c}, weight, pulse rate, and diastolic blood pressure. Predicted outcomes of these measures relative to the comparators (predicted HbA_{1c} at 52 weeks relative to sitagliptin and predicted outcomes at 26 weeks relative to placebo for the other 3 measures) were combined into a single metric, a clinical utility index (CUI), to assess relative benefit/risk for each DU dose. When sufficient data accumulated, DU dose selection would occur or the trial would terminate, based on prespecified decision rules. Dose selection would occur if the maximum CUI dose provided clinically meaningful benefit. This dose would then continue in the study and the program. One additional, lower DU dose would also be selected if it had an acceptable CUI and was ≤50% of the maximum CUI dose (to ensure pharmacokinetic separation). If dose selection occurred, patients randomised to the selected DU doses or the comparator arms would continue seamlessly on treatment; randomisation to the selected DU doses and the comparator arms would continue until the planned total sample size was reached.
Results: Of 1202 randomised patients, the initial 230 participated in dose-finding. A Data Monitoring Committee discontinued DU 3.0 mg before dose selection due to concerns about increased incidence of gastrointestinal adverse events and elevated pulse rate. The DU 1.5 mg (maximum CUI) and 0.75 mg doses were selected (Table 1).
Conclusion: The adaptive algorithm facilitated inclusion of a large number of doses during dose-finding, efficiently allocated patients to doses of greater clinical value, and exposed fewer patients to less-desirable doses for the minimum time necessary to make a dose decision. DU 1.5 mg was selected as the optimal dose and DU 0.75 mg was selected as the lower dose to be continued for the purposes of confirmation of long-term safety and efficacy of dulaglutide in AWARD-5 and the entire Phase 3 program.

Table 1. Model-Predicted Adjusted Mean (95% CI) Changes from Baseline and Mean Utility Values

Treatment	HbA_{1c} (%) 52-week sitagliptin-adjusted	Weight (kg) 26-week placebo-adjusted	Pulse Rate (beats/min) 26-week placebo-adjusted	Diastolic Blood Pressure (mmHg) 26-week placebo-adjusted	Mean utility (95% credible interval)

Consistent reduction of postprandial glucagon and insulin by lixisenatide in the GetGoal clinical trial programme

C.J. Bailey[1], R. Berria[2], W. Stager[2], J.-F. Gautier[3], R. Aronson[4], B. Ahrén[5];
[1]Diabetes Research, Life and Health Sciences, Aston University, Birmingham, UK, [2]Sanofi, Bridgewater, USA, [3]Saint-Louis Hospital, Paris, France, [4]LMC Diabetes & Endocrinology, Toronto, Canada, [5]Lund University, Lund, Sweden.

Background and aims: Glucagon-like peptide-1 (GLP-1) receptor agonists improve islet function and delay gastric emptying in subjects with type 2 diabetes mellitus. We evaluated 2-hour glucose, glucagon and insulin changes following a standardized mixed-meal tolerance test before and after 24 weeks of treatment with the once-daily prandial GLP-1 receptor agonist lixisenatide (approved for a therapeutic dose of 20 µg once daily) in six randomized, placebo-controlled studies within the lixisenatide Phase III GetGoal programme. In the studies, the mixed-meal test was conducted before and after: (1) lixisenatide treatment in patients insufficiently controlled despite diet and exercise (GetGoal-Mono), (2) lixisenatide treatment in combination with oral antidiabetic drugs (OADs) (GetGoal-M and GetGoal-S), or (3) lixisenatide treatment in combination with basal insulin ± OAD (GetGoal-Duo 1, GetGoal-L and GetGoal-L-Asia).
Materials and methods: A meta-analysis was performed (lixisenatide n=1124 vs placebo n=707) combining ANCOVA least squares (LS) mean values using an inverse variance weighted analysis.
Results: Lixisenatide significantly reduced 2-hour postprandial glucose from baseline (LS mean difference vs placebo: -4.9 mmol/L, p<0.0001, Figure) and glucose excursions (LS mean difference vs placebo: -4.5 mmol/L, p<0.0001). As measured in two studies, lixisenatide also reduced postprandial glucagon (LS mean difference vs placebo: -19.0 ng/L, p<0.0001) and insulin (LS mean difference vs placebo: -64.8 pmol/L, p<0.0001), although the glucagon/insulin ratio was increased (LS mean difference vs placebo: 0.15, p=0.02) compared with placebo.
Conclusion: The results show that lixisenatide potently reduces the glucose excursion after meal ingestion in subjects with type 2 diabetes, in association with marked reductions in glucagon and insulin levels. It is suggested that diminished glucagon secretion and slower gastric emptying contribute to reduced hepatic glucose production and delayed glucose absorption, enabling postprandial glycaemia to be controlled with less demand on beta-cell insulin secretion.

Once-daily lixisenatide in combination with basal insulin ± OADs in patients with type 2 diabetes selectively reduces postprandial hyperglycaemic daytime exposure

R. Gómez-Huelgas[1], M.C. Riddle[2], Y. Seino[3], B. Cariou[4], C. Roy-Duval[5], C. Hecquet[5], A. DiGenio[6], J. Rosenstock[7];
[1]Internal Medicine Department, Hospital Regional Universitario Carlos Haya, Malaga, Spain, [2]Oregon Health & Science University, Portland, USA, [3]Kansai Electric Power Hospital, Osaka, Japan, [4]Department of Endocrinology, Nantes University Hospital, [5]Sanofi, Paris, France, [6]Sanofi, Bridgewater, [7]Dallas Diabetes and Endocrine Center, Dallas, USA.

Background and aims: Basal insulin reduces basal hyperglycaemia (BHG), but HbA_{1c} may remain high due to persisting postprandial hyperglycaemia (PPHG). Lixisenatide is a new once-daily prandial glucagon-like peptide-1 (GLP-1) receptor agonist, which was granted marketing authorization in Europe in February 2013 for the treatment of Type 2 diabetes mellitus (T2DM). Lixisenatide has been demonstrated to reduce PPHG and HbA_{1c} with no weight gain, or with weight loss, and thus has properties that are complementary to those of basal insulin.
Materials and methods: Patient-level data were pooled from three randomized Phase III studies to evaluate once-daily lixisenatide + standard of care (SOC; basal insulin ± oral agents) versus placebo + SOC, to quantify the effects of lixisenatide on BHG and PPHG exposures. BHG (24-hr area above 5.6 mmol/L and under the fasting level) and incremental PPHG (area above fasting and under self-monitored 7-point plasma glucose profiles [AUC_{24h}]) exposures were calculated.
Results: The 753 eligible patients with evaluable profile data had a mean age of 57 years, BMI of 29.8 kg/m², diabetes duration of 11.5 years, HbA_{1c} of 8.2% and a fasting glucose of 7.5 mmol/L. At baseline, mean daytime BHG and PPHG exposures were 49.2 and 55.1 mmol/L/hr, respectively. Mean BHG and PPHG contributions to hyperglycaemia were 42% and 58%, respectively. After 24 weeks of treatment, adjusted least squares (LS) mean HbA_{1c} change in the lixisenatide + SOC group was -0.8% compared with -0.3% in the placebo + SOC group (p<0.0001). The BHG exposure values for lixisenatide + SOC and placebo + SOC were similar (adjusted LS mean change for AUC_{24h} -13 vs -11 mmol/L/hr [NS]), but PPHG exposure was reduced more with lixisenatide + SOC compared with placebo + SOC (adjusted LS mean change -21 vs -10 mmol/L/hr, p<0.0001). The mean BHG and PPHG contributions to hyperglycaemia were 46% vs 54% with lixisenatide + SOC and 39% vs 61% with placebo + SOC, respectively.
Conclusion: This analysis suggests that once-daily lixisenatide complements the effects of basal insulin on glycaemic control in T2DM, decreasing HbA_{1c} mainly by reducing PPHG.

Liraglutide demonstrates similar pharmacokinetic properties in patients with type 1 and type 2 diabetes

S. Klim[1], S.H. Ingwersen[1], L. Jensen[2], F. Kiyomi[3], J. Mader[4], S. Heller[5], T.R. Pieber[4];
[1]Quantitative Clinical Pharmacology, Novo Nordisk A/S, Søborg, [2]Pharmacology Diabetes, Novo Nordisk A/S, Søborg, Denmark, [3]Clinical Statistics, Novo Nordisk Pharma Ltd, Tokyo, Japan, [4]Endocrinology & Metabolism, Medical University of Graz, Austria, [5]Endocrinology & Metabolism, University of Sheffield, UK.

Background and aims: Liraglutide is a well established treatment in patients with type 2 diabetes (T2D) and is currently under investigation as a treatment option in patients with type 1 diabetes (T1D) as adjunct to insulin. The aim of the following pharmacokinetic (PK) analysis was to compare PK properties of liraglutide in T1D and T2D.
Materials and methods: We assessed the PK properties of liraglutide in a randomised, placebo controlled, double blind, crossover trial investigating effects of liraglutide as adjunct to insulin on counter regulatory responses to hypoglycaemia in T1D. 45 adults with T1D were allocated to 1 of 3 dose groups of liraglutide (0.6, 1.2 or 1.8 mg/day) or placebo for 4 weeks in a cross-over design with a washout period of 2-3 weeks. Steady state PK profiles over 60 hours were obtained at the end of each treatment period. The PK analysis was conducted via both noncompartmental and population PK analyses. Data from this trial were compared with PK data from a randomised, double blind, crossover trial in subjects with T2D evaluating the effect of 1.8 mg liraglutide/placebo on postprandial lipid response. The liraglutide concentration-time profile was adequately described by a linear one compartment model with first order absorption and elimination parameterised with apparent clearance (CL/F), apparent volume of distribution (V/F) and absorption rate constant (K_A). Effects of body weight and sex on CL/F and body weight on V/F were estimated to account for body weight and male/female ratio differences in the two trials.
Results: 52 PK profiles (T1D:40, T2D:12) were used for the analysis. Mean body weight [minimum; maximum] was 74.2 kg [55.5; 92.2] in T1D and 82.4 kg [71.6; 104.1] in T2D. The percentage of males was 65% (26 males vs 14 females) in T1D and 50% (6/6) in T2D. The exposure of 1.8 mg liraglutide was similar in T1D and T2D ($AUC_{ss,0\text{-}24h}$ = 569771(26%) pmol*h/l in T1D vs 561404(36%) pmol*h/l in T2D; C_{max} = 29751(28%) pmol/l in T1D vs 29820(39%) pmol/l in T2D [geometric mean(CV%)]). The mean PK profiles following liraglutide doses of 0.6, 1.2 and 1.8 mg in T1D and 1.8 mg in T2D are shown in figure. The population PK analysis demonstrated linear (dose independent) PK properties of liraglutide in T1D. The covariate analysis revealed comparable CL/F and V/F, and hence exposure, between T1D and T2D, with a lower between subject variability of CL/F in T1D (CV% = 21) compared to T2D (CV% = 39).
Conclusion: In conclusion, similar liraglutide PK properties were observed in T1D and T2D.

Figure: Liraglutide concentration time profiles for 0.5, 1.2 and 1.8 mg dose groups in T1D and for 1.8 mg liraglutide in T2D.

Treatment with liraglutide as adjunct to insulin in type 1 diabetes; effects on counter regulatory response to hypoglycaemia: a randomised, double blind, crossover trial

T.R. Pieber[1], S. Deller[2], M. Brunner[1], L. Jensen[3], E. Christiansen[4], F. Kiyomi[5], S.R. Heller[6];
[1]Endocrinology & Metabolism, Medical University of Graz, [2]Medical Research, Medical University of Graz, Austria, [3]Pharmacology Diabetes, Novo Nordisk A/S, Søborg, [4]GLP-1 & Obesity, Novo Nordisk A/S, Søborg, Denmark, [5]Novo Nordisk Pharma Ltd, Tokyo, Japan, [6]Endocrinology & Metabolism, University of Sheffield, UK.

Background and aims: The counter regulatory hormone (CRH) response to hypoglycaemia is important in type 1 diabetes (T1D). This trial aimed to investigate if liraglutide as adjunct to insulin treatment blunts the counter regulatory response during hypoglycaemia in subjects with T1D compared to placebo as adjunct to insulin.
Materials and methods: 45 adults with T1D were randomised to 1 of 3 dose groups of liraglutide (0.6, 1.2 or 1.8 mg/day) and placebo as add on to insulin for 4 weeks in a placebo controlled, crossover design with a wash out period of 2-3 weeks between treatments. At the end of each treatment period, a stepwise hypoglycaemic clamp was performed via controlled i.v. insulin/glucose infusion. The successive plasma glucose (PG) levels were: 5.5, 3.5, 2.5 mmol/L (nadir) and 4.0 mmol/L (recovery). The evening before the clamp, sampling for glucagon and plasma glucose was performed (ambient hyperglycaemic PG level). During the clamp, CRHs (glucagon, adrenalin, noradrenalin, cortisol and growth hormone) and vital signs (pulse, blood pressure) were measured at each of the successive PG levels. Glucose infusion rate (GIR) was assessed, and a hypoglycaemic symptoms questionnaire and cognitive function tests were carried out.
Results: Baseline characteristics were similar between groups: age 34.5±11.2 years, BMI 23.9±2.4 kg/m², HbA_{1c} 7.6±0.8%, T1D duration 16.6±9.4 years [mean±SD]. At nadir PG, no significant differences in glucagon and no systematic differences in other CRHs were seen between treatments (see Table). However, a trend towards lower glucagon level at increasing liraglutide dose was seen at nadir PG levels. Change in glucagon from PG 5.5 mmol/L to nadir PG demonstrated little glucagon response to hypoglycaemia in all groups with no difference between treatments, consistent with the duration of T1D in the trial population. Increased concentrations of other CRHs in response to hypoglycaemia were seen with no differences in change from PG 5.5 mmol/L to nadir PG between treatments. Pulse was higher for liraglutide at nadir PG, but with similar change from PG 5.5 mmol/L to nadir PG across groups. AUC_{GIR} indicated less glucose was needed to obtain PG levels with liraglutide treatment with a similar trend during recovery from hypoglycaemia. Cognitive tests and hypoglycaemic symptoms questionnaire showed no systematic differences in responses between groups at all PG levels.

Safety and efficacy of lobeglitazone monotherapy in patients with type 2 diabetes mellitus over 52 weeks: a randomised open-label trial
S. Kim[1], S. Kim[1], D. Kim[2], J.-T. Woo[3], H. Jang[4], C. Chung[5], K. Ko[6], J. Park[7], Y. Park[8], S. Kim[9], D. Choi[1];
[1]Internal Medicine, Korea University College of Medicine, Seoul, [2]Internal Medicine, Hallym University Kangdong Sacred Heart Hospital, Seoul, [3]Internal Medicine, Kyung Hee University Hospital, Seoul, [4]Internal Medicine, Seoul National University Bundang Hospital, Bundang, [5]Internal Medicine, Wonju Christian Hospital, Wonju, [6]Internal Medicine, Inje University Sanggye Paik Hospital, Seoul, [7]Internal Medicine, Inje University Pusan Paik Hospital, Pusan, [8]Internal Medicine, Hanyang University Guri Hospital, Guri, [9]Internal Medicine, Soon Chun Hyang University Cheonan Hospital, Cheinan, Republic of Korea.

Background: Lobeglitazone is a novel PPAR-γ agonist with substituted pyrimidine derivatives containing TZD, and is expected to improve insulin sensitivity and blood lipid profile with a lower effective dose. We recently reported that lobeglitazone 0.5 mg monotherapy improved glycemic control over 24-week in patients with type 2 diabetes mellitus (T2DM) inadequately controlled on diet and exercise. In addition, lobeglitazone treatment significantly improved lipid profiles compared to placebo. This 52-week extension study was to assess the long-term safety and efficacy of lobeglitazone.
Methods: Following a 24-week, multicenter, randomized, double-blind, parallel-group, placebo controlled study, patients entered a 28-week extension study. In the open-label extension study, patients treated with placebo were switched to lobeglitzone 0.5 mg (the group switched, Group S) while the patients who were randomly assigned to lobeglitazone 0.5 mg at baseline continued the same treatment (the group maintained, Group M) for the entire 52 weeks.
Results: Among 173 patients who were randomly assigned (a 2:1 ratio) to lobeglitazone 0.5 mg (n=115) or matching placebo (n=58), 144 patients completed the 24-week treatment period. Of them, 94 patients (Group M; 65 vs Group S; 29) entered the extension study. The mean reduction from baseline in HbA1c at the end of the base study (week 24) were - 0.53% (P<0.001) in the Group M and the benefits seen with lobeglitazone treatment were sustained during the 52-week extension period (from 7.79% to 7.3%, mean difference -0.5%, P<0.001). Also, in the Group S, HbA1c was significantly decreased to -0.53% (from 8.01% at 24 weeks to 7.48% at 52 weeks, P<0.001). In addition, lobeglitazone treatment in both groups significantly improved HDL cholesterol, triglycerides, small dense LDL cholesterol and free fatty acid. As expected, weight gain was observed in the Group M (+ 1.48 kg) over 52-weeks and in the Group S (+ 1.65 kg) during the extension period (from 24 weeks to 52 weeks). The other safety profile was good in the two groups and lobeglitazone treatment was also well tolerated.
Conclusion: Lobeglitazone 0.5 mg showed a favorable balance in the efficacy and safety profile in Korean patients with type 2 diabetes, and clinical benefits were maintained for 52 weeks.

A novel oral dual-action amylin and calcitonin receptor agonist (UGP302) rebalances insulin and glucagon action to attenuate diabetic hyperglycaemia in Zucker diabetic fatty rats
M. Feigh[1], S.T. Hjuler[1], K.V. Andreassen[1], S. Gydesen[1], I. Ottosen[1], N. Metha[2], W. Stern[2], C. Christiansen[1], M.A. Karsdal[1], K. Henriksen[1];
[1]Nordic Bioscience, Herlev, Denmark, [2]Unigene Laboratories Inc., Boonton, USA.

Background and aims: Oral delivery of the peptide hormone salmon Calcitonin (sCT) possesses weight and glucoregulatory effects in obese type 2 diabetic rats by dual-action targeting the amylin and calcitonin receptor. UGP302 is a novel peptide mimetic with an enhanced in vitro pharmacological profile to native sCT. In here, we investigated the anti-diabetic efficacy of oral UGP302 vs oral sCT in a proof of concept study using Zucker diabetic fatty (ZDF) rats, a golden standard animal model of type 2 diabetes.

Materials and methods: Male ZDF rats were treated with oral sCT or UGP302 (0.25, 0.5, 1 or 2 mg/kg) or oral vehicle twice daily for 7 weeks. Fasting and non-fasted plasma glucose and HbA1c were determined to evaluate glucose homeostasis. Furthermore, levels of pancreatic glucoregulatory hormones (insulin and glucagon) were measured to examine insulinotropic and glucagonostatic actions, respectively. Additionally, OGTT and insulin tolerance test (ITT) were performed to investigate glucose tolerance and insulin sensitivity. Finally, pancreatic insulin and glucagon content were analyzed to estimate pancreatic islet beta-cell and alpha-cell mass.
Results: Oral UGP302 attenuated diabetic hyperglycemia during the intervention period. At study end, oral UGP302 at doses of 1 mg/kg and 2 mg/kg reduced blood glucose by approx 8 mmol/l and HbA1c by 1.6% compared to vehicle ($p < 0.001$). Furthermore, oral UGP302 at doses of 1 mg/kg and 2 mg/kg improved glucose intolerance during OGTT by reducing incremental area under the curve by ~ 50% when compared to vehicle ($p < 0.001$). Additionally, at doses of 1 mg/kg and 2 mg/kg, oral UGP302 exerted insulin sensitizing effects and enhanced blood glucose disposal during ITT by approx 23% compared to vehicle ($p < 0.001$). Lastly, at study end compared to vehicle, oral UGP302 at 1 mg/kg and 2 mg/kg doses sustained hyperinsulinemia ($p < 0.01$), and ameliorated hyperglucagonemia ($p < 0.01$), in conjunction with preserved pancreatic insulin and glucagon content. In contrast, only at highest dosing regimen (2 mg/kg) did oral sCT induce a comparable anti-hyperglycemic effect, alleviation of insulin resistance and impact on pancreatic glucoregulatory hormones.
Conclusion: Oral UGP302 is a superior dual-action amylin and calcitonin receptor agonist to native salmon Calcitonin. Oral UGP302 exerts anti-hyperglycemic efficacy by rebalancing insulin and glucagon action and preserving pancreatic islet glucoregulatory hormonal mass and secretory function. These data indicate the clinical usefulness of oral UGP302 as anti-diabetic treatment.

Dual-action targeting the amylin and calcitonin receptor by oral salmon calcitonin improves glucose homeostasis and insulin sensitivity in an animal model of type 2 diabetes
S.T. Hjuler, M. Feigh, K.V. Andreassen, M.A. Karsdal, K. Henriksen;
Diabetes group, Nordic Bioscience, Herlev, Denmark.

Background and aims: Oral salmon calcitonin (sCT), a dual-action amylin and calcitonin receptor agonist, has previously been demonstrated to attenuate diabetic hyperglycemia in obese diabetic rats, possibly through enhanced insulin action. The present study investigated oral sCT as anti-diabetic intervention in combined diet-induced obese and streptozotosin-type 2 diabetic animals, focusing on the effect on insulin sensitivity.
Materials and methods: Diet-induced obese (DIO) rats were given a low dose (25 mg/kg) of streptozotocin (STZ) resulting in diabetic hyperglycemia without hypoinsulinemia. The DIO-STZ rats were orally dosed with either 0.5 mg/kg salmon calcitonin (sCT) or its oral vehicle 5-CNAC once daily for 21 days. The effects of chronic treatment with sCT were evaluated with regards to fasting and non-fasting blood glucose, glycated hemoglobin (HbA1c), insulin sensitivity, glucose tolerance, and circulating glucagon levels and both circulating insulin and insulin content extracted from pancreas isolated at study end.
Results: Oral sCT improved hyperglycemia during the intervention period resulting in 5 mM reduction of PPG at study end, when compared to vehicle ($p<0.01$). During an oral glucose tolerance test, oral sCT improved glucose intolerance by reducing the area under the curve with ~35 % when compared to vehicle ($p<0.001$). Furthermore, oral sCT reduced fasting blood glucose and HbA1c at study end by ~7 mM and 1 % respectively ($p<0.05$). Furthermore sCT exerted a glucagonostatic effect. During OGTT sCT reduced the area under the curve of glucagon with ~75 % ($p<0.05$). Both the vehicle and sCT groups lost weight after injections with STZ with no significant difference between groups. Oral sCT did not exert an insulinotropic action; neither the basal fasting insulin nor insulin levels during OGTT were significantly different in the treatment group. In contrast, compared to vehicle group, oral sCT caused a 2-fold increase in glucose disappearance rate (K_{ITT}) during intravenous insulin tolerance test ($p<0.01$), indicating increased insulin sensitivity (Fig. 1). Finally there was as indication towards β-cell preservation when measuring insulin content in pancreas isolated at study end where the sCT group.
Conclusion: In conclusion, oral sCT, as interventional therapy and irrespective of inducing weight loss, improved glucose homeostasis and enhanced insulin action in diet-induced obese type 2 diabetic animals. Furthermore, oral sCT improved glucose intolerance by partly influencing gastric emptying and exerting glucagonostatic action and, importantly, by increasing insulin sensitivity. These non-insulinotropic systemic effects and preservation of insulin-producing β-cells could hold great promise for future treatment and demonstrates oral sCTas a therapeutic agent in type 2 diabetes.

Effect of exogenous glucagon vs spontaneous recovery from hypoglycaemia in subjects with type 2 diabetes treated with a novel glucokinase activator AZD1656 and metformin
A. Krentz[1], L. Morrow[1], M. Petersson[2], E. Norjavaara[2], M. Hompesch[1];
[1]Profil Institute for Clinical Research, Inc, Chula Vista, USA, [2]Astra Zeneca R&D, Mölndal, Sweden.

Background and aims: We studied the effect of exogenous glucagon on recovery from insulin-induced hypoglycaemia in subjects with type 2 diabetes treated with the novel glucokinase activator AZD1656 in combination with metformin.
Materials and methods: Single centre randomized, open, two-way cross-over phase I, automated (Biostator®) glucose clamp study (NCT00817271) of 8 subjects (7 men and 1 woman, mean age 58.6 years, body mass index 28.1 kg/m^2). A 2-day titration phase commenced with 40 mg AZD1656 bid escalating to 80 mg bid if tolerated. Three subjects received 40 mg AZD1656 bid and 5 subjects 80 mg bid for 4 days, followed by a single dose of 80 mg or 160 mg AZD1656 respectively on day 5 and day 8. All subjects received a stable dose of metformin bid ranging from 1000 to 2250 mg daily. After an overnight fast on days 5 and 8 controlled hypoglycaemia was induced using an exogenous i.v. insulin infusion. Plasma glucose was lowered in a stepwise fashion over 3 hours to attain a target nadir of 2.7 mmol/L sustained for 30 minutes, at the end of which the hypoglycaemic clamp was released. In random sequence subjects either received an intramuscular injection of 1 mg glucagon or were allowed to recover from hypoglycaemia without exogenous glucagon.
Results: Mean plasma glucose at 20 minutes after release of the hypoglycaemic clamp was 3.1 ± 0.3 v 4.9 ± 0.8 mmol/l for AZD1656 alone and AZD1656+glucagon, respectively. Plasma glucagon AUC0-6h was lower (-72%, 95% CI [-75% to -67%], $p<0.001$) for AZD1656 alone. Catecholamine and cortisol responses were similar for both treatments. Growth hormone (GH) response was lower for AZD1656 alone (-18%, 95% CI [-29% to -7%], $p=0.01$) consistent with the physiological effect of glucagon on GH secretion. No safety or tolerability concerns were observed.
Conclusion: Exogenous glucagon was effective as a rescue treatment for hypoglycaemia during treatment with AZD1656 in combination with metformin in subjects with type 2 diabetes.

Evidence that two divergent mechanisms contribute to blood glucose lowering by imidazoline compounds in mice
K. Stadlbauer[1], Z. Lehner[1], N. Stamenkovic[1], L. Surman[1], I. Rustenbeck[2], A. Luger[1], C. Fürnsinn[1];
[1]Department of Medicine III, Division of Endocrinology & Metabolism, Medical University of Vienna, Austria, [2]Institute of Pharmacology and Toxicology, University of Braunschweig, Germany.

Background and aims: Evidence suggests that imidazoline derivatives can directly amplify glucose-induced insulin secretion by β-cells via at least two

mechanisms, which are closing of K_{ATP} channels and antagonism at adrenergic α_{2A}-receptors. The relative importance of these two mechanisms for the antihyperglycaemic effects *in vivo* is a matter of debate. This study was to clarify this matter for two classic imidazoline compounds, phentolamine (PHE) and idazoxan (IDA).
Materials and methods: The effects of PHE and IDA on insulin secretion of perifused islets from C57BL-mice were examined in the presence of inhibitors of insulin release which oppose the mechanisms putatively addressed by imidazolines: 250µmol/l of the K_{ATP} channel opener diazoxide (DIAZ), or 1µmol/l of the α_2-adrenoceptor agonist UK14,304 (UK). To unmask the mechanisms predominately responsible for the antihypergycaemic effect, the minimal doses of PHE and IDA needed to counteract hyperglycaemia triggered by administration of the inhibitors were compared in C57BL-mice (250mg/kg DIAZ, p.o.; 100µg/kg UK, i.p.).
Results: In isolated islets, PHE and IDA (100µmol/l) were equally strong as amplifiers of glucose-stimulated insulin release in the presence of the α_2-adrenoceptor agonist (fmol insulin released per islet during 30min of stimulation with high glucose: UK alone, 1.7±0.3; UK+PHE, 177.2±32.1; UK+IDA, 176.4±29.7; PHE vs IDA, ns), but PHE was superior in counteracting inhibition of insulin secretion by the K_{ATP} channel opener (DIAZ alone, 2.2±0.7; DIAZ+PHE, 161.2±19.1; DIAZ+IDA, 11.7±6.4; PHE vs IDA, p<0.001). Our results suggest similar effects via antagonism at the α_{2A}-adrenoceptor, but superiority of PHE via another mechanism involving closure of K_{ATP} channels. The assumption underlying the *in vivo*-experiments - that an α_{2A}-antagonist would be stronger in counteracting UK, whereas a K_{ATP} channel blocker would be superior in counteracting DIAZ - was confirmed with the non-imidazoline α_2-antagonist yohimbine and with the K_{ATP} channel-blocking sulfonylurea gliclazide. In line with the observations made *in vitro* and resembling the effects of yohimbine, a low dose of 0.1mg/kg IDA counteracted hyperglycaemia induced by the α_2-agonist but not by the K_{ATP} channel-opener (incremental $AUC_{glucose}$ in mol/l*min: UK alone, 1.60±0.06, vs UK+IDA, 1.06±0.15, p=0.007; DIAZ alone, 1.16±0.16, vs DIAZ+IDA, 1.12±0.08, ns). At variance to this, the same minimal dose of PHE was required to counteract hyperglycaemia caused by UK and DIAZ, with no effects obtained at 2mg/kg but robust effects at 4mg/kg PHE (UK alone, 1.40±0.10, vs UK+2mg/kg PHE, 1.19±0.12, ns, and vs UK+4mg/kg PHE, 0.72±0.11, p<0.001; DIAZ alone, 1.11±0.12, vs DIAZ+2mg/kg PHE, 0.99±0.09, ns, and vs DIAZ+4mg/kg PHE, 0.58±0.06, p<0.001).
Conclusion: The results indicate that α_{2A}-antagonism as exerted by IDA is sufficient for an antihyperglycaemic effect *in vivo*, whereas closure of K_{ATP}-channels makes a major contribution to glucose lowering induced by PHE. Hence, at least two divergent mechanisms account for the antihypergycaemic activities of imidazolines, whereby the relative contributions of each mechanism can markedly differ between individual imidazoline compounds.

MTBL0036, a promising antidiabetic candidate, impacts both insulin action and insulin secretion in type 2 diabetic rats
M. El Hage[1], G. Moinet[1], B. Ferrier[1], R. Nazaret[1], G. Baverel[1,2], G. Martin[2], A. Conjard-Duplany[2];
[1]Metabolys Inc., [2]Metabolic Biochemistry and Pathophysiology, Lyon, France.

Background and aims: The objective of the present study was to establish the characteristics of the effect of MTBL0036, a new optimized and patented antidiabetic drug candidate, on glucose metabolism and insulin secretion in the STZ-N0 rat, a good animal model of type 2 diabetes.
Materials and methods: MTBL0036 was administered per os as a suspension in 0.5% methylcellulose 60 min before an oral glucose load (2g/kg), and control 17h-fasted animals received only the vehicle. The glycemia was measured using a glucometer (Lifescan one Touch Ultra, Lifescan, J&J company, USA)and, after the glucose load, the Areas Under the Curves (AUCs) were calculated using the GraphCalc software. The plasma concentration of insulin was measured by an immunoassay. Precision-cut liver slices from 48h-fasted STZ-N0 rats were also incubated in the presence of 5 mM L-lactate to study the effect of MTBL0036 on lactate gluconeogenesis.
Results: Administration of MTBL0036 (50 and 200 mg/kg) did not cause hypoglycemia in fasted rats but reduced in a statistically significant manner by 51 % and 64-80%, respectively, the AUCs for glucose after the oral glucose load. The administration of metformin (200mg/kg), the gold standard for the treatment of type 2 diabetic patients, reduced by 64% the AUC for glucose after the same oral glucose load. The administration of MTBL0036 (200 mg/kg) also augmented in a statistically significant manner the plasma concentration of insulin both before and after the glucose load. MTBL0036 (0.5 and 2 mM) reduced lactate gluconeogenesis in precision-cut liver slices with an IC_{50} which was less than that of metformin.
Conclusion: MTBL0036, is a very promising antidiabetic drug candidate because, unlike current antidiabetic drugs on the market, it has the potential to impact the three major defects observed in type 2 diabetes: (i) decreased peripheral glucose utilization, (ii) increased gluconeogenesis and (iii) deficit of insulin secretion.

1014

A one-week phase 1 trial with the DGAT1 inhibitor AZD7687: lipid handling, hormone secretion and adverse effects in the gut
H. Denison[1], C. Nilsson[1], L. Löfgren[1], A. Al-Shurbaji[1], A. Himmelmann[1], G. Mårtensson[1], H. Tornqvist[1], M. Knutsson[1], J.W. Eriksson[1,2];
[1]AstraZeneca, Mölndal, [2]Uppsala University, Sweden.

Background and aims: Inhibition of diacylglycerol acyltransferase 1 (DGAT1) has been proposed as a treatment for type 2 diabetes and obesity, and preclinical data have suggested insulin sensitization and weight loss. Proof of mechanism with regards to gut DGAT1 inhibition in man has recently been provided for the reversible, selective DGAT1 inhibitor AZD7687. This clinical study explored the tolerability and pharmacodynamic effects of different dose levels of AZD7687 during one week treatment.
Material and methods: Randomized, single-blind, placebo-controlled study in 62 overweight/obese male subjects. AZD7687 (1, 2.5, 5, 10, 20 mg per day n=6 or 12 for each) or placebo (n=20) was administered during 8 days in total. Plasma AZD7687 exposure was measured repeatedly. Postprandial serum triacylglycerol (TAG) excursion was measured during 8 hours after a standardized mixed meal with fat energy content of 45%, before and during treatment, to assess effects on gut DGAT1 activity. Gut hormone profiles (GLP-1, PYY) and paracetamol challenge to assess gastric emptying were performed.
Results: A consistent dose-dependent reduction of post-prandial TAG excursion was demonstrated with AZD7687 at doses of ≥5 mg as compared to placebo (p<0.01) indicating inhibition of gut DGAT1. Significant increases (p<0.05) of plasma GLP-1 and plasma PYY were seen at these dose levels, but no significant sustained effect on gastric emptying was demonstrated. There were no consistent effects on plasma glucose, insulin or lipids. Marked gastrointestinaI side effects, mainly diarrhoea, occurred at drug dose levels that inhibited TAG excursions by ≥50% (i.e. doses ≥5 mg per day). At doses higher than 5 mg, 11/18 subjects discontinued treatment due to diarrhoea. Exploratory data suggest that increased free fatty acid exposure and inflammation in the gut may contribute to the GI side effects.
Conclusion: Effects on lipid handling and hormone secretion in the gut were demonstrated during one-week treatment of overweight/obese men with the DGAT1 inhibitor AZD7687. However, frequent gastrointestinal side effects occurred and were dose-limiting. The utility of DGAT1 inhibition as a novel treatment modality in diabetes and obesity can be questioned due to lack of therapeutic window.
Clinical Trial Registration Number: NCT01119352

1015

Metabolic effects and safety of two selective 11β-HSD1 inhibitors (RO5093151 (RO151) and RO5027838 (RO838) in metformin-treated patients with type 2 diabetes
S. Fuerst-Recktenwald[1], T. Heise[2], M. Hompesch[3], T. Pieber[4], H.-U. Haering[5], C. Kapitza[2], M. Abt[1], M. Ramsauer[1], L. Morrow[3];
[1]Hoffmann-La Roche, Basel, Switzerland, [2]Profil, Neuss, Germany, [3]Profil Institute for Clinical Research Inc., Chula Vista, USA, [4]University of Graz, Austria, [5]University of Tuebingen, Germany.

Background and aims: The metabolic effects of two selective 11β-HSD1 inhibitors (RO151 and RO838) were assessed in a randomised, controlled study in patients with type 2 diabetes.
Materials and methods: Patients either received placebo (PBO) (n=21), RO151 5mg BID (n=24) or 200mg BID (n=20), or RO838 50 mg QD (n=21) or 200mg QD (n=24) for 28 days plus a stable dose of metformin. Metabolic assessments (including oral glucose tolerance and/or standardized meal tests) and safety assessments (including ACTH stimulation test) were done at baseline and around 14 and 28 days of treatment.
Results: Key demographics at baseline were similar between groups (mean ranges: age 53-57 yrs, BMI 32-33 kg/m², diabetes duration 6.5-9.4 yrs, FPG

9.4 - 9.7 mmol/l). Despite the short treatment duration, both RO151 and RO838 showed trends for improved HbA_{1c}. Improvements in several insulin sensitivity parameters were seen with 200 mg RO151 but were not significant. While there was a slight decrease in body weight with PBO (-0.28 kg), greater reductions (-0.86 to -1.67 kg) occurred in all active treatment groups reaching statistical significance vs.PBO in the RO151 200mg BID group only (LS mean -1.39 kg, 95% CI -2.54, -0.23 kg; p=0.019). Lipid parameters did not consistently improve with either compound; mild increases in triglycerides and VLDL cholesterol (vs. PBO) with RO838 were not significant. Both compounds were well tolerated. Slight non-significant changes in systolic blood pressure were seen with 5 mg RO151 (decreases in day, night and 24h values) and 200 mg RO838 (increases in semi-supine values which were not repeated in the 24 hour ABPM). Increased concentrations of ACTH and adrenal androgen precursors were found with RO151, but not with RO838.
Conclusion: Modest metabolic improvements were seen, particularly with the higher dose of RO151. Longer studies are needed to investigate potential benefits and risks of these compounds.

1016

Pharmacological characterisation of 55P0251, a derivative from a novel class of molecules with distinct antihyperglycaemic activity in rodents
C. Fürnsinn[1], K. Stadlbauer[1], Z. Lehner[1], B. Brunmair[1], I. Adorjan[2], K. Frobel[2], A. Luger[1], L. Bauer[2];
[1]Department of Medicine III, Division of Endocrinology & Metabolism, Medical University of Vienna, [2]55pharma Drug Discovery & Development AG, Vienna, Austria.

Background and aims: In an effort to develop plant-derived molecules, we discovered a whole class of novel compounds with distinct anti-hyperglycaemic activity. An extensive derivatisation program was governed by OGTTs in orally treated mice, which ascertained that anti-hypergylcaemic activity was accompanied by reasonable oral bioavailability and absence of severe acute toxicity. We here report pharmacological characteristics of one selected derivative, 55P0251.
Materials and methods: Development of new derivatives and analysis of structure-activity relationship (SAR) were guided by a standard OGTT (3g/kg) in healthy male C57BL/6J-mice performed 45min after oral administration of the respective compound. Further procedures used for pharmacological characterisation are addressed in the results section.
Results: In the standard OGTT in mice, 55P0251 had a minimal effective dose of 0.7mg/kg and an ED_{50} of 1.6mg/kg (e.g. total AUC in mol/l*min: vehicle, 1.58±0.06; 9mg/kg 55P0251: 1.02±0.05, p<0.0001). An intravenous glucose tolerance test in rats (1g/kg) revealed that improvement of glucose tolerance by 55P0251 (total AUC in mol/l*min: vehicle, 1.25±0.04; 22.5mg/kg, 1.06±0.07, p=0.04; 90mg/kg, 0.87±0.03, p<0.0001) was related to elevated plasma insulin (AUC in nmol/l*min: vehicle, 15±2; 22.5mg/kg, 31±3, p=0.001; 90mg/kg, 44±5, p<0.0001). A parallel increase in circulating C-peptide indicated that this was due to higher insulin release (AUC in nmol/l*min: vehicle, 33±6; 90mg/kg, 180±22, p<0.0001). 55P0251 did not bind to the sulfonyurea receptor and when directly compared to gliclazide in the standard OGTT in mice, it exhibited an attractive ratio of hypoglycemic activity (change in basal glucose after 45min, mmol/l: vehicle, +0.75±0.21; 8mg/kg gliclazide, -2.00±0.24; 10mg/kg 55P0251, +0.27±0.37; gliclazide vs P550251, p=0.0002) to anti-hyperglycaemic activity (incremental AUC, mmol/l*min: vehicle, 373±39; gliclazide, 229±47; 55P0251, -16±45; gliclazide vs 55P0251, p=0.002), suggesting a favourable therapeutic profile over sulfonylurea drugs. Although glucose-dependent amplification of insulin release is reminiscent of drugs that interfere with the GLP-1 system, we neither obtained evidence for 55P0251-induced activation of the GLP-1 receptor (no signal transduction in vitro), nor for inhibition of dipeptidyl peptidase-4 (no direct effect on enzyme, no loss of activity with parenteral glucose administration). Pharmacokinetic attributes (ADME) were examined in orally and intravenously dosed rats. After oral administration of 22.5mg/kg, 55P0251 (given as hydrochloride salt) had a plasma half-life ($t_{1/2}$) of 3.2h, a bioavailability (F) of 58%, and a peak plasma concentration (c_{max}) of 4.3µmol/l reached after 2h (t_{max}).
Conclusion: 55P0251, which belongs to a newly discovered class of molecules, has potent anti-hyperglycaemic action in rodents. While 55P0251 seems to act via amplification of glucose-stimulated insulin release, its molecular mechanism of action obviously differs from those of drugs in clinical use. The compound has attractive pharmacokinetic properties and shows less hypoglycaemic activity than a sulfonylurea.

The effect of diiodothyronine mimetic on insulin sensitivity in male cardiometabolic patients: a double-blind randomised trial
F.M. van der Valk[1], C.H. Hassing[1], M.E. Visser[1], P. Thakkar[2], K. Pathak[2], A. Mohanan[2], C. Dutt[2], V. Chauthaiwale[2], M.T. Ackermans[3], M.J. Serlie[4], M. Nieuwdorp[1], E.S.G. Stroes[1];
[1]Vascular Medicine, Academic Medical Centre, Amsterdam, Netherlands, [2]Clinical Research Department, Torrent Pharmaceuticals Limited, Village-Bhat, India, [3]Clinical Chemistry, Laboratory of Endocrinology, [4]Endocrinology, Academic Medical Centre, Amsterdam, Netherlands.

Background and aims: Obesity and its associated cardiometabolic co-morbidities are increasing worldwide. Since thyroid hormone mimetics are capable of uncoupling the beneficial metabolic effects of thyroid hormones from their deleterious effects on heart, bone and muscle, this class of drug is considered as adjacent therapeutics to weight-lowering strategies. This study investigated the safety and efficacy of TRC150094, a thyroid hormone mimetic.
Materials and methods: This 4-week, randomised, placebo-controlled, double-blind trial was conducted in India and The Netherlands. Forty subjects were randomised at a 1:1 ratio to receive either TRC150094 dosed at 50 mg or placebo once daily for 4 weeks. Hyperinsulinaemic euglycaaemic clamp and ^{1}H-Magnetic Resonance Spectroscopy were performed before and after treatment.
Results: At baseline, subjects were characterised by markedly impaired hepatic and peripheral insulin sensitivity, compared to reference values observed in healthy, non-obese control subjects. TRC150094 dosed 50mg once daily was safe and well tolerated. Hepatic nor peripheral insulin sensitivity did not improve after TRC150094 treatment, expressed as the suppression of Endogenous Glucose Production from 59.5 to 62.1%; p = 0.477, and as the rate of glucose disappearance from 28.8 to 26.4 $\mu mo/kg^{-1}min^{-1}$, p = 0.185. Although T2's mechanism of action is expected to stimulate lipolysis and fatty acid oxidation, TRC150094 administration did not result in differences in fasting plasma free fatty acids from 0.51 to 0.51 mmol/L, p= 0.887 or in insulin-mediated suppression of lipolysis from 57 to 54%, p = 0.102. Also, intrahepatic triglyceride content was unaltered. To evaluate whether the response differed between subjects with mild and severe metabolic derangement, we analyzed the subjects with a mean triglyceride level above 1.64 mmol/L, however, the small subgroup did not reach statistical significance.
Conclusion: Collectively, these data show that, in contrast to the potent metabolic effects in experimental models, TRC150094 at a dose of 50mg daily does not improve the metabolic homeostasis in subjects at an increased cardiometabolic risk. Further studies are needed to evaluate whether TRC150094 has beneficial effects in patients with more severe metabolic derangement, such as overt diabetes mellitus and hypertriglyceridaemia.

How many OADS before initiating insulin? A retrospective study of outcomes associated with initiation of basal insulin after failing oral antidiabetic drugs

P. Levin[1], S. Zhou[2], W. Wei[2], E. Durden[3], A.M. Farr[3], J. Gill[2];
[1]MODEL Clinical Research, Towson, [2]Sanofi US, Bridgewater, [3]Truven Health Analytics, Ann Arbor, USA.

Background and aims: Current ADA/EASD guidelines recommend timely insulin initiation among patients with type 2 diabetes mellitus (T2DM) after failing oral antidiabetic drugs (OADs). However, research on the association between timing of insulin initiation and health outcomes in a real-world setting is limited. This study assessed clinical, utilization, and cost outcomes associated with timing of basal insulin initiation among T2DM patients previously treated with 1, 2, or 3+ OADs.
Materials and methods: This retrospective study, using the linked MarketScan® Commercial and Medicare Supplemental Databases and GE Centricity EMR databases from 2004-2011, included adult T2DM patients who initiated basal insulin after being treated with OADs only, and had continuous medical and pharmacy health plan coverage for ≥ 6 months before (baseline) and ≥ 12 months after initiation (follow-up). The population was stratified by the number of baseline OADs (1, 2, or 3+ OADs) as a proxy for timing of insulin initiation. HbA1c reduction from baseline, proportion of patients achieving HbA_{1c} < 7.0%, hypoglycaemia rates, treatment persistence, changes in body weight and body mass index (BMI), and health care utilization and costs were evaluated during a 12-month follow-up period. Confounding was addressed using the inverse probability of treatment weighting method.
Results: A total of 1,830 patients were included (baseline mean age: 57.2 years; HbA_{1c}: 9.2%; body weight: 99.5 kg; BMI: 34.5; hypoglycaemia rate: 3.0%; 1 OAD: 24.6%; 2 OADs: 40.3%; 3+ OADs: 35.1%). At baseline, no significant differences were observed between the 3 groups except for gender (female: 52.0% vs 47.0% vs 42.5%, P = 0.008) and the proportion of patients with all-cause hospital/emergency department (ED) visits (hospital: 21.1% vs 18.0% vs 13.9%, P = 0.006; ED: 27.8% vs 21.0% vs 18.5%, P = 0.001). Weighted results from a 12-month follow-up showed that the 1 OAD group had the greatest HbA1c reduction (−1.7% vs −1.0% vs −0.9%, P < 0.0001), the highest proportion of patients achieving HbA1c < 7.0% (38.2% vs 26.7% vs 19.6%, P < 0.0001), and the lowest overall and hospital/ED hypoglycaemia rates (overall: 2.7% vs 6.6% vs 5.0%, P = 0.0002; hospital/ED: 0.9% vs 1.9% vs 3.7%, P = 0.0001), despite its lower treatment persistence rate (51.7% vs. 58.0% vs. 68.7%, P < 0.0001). No significant differences were observed in change in body weight (+1.2 kg vs +1.6 kg vs +1.0 kg, P = 0.541), change in BMI (+0.5 vs +0.6 vs +0.4, P = 0.593), or total health care costs (all-cause: $21,167 vs $21,060 vs $20,133, P = 0.921; diabetes-related: $6,574 vs $6,257 vs $6,581, P = 0.926). When stratified by baseline BMI, HbA1c reduction was greater in the 1 OAD group when baseline BMI was ≤ 30 (−2.7% vs −1.5% vs −1.5%, P = 0.001) and 31–35 (−1.9% vs −0.7% vs −0.7, P = 0.0009), but similar when BMI was > 35 (−0.9% vs −1.0% vs −0.7%, P = 0.584).
Conclusion: These data illustrated that initiating insulin therapy among patients previously treated with 1 OAD resulted in greater HbA_{1c} reductions and lower rates of hypoglycaemia than adding basal insulin to treatment with > 2 OADs. This data supports the call for timely initiation of insulin therapy for T2DM patients not maintaining glycemic control with OADs.

Delay in starting insulin after failure of other treatments in patients with type 2 diabetes

I. Zografou[1], M. Strachan[2], J. McKnight[2];
[1]Diabetes Centre, Hippocratio General Hospital, Thessaloniki, Greece, [2]Metabolic Unit, Western General Hospital, Edinburgh, UK.

Background and aims: In type 2 diabetes mellitus (T2DM), therapies to maintain blood glucose control usually fail after several years. The aim of this study was to estimate the time to insulin initiation, the glycaemic burden that patients are exposed prior to conversion to insulin and their HbA_{1c} level at that time and a year later.
Materials and methods: Retrospective study. From our data base (Scottish Care Information-Diabetes Collaboration of Western General Hospital, Edinburgh Scotland) we identified patients with T2DM who started insulin therapy from 1-1-2002 to 30-6-2011. Exclusion criteria were conversion in insulin therapy less than 12 months from diagnosis, during pregnancy, acute illness or hospitalization. We also excluded patients with insufficient data for at least 3 visits. Finally, from 1221 files with sufficient data, 509 patients fulfilled the inclusion criteria. In these patients we estimated the duration of diabetes prior to conversion to insulin therapy, the months they spent with HbA_{1c} above 7%, 8% or 9% until starting insulin, HbA_{1c} and body weight (BW) at the time of conversion, at 6 and at 12 months before and after conversion.
Results: Our patients usually started insulin therapy 7.2+4.7 years (mean + SD) after diagnosis of T2DM. Mean HbA_{1c} was 10.3+1.6% at the time of conversion, 9.1+1.4% at -6 months, 8.7+1.6% at -12 months, 8.5+1.3% at +6 months and 8.3+1.4% at +12 months. Body weight (BW) was 89.7+21.6kg at conversion and 92.9+21.0kg at +12 months. Patients spent a mean period of 57.3+41.7 months with HbA_{1c} >7%, 32.1+31.7 months with HbA_{1c} > 8% and 14.9+17.7 months with HbA_{1c} > 9%. Insulin treatment resulted in a decrease in HbA_{1c} at 12 months of 2.0% (p<0.0001) but an increase in BW by 3.2kg (p<0.0001). After 12 months HbA_{1c} was <7% for 15.1% of the patients vs 8.8% 12 months before conversion and <9% for 7.4% vs 6.6%.
Conclusion: Healthcare professionals delay the initiation of insulin in patients with type 2 diabetes until their HbA_{1c} exceeds 10%. As a result patients are exposed to a significant glycaemic burden. Change in treatment improves their glycaemic control for the next 12 months.

Durability of therapeutic intensification strategies in patients with uncontrolled type 2 diabetes

M. Korytkowski[1], M. Brooks[1], D. DeAlmeida[1], M. Lombardero[1], J. Kanter[2], T. Orchard[1], L. Siminerio[1];
[1]University of Pittsburgh, [2]University of Pittsburgh Medical Center, Pittsburgh, USA.

Background and aims: Achieving desired glycaemic targets in type 2 diabetes (T2D) depends in part on medication efficacy and durability. A recent algorithm for pharmacologic intensification in patients with T2D uncontrolled on current medications recommends an individualised approach when choosing among the different classes of glucose lowering agents. There is little information available describing therapeutic durability and efficacy with different pharmacologic strategies in the clinical setting. To address this, we sought to identify therapeutic durability at one year following intensification with insulin, GLP-1 analogue or a third oral diabetes medication (ODM) in a class different from current therapy in patients with T2D with A1C ≥ 7% on one or two ODM.
Materials and methods: 1802 patients were identified between 2005-2011 from a US university based EMR and grouped according to intensification strategy with insulin (n=416), GLP-1 (n=68), or ODM (n=1408). Patients were grouped in one of 4 categories: intensification agent continued without additional therapy (Group1); intensification agent discontinued without additional therapy (Group 2); intensification agent discontinued with addition of another agent (Group 3); or intensification agent continued with addition of another agent (Group 4). The percent of patients in Group 1, identified as Durable Therapy, were compared with Groups 2-4 at one year following intensification (Table).
Results: Therapeutic durability was highest in those intensified with insulin and lowest in those intensified with GLP-1 agents (p<0.001) even after adjusting for baseline A1C, age, gender, race, and BMI (p<0.001). Compared to intensification with insulin, the adjusted OR for durability of therapy with GLP-1 agents was 0.17 (0.10-0.30), and with ODM 0.32 (0.23-0.43).
Conclusion: We conclude that in this observational study those patients with uncontrolled T2D who have intensification of glycaemic therapy with insulin are more likely to have this continued at one year than those who receive GLP-1 agents or an additional ODM. Further investigation into factors associated with persistence of different intensification strategies in patients with uncontrolled T2D is recommended.

Is assessment of postprandial hyperglycaemia useful in determining whether to initiate prandial therapy after basal insulin fails to achieve glycaemic control?

C. Shaefer[1], T. Reid[2], A. DiGenio[3], A. Vlajnic[3], R. Zhou[4];
[1]Georgia Health Sciences University, Augusta, [2]Mercy Diabetes Center, Janesville, [3]Sanofi US, Inc., Bridgewater, [4]Medpace, Cincinnati, USA.

Background and aims: We recently illustrated that after 24 weeks of basal insulin therapy in patients (pts) with type 2 diabetes mellitus (T2DM), HbA_{1c} ≥7.0% alone is a more inclusive indicator of postprandial glucose (PPG) defects than HbA_{1c} ≥7.0% and high fasting plasma glucose (FPG; ≥7.2 mmol/L) in patients with a high PPG (≥10 mmol/L) 2 hours after any meal. Here we investigated basal vs postprandial contributions to hyperglycaemic exposure (HE) in pts with high PPG and in pts with HbA_{1c} ≥7.0% but PPG <10 mmol/L after each meal. We also explored whether there is a threshold PPG that should be avoided, or if change between pre- and postprandial glucose levels (ΔPPG) is a better indicator of glycaemic control.
Materials and methods: Patient-level data from 6 randomized controlled trials in adult pts with T2DM collecting 7-point self-monitored blood glucose (SMBG) data and titrating insulin glargine for ≥24 weeks were pooled and analyzed (N=1,699). HE (>5.6 mmol/L) due to basal hyperglycaemia (BHG) and postprandial hyperglycaemia (PPHG) were calculated and compared at baseline and endpoint in pts with HbA_{1c} ≥7.0%, with or without a PPG ≥10 mmol/L after any meal, who had controlled or high FPG. Contributions to HE were also investigated in pts with HbA_{1c} ≥7.0% according to whether they had a ΔPPG ≥2.2 or 2.8 mmol/L around any meal.
Results: In total, 496 pts had HbA_{1c} ≥7.0% at endpoint: 340 with PPG ≥10 mmol/L after any meal and 156 with PPG <10 mmol/L after each meal (Table). At baseline, the relative contribution of BHG vs PPHG to HE was numerically higher in pts with HbA_{1c} ≥7.0% and PPG <10 mmol/L after each meal. After 24 weeks of treatment, across the whole patient population, the contribution of PPHG to HE in relation to BHG increased. Interestingly, regardless of whether a patient with HbA_{1c} ≥7.0% had a PPG ≥10 mmol/L after any meal or PPG <10 mmol/L after each meal, the contribution of PPHG to HE was >60%. Across both PPG groups, those pts with high FPG appeared to have a lower, but still substantial, relative contribution from PPHG compared with patients within target FPG levels (Table). When comparing contributions to HE according to whether pts had a ΔPPG ≥2.2 or 2.8 mmol/L around any meal, a similar pattern was observed (data not shown), though relative PPHG contributions were somewhat greater in magnitude than those observed with the PPG < or ≥10 mmol/L thresholds.
Conclusion: In pts systematically titrated with insulin glargine for 24 weeks, but not at target HbA_{1c}, there is a substantial contribution to HE from PPHG, regardless of FPG or PPG level. ΔPPG seems to be a stronger indicator of PPHG contribution than PPG level. This strong PPHG contribution to poor glycaemic control in pts titrated with basal insulin but not at target HbA_{1c} suggests an ideal therapy may be basal insulin plus a prandial agent.

Four-year evolution of insulin regimens, glycaemic control, hypoglycaemia and body weight after starting insulin therapy in type 2 diabetes across three continents

P. Home[1], M.-P. Dain[2], N. Freemantle[3], R. Kawamori[4], M. Pfohl[5], V. Pilorget[2], W. Scherbaum[6], G. Vespasiani[7], M. Vincent[2], B. Balkau[8];
[1]Newcastle University, Newcastle upon Tyne, UK, [2]Sanofi, Paris, France, [3]Department of Primary Care and Population Health, University College London, UK, [4]Department of Medicine, Juntendo University, Tokyo, Japan, [5]Evangelisches Bethesda-Krankenhaus Duisburg GmbH, Duisburg, [6]University Hospital Düsseldorf, Germany, [7]Diabetology and Metabolic Disorders Centre, Madonna del Soccorso Hospital, San Benedetto del Tronto, Italy, [8]INSERM, U1018, University Paris Sud 11, Villejuif, France.

Background and aims: Many different patterns of insulin therapy are used in the years after starting insulin treatment in people with type 2 diabetes. Our aim was to describe and understand these patterns and the associated outcomes over 4 years in diverse clinical environments.
Materials and methods: Data from people starting any insulin was collected in 12 countries in 3 continents. Baseline data were retrospective to avoid influence on insulin choice, follow-up data prospective, and both were extracted from regular clinical care records. Funding was provided only for data extraction.
Results: Of 2999 people enrolled in the study, 2272 people were followed over the 4 years. Baseline characteristics were typical of people starting insulin with diabetes duration 10.6 (mean, SD 7.8) yr, HbA1c 9.5 (1.9) % (80 (21) mmol/mol) and BMI 29.3 (6.2) kg/m^2. Starting insulin therapy was any basal for 52%, any premix 23%, meal-time (MT)+basal 14%, MT alone 8% and other insulin regimens 3%, and evolved at 4 years to 30%, 25%, 33%, 2%, and 5%, respectively, with 5% no longer taking insulin. Only 1258 people (53%) were on their baseline regimen at 4 years. Persistence differed by baseline insulin (Table), but was similar for premix and MT+basal. Baseline HbA1c (above) decreased to 7.7 (1.5) % (60 (16) mmol/mol) at 1 year and 7.6 (1.0) % (59 (11) mmol/mol) at 4 years. The change from baseline was similar by insulin regimen (Table), though modestly higher on more complex insulin regimens. Hypoglycaemia affected <20% of people taking any regimen in the last 6 months of the study, with rates indistinguishable for overall and nocturnal events, but too uncommon to draw conclusions for severe hypoglycaemia (Table). Hypoglycaemia did not vary by achieved HbA1c. Body weight increased by 2.7 (7.5) kg over 4 years, ranging from +4.2 (7.6) kg for MT+basal insulin to -2.2 (1.7) kg for no insulin therapy (Table).

Conclusion: Different insulin regimens were started in different populations, and evolved differently in terms of change of regimen and dose, but were associated with similar outcomes apart from body weight change.

Is FPG variability linked to dose escalation during basal insulin titration, leading to excess insulin, weight gain and hypoglycaemia in type 2 diabetes mellitus?

A.B. King[1], J. Stewart[2], A. Vlajnic[2], J. Liang[3];
[1]Diabetes Care Center, Salinas, [2]Sanofi US, Inc., Bridgewater, [3]Medpace, Cincinnati, USA.

Background and aims: Once attained, maintenance of target fasting plasma glucose (FPG) requires continued upward titration of once-nightly basal insulin in some patients with type 2 diabetes mellitus (T2DM), possibly due to increased FPG variability. This may lead to weight gain and hypoglycemia. A recent study showed that intra-day glycemic variability (both before initiation and during insulin treatment) is significantly associated with the risk of hypoglycemia during treatment.
Materials and methods: Data was analyzed from a 24-week trial, INITIATE. Starting from 10 IU once nightly, insulin glargine dose was increased 2-4 IU if FPG was >99 mg/dL for 3 days and decreased 2 IU/day if FPG was <72 mg/dL and symptomatic hypoglycemia occurred. Correlations between dose change after reaching goal, and variability of FPG (measured by SD), weight change, and hypoglycemia were assessed. Quartiles of SD (<20, ≥20 to <26, ≥26 to <35, and ≥35 mg/dL) were compared.
Results: Presented values are means. Of 101 patients with T2DM with daily self-monitored FPG and dose data (age 58 years; men 66%; weight 93 kg; HbA1C 8.8%), 95% (96 patients) achieved FPG goal (<100 mg/dL) during the study. FPG goal was first reached in 42 days at 0.39 IU/kg, increasing to 0.58 IU/kg by study end. FPG was 88 mg/dL at first goal achievement and 116 mg/dL at week 24 (paired t-test (P<0.0001). FPG SD correlated with dose change after reaching goal to study end (r=0.2837, (P=0.0051) and also with FPG SD for the first 3 days after insulin initiation but before titration (r=0.4339, P<0.0001). Dose change after reaching goal correlated weakly with weight gain from reaching goal to study end (r=0.2002, P=0.0505), but not with occurrence of any type of hypoglycemia after reaching goal. Dose change and weight gain were higher in the highest FPG SD group than in the lowest (ANOVA P<0.04), as was incidence of all types of hypoglycemia (except severe), but only numerically so (data not shown). No patient had severe hypoglycemia.
Conclusion: High SD after reaching FPG goal is associated with higher insulin dose, weight gain, and possibly increased hypoglycemia. Presence of high FPG SD during the first three days of insulin treatment suggests that FPG variability may be a patient characteristic that can be detected early. Investigations of causes for increased FPG variability are warranted.

Two prandial insulin approaches for achieving adequate glycaemic control in patients not at goal HbA_{1c} on basal insulin plus oral agents alone: the AUTONOMY study

S. Edelman[1], J. Johnson[2], R. Liu[2], K. Deschamps[2], L.C. Glass[2];
[1]Veterans Affairs Medical Center, University of California San Diego, [2]Eli Lilly, Indianapolis, USA.

Background and aims: There is limited evidence on optimal methods of prandial insulin dose adjustment, especially in the general practitioner setting. AUTONOMY evaluated two approaches to introduce lispro insulin therapy in patients with type 2 diabetes mellitus (T2DM) not achieving adequate glycaemic control on basal insulin plus oral agents. The study looked at changes in glycated hemoglobin (HbA1c), body weight, fasting blood glucose (FBG), and 1,5anhydroglucitol (1,5-AG) after 24 weeks of treatment with one of two patienttitrated basal-bolus algorithms. In addition, 7-point self-monitored blood glucose (SMBG) profile, hypoglycaemia, and adverse events data evaluation was conducted.
Materials and methods: Two independent multicentre, randomised, open-label, parallel studies (A and B) were performed under one protocol in 1106 patients. Inclusion criteria included patients aged 18 to 85 years currently treated with insulin glargine (GLA), NPH, NPL, or detemir (≥20 U/day) plus oral antihyperglycaemic agents for ≥3 months, with a HbA1c >7.0% and ≤12.0%, and who were considered appropriate candidates for prandial insulin therapy. Patients entering the trial on non-GLA basal insulins where converted to GLA and those needing basal optimization (based on goal fasting glucose) underwent a GLA 6-week optimization lead-in. At randomisation, patients were initiated on one of two bolus insulin treatment algorithms for a total of 24 weeks. Both algorithms added pre-meal lispro sequentially to a single meal and patients self-adjusted prandial insulin, with insulin management study diaries, either every 3 days (Q3D), based on previously published algorithm, or by 1 unit of insulin every day (Q1D).
Results: At Week 24, each individual study demonstrated that both algorithms resulted in a clinically equivalent and significant reduction in HbA1c and an increase in 1,5-AG. In addition, close to one-half of patients achieved a goal HbA1c of ≤7% with a low incidence and rate of nocturnal and severe hypoglycaemia (Table).
Conclusion: The AUTONOMY study is the first to demonstrate that in T2DM patients on basal insulin prandial therapy can be effectively and safely initiated in a clinical setting across a broad age range and that self-titration of mealtime lispro can be accomplished by using either of two simple algorithm without the complexity of carbohydrate counting or insulin correction factor.

Insulin lispro mix 25/75 twice daily (LM25) vs basal insulin glargine once daily and prandial insulin lispro once daily (BP) in type 2 diabetes: insulin intensification

F.J. Tinahones[1], J.L. Gross[2], A. Onaca[3], Z. Zhou[4], S. Cleall[5], A. Rodriguez[6]; [1]Hospital Universitario Virgen de la Victoria, Málaga, Spain, [2]Hospital de Clínicas de Porto Alegre, Rio Grande do Sul, Brazil, [3]Pelican Hospital of Oradea, Romania, [4]Diabetes Center, Institute of Metabolism and Endocrinology, The Second Xiangya Hospital and Key Laboratory of Diabetes Immunology, Changsha, China, [5]Eli Lilly, Windlesham, UK, [6]Lilly Spain, Alcobendas, Spain.

Background and aims: Recent ADA/EASD consensus statements consider different approaches for intensifying insulin therapy in T2D. Head-to-head data comparing premixed insulin analogs vs addition of prandial insulin in patients inadequately controlled on a basal-only insulin regimen (BO) are lacking. We compared efficacy and safety of two insulin intensification strategies (LM25 vs BP) in patients inadequately controlled on once-daily basal insulin glargine + metformin and/or pioglitazone.
Materials and methods: This multinational, randomised, open-label, parallel-arm, phase IV trial compared efficacy and safety of LM25 and BP (+ metformin and/or pioglitazone) over 24 weeks in patients with T2D and HbA_{1c} 7.5-10.5% despite BO and fasting plasma glucose ≤6.7 mmol/L (>6.7 mmol/L if basal insulin could not be further titrated). Primary objective was to assess non-inferiority (NI) of LM25 vs BP (NI margin 0.4%, two-sided significance level 0.05, using likelihood-based mixed model repeated measures analysis).
Results: Patients [mean (SD) age 57.5 (9.52) years] from 11 countries were randomised to LM25 (n=236) or BP (n=242) [mean (SD) baseline HbA_{1c} 8.65 (0.79)% and 8.60 (0.75)%, respectively]. Estimated change [least squares (LS) mean (95% CI)] in HbA_{1c} at 24 weeks was -1.30 (-1.44, -1.16)% units with LM25 and -1.08 (-1.22, -0.94)% units with BP. NI was shown between the two treatment strategies [LS mean (95% CI) treatment difference -0.22 (-0.39, -0.05)]; gated superiority assessment showed a statistically significant advantage for LM25 (p=0.010). LS mean (95% CI) daily self-monitored blood glucose (SMBG) levels fell to 8.03 (7.82, 8.23) mmol/L with LM25 and to 8.14 (7.93, 8.35) mmol/L with BP at 24 weeks. Glycaemic variability, measured using SMBG, did not differ between treatments during the study. Overall, mean (SD) rates of documented symptomatic (≤3.9 mmol/l) and nocturnal hypoglycaemia were 7.21 (14.55)/year and 1.54 (4.58)/year with LM25 and 7.72 (15.67)/year and 1.82 (5.25)/year with BP, respectively; 2 patients experienced severe hypoglycaemia (both with LM25; neither required treatment discontinuation). LS mean (95% CI) bodyweight increase at 24 weeks was 1.13 (0.75, 1.52) kg with LM25 and 0.50 (0.11, 0.89) kg with BP (p=0.018). Total mean (SD) daily insulin doses were 53.1 (24.6) IU with LM25 and 50.8 (22.0) IU with BP at last visit. Insulin Treatment Satisfaction and Perception about Medications-Diabetes 21 questionnaires data at last visit showed no statistically significant differences between treatments.
Conclusion: In patients with T2D inadequately controlled on once-daily basal insulin glargine + metformin and/or pioglitazone, intensification with either LM25 or BP improved glycaemic control, although HbA_{1c} reduction was greater with LM25 than with BP. Both regimens were similarly tolerated. LM25 is therefore a valid strategy to intensify insulin treatment in patients inadequately controlled with a BO.

Intensification of basal insulin therapy with step-wise addition of insulin aspart boluses compared with basal-bolus therapy: the FullSTEP study

H. Rodbard[1], V.E. Visco[2], H. Andersen[3], L.C. Hiort[3], D.H.W. Shu[4]; [1]Endocrine and Metabolic Consultants, Rockville, USA, [2]DIM Clinica Privada, Buenos Aires, Argentina, [3]Novo Nordisk, A/S, Bagsværd, Denmark, [4]Division of Endocrinology, University of British Columbia, Vancouver, Canada.

Background and aims: When patients who are receiving basal insulin ± oral agents (OADs) fail to achieve a target HbA_{1c} of 7.0 %, one can transition to use of combined therapy with use of one, two or three boluses of a rapid-acting insulin analogue. The present randomised, open-label, parallel-group, multinational, 32-week trial compared the efficacy and safety of a step-wise insulin regimen with a basal-bolus insulin regimen in patients with type 2 diabetes inadequately controlled on basal insulin + OADs. Patients had used basal insulin (NPH, insulin detemir or insulin glargine), administered once or twice daily for a minimum of 6 months prior to the study. Patients had not regularly received prandial insulin prior to starting the trial, except during any hospitalisation.
Materials and methods: 590 subjects entered into an 8-week run-in period where they were switched from their previous basal insulin to once-daily insulin detemir at bedtime. Then, subjects with HbA_{1c} 7.0-9.0 % and fasting plasma glucose (FPG) ≤8.9 mmol/L (n=401, mean age 59.8 years; HbA_{1c} 7.9 %; diabetes duration 12.6 years) were randomised 1:1 to step-wise or basal-bolus treatment groups. The basal-bolus group received insulin aspart three-times daily for the duration of the trial (32 weeks). In the step-wise group, insulin aspart was introduced before the largest meal (period 1) and continued if HbA_{1c} remained <7.0 %. At 11 weeks (period 2) and again at 22 weeks (period 3), subjects with HbA_{1c} remaining ≥7 % were prescribed an additional insulin aspart bolus injection at the next larger meal.
Results: At 32 weeks, 17.4, 27.4 and 40.3% of the randomised step-wise subjects were receiving one, two or three daily boluses, respectively. The dropout rate was significantly lower for the step-wise (14%) than for the basal-bolus (26%) group. HbA_{1c} change from baseline (last observation carried forward) was −0.98% for the step-wise and −1.12% for the basal-bolus groups: Mean treatment difference (MTD) 0.14 [95% CI: −0.02;0.30]; NS. FPG was also comparable for the treatment groups (MTD 0.12 mmol/L; NS). Subjects in the step-wise group experienced fewer hypoglycaemic episodes compared with those on basal-bolus (rate ratio 0.58 [95% CI: 0.45;0.75]; $p<0.001$). Body weight was comparable for the groups (MTD −0.48 kg; NS), as was BMI (MTD −0.17 kg/m^2; NS). Patient-reported outcomes determined by DiabMedSat indicated better overall patient satisfaction with the step-wise regimen compared with the basal-bolus regimen ($p<0.01$). At 32 weeks, nearly half of all subjects (44.8%) randomised to the step-wise regimen required only one or two bolus injections per day. There were no differences in treatment-emergent adverse events between the two treatment regimens.
Conclusion: Step-wise intensification of prandial insulin therapy provides glycaemic control that is comparable to a basal-bolus regimen after 32 weeks, with a significantly lower risk of hypoglycaemia, improved patient satisfaction and no differences in weight change or treatment-emergent adverse events.

Addition of liraglutide vs addition of a single dose of insulin aspart to insulin degludec plus metformin in patients with type 2 diabetes

C. Mathieu[1], H.W. Rodbard[2], B. Cariou[3], Y. Handelsman[4], A. Philis-Tsimikas[5], A. Ocampo Francisco[6], A. Rana[6], B. Zinman[7]; [1]UZ Leuven, Leuven, Belgium, [2]Endocrine and Metabolic Consultants, Rockville, USA, [3]Nantes University Hospital, Nantes, France, [4]Metabolic Institute of America, Tarzana, [5]Scripps Whittier Diabetes Institute, La Jolla, USA, [6]Novo Nordisk A/S, Søborg, Denmark, [7]Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, Canada.

Background and aims: Previous studies have evaluated the efficacy and safety of adding a glucagon-like peptide-1 (GLP-1) analogue to basal insulin or vice versa in type 2 diabetes. The aim of this trial was to evaluate the efficacy and safety of intensifying treatment with ultra-long-acting insulin degludec (IDeg) plus metformin with the addition of a GLP-1 analogue (liraglutide [Lira]) or a single dose of mealtime insulin aspart (IAsp) in patients with type 2 diabetes.
Materials and methods: In this treat-to-target trial, subjects who remained inadequately controlled (i.e. HbA_{1c} ≥7%) after completing 104 weeks on IDeg once daily plus metformin (Met) were randomised to intensify treatment with either Lira once daily (N=88) or IAsp with largest meal once daily (N=89) for an additional 26 weeks. The primary endpoint was the difference in change in HbA_{1c} at 26 weeks between the two arms.
Results: Mean baseline HbA_{1c} was 7.7% in both arms. HbA_{1c} reduction was significantly greater with IDeg + Lira (−0.74%) than IDeg + IAsp (−0.39%) at Week 26 (estimated treatment difference [ETD] {IDeg + Lira}−{IDeg + IAsp}: −0.32% $[-0.53; -0.12]_{95\%CI}$; p=0.002). After 26 weeks, mean HbA_{1c} was 7.0% with IDeg + Lira and 7.3% with IDeg + IAsp. Significantly more subjects achieved the combined endpoint of HbA_{1c} <7%, without confirmed hypoglycaemia (plasma glucose <3.1 mmol/L or severe hypoglycaemia) and without weight gain with IDeg + Lira (49.4%) vs IDeg + IAsp (7.2%); estimated odds ratio {IDeg + Lira}/{IDeg + IAsp}: 13.8 [5.2; 36.3]; p<0.0001. With lower HbA_{1c} at end of trial, IDeg + Lira subjects experienced 87% less

confirmed hypoglycaemia vs IDeg + IAsp (1.00 and 8.15 events/patient-year, respectively; p<0.0001), 86% less nocturnal confirmed hypoglycaemia (0.17 and 1.11 events/patient-year, respectively; p=0.0002), and significantly greater weight loss (−2.8 kg) vs IDeg + IAsp (+0.9 kg); ETD {IDeg + Lira}−{IDeg + IAsp}: −3.8 kg [−4.7; −2.8]; p<0.0001. IDeg + Lira subjects initially reported more nausea (20.7% patients vs 1.2% for IDeg + IAsp) although incidence decreased within 2 weeks. No differences were seen between arms in adverse events or standard safety parameters.

Conclusion: Intensification with addition of liraglutide to insulin degludec once daily + metformin in patients with type 2 diabetes improved long-term glycaemic control, with weight loss and less hypoglycaemia compared with addition of a single daily dose of IAsp with the largest meal.

Novel formulations BIOD-238 and BIOD-250 result in more rapid absorption and declines from peak than Humalog®

J. Kaye[1], A. Krasner[2], L. Canney[2], P. Pichotta[2], P. Simms[2], J. Krishnarajah[1], E. De Souza[2];
[1]Linear Clinical Research, Perth, Australia, [2]Biodel Inc., Danbury, USA.

Background and aims: Currently available prandial insulins do not provide optimal postprandial glucose coverage when dosed with meals. Formulations of human insulin and insulin analogs containing citrate and sodium-EDTA (Na_2EDTA) have been shown to be more rapidly absorbed than the commercially available formulation of insulin lispro (Humalog®, HU). BIOD-238 and BIOD-250 are novel Na_2EDTA/citrate formulations of HU. BIOD-250 also contains magnesium sulfate which has previously been shown to mitigate Na_2EDTA-mediated local injection site discomfort.

Materials and methods: A single-center, randomized, double-blind three-period crossover study evaluating the pharmacokinetics of 0.2 unit/kg injections of BIOD-238 and BIOD-250 compared to HU was performed in 12 subjects with type 1 diabetes. Local injection site toleration measured with 100 mm visual analog scale (VAS), absolute and relative discomfort scores were also assessed after each test injection.

Results: Pharmacokinetic parameters are summarized in Table 1. Mean times to half maximal insulin concentrations ($T_{ins50\%Early}$), times to maximal insulin concentrations (T_{insMax}) and areas under the curve (AUC) for the first 30 and 45 minutes all indicated significantly increased early lispro absorption for both BIOD-238 and BIOD-250 compared to HU. Mean times to half maximal concentration after the peak ($T_{ins50\%Late}$) and $AUC_{120\text{-}480min}$ indicated that BIOD-238 and BIOD-250 were associated with more rapid declines from peak concentrations relative to HU. The mean VAS score was numerically lower, but not significantly different for BIOD-250 compared to HU (2.7 ± 1.6 mm for BIOD-250 and 8.2 ± 4.5 mm for HU). The mean VAS score for BIOD-238 was significantly higher than that associated with HU (24.2 ± 7.0 mm, p=0.029 vs. HU). Assessments of absolute and relative injection discomfort severity scores mirrored VAS results. Higher doses/injection volumes were associated with increased VAS discomfort scores for BIOD-238, BIOD-250, and HU. General safety results were comparable between treatments.

Conclusion: BIOD-238 and BIOD-250 are associated with more rapid absorption and more rapid declines from peak compared to HU. BIOD-250 and HU cause comparable injection site discomfort.

New insulin glargine formulation has a flat and prolonged steady state profile in subjects with type 1 diabetes

T. Jax[1], T. Heise[1], R. Dahmen[2], K. Bergmann[2], A. Lehmann[2], J. Tillner[2], R.H.A. Becker[2];
[1]Profil, Neuss, [2]Sanofi-Aventis Deutschland GmbH, Frankfurt am Main, Germany.

Background and aims: The new insulin glargine formulation with 300 U/mL (Gla-300) provides a prolonged duration of action compared with insulin glargine 100 U/mL (Gla-100) at single subcutaneous doses. This study investigated how these characteristics transfer into steady state.
Materials and methods: This randomized, double-blind, 2x2 crossover study in two parallel cohorts of subjects with type 1 diabetes (T1DM) compared the pharmacodynamic (PD) and pharmacokinetic (PK) properties, and the safety of once-daily administration of 0.4 U/kg (cohort 1, n=18) and 0.6 U/kg (cohort 2, n=12) Gla-300, with a standard dose of 0.4 U/kg Gla-100. Treatment was administered in an 8-day regimen with an automated euglycemic clamp over 36 h after the last injection.
Results: At steady state, the mean, smoothed, body-weight-standardized glucose infusion rate (GIR) of Gla-300 (0.4 U/kg once daily) showed a stable, plateau-like profile over 24 h after dosing, and a slow decline beyond, with activity until clamp end. Maximum GIR and fluctuation of the individual GIRs were lower, and euglycemia (duration until last smoothed blood glucose [BG] value ≤ 105 mg/dL) was maintained for longer with 0.4 U/kg Gla-300 compared with 0.4 U/kg Gla-100 (mean of 32 h and 29 h, respectively). Correspondingly, a daily dose of 0.6 U/kg Gla-300 resulted in a similarly flat GIR profile, but showed greater and longer activity (maintaining euglycemia for around 34 h) with a higher GIR compared with the lower dose. Serum insulin glargine concentrations corroborated the PD findings, with a flatter and more stable profile during the euglycemic clamp with Gla-300 compared with Gla-100. Exposure increased with dose for Gla-300 and was quantifiable until 32 h and 36 h with 0.4 and 0.6 U/kg Gla-300, respectively, compared with 28 h with 0.4 U/kg Gla-100. Both dose levels of Gla-300 and 0.4 U/kg Gla-100 were well tolerated.
Conclusion: This study in subjects with T1DM shows that, at steady state, the new insulin glargine formulation confers an even flatter and more stable PK/PD profile with longer and tighter BG control than Gla-100.

LY2605541 exhibits a flatter glucodynamic profile than insulin glargine at steady state in subjects with type 1 diabetes

L.A. Morrow[1], M. Hompesch[1], S.J. Jacober[2], S.L. Choi[3], Y. Qu[2], V. Sinha[4];
[1]Profil® Institute for Clinical Research, Inc., Chula Vista, [2]Eli Lilly and Company, Indianapolis, USA, [3]Lilly-NUS Centre for Clinical Pharmacology Pte Ltd, Singapore, [4]Formerly Eli Lilly, Indianapolis, USA.

Background and aims: LY2605541 (LY) is a novel basal insulin analogue with prolonged duration of action. Euglycaemic clamp procedures were used to examine the pharmacodynamics of this new insulin, in comparison with insulin glargine (GL).
Materials and methods: In an open-label, randomised Phase 2 crossover type 1 diabetes mellitus substudy, subjects (n=23) underwent 24-hour Biostator-controlled euglycaemic clamps after 8 weeks treatment with GL or LY. Clinically titrated basal insulin doses (LY: 16 to 64 U, GL: 19 to 60 U) were administered the morning of the clamp. Local regression analysis (LOESS) was used to derive a glucose infusion rate (GIR) profile for each treatment group.
Results: At baseline, mean BMI was 26.8 kg/m^2 ± 4.2 (SD); mean HbA_{1c} was 7.7% ± 1.0. Endpoint dose was 0.43 U/kg ± 0.13 for LY and 0.42 U/kg ± 0.10 for GL. Daily mean blood glucose was 7.7 mmol/L ± 1.2 for LY and 7.9 mmol/L ± 1.2 for GL, p=0.64. Mean hypoglycaemia episodes/30 days were 2.7 ± 2.3 (total) and 0.5 ± 0.8 (nocturnal) for LY and 3.0 ± 2.4 (total) and 0.7 ± 1.1 (nocturnal) for GL, p=0.11 (total) and 0.43 (nocturnal). Mean GIR normalized to unit of insulin was less for LY than GL and persistent over 24 hours. The GIR profile for LY (shown in figure) is consistent with the peak to trough fluctuation ratio of <1.5 that was previously reported. Inter-subject GIR variability (SD) was 0.67 for LY and 0.53 for GL. Eight LY and 1 GL subjects had minimal GIRs over 24 hours (defined as <800 mg/kg), indicating optimal glucose control. Mean total glucose infused ($G_{TOT(024)}$) was 1.22 g/kg ± 0.82 for LY and 1.90 g/kg ± 1.01 for GL, p<0.001. Mean $G_{TOT(0-6)}$ was 0.21 g/kg ± 0.22 for LY and 0.41 g/kg ± 0.22 for GL, p<0.01. Mean $G_{TOT(18-24)}$ was 0.28 g/kg ± 0.18 for LY and 0.35 g/kg ± 0.23 for GL, p=0.20.
Conclusion: LY has a flatter profile than GL, with potentially more stable and predictable metabolic control. LY may have a novel mechanism of action as $G_{TOT(0-24)}$ for LY is less than for GL although LY and GL provide similar glycaemic control.

Single dose of new insulin glargine Gla-300 formulation has a flatter and prolonged PK/PD profile than Gla-100 in Japanese subjects with type 1 diabetes

M. Shiramoto[1], T. Eto[1], A. Watanabe[1], S. Irie[1], A. Fukuzaki[2], K. Bergmann[3], Y. Takahashi[2], R. Dahmen[3], M. Koyama[2], R.H.A. Becker[3];
[1]Hakata Clinic, LTA Clinical Pharmacology Center, Fukuoka, [2]Sanofi-Aventis, Tokyo, Japan, [3]Sanofi-Aventis Deutschland GmbH, Frankfurt am Main, Germany.

Background and aims: Insulin glargine in its commercially available formulation, Gla-100, offers 24-hour basal insulin supply after single-dose subcutaneous (SC) injection. A new formulation containing 300 U/mL insulin glargine (Gla-300) is being developed to improve its activity profile.
Materials and methods: This is a double blind, randomized, cross-over study using the automated euglycemic clamp technique over 36 h. The pharmacodynamic (PD) and pharmacokinetic (PK) properties of Gla-300 versus Gla-100 formulation were compared in 18 Japanese subjects with type 1 diabetes (T1DM). Single SC doses of 0.4 and 0.6 U/kg Gla-300 and 0.4 U/kg Gla-100 were tested.
Results: The profiles of smoothed (locally weighted scatterplot smoothing factor = 0.12) bodyweight-adjusted glucose infusion rate (GIR), blood glucose (BG) and serum insulin concentrations (INS) were different for the two formulations. After administration, Gla-300 GIR gradually increased until approximately 12 h, and thereafter slightly declined up to 24 h and subsequently remained stable until the end of clamp at 36 h. In contrast, the Gla-100 profile was characterized by a smooth increase in GIR over the first hour, with a maximum GIR at around 12 h, and declining thereafter. BG was more tightly controlled with Gla-300 than Gla-100 beyond 24 h, consistent with more sustained action of Gla-300. In line with GIR profiles, INS profiles of Gla-300 were even flatter than Gla-100. All treatments were well tolerated with no differences in safety-related parameters between treatments.
Conclusion: Gla-300 formulation provides even flatter and prolonged PK/PD profiles as compared with Gla-100 in Japanese subjects with T1DM.

Metabolism of insulin glargine in humans is the same regardless of formulation, Gla-100 or Gla-300

A. Steinstraesser, R. Schmidt, K. Bergmann, R. Dahmen, R.H.A. Becker;
Sanofi-Aventis Deutschland GmbH, Frankfurt am Main, Germany.

Background and aims: Gla-300, a new insulin glargine formulation comprising 300 U/mL with an improved pharmacokinetic (PK) and pharmacodymanic (PD) profile compared with Gla-100 has been developed. Insulin glargine (M0) is a 21^{A}-Gly modified mimic of the final intermediate of natural human insulin. Similar to maturation of human insulin in beta-cells, after subcutaneous (SC) injection of insulin glargine, enzymatic removal of the two C-terminal arginines upon redissolution from the subcutaneous depot yields 21^{A}-Gly-human insulin (M1), the predominant metabolite found in circulation responsible for metabolic effects, as demonstrated for Gla-100 (100 U/mL). Subsequent loss of threonine at position 30^{B} yields Des-29^{B}-Thre-M1 (M2). Both M1 and M2 have lower receptor affinity for Insulin-Like Growth Factor 1 (IGF-1), as well as lower mitogenic properties compared with the parent compound and human insulin. The present sub-investigation was to demonstrate that the metabolism of insulin glargine is the same regardless of formulation.
Materials and methods: Blood samples were obtained from 30 subjects with type 1 diabetes (T1DM) treated for 8 days in a single-center, double-blind, 2-treatment, 2-period, 2-sequence cross-over study in two cohorts. A 36 h euglycemic clamp was conducted on Day 8. Subjects received either 0.4 (cohort 1; n=18) or 0.6 U/kg/day Gla-300 (cohort 2; n=12) and 0.4 U/kg/day Gla-100 once daily in randomized period order. Trough values of M0, M1, and M2 were determined for 7 days, and a full PK profile was determined on Day 8. Liquid Chromatography Tandem Mass Spectrometry with prior immunoaffinity enrichment was applied with a Lower Limit of Quantification [LLOQ] ≤ 0.2 ng/mL to separately determine M0, M1 and M2. Conventional unspecific radioimmunoassay (RIA) determination (LLOQ ≤ 5.02 μU/mL) was used for total active insulin content (M0, M1, M2 combined) and comparison of Day 8 samples.
Results: At trough during the first 7 days, M1 was quantifiable after the 2nd to 3rd injection regardless of treatment and dose, pointing to some accumulation. On the profiling Day 8, M1 concentrations for Gla-300 were dose dependent, yet displayed similar flat PK profiles of lower peak-to-trough ratio compared with M1 profiles of Gla-100. This was in line with comparative RIA data. M0 and M2 were below LLOQ in all but a few trough samples of one subject of each cohort, and while M2 was detected in more than one sample of only these two subjects on the profiling Day 8, M0 was detected in few samples of seven further subjects. The findings match observations on insulin glargine metabolism obtained with Gla-100 in subjects with T1DM.
Conclusion: Insulin glargine metabolism in humans is the same regardless of the formulation (Gla-100 or Gla-300) and 21^{A}-Gly-human insulin (M1) is the main circulating active component.

Euglycaemic single dose clamp profile of new insulin glargine formulation in subjects with type 1 diabetes is flat and prolonged

J.A. Tillner[1], K. Bergmann[1], L. Teichert[1], R. Dahmen[1], T. Heise[2], R.H.A. Becker[1];
[1]Sanofi-Aventis Deutschland GmbH, Frankfurt am Main, [2]Profil Institute for Metabolic Research, Neuss, Germany.

Background and aims: Insulin glargine 100 U/mL (Gla-100) has become a standard of care in diabetes as it provides a 24 h basal insulin supply after single-dose subcutaneous injection. A novel formulation containing 300 U/mL insulin glargine (Gla-300) with improved pharmacokinetics (PK) and pharmacodynamics (PD) is being developed. The aim of this study was to assess the PD and PK properties of this novel formulation in subjects with type 1 diabetes (T1DM).
Materials and methods: This study compared single subcutaneous doses of 0.4, 0.6, and 0.9 U/kg Gla-300 and 0.4 U/kg Gla-100 administered to 24 subjects with T1DM in a double-blind, randomized, 4-sequence, crossover study. The automated (Biostator) euglycemic clamp technique was used over 36 hours.
Results: The profiles of serum insulin concentrations (INS), blood glucose (BG), and smoothed body-weight-standardized glucose infusion rate (GIR) were different for the two formulations. Gla-100 GIR reached its maximum at 12 h and thereafter declined towards 36 h in line with the characteristic end-of-action phenomenon. This was consistent with BG values remaining at a euglycemic level (duration until last smoothed BG value ≤ 105 mg/dL) beyond 24 h and then slowly increasing until the end of the clamp period. GIR AUCs increased dose dependently for 0.4, 0.6, and 0.9 U/kg Gla-300 with a similar shape to the PD profiles over 36 hours, showing an increase from 2 h until around 12 h, followed by a slight decline thereafter, with ongoing activity up to 36 h. Gla-300 showed flatter profiles (i.e., lower maximum GIR), with less fluctuation in individual GIRs compared with Gla-100, and lasting BG control at the end of the clamp. All treatments were well tolerated with no differences in safety-related parameters between treatments. In line with GIR profiles, INS profiles of Gla-300 increased dose dependently and were flatter than with Gla-100.
Conclusion: The new insulin glargine formulation provides prolonged activity and a flatter PK/PD profile compared with Gla-100 in subjects with T1DM.

Insulin degludec multi-hexamers retain the native protein fold of human insulin

D.B. Steensgaard, M. Norrman, J. Bearham, C.B. Andersen, A.V. Friderichsen, H.M. Strauss, G. Schluckebier, I. Jonassen;
Novo Nordisk A/S, Måløv, Denmark.

Background and aims: Insulin degludec (IDeg), an ultra-long-acting basal insulin, forms a soluble and stable depot of multi-hexamers after subcutaneous injection with a subsequent slow release of monomers into circulation, resulting in a duration of action of greater than 42 hours. In a formulation that includes both zinc and phenol, IDeg is organised as finite di-hexamers, but upon injection, dissociation of phenol allows the soluble depot of IDeg multi-hexamers to form. The depot is composed of long strands of multi-hexamers with a width of 6.3 ± 0.9 nm as observed by transmission electron microscopy.
Materials and methods: We have conducted various types of spectroscopy to provide insight into the structure of the IDeg molecule and its organisation and self-assembly in the multi-hexamer.
Results: Circular dichroism, Infrared-, and Raman- spectroscopy showed that the fold of the protein backbone in the multi-hexamer is very similar to that of native insulin. The alpha-helical band is predominant and no signs of increased beta-sheet structure relative to that of human insulin were observed. Small angle x-ray scattering demonstrated the presence of strongly elongated structures with a repeated structural unit distanced by 34.8 Å, as indicated by a Bragg peak. The repeated distance originates from hexameric stacking and is close to the inter-hexameric distance also found in classical crystals of human insulin. In contrast, amyloid fibril structures are characterised by a Bragg peak of 4.7 Å and a predominant beta-sheet structure.
Conclusion: In conclusion, the IDeg multi-hexamers are composed of micrometer long linear arrays of hundreds of insulin hexamers. The ultra-long duration of action for IDeg relies on the formation of soluble multi-hexamers in subcutaneous tissue, and the protein fold adopted by insulin degludec in these multi-hexamers is very similar to that of human insulin.

Pharmacokinetics and pharmacodynamics of insulin glargine, changes in glucose and lipid metabolism after either evening or morning injection in type 2 diabetes mellitus

F. Porcellati, P. Lucidi, P. Candeloro, P. Cioli, A. Marinelli Andreoli, G.B. Bolli, C.G. Fanelli;
Internal Medicine, University of Perugia, Italy.

Background and aims: We have already shown the differential pharmacokinetics and pharmacodynamics (PK/PD) of insulin glargine (GLA), when administered in T2DM at different time of the day.
Materials and methods: Here we report GLA effects on glucose (G) fluxes (deuterated G), lipid metabolism (plasma FFA, β-OH-butyrate) in 9 persons with T2DM (mean±SD: age 62±3.5 yrs; BMI 28±3.6 kg/m^2; A1C 7.2±1.1%, known T2DM duration 19±9.9 yrs), during a 24h euglycemic G clamp (cross-over study), with GLA given s.c. (0.4 U/kg), either at 10 AM or at 10 PM.

Results: Total G metabolism (GIR_AUC$_{0\text{-}24h}$) was similar (1012±731, 1058±606 mg/kg, p=0.654), but AUC$_{0\text{-}12h}$ was greater in AM vs PM (589±397 vs 358±259 mg/kg, p=0.010), whereas the opposite was observed for AUC$_{12\text{-}24h}$ (424±357 vs 700±420 mg/kg, AM and PM, p=0.005). PK of GLA and C-peptide levels did not differ in the two studies. The differential insulin activity in AM vs PM on G metabolism was explained by changes in endogenous G production (EGP) with greater suppression in initial 12 h and lower in second 12 h, when GLA was given at 10 AM; the opposite occurred whit GLA given at 10 PM (AUC$_{0\text{-}12h}$ 510±284 vs 744±384 mg/Kg, AM and PM, p=0.066). G utilization was not stimulated. Lipolysis was more suppressed with PM vs AM administration (FFA AUC$_{0\text{-}24h}$ 7.5±1.7 vs 9.2±1.7 mmol.h/L, p<0.001; β-OH AUC$_{0\text{-}24h}$ 6.8±5.0 vs 18±12 mmol.h/L, PM and AM, p<0.003).
Conclusion: PD of insulin GLA in T2DM is dependent on the time of daily injection. Evening administration results in greater GIR requirements in the second 12 h of day (afternoon), in contrast, to morning administration which displays a sensible reduction in metabolic activity from 12 h to 24 h after injection. GLA also suppressed lipolysis to a greater extend in PM vs AM administration. Since PK and C-peptide were similar in the 2 studies, the differential PD might reflect the contribution of diurnal fluctuation in insulin sensitivity (higher in afternoon vs early morning) inducing EGP changes

Adipose tissue levels of human insulin and insulin detemir measured with open flow microperfusion (OFM) during constant intravenous infusion

C. Höfferer[1], T.R. Pieber[1,2], D. Tutkur[1], S.I. Mautner[1,2], J. Damgaard[3], H. Naver[3], C.B. Jeppesen[3], E. Nishimura[3], C.L. Brand[3], C. Fledelius[3], F. Sinner[1,2];
[1]Health, Joanneum Research, Graz, [2]Endocrinology and Metabolism, Medical University Graz, Austria, [3]Diabetes Research Unit, Novo Nordisk, Malov, Denmark.

Background and aims: Human insulin and insulin detemir are easily measured in plasma, whereas sampling larger molecules (>50 kDa) directly in the tissue is difficult with conventional membrane-based techniques. In contrast to human insulin, the majority of insulin detemir is bound to albumin, resulting in a large molecular weight of 67 kDa. By using open flow microperfusion (OFM), a novel membrane-free sampling technique, we were able to compare the pharmacokinetics and pharmacodynamics of human insulin and insulin detemir in subcutaneous adipose tissue and plasma.
Materials and methods: Anaesthetized, diet-induced-obese Sprague Dawley rats were clamped to euglycemia (8 mM) by adjusting the glucose infusion rate (GIR) during constant intravenous insulin infusions. Human insulin was infused at 21 and 42 pmol/min/kg and insulin detemir at 209 and 417 pmol/min/kg to achieve equipotency. 3 OFM probes per rat were implanted in subcutaneous adipose tissue. OFM samples and arterial plasma samples were collected continuously and assayed for human insulin and insulin detemir with specific immunoassays.
Results: Steady-state GIRs were reached at similar times for both insulins. Steady-state concentrations of human insulin and insulin detemir were reached after 100 min in plasma and 200 and 300 min in tissue. At steady-state, GIR was ca. 50 and 90% of maximal GIR for human insulin and insulin detemir. GIRs correlated more strongly with tissue-insulin concentrations than plasma-insulin concentrations.
Conclusion: Our data show that OFM can be used to sample insulin in adipose tissue irrespective of the molecular weight of the insulin. By using OFM, we were able to show that compared to human insulin, insulin detemir appears considerably later in adipose tissue - probably due to its greater molecular size on albumin binding.

Determination of glargine and the metabolites M1 and M2 by using a combination of insulin assays of different specificity

J.M. Axelsson, A. Carlsson, E. Karamihos, H. Ritzén, R. Gunnarsson;
Mercodia AB, Uppsala, Sweden.

Background and aims: Glargine is a long acting insulin analog, with a substitution of glycine for asparagine at A21 and two arginines added to the carboxy terminal of the insulin B chain. After injection, glargine is enzymatically transformed to its metabolites M1 and M2. The cross-reactivity of both glargine and its metabolites in insulin assays makes specific measurement of glargine a complex issue. The aim of this study was to find a method for determination of glargine and its metabolites along with endogenous insulin in human samples.
Materials and methods: We used two well-characterized, commercially available ELISAs to develop a method for determination of insulin, glargine and its metabolites in human samples. An alternative protocol was developed for one of the assays, where the cross-reactivity to glargine and its metabolites would be reduced, but endogenous insulin still detected - an "endogenous insulin ELISA". In the second assay, the cross reaction of glargine and its metabolites was determined - a "total insulin ELISA". The recovery of endogenous insulin, glargine, M1 and M2 was determined in human samples, using these two assays.
Results: The "endogenous insulin ELISA" was highly selective, with 100% cross reactivity to insulin, and non-detectable cross-reactivity to glargine, M1 and M2 within physiological insulin range. The "total insulin ELISA" showed a cross reactivity of 44% to glargine, 41% to M1 and 28% to M2. The recovery of endogenous insulin was 80 - 102 % using the "endogenous Insulin ELISA" in samples spiked with glargine, M1 or M2. Using the "total insulin ELISA", the recovery of glargine in spiked samples was 100 - 106%, the recovery of M1 was 91 - 102%, and M2 was 90-102%.
Conclusion: We conclude that measurement of insulin, glargine and its metabolites in human samples is possible by using two different insulin ELISAs with different specificity. The method described may be a valuable tool to determine glargine or its metabolites in patient samples.

PS 084 Insulin therapies: basal and novel combination

1038

Postprandial glycaemic control following a fixed-ratio combination of insulin degludec and liraglutide compared to each component individually in patients with type 2 diabetes

J.B. Buse[1], S.C.L. Gough[2], H.W. Rodbard[3], V.C. Woo[4], S. Linjawi[5], P. Poulsen[6], L.H. Damgaard[6], B.W. Bode[7];
[1]UNC, Chapel Hill, USA, [2]Oxford Centre for Diabetes Endocrinology and Metabolism, University of Oxford, UK, [3]Endocrine and Metabolic Consultants, Rockville, USA, [4]University of Western Ontario, Winnipeg, Canada, [5]Coffs Endocrine & Diabetes Services, Coffs Harbour, Australia, [6]Novo Nordisk A/S, Søborg, Denmark, [7]Atlanta Diabetes Associates, Atlanta, USA.

Background and aims: Fasting and postprandial plasma glucose levels are key determinants of overall glycaemic control (HbA_{1c}). Here we investigate the complementary modes of action of insulin degludec (IDeg), an ultra-long-acting basal insulin, and liraglutide (Lira), a GLP-1 analogue, as the fixed-ratio combination IDegLira on postprandial glycaemic control following the 3 main meals of the day.
Materials and methods: In this 26-week randomised, open-label trial in patients with type 2 diabetes (T2D) inadequately controlled on metformin ± pioglitazone (n=1663; mean age: 55 yrs; diabetes duration: 6.6 yrs; HbA_{1c}: 8.3%; BMI: 31.2 kg/m^2), IDegLira was given once daily and compared to IDeg or Lira (1.8 mg) given alone. Postprandial control was assessed via 9-point self-measured plasma glucose (9P-SMPG) profiles and 72-h continuous glucose monitoring (CGM; conducted in a subgroup of patients [n=260]). Postprandial PG (PPG) increment (derived from 9P-SMPG) was calculated as the change in pre-meal levels (breakfast, lunch or dinner) to 90 min post meal. Postprandial increment in interstitial glucose was calculated as the area under the curve (AUC) above the pre-meal value from t=0 to 4 h ($iAUC_{0\text{-}4h}$).
Results: After 26 weeks, overall mean SMPG level of the 9-point profile had decreased to 7.1, 7.4 and 8.0 mmol/l with IDegLira, IDeg and Lira, respectively. The reduction from baseline in mean SMPG levels was significantly greater for IDegLira vs IDeg (3.2 vs 3.0 mmol/l; estimated treatment difference (ETD): -0.30 mmol/l [-0.50; -0.09], p=0.004), and for IDegLira vs Lira (3.2 vs 2.1 mmol/l; ETD: -0.93 mmol/l [-1.13; -0.73], p<0.0001). Pre-breakfast SMPG levels were similar for IDegLira and IDeg (5.8 vs 5.7 mmol/l) but higher in the Lira group (7.2 mmol/l). IDegLira reduced mean PPG increment over all main meals significantly more than IDeg (by 0.4 vs 0.2 mmol/l; ETD: -0.45 mmol/l [-0.63; -0.28], p<0.0001). A similar reduction was observed for IDegLira and Lira (ETD: 0.06 mmol/l [-0.11; 0.23], p=0.48). Similar results were obtained with CGM where $iAUC_{0\text{-}4h}$ (over all main meals) was significantly smaller with IDegLira vs IDeg (ETD: -0.34 mmol/l [-0.57; -0.11], p=0.0047) but similar for IDegLira and Lira (ETD: 0.10 mmol/l [-0.14; 0.33], p=0.41). Reductions in individual meal PPG increments were comparable for IDegLira and Lira. However, for each individual meal, significantly greater reductions in PPG increment (of similar magnitude) were observed for IDegLira vs IDeg. For CGM, $iAUC_{0\text{-}4h}$ was numerically lower at lunch and significantly lower at breakfast and dinner with IDegLira vs IDeg.
Conclusion: Once-daily IDegLira provides improved postprandial glycaemic control following all 3 main meals of the day (breakfast, lunch and dinner). For all meals, reductions in PPG increments were significantly greater than IDeg, whereas the effects of IDegLira and Lira were similar. The combined effects of IDeg and Lira on fasting and postprandial glucose levels results in a substantial overall improvement in glycaemic control as compared to each component individually.

A novel concentrated recombinant human insulin formulation with improved ultra-rapid prandial and similar basal absorption as insulin lispro protomine mixes

R. Pohl, R. Hauser, B.R. Wilson, M. Li, M. Guinness, P. Reddy, M. Jackson, E. De Souza;
Biodel Inc, Danbury, USA.

Background and aims: Formulations of U-100 recombinant human insulin (RHI) and insulin lispro (IL) containing EDTA and citrate show increased rates of absorption after subcutaneous (sc) injection in man compared to commercial formulations of RHI and IL. BIOD-530 and BIOD-531 are similar EDTA/citrate formulations with RHI concentrations of 400 U/ml. In previous studies in diabetic pigs, BIOD-530 had a significantly faster onset and similar duration of action to RHI U-500 which provides both prandial and basal coverage in type 2 diabetes patients requiring larger injection volumes. BIOD-531 was developed with $MgSO_4$ to mitigate EDTA related injection site discomfort. The aim of this study was to compare pharmacokinetic (PK) and pharmacodynamic (PD) profiles in diabetic miniature swine of BIOD-531 with U-100 formulations of mixtures of IL-Protamine (ILP) and IL 50/50 (ILP/IL 50/50) and 75/25 (ILP/IL 75/25) which also provide both prandial and basal coverage in patients with diabetes.
Materials and methods: Test formulations consisted of ILP/IL 75/25, ILP/IL 50/50 and BIOD-531. On the morning of each crossover study, miniature diabetic swine were given a sc dose (0.25 U/kg) of test formulation followed by a meal. Study 1 and Study 2 compared BIOD-531 with ILP/IL 75/25 and ILP/IL 50/50, respectively. Blood glucose and plasma insulin were sampled from -30 to 480 min post dose. Plasma insulin was measured by an ELISA method and glucose concentration determined by YSI. Time to half maximal concentration ($T_{50\%early}$) was calculated for each swine and averaged for each test article. Results of each study compared BIOD-531 to ILP/IL 75/25 or 50/50 mixtures using Students t-test.
Results: Concentration vs. time profiles are shown in the figure below; data for BIOD-530 and IL are included as a reference. Insulin concentration rose to higher peaks after BIOD-531 injection compared to either ILP/IL mixture. Despite rising to a higher peak, the absorption rates as reflected by $T_{50\%early}$ (min) and $AUC_{0\text{-}30min}$ (μU/ml*min) of BIOD-531 (Study 1: 25±5 and 1582±397; Study 2: 11±2 and 1475±134, respectively) were more rapid than ILP/IL 75/25 (35±6 and 351±82*, respectively) or ILP/IL 50/50 (23±3* and 777±128*, respectively) and resulted in a more rapid decline of glucose concentrations (*p<0.05 vs. BIOD-531). The duration of action as reflected by the percent total $AUC_{180\text{-}480min}$ was similar across the formulations: BIOD-531 (32-43%), ILP/IL 75/25 (45%) and ILP/IL 50/50 (35%). The glucose concentrations of all three formulations remained suppressed up to 480 min while insulin and glucose concentrations returned towards baseline levels around 240 min following IL administration.
Conclusion: BIOD-531 has a rapid onset of action comparable to IL and a similar basal control profile to ILP/IL pre-mixed insulins. BIOD-531 has the potential to deliver improved prandial and comparable basal coverage as pre-mixed insulins with lower injection volumes.

IDegAsp shows distinct prandial and basal glucose-lowering effects at steady state in subjects with type 1 diabetes

T. Heise[1], L. Nosek[1], H. Hastrup[2], S. Chenji[3], O. Klein[1], H. Haahr[2];
[1]Profil Institut für Stoffwechselforschung, Neuss, Germany, [2]Novo Nordisk A/S, Søborg, Denmark, [3]Novo Nordisk GSC, Bangalore, India.

Background and aims: Insulin degludec/insulin aspart (IDegAsp) is a soluble co-formulation of 70% insulin degludec (IDeg) and 30% insulin aspart (IAsp) providing both ultra-long-acting basal coverage and a prandial insulin bolus in a single injection. The aim of this trial was to investigate the pharmacodynamic properties of IDegAsp at steady state in subjects with type 1 diabetes (T1DM).
Materials and methods: This was a single-centre, multiple-dose trial in subjects with T1DM. In order to achieve steady state of the basal component, subjects received IDeg once daily (0.42 U/kg) for 5 consecutive days. Separate bolus doses of IAsp were administered as needed for safety and glycaemic control. On Day 6 a 30-h euglycaemic clamp procedure was performed (Biostator, blood glucose target: 100 mg/dL) immediately following a single dose of 0.6 U/kg IDegAsp (comprising 0.42 U/kg IDeg and 0.18 U/kg IAsp).
Results: Twenty-two subjects (mean: age 40 years, duration of diabetes 23 years, BMI 24.6 kg/m^2, HbA_{1c} 7.9%) were exposed to treatment. The mean glucose infusion rate (GIR) profile showed a rapid onset of action and a distinct peak followed by a flat, prolonged basal action (Figure 1). The median time to maximum glucose-lowering effect of IDegAsp ($tGIR_{max}$) was 2.5 h. Duration of action (from dosing until blood glucose was consistently >150 mg/dL) extended beyond 30 h in all subjects.
Conclusion: In conclusion, at steady state the glucose-lowering effect of IDegAsp in subjects with T1DM was characterised by a distinct peak action due to IAsp, and a separate and stable basal action from IDeg sustained for >30 hours. This profile may constitute a clinical advance, allowing for the combination of specific meal coverage with full 24-h basal insulin coverage.

IDegAsp produces a dose-proportional glucose-lowering effect in subjects with type 1 diabetes

L. Nosek[1], T. Heise[1], O. Klein[1], H.-V. Coester[1], C. Roepstorff[2], A. Svendsen[2], H. Haahr[2];
[1]Profil Institut für Stoffwechselforschung, Neuss, Germany, [2]Novo Nordisk A/S, Søborg, Denmark.

Background and aims: Insulin degludec/insulin aspart (IDegAsp) is a 70%/30% combination of insulin degludec (IDeg) and insulin aspart (IAsp), providing both an ultra-long-acting basal component and a rapid-acting bolus component in a single injection. The aim of this trial was to investigate the pharmacodynamic properties of three clinically relevant dose levels (0.4, 0.6 and 0.8 U/kg) following a single dose of IDegAsp in subjects with type 1 diabetes (T1DM).
Materials and methods: This was a double-blind, single-dose incomplete block crossover trial in subjects with T1DM. In order to measure glucose-lowering effect, a 26-h euglycaemic clamp procedure (Biostator, blood glucose target: 100 mg/dL) was performed immediately following each 0.4, 0.6 or 0.8 U/kg dose of IDegAsp.
Results: A total of 33 C-peptide negative subjects with T1DM (mean: age 39 years, duration of diabetes 17 years, BMI 25.1 kg/m^2, HbA_{1c} 8.0%) were included in this study. With increasing IDegAsp dose level, both the 24-hour area under the glucose infusion rate (GIR) curve (area under the curve $[AUC]_{GIR,0\text{-}24h,SD}$) and the maximum GIR ($GIR_{max,SD}$) increased significantly and proportionally. The estimated log dose-log $AUC_{GIR,0\text{-}24h,SD}$ (slope = 1.19, 95% CI: [0.99; 1.40] and log dose-log $GIR_{max,SD}$ (slope = 0.89 [0.66,1.13]) both supported dose proportionality as 1.0 was included in the 95% CI in each case. The 24-hour single-dose GIR profile of IDegAsp showed both a distinct peak action due to prandial IAsp and a separate and stable basal action from IDeg (Figure 1).
Conclusion: IDegAsp produces a proportional dose-response across three clinically relevant dose levels and a pharmacodynamic profile with separate prandial and basal components in subjects with T1DM.

Clinical efficacy and safety of insulin glargine as compared to other insulin preparations in the treatment of type 2 diabetes mellitus: a systematic review and meta-analysis

P. Wojciechowski[1], P. Rys[1], A. Rogoz-Sitek[1], G. Niesyczynski[1], A. Syta[2], J. Lis[2], M.T. Małecki[3];
[1]HTA Consulting, Cracow, [2]Sanofi Poland, Warsaw, [3]Department of Metabolic Diseases, Jagiellonian University, Medical College, Cracow, Poland.

Background and aims: Many patients with type 2 diabetes mellitus (T2DM) require insulin to achieve a proper glycemic control. Available systematic reviews have assessed only selected insulin preparations giving no definitive answer on whether insulin glargine (IGlar) provides additional clinical benefits to T2DM patients. To our knowledge this is the first systematic review combining all data for comparison of IGlar with other insulins enabling to make synthetic and reliable conclusions.
Materials and methods: The analysis was based on clinical trials, both randomized (RCTs) and nonrandomized (nRCTs), identified by a systematic literature search of medical databases (MEDLINE, EMBASE, CENTRAL and etc.) up to December 2012. Relevant studies compared IGlar, added to oral drugs (OAD) or in combination with bolus insulin, with human insulin (NPH) or insulin detemir (IDet) in the same regimen, as well as with premixed insulin (MIX). Results were presented as weighted mean difference (WMD), RR with a 95% CI.
Results: We found 29 relevant RCTs involving 7293 patients followed for 12-52 weeks. Pooled data from RCTs assessing insulin as add on to OAD showed that the probability of achieving target HbA1c level without any hypoglycemia was significantly higher with IGlar +OAD than with NPH + OAD (RR = 1.32 [1.09, 1.59]) or MIX without OAD (RR = 1.61 [1.22, 2.13]) and comparable to those observed for IDet+OAD (RR = 1.07 [0.87, 1,.33]) and MIX+OAD (RR = 1.09 [0.86, 1.38]). With respect to fasting glucose level IGlar+OAD showed significant advantage over NPH+OAD (WMD = -0.26 mmol/l [-0.32, -0.20]), MIX without OAD (WMD = 0.93 mmol/l [-1.39, -0.46]) and IDet+OAD (WMD = -0.30 mmol/l [-0.58, -0.02]). Symptomatic hypoglycemic episodes in patients on IGlar+OAD were observed with similar frequency as in those who were treated with IDet+OAD (WMD = -1.37 [-3.45, 0.71]), but were significantly lower in comparison with NPH+OAD (WMD = -2.32 [-4.14, -0.51]) and MIX with or without OAD (WMD = -5.80 [-8.72, -2.88]; WMD = -4.89 [-7.41, -2.36], respectively). Pooled data from RCTs assessing basal-bolus regimen revealed that the percentage of patients achieving target HbA1c was similar to NPH (RR = 1.14 [0.91, 1.44]) and significantly higher than MIX (RR = 1.26 [1.12, 1.42) or IDet (RR = 1.38 [1.11, 1.72]). The risk of severe hypoglycemia was lower in IGlar than in NPH (RR = 0.77 [0.63, 0.94]), with no statistically significant differences in comparison with MIX (RR = 0.74 [0.46, 1.20]) and IDet (RR = 1.10 [0.54, 2.25]). IGlar+OAD has comparable safety profile to NPH, with less frequent adverse events leading to treatment discontinuation than MIX+OAD (RR = 0.41 [0.22, 0.76]) and IDet+OAD (RR = 0.40 [0.24, 0.69]). Also severe adverse reaction were less common for IGlar+OAD when compared with MIX+OAD (RR = 0.71 [0.52; 0.98]). IGlar used together with bolus insulin revealed similar safety profile as other options. Supportive data from 21 nRCTs involving 26639 patients followed for up to 18 months confirmed that in a real-life setting IGlar is an effective option also for those patients in whom glycemic control remains inadequate despite human insulin treatment.
Conclusion: IGlar can provide better or comparable glycemic control with the same or even better safety profile as most of the alternative treatment options.

Lower within-subject variability in mean blood glucose concentration with insulin degludec vs insulin glargine: a meta-analysis of patients with type 2 diabetes

L.F. Meneghini[1], S.B. Harris[2], M. Evans[3], S. Rasmussen[4], T. Johansen[4], T.R. Pieber[5];
[1]University of Miami Miller School of Medicine, Miami, USA, [2]University of Western Ontario, London, Canada, [3]Llandough Hospital, Cardiff, UK, [4]Novo Nordisk A/S, Søborg, Denmark, [5]Medical University of Graz, Austria.

Background and aims: Insulin degludec (IDeg) is a new ultra-long-acting basal insulin shown to have low day-to-day variability in a euglycaemic clamp study. In this *post-hoc* meta-analysis of patients with type 2 diabetes (T2D), we compared day-to-day variability in mean self-measured blood glucose (derived from 9-point profiles; 9P-SMPG) between IDeg and insulin glargine (IGlar).
Materials and methods: This patient-level meta-analysis included all five phase 3a, randomised, open-label, treat-to-target trials (26 or 52 week) in which once-daily IDeg and IGlar have been compared. 9P-SMPG profiles comprised measurements made before and 90 min after the start of breakfast, lunch and main evening meal, before bedtime, at 4 AM, and before start of breakfast the next day. Within-subject variability (CV%) in the overall mean plasma glucose (PG) concentration of the 9P-SMPG profile (area under the profile) was estimated from profiles recorded at weeks 12, 16, and 26 (26-week trials) and weeks 12, 16, 26, 40, and 52 (52-week trials), using a linear mixed model.
Results: Estimated within-subject variability in mean 9P-SMPG was significantly lower by 7-10% for IDeg vs IGlar for patients on basal insulin plus OAD therapy, as well as the subset of previously insulin-naïve patients (Table).
Conclusion: In conclusion, IDeg is associated with significantly lower within-subject day-to-day variability in mean blood glucose concentration than IGlar in patients with T2D receiving basal insulin plus OAD therapy.

Population	Insulin degludec (IDeg)		Insulin glargine (IGlar)		IDeg/IGlar (ratio [95% CI])
	n	CV%	n	CV%	
T2D (BB)	692	16.0	236	16.3	0.98 [0.93; 1.04]
T2D (BOT)	1370	13.8	789	14.9	0.93 [0.89; 0.96]*
T2D (BOT-IN)	1162	13.8	581	15.2	0.90 [0.86; 0.94]*

n = number of subjects; CV% = coefficient of variation; T2D = Trials 3579, 3672, 3582, 3586 and 3668 (excluding IDeg flexible dosing group); BB = basal-bolus therapy (Trial 3582); BOT = basal insulin plus OAD therapy (Trials 3579, 3672, 3586, 3668 [excluding flexible dosing group]); BOT-IN = previously insulin-naive patients on BOT therapy (Trials 3579, 3762 and 3586); *p<0.05

Superior FPG control and reduced hypoglycaemia with IDegAsp vs BIAsp 30 in adults with type 2 diabetes mellitus inadequately controlled on pre/self-mixed insulin: a randomised phase 3 trial

G. Fulcher[1], G. Bantwal[2], J.S. Christiansen[3], T. Andersen[4], H. Mersebach[4], L.K. Niskanen[5];
[1]Diabetes and Endocrinology, Royal North Shore Hospital, Sydney, Australia, [2]St Johns Medical College Hospital, Bangalore, India, [3]MEA, Aarhus University Hospital, [4]Novo Nordisk A/S, Søborg, Denmark, [5]School of Medicine, University of Eastern Finland, Helsingfors, Finland.

Background and aims: Insulin degludec/insulin aspart (IDegAsp) is a soluble co-formulation of insulin degludec (70%) and insulin aspart (30%) that provides both an ultra-long-acting basal and a rapid acting prandial component in a single injection. This trial compared the efficacy and safety of

IDegAsp vs biphasic insulin aspart 30 (BIAsp 30) in adults with type 2 diabetes (TD2M) inadequately controlled with once daily or twice daily (BID) pre-mixed or self-mixed insulin regimens, with or without additional oral anti-diabetic drugs (OADs).

Materials and methods: In this 26-week randomised open-label multinational treat-to-target phase 3 trial, participants (mean: age 58.7 years, HbA_{1c} 8.4%, fasting plasma glucose [FPG] 8.7 mmol/L, BMI 29.3 kg/m^2) were randomised (1:1) to BID injections of IDegAsp (n=224) or BIAsp 30 (n=223) and ongoing OADs were permitted. Injections were administered with breakfast and the main evening meal and dose-titrated according to a pre-breakfast and pre-main evening meal self-measured plasma glucose target of 4-5 mmol/L.

Results: After 26 weeks, mean HbA_{1c} was 7.1% for both treatment groups and IDegAsp was within the prespecified non-inferiority margin for mean change in HbA_{1c} from baseline (primary endpoint; estimated treatment difference [ETD] -0.03%-points, 95% CI -0.18; 0.13). IDegAsp was superior in lowering FPG compared with BIAsp 30 (ETD -1.14 mmol/L, 95% CI -1.53; -0.76, p<0.001) by the end of the trial. Final mean daily insulin dose was 1.08 U/kg for IDegAsp and 1.20 U/kg for BIAsp 30 (estimated rate ratio [RR] 0.89, 95% CI 0.83; 0.96, p=0.002). Significantly fewer confirmed hypoglycaemia episodes (self-reported PG <3.1 mmol/L or severe episode requiring assistance) were reported for IDegAsp compared with BIAsp 30: 9.7 vs 14.0 events per year, respectively (estimated RR: 0.68, 95% CI 0.52; 0.89, p=0.0049). The rate of nocturnal confirmed hypoglycaemia episodes (onset 00.01-05.59, inclusive) was also significantly lower with IDegAsp compared to BIAsp 30 (0.7 vs 2.5 events per year, estimated RR 0.27, 95% CI 0.18; 0.41, p<0.0001); the rate of severe hypoglycaemia was numerically lower (0.09 vs 0.25 events per year, estimated RR 0.50, 95% CI 0.19; 1.30, p=ns). During the maintenance period (post-16 weeks' treatment) significantly lower overall rates of confirmed (estimated RR 0.61, 95% CI 0.45; 0.83, p=0.0015), nocturnal confirmed (estimated RR 0.23, 95% CI 0.13; 0.41, p<0.0001) and severe (estimated RR 0.11, 95% CI 0.01; 0.91, p=0.04) hypoglycaemia episodes were observed for IDegAsp vs BIAsp 30.

Conclusion: IDegAsp BID in T2DM effectively improves long-term glycaemic control measured by HbA_{1c} (non-inferior to BIAsp 30), and is superior to BIAsp 30 in lowering FPG. IDegAsp was also associated with significantly lower rates of overall- and nocturnal- confirmed hypoglycaemia episodes compared with BIAsp 30, especially during the maintenance period. These results indicate comparable overall glycaemic efficacy and a favourable safety profile compared with BIAsp 30 when switching from once- or twice-daily pre/self-mixed insulin to IDegAsp as part of an insulin intensification or dose optimisation regimen.

Superior FPG control and less nocturnal hypoglycaemia with IDegAsp vs BIAsp 30 in Asian subjects poorly controlled on basal or pre/self-mixed insulin: randomised phase 3 trial

J.S. Christiansen[1], F.C.C. Chow[2], D.S. Choi[3], S. Taneda[4], K. Hirao[5], Y. Park[6], T. Andersen[7], M.-A. Gall[8], S. Kaneko[9];
[1]MEA, Aarhus University Hospital, Denmark, [2]Department of Medicine & Therapeutics, Prince of Wales Hospital, Hong Kong, China, [3]Korea University Anam Hospital, Seoul, Republic of Korea, [4]Diabetes Center, Manda Memorial Hospital, Hokkaido, [5]Department of Internal Medicine, HEC Science Clinic, Yokohama, Japan, [6]Internal Medicine, Hanyang University Hospital, Seoul, Republic of Korea, [7]Novo Nordisk A/S, Søborg, [8]Global Development, Novo Nordisk A/S, Søborg, Denmark, [9]Diabetes and Endocrine Division and Lifestyle, Takasuki Red Cross Hospital, Ōsaka, Japan.

Background and aims: Insulin degludec/insulin aspart (IDegAsp) is a soluble co-formulation of the novel basal insulin degludec (70%) and insulin aspart (30%) combining ultra-long-acting basal coverage and a rapid-acting bolus in a single injection. This trial investigated the efficacy and safety of IDegAsp and biphasic insulin aspart 30 (BIAsp 30) in Asian subjects with type 2 diabetes (T2DM) inadequately controlled on once or twice daily (BID) basal, premixed or self-mixed insulin, with or without metformin.

Materials and methods: In this pan-Asian (Hong Kong, Japan, Malaysia, South Korea, Taiwan) 26-week, randomised, open-label, treat-to-target phase 3 trial, participants (mean: age 59.8 y, HbA_{1c} 8.4%, fasting plasma glucose [FPG] 7.9 mmol/L, BMI 25.4 kg/m^2) were randomised (2:1) to BID injections of IDegAsp (n=282) or BIAsp 30 (n=142) plus continuing any previous metformin treatment. Both insulins were administered with breakfast and main evening meals and dose-titrated according to a pre-breakfast and pre-main evening meal self-measured plasma glucose target of 4-5 mmol/L.

Results: After 26 weeks, mean HbA_{1c} was 7.1% for IDegAsp and 7.0% for BIAsp 30; IDegAsp was non-inferior (predefined margin 0.4%) to BIAsp 30 for mean change in HbA_{1c} from baseline (primary endpoint) as expected in a treat-to-target trial (estimated treatment difference [ETD] IDegAsp-BIAsp 30: 0.05%-points, 95% CI -0.10; 0.20). IDegAsp was superior to BIAsp 30 in lowering FPG (ETD -1.06 mmol/L, 95% CI -1.43; -0.70, p<0.001), with levels reduced to 5.4 mmol/L and 6.5 mmol/L, respectively, by the end of the trial. The mean daily insulin dose after 26 weeks' treatment was 0.79 U/kg for IDegAsp and 0.99 U/kg for BIAsp 30 (estimated rate ratio [RR] 0.79, 95% CI 0.73; 0.85, p<0.0001). The rate of confirmed hypoglycaemia (self-reported PG <3.1 mmol/L or severe episode requiring assistance) was similar between IDegAsp and BIAsp 30 (9.6 episodes/y vs 9.5 episodes/y, estimated RR 1.00, 95% CI 0.76; 1.32, p=ns), while the rate of nocturnal confirmed hypoglycaemia (onset from 00.01 to 05.59) was numerically (33%) lower with IDegAsp (estimated RR 0.67, 95% CI 0.43; 1.06, p=ns). The rate of severe hypoglycaemia was not significantly different for IDegAsp and BIAsp (0.05 and 0.03 episodes/y, estimated RR 1.3, 95% CI 0.24; 7.03, p=ns). During the maintenance period (post-16 weeks' treatment) there was a trend towards lower overall confirmed (estimated RR 0.84, 95% CI 0.6; 1.19, p=ns), nocturnal confirmed (estimated RR 0.70, 95% CI 0.39; 1.26, p=ns) and severe (estimated RR 0.69, 95% CI 0.05; 9.8 p=ns) hypoglycaemia rates for IDegAsp vs BIAsp 30. There was no difference in observed adverse event rates between treatment groups.

Conclusion: IDegAsp dosed BID effectively improves long-term glycaemic control and provides superior FPG reductions with a trend towards fewer nocturnal confirmed hypoglycaemia episodes at approximately 20% lower final dose compared with BIAsp 30. These results indicate IDegAsp is a promising treatment option for Asian subjects with T2DM requiring both basal and prandial insulin coverage.

PS 085 Hypoglycaemia in type 1 and type 2 diabetes

1046

Temporal variations in hypoglycaemia occurring in hospital in people with diabetes who are at risk of hypoglycaemia

R. Rajendran, C. Kerry, S. Mitchell, S. Sharma, A. Rayman, G. Rayman;
Diabetes and Endocrinology, The Ipswich Hospital NHS Trust, UK.

Background and aims: Hypoglycaemia is a major concern when tight glycaemic control is targeted amongst patients with diabetes in hospital. Our hospital is a medium sized acute district general hospital with approximately 550 inpatient beds. The aim of our study was to determine whether there were temporal patterns in hypoglycaemia episodes amongst patients with diabetes who are at risk of hypoglycaemia, whilst in hospital.
Materials and methods: All capillary blood glucose (CBG) readings in all hospitalised adult patients (≥16 years) measured on Precision Xceed Pro™ blood glucose meters, the only CBG measurement system across the entire hospital, were remotely captured over a two month period. Patients who did not have diabetes and those with diabetes on diet alone or single or combination of glucose lowering therapies not associated with hypoglycaemia, for e.g. metformin, dipeptidyl peptidase-4 inhibitors, glucagon-like peptide-1 analogues were excluded. Therefore, CBG measurements of only those at risk i.e. insulin and/or sulphonylurea treated patients were included in the analysis. We classified mild hypoglycaemia as CBG readings between 3.0 to 3.9mmol/l and severe as CBG readings <3mmol/l. CBG readings <4mmol/l within four hours of a previously documented hypoglycaemic episode were excluded since this could reflect re-testing following the previous hypoglycaemic episode.
Results: There were 15,844 CBG tests in the 'at risk' group, of which 8,549 tests were performed between 09:00 to 20:59 hours (daytime) and 7,295 tests between 21:00 and 08:59 hours (night time). There were 771 hypoglycaemic episodes, 4.9% of all tests. Nocturnal hypoglycaemia was significantly higher than daytime hypoglycaemia ($p<0.0001$); 542 nocturnal versus 229 during daytime. Both mild and severe hypoglycaemic episodes were significantly higher at night (338 and 204 respectively), 2.68 and 1.98 times more frequent than daytime hypoglycaemia (126 and 103 respectively), $p<0.0001$.
Conclusion: Hypoglycaemia occurred more frequently between 21:00 and 08:59 hours in patients with diabetes at risk of hypoglycaemia. We speculate that this could be due to inadequate carbohydrate intake during this period as the inter-meal timings between evening meal and next day breakfast in our hospital is between 12-14 hours and carbohydrate containing bedtime snacks are not always available.

1047

Frequency and characteristics of iatrogenic hypoglycaemia requiring medical assistance: a multicentre study of tertiary hospitals

M. Mylona[1], S. Kalopita[2], L. Lanaras[2], A. Papazafiropoulou[3], S. Pappas[3], S. Karamagkiolis[4], V. Vazyntari[5], A. Melidonis[5], A. Xilomenos[6], M. Voukali[7], M. Chryssochoou[8], D. Kapsalas[9], N. Aggelis[4], V. Ntova[6], S. Liatis[1];
[1]Diabetes Center, First Department of Internal Medicine, Laiko Hospital, Athens, [2]Department of Internal Medicine, General Hospital of Lamia, [3]Third Department of Internal Medicine and Diabetes Center, Nikaia General Hospital, Athens, [4]Department of Internal Medicine, General Hospital of Larissa, [5]Diabetes Center, Tzaneio Hospital, Athens, [6]Department of Internal Medicine, General Hospital of Agrinio, [7]Diabetes Center, Konstantopouleio Hospital, Athens, [8]Department of Pathophysiology, Athens University Medical School, Laiko Hospital, Athens, [9]First Department of Internal Medicine, General Hospital of Volos, Greece.

Background and aims: Hypoglycemia in diabetes usually results as a consequence of treatment, aiming at correction of hyperglycemia. Iatrogenic hypoglycemia is considered as a major factor contributing in morbidity and mortality of patients with diabetes. Aim of the present study was to examine the frequency, clinical characteristics and outcome of iatrogenic hypoglycemia requiring medical assistance.
Materials and methods: Eight hospitals (nine clinics) in five cities participated in this 22-month, prospective survey of documented iatrogenic hypoglycemia at the emergency departments (ED). The clinical characteristics of all patients were recorded at presentation and during hospitalization, if required. Patients were compared to a control group consisted of patients with diabetes, visiting the outpatient diabetes clinics of the same hospitals, during the same time period.
Results: During a median follow-up of 18 months, 295 episodes of iatrogenic hypoglycemia in 294 patients (146 men) were recorded. The frequency differed between centers and ranged between 0.25 and 0.78 cases per 100 patients. The majority (267 episodes, 90.5%) was patients with type 2 diabetes (T2D, mean age 76.8±10.0 years), while 24 (8.1%) episodes were recorded in 23 patients with type 1 diabetes (T1D, mean age 42.7±18.3 years). The mean plasma glucose value at presentation was 38.1±23.9 mg/dL. Hospitalization was required in 66.7% of patients (23.8% in T1D). Total in-hospital mortality was 4.4%, entirely regarding patients with T2D. Two deaths have been attributed to hypoglycemia itself and two others have been considered as its direct consequence (aspiration pneumonia). There were two documented fatal myocardial infarctions. Out of the 267 T2D patients, 113 (42.3%) had been on insulin therapy. Out of the 154 non-insulin treated T2D patients, 143 (94.1%) had been taking sulfonylureas (SU).60.5% of the patients had an e-GFR (aMDRD) < 60 ml/min. Compared to the control group, T2D patients with hypoglycemia were older, had longer disease duration, higher prevalence of serious comorbidities, lower eGFR and were more likely to receive treatment with SUs:
Conclusion: Hypoglycemia requiring medical assistance is a moderately frequent condition at the EDs of tertiary hospitals, with a mortality rate close to 5%. The majority of patients have T2D, they are elderly individuals suffering from serious medical conditions and in their great majority are treated with insulin or SUs.

1048

Diabetic autonomic neuropathy predicts severe hypoglycaemia in patients with type 2 diabetes mellitus: a ten-year follow up study

Y. Ahn, S.-H. Ko, S.-H. Ko, S. Moon, J.-S. Yun;
Department of Internal Medicine,Division of Endocrinology and Metabolism, College of Medicine, The Catholic University of Korea, Gyeonggi-do, Republic of Korea.

Background and aims: We investigated factors that might influence the development of severe hypoglycaemia (SH) in patients with type 2 diabetes
Materials and methods: From 2000 to 2002, an autonomic function test (AFT) was performed on 955 patients with type 2 diabetes aged 25-75 years and these patients were followed-up in 2011 and 2012. SH was defined as hypoglycaemic episodes requiring hospitalization or medical care in an emergency department. The severity of AFT was classified using the AFT score. We used the Cox proportional hazard regression analysis to test associations between the SH episodes and potential explanatory variables
Results: The median follow-up time was 9.5 years. At baseline, the total study population consisted of 404 (60.4%) women, the mean age of the total study population was 56.0 ± 10.0 years and a mean duration of diabetes was 9.1 ± 6.4 years. The incidence of severe hypoglycaemia was 1.54 per 100 patient-years. The patients with severe hypoglycaemia were more frequently female, were older, had a longer duration of diabetes, and received more insulin and ACE inhibitor treatment. Poor glycaemic control, renal impairment, and diabetic microvascular complications also were more present in the group with severe hypoglycaemia at baseline. The Cox hazard regression analysis revealed that the development of SH was associated with an abnormal AFT score (normal autonomic function vs. mild autonomic dysfunction, hazard ratio 2.41, $P = 0.005$; normal autonomic function vs. moderate to severe autonomic dysfunction, HR 4.33, $P < 0.001$) in a univariate analysis. After adjusting for gender, age, duration of diabetes, estimated glomerular filtration rate, HbA_{1c}, treatment of insulin and ACE inhibitor/ARB, severe autonomic failure predicts the development of severe hypoglycaemia (normal autonomic function vs. moderate to severe autonomic dysfunction, HR 2.43, $P = 0.004$), and a higher AFT score tends to have a higher risk of the development of severe hypoglycaemia (P for trend = 0.015).
Conclusion: The development of SH was independently associated with autonomic dysfunction in patients with type 2 diabetes.

1049

Behaviours and impact of hypoglycaemia in type 2 diabetes mellitus

C. Therapontos[1], S.H. Ong[2], A.K. Kawata[3], P. Mavrogenis[1], K. Kulich[2], W.-H. Chen[3], K. Coyne[3], on behalf of the HYPO-Cyprus Study Investigators; [1]Novartis Pharma Services Inc., Nicosia, Cyprus, [2]Novartis Pharma AG, Basel, Switzerland, [3]United BioSource Corporation, Bethesda, USA.

Background and aims: To examine the behaviors and impact of hypoglycemia on health-related quality of life (HRQoL) in diabetes patients.
Materials and methods: Patients were adults with type 2 diabetes mellitus (T2DM) on antidiabetic treatment from a cross-sectional, epidemiological study conducted in Cyprus (HYPO-Cyprus). Demographic and clinical data were collected. Patients completed the Hypoglycemic Perspectives Questionnaire (HPQ), Audit of Diabetes Dependent Quality of Life (ADDQoL-19), treatment satisfaction questionnaire, and EuroQol-5 Dimensions (EQ-5D). HPQ assessed symptoms, behaviors, and impact of hypoglycemia on T2DM patients in 3 domains (Symptoms, Compensatory Behaviors [CB], Worry) and a single-item of global symptom awareness. Analyses examined the relationship between HPQ and other patient-reported and clinical outcomes.
Results: The sample was 500 T2DM patients with a mean age of 61±10 years; 32.6% were women. Nearly half were obese (45.6% BMI≥30). Average duration of diabetes was 11 years (±7.8); half of patients had uncontrolled diabetes (50.6% HbA1c≥7%). Better diabetes HRQoL was associated with needing fewer compensatory behaviors (r=-0.30) and having less worry (r=-0.34; p<0.001). Fewer CB (r=-0.12) and less worry (r=-0.16) also corresponded to higher overall health ratings (p<0.01). More symptoms, CB, and worry were related to lower patient satisfaction with their current medication (p<0.001) and more desire to change medications (p<0.05). A small association was identified between higher symptom awareness (r=0.21) with higher HbA1c level (p<0.01). Patients with one or more low blood sugar events in the past 7 days and those with at least one severe event in the past year engaged in more CB and had higher symptom awareness than those with no events (all p<0.001).
Conclusion: Results suggest that hypoglycemia behaviors and impact are related to HRQoL, treatment satisfaction, and recent hypoglycemia events for T2DM patients. The impact of hypoglycemic events should not be underestimated.

Physical health status and nocturnal hypoglycaemia with insulin degludec vs insulin glargine: a 2-year trial in insulin-naïve patients with type 2 diabetes

Y. Handelsman[1], B. Cariou[2], H.W. Rodbard[3], B. Zinman[4], M.L. Wolden[5], A. Rana[5], C. Mathieu[6];
[1]Metabolic Institute of America, Tarzana, USA, [2]Nantes University Hospital, France, [3]Endocrine and Metabolic Consultants, Rockville, USA, [4]Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, Canada, [5]Novo Nordisk A/S, Søborg, Denmark, [6]UZ Leuven, Belgium.

Background and aims: Insulin degludec is a new basal insulin with an ultra-long and stable glucose-lowering effect. We compared once-daily insulin degludec and insulin glargine (randomised 3:1) both in combination with metformin ± DPP-4 inhibitors in an open-label, treat-to-target trial of 2 years duration in patients with type 2 diabetes (T2D).
Materials and methods: Health status was assessed at baseline and 105 weeks using the Short Form 36 (SF-36 v2) questionnaire. SF-36 scores were analysed (intention-to-treat population) using ANOVA, with adjustments for relevant covariates. After an initial 1-year study period, insulin degludec improved overall SF-36 physical health and functioning compared with insulin glargine. This was followed by a 1-year extension in which subjects maintained their randomised treatment assignment.
Results: Of 1,030 subjects, 725 entered the extension and 659 (insulin degludec: 505; insulin glargine: 154) completed 2 years of treatment. At 105 weeks, insulin degludec was similar to insulin glargine with respect to change in HbA_{1c} from baseline, but was associated with a significantly greater reduction in fasting plasma glucose (FPG) (-0.38 mmol/L [95% CI: -0.70; -0.06], p=0.02). Rates of overall confirmed hypoglycaemia (PG <3.1 mmol/L, or severe) were similar between groups, whereas the rate of nocturnal confirmed hypoglycaemia (any episode between midnight and 6:00AM) was significantly lower (by 43%, p<0.01) for insulin degludec. Consistent with previously reported findings for the initial 1-year trial period, the overall physical component score was significantly better with insulin degludec vs insulin glargine after 2-years (treatment contrast (TC): 1.1 [0.1; 2.1], p<0.05). This was largely due to significantly better physical functioning (TC: 1.1 [0.0; 2.3], p<0.05) and bodily pain sub-domain scores (TC: 1.5 [0.2; 2.9], p<0.05). Consistent with 1-year data, other SF-36 domain scores showed no significant differences between groups.
Conclusion: In conclusion, a significantly better physical health status and lower risk of nocturnal hypoglycaemia is maintained for insulin degludec vs insulin glargine following the second year of treatment of insulin-naïve patients with T2D.

Achieving fasting plasma glucose target without nocturnal hypoglycaemia: a pooled analysis of studies in type 2 diabetes comparing insulin degludec vs insulin glargine

B. Zinman[1], J. Vora[2], M. Niemeyer[3], M.-A. Gall[3], C. Mathieu[4];
[1]Samuel Lunenfeld Research Institute, Mount Sinai Hospital, Toronto, Canada, [2]Royal Liverpool University Hospitals, UK, [3]Novo Nordisk A/S, Søborg, Denmark, [4]UZ Leuven, Belgium.

Background and aims: Insulin degludec (IDeg), a new basal insulin that forms soluble multi-hexamers after subcutaneous injection, has an ultra-long and stable glucose-lowering effect. These properties may lead to less nocturnal hypoglycaemia compared with other basal insulin analogues, and should allow more patients to reach fasting plasma glucose (FPG) target safely.
Materials and methods: In this pooled analysis, we investigated the proportion of patients with type 2 diabetes (T2D) achieving laboratory-measured target FPG (<5 mmol/L) without nocturnal confirmed hypoglycaemia in four open-label, randomised, treat-to-target trials where patients (n=2380) received either IDeg or insulin glargine (IGlar), both once-daily in combination with OADs, for 26 or 52 weeks. Confirmed hypoglycaemia was defined as PG <3.1 mmol/L or severe episodes requiring assistance, and nocturnal confirmed hypoglycaemia defined as any episode between midnight and 6:00AM.
Results: A greater proportion of patients achieved the FPG target, and fewer patients experienced nocturnal confirmed hypoglycaemia with IDeg than with IGlar (table). The chance of achieving FPG target without confirmed nocturnal hypoglycaemia was 82% higher with IDeg: estimated odds ratio IDeg/IGlar = 1.82 $[1.49; 2.22]_{95\%CI}$.
Conclusion: In conclusion, T2D patients are more likely to reach FPG target without nocturnal confirmed hypoglycaemia with IDeg than with IGlar. These findings may have important implications for achieving target levels of glycaemic control in clinical practice.

Trial ID; N FAS IDeg/IGlar	Number (%) meeting FPG target (<5 mmol/L)			Number (%) without nocturnal confirmed hypoglycaemia		Number (%) meeting FPG target without nocturnal confirmed hypoglycaemia		*Statistical Analysis Est. odds ratio*

The endpoint was analysed using a logistic regression model with logit link. The model included treatment, sex, trial, antidiabetic treatment at screening, and region as fixed factors, and age and baseline FPG as covariates. Subjects were insulin-naïve in trials 3579, 3672, 3586. Trial 3668 included both insulin-naïve and non-naïve subjects. In trial 3668, subjects in the IDeg flexible-dosing group were excluded. N FAS = number of subjects in the full analysis set. In all trials, subjects were treated with basal insulin once daily + OADs.

Higher rates of confirmed hypoglycaemia are associated with greater within-subject variability in fasting blood glucose in type 1 and type 2 diabetes: a meta-analysis

B.W. Bode[1], T. Heise[2], T.R. Pieber[3], T. Johansen[4], S. Rasmussen[4], D.L. Russell-Jones[5];
[1]Atlanta Diabetes Associates, Atlanta, USA, [2]Profil, Neuss, Germany, [3]Medical University Graz, Austria, [4]Novo Nordisk A/S, Søborg, Denmark, [5]Royal Surrey County Hospital & University of Surrey, Guildford, UK.

Background and aims: In this *post-hoc* meta-analysis of insulin-treated patients with type 1 (T1D) and type 2 diabetes (T2D), we investigated whether there is an association between hypoglycaemia rate and the extent to which pre-breakfast blood glucose varies from day to day.
Materials and methods: This patient-level meta-analysis included all open-label, randomised, treat-to-target phase 3a trials (26 or 52 weeks) in which once-daily insulin degludec (IDeg) was compared to insulin glargine (IGlar) in T1D (2 trials) and T2D (5 trials). Within-subject variability (CV%) in self-measured pre-breakfast plasma glucose (PG) was determined from three consecutive daily measurements made in the final week (week 26 or 52) of each trial. CV% was compared between patients with a rate of confirmed hypoglycaemia (PG <3.1 mmol/L, or severe) within the upper quartile (top 25%) and those outside this range (bottom 75%) using a linear mixed model, which allows for heterogeneity in the residual variance for each group.
Results: For both IDeg and IGlar, estimated day-to-day variability in pre-breakfast PG was significantly higher for patients with the highest rates of confirmed hypoglycaemia (top 25%) than those with lower rates (bottom 75%), regardless of diabetes type or T2D subpopulation (Table).
Conclusion: In conclusion, for both IDeg and IGlar, higher rates of confirmed hypoglycaemia are associated with greater within-subject variability in fasting blood glucose in patients with T1D and T2D.

Recurrent severe hypoglycaemia in type 1 diabetes: potential for prevention?

M.M. Henriksen, R. Due-Andersen, B. Thorsteinsson, U. Pedersen-Bjergaard;
Department of Cardiology, Nephrology and Endocrinology, Hillerød Hospital, Denmark.

Background and aim: Recurrent severe hypoglycaemia (SH) in type 1 diabetes is a major clinical problem affecting up to 20% of patients in unselected cohorts. While solitary episodes of severe hypoglycaemia are hardly preventable, recurrent episodes are potentially subject to prevention. This study was aimed at characterising recurrent episodes of severe hypoglycaemia in order to explore the potential for prevention of such events in a well-defined cohort of patients with type 1 diabetes.
Material and methods: A cohort of 230 consecutive patients with type 1 diabetes was followed prospectively for one year and reported characteristics of SH within 24 hours. Characteristics of recurrent episodes were explored and compared to those of solitary episodes.
Results: A total of 239 episodes of SH were reported by 86 patients during the period, corresponding to 1.0 episode per patient per year; 82% of the episodes were recurrent (corresponding to 2 or more episodes per patient). The incidence of coma and seizure did not differ between solitary (21%) and recurrent (23%) SH. Recurrent SH occurred more often in subjects with reduced hypoglycaemia awareness (solitary: 65% vs. recurrent: 88%; p<0.005) and were characterised by absence of warning symptoms (solitary: 42% vs. recurrent: 66%; p<0.005) and occurrence during daytime (07-18, solitary: 26% vs. recurrent: 42%; p=0.042). The majority of episodes of SH took place at home (solitary: 65%; recurrent: 71%) and only few at work (solitary: 2%; recurrent: 8%) or elsewhere (solitary: 30%; recurrent: 19%) with no differences between solitary and recurrent episodes. Recurrent episodes tended to be less well explained (33% vs. 46%; p=0.11).
Conclusion: A large proportion of SH in patients with type 1 diabetes is recurrent and thereby potentially preventable. Focus should be directed towards patients with reduced hypoglycaemia awareness and measures include efforts to restore hypoglycaemia awareness, improvement of self-care including frequent scheduled carbohydrate ingestion and intensified blood glucose self-monitoring.

Gender differences in personality traits and resilience concerning glycaemic control and hypoglycaemia in patients with type 1 and type 2 diabetes

W.C. Keweloh[1], F. Zillich[2], K. Wick[2], N. Müller[1], C. Kloos[1], T. Lehmann[3], G. Wolf[1], U.A. Müller[1];
[1]Endocrinology and Metabolic Diseases, Internal Medicine III, [2]Institute of Psychosocial Medicine and Psychotherapy, [3]Institute of Medical Statistics, Information Sciences and Documentation, University Hospital, Jena, Germany.

Aim: Structured therapy and education programs for patients with Type 1 (T1D) and Type 2 diabetes (T2D) have been shown to improve HbA1c and to reduce rates of hypoglycaemia. But not all patients succeed to reach their treatment goals after participating in such a program. We assessed personality traits and resilience to explain differences in therapeutic outcome with regard to gender differences.
Methods: We conducted a cross-sectional study of patients with T1D and T2D in a tertiary care centre in Germany during a period of three months (n=661, 161 T1D: 94 men / 67 women, 50.32 / 54.05 years, duration of diabetes (DD) 20.53 / 19.39 years, social economic status (SES) 13.22 / 11.91, HbA1c 7.4 / 7.64%, 500 T2D: 298 men / 202 women, 67.2 / 67.8 years, DD 15.4 / 15.5 years, SES 12.26 / 10.75, HbA1c 7.3 / 7.5%). We assessed the short version of the Big Five Inventory (BFI-S) with extraversion (EX), agreeableness (AG), conscientiousness (CO), neuroticism (NE) and openness (OP), resilience scale (RS-13), treatment satisfaction (DTSQ standard) and SES (score 3-15). Quality of diabetes care was measured by HbA1c, BP, BMI and rates of serious and severe hypoglycaemia (glucose or glucagon injection).
Results: In men with T1D OP explains 4.7% of the variance in severe hypoglycaemia/year. Men with more hypoglycaemic events have lower scores in OP and RES (R=-.262), p<.05. HbA1c is explained in 17.2% by a model of DTSQ (R=-.219), age (R=-.253) and EX in men and in 8.7% by OP (R=-.308) in women, p<.05. In women higher HbA1c is related to lower SES (R=-.269, p<.05) and lower mean HbA1c is accompanied by higher scores in OP (R=-.339, p<.01). Men with higher RES have lower scores in NE (R=-.35), less severe hypoglycaemia (R=-.262), higher scores in OP (R=.247), CO (R=.354) and SES (R=.25). NE and OP explain 22% of the variance in RES, p<.01. Women show higher RES having higher scores in CO (R=.30) explaining 9.6% of occurring differences and show lower scores in NE (R=-.326), p<.01. In men with T2D higher scores in EX mean less serious hypoglycaemic events compared to first visit, R=-.163 vs. .185, p<.01. In regression analysis EX explains 4.5% of the rates of serious hypoglycaemic events and 9.8% of the rates at first visit in a model with insulin dose adjustment (R=.273), p<.01. NE explains 7.6% of the variance in HbA1c in women, p<.01. Higher scores in HbA1c are associated with lower scores in CO, RES and DTSQ and higher scores in NE (R=.149), p<.05. In men variance in RES is explained in 19.9% by a model of NE (R=-.289), CO (R=.277) and OP (R=.28), in women in 23.3% by NE (R=-.335), SES (R=.293) and CO (R=.277), p<.01. In both T1D and T2D women show no significant findings concerning hypoglycaemia.
Conclusion: Out of five personality traits openness and extraversion can explain differences in metabolic control and the risk of serious and severe hypoglycaemia in men with diabetes mellitus.

PS 086 Insulin adjustment and self-management

Evaluation of a real-time carbohydrate counting course during a clinic setting in the management of diabetes type 1

H. Forde, M.C. Durkan, H. Clarke;
[1]Diabetes , Endocrinology & Metabolism, Galway University Hospital Group / Portiuncula Hospital, Galway, Ireland.

Background and aims: DAFNE is a carbohydrate counting course used in patients with DM1. It is delivered over a week and effective provision of the program is difficult with staff curtailments in our current economy, and patients unable to commit a full week . Published results from Dafne are also disappointing. There was no evidence from the Irish Dafne group to show durable effect, although rates of hypoglycemia were lower. Recent Danish studies have suggested that one can deliver a modified Dafne program, within the remit of a clinic setting.
Materials and methods: Our study aimed to (1) examine the feasibilility of delivering a carbohydrate counting' (CC) program in the setting of a routine diabetes clinic , (2) evaluate the use of CC in managing DM1 and (3) compare outcomes with a control group not using CC . 20 patients with DM1 were randomly selected and assigned to one of 2 groups (CC or a dietary lecture). All had baseline HbA1c, lipids and BMI, recorded. All completed a Berger QOL questionnaire, and were specifically asked about hypogylcemia . They were all re-assessed after 24 weeks.The CC group attended a 3 hour workshop and met with the physician so that their insulin sensitivity index and carbohydrate ratios could be individually calculated. They had been asked to bring their own 'usual foods'. They also brought their own delphware (for more precise portion estimation), and were taught CC by the diabetes nurse. The control group attended a 2 hour lecture delivered by a dietician.The CC course was easily delivered in a clinic setting. It became clear however, that while patients were motivated, they found it laborious measuring food portions, and making calculations . Continuous engagement was problematic.
Results: At 24 weeks, HbA1c in the CC group increased, $p < 0.01$. It remained unchanged in the control group ($p = 0.944$). Independent T-Test showed that the CC intervention was not more effective ($p = 0.834$).There was a non- significant trend towards a reduction in hypoglycaemic events in the CC group ($p = 0.51$) . There was no diference between both groups.There was a non- significant difference in QOL between both groups, with the CC group reporting less anxiety about hypoglycemia. Interestingly, the CC group had poorer self reported QOL, (24.79 Vs 13.78). This may have hampered their ability to engage with interventions. Paired samples T test showed no significant difference in BMI in the CC patients, p value = 0.863, nor in the control group , p value = 0.536. Independent T-test confirmed this. 80% of the patients in CC group had a reduction in LDL, that was not statistically significant, p=0.253. 50% of patients in the control group had an increase in LDL. Independent T test confirmed no significant change in LDL (p=0.508). In summary, It is feasible to deliver this program. Patient selection is important. Enthusiasm does not equal success, and ongoing motivation is a limitation. Our results did not show improvement in A1c and the numbers were to small to show significant difference in hypoglycemia rates but the trend matches published data. CC success may not lie in primarily reducing HbA1c which hitherto has been the 'holy grail', but in reducing hypoglycemia (and improving safety) and improving QOL.
Conclusion: These qualitative results are additionally concordant with the recent position statements for management of DM.

1056

Which principles patients with diabetes type 1 use for self-adjustment of insulin dose?

G. Kramer, N. Müller, C. Kloos, G. Wolf, U.A. Müller;
Dept. Internal Medicine III, University Hospital Jena, Germany.

Background and aims: Self-adjustment of the insulin dose to different blood glucose levels, carbohydrate intake, exercise or illness is a core part of intensified insulin therapy an a prerequisite for the prevention acute and chronic complications. Structured treatment and education programmes for patients with type 1 diabetes provide rules for self-adjustment of insulin, which are extensively trained. The aim of this study was to register the patients' current principles for self-adjustment of the insulin dose and to check the ability for correct adjustment.
Materials and methods: In a tertiary care centre 117 patients with diabetes type 1 were included (mean HbA1c 7.9%, age 53 years, diabetes duration 23.6 years, BMI 27.7kg/m2) from 01.08 to 31.10.2012. The number of daily insulin dose adjustments was drawn from the last 28 days of the patients' diary. The type of insulin adjustment, insulin-to-carbohydrate ratio and the factor of correction were assessed by a structured interview as well as patients ability to find the correct dose in five structured case studies. All patients had participated in a structured education programme of 20 hours, 46% of them within the last 3 years.
Results: 103 patients (89%) are documenting their therapy in a diary regularly. The average self adjustment of the insulin dose was 2.6±1.3 per day. About half of all patients (51%) claimed to adjust their insulin dose using a rule (correction factor or correction scheme). The rest adapt their insulin dose based upon personal experience or feeling. There were no differences concerning HbA1c (7.8±0.9 vs. 7.9±1.0 p=0.56) or mild hypoglycaemia/ week (1.4±2.0 vs. 1.5±1.4 p=0.91) or severe hypoglycaemia/last 12 months (0.04±0.2 vs. 0.14±0.4 p=0.56) comparing patients using rules or not. 89 patients (76.7%) were able to give their meal-related insulin-to-carbohydrate ratio and 76 (65.5%) knew the associated correction factor/scheme. In case of high premeal blood glucose 26 patients (22%) reported to perform an injection-meal interval "always" or "often", 36 patients (31%) "sometimes" or "rarely" and 53 patients (46%) "never". Good ability to solve the case examples (4 or 5 of 5) showed 59 patients (49%) and 14 patients (12%) had moderate ability (1 to 3 of 5) and 44 (38%) poor ability (0 of 5 correct examples).
Conclusion: Although all patients participated in a structured treatment and education programme at least once, only about 49% were able to answer 4 or 5 of 5 case examples correctly. Patients, who make their daily adjustments of the insulin dose based upon feeling or personal experience did not show worse metabolic control. Teaching sophisticated rules for self-adjustment of insulin dose could be exaggerating for a considerable number of patients.

1057

Carbohydrate counting competency index (C31) is a clinically meaningful measure of carbohydrate counting skills in patients with diabetes: results from ABACUS

C.G. Parkin[1], D.A. Cavan[2], R. Ziegler[3], I. Cranston[4], K. Barnard[5], J. Ryder[6], C. Vogel[7], W. Koehler[8], I. Vesper[9], B. Petersen[9], K. Friedman[9], M.A. Schweitzer[9], R.S. Wagner[9];
[1]CGParkin Communications, Inc., Boulder City, USA, [2]Bournemouth Diabetes and Endocrine Centre, UK, [3]Diabetes Clinic for Children and Adolescents, Muenster, Germany, [4]Academic Department of Diabetes & Endocrinology, Queen Alexandra Hospital, Portsmouth, [5]University of Southampton, [6]Royal Bournemouth Hospital, UK, [7]Internistisches Fachaerztezentrum, Langen, [8]Baseline Statistics GmbH, Mannheim, Germany, [9]Roche Diagnostics, Indianapolis, USA.

Background and aims: Carbohydrate (CHO) counting is a core skill for patients with diabetes who wish to practice effective meal-bolus insulin therapy. While the principles are straightforward, applying this skill reliably over diverse meals is challenging, and clinicians' ability to identify patients who have difficulties with CHO counting is often suboptimal. We developed a metric to assess and compare CHO skills in patients enrolled in the Automated Bolus Advisor Control and Usability Study (ABACUS).
Materials and methods: The ABACUS study was a large, 26-week, prospective, randomized, controlled, multi-national study of suboptimally controlled patients treated with multiple daily insulin injection (MDI) therapy, with mean (SD) baseline HbA1c 8.9 (1.2)%. At entry and study end, all patients were asked to provide CHO estimates for 10 photographic standard meal plates (DAFNE) of known CHO content, from which two scores were calculated.
Results: We assessed study patients' CHO counting competency based on two scores: mean meal error (MME) and mean meal absolute error (MMAE). The MME score is an indicator of accuracy in estimating the CHO content of a given meal, with "0" being a perfect score. The MMAE score was an indicator of variability, indicating the average range (number of CHO grams) above and below patients' MME; the lower the number, the less variability. The scores were combined into a single metric: CHO Counting Competency index (C3i). The C3i can be expressed numerically (MME:MMAE) or visually plotted on a scale as MME ± MMAE. Figure 1 presents examples of plotted C3i assessments.
Conclusion: The C3i metric provides information that allows clinicians to identify and address CHO counting deficits and then evaluate changes in

competency over time. The metric can also be applied in clinical research for comparison purposes, providing a standardized measure of average CHO competency within study groups at baseline and study end.

Use of an automated bolus advisor may improve carbohydrate counting competence in patients treated with multiple daily insulin injection therapy: results from ABACUS

J. Ryder[1], D.A. Cavan[2], R. Ziegler[3], I. Cranston[4], K. Barnard[5], C. Vogel[6], W. Koehler[7], B. Petersen[8], I. Vesper[8], K. Friedman[8], M.A. Schweitzer[8], R.S. Wagner[8];
[1]Royal Bournemouth Hospital, [2]Bournemouth Diabetes and Endocrine Centre, UK, [3]Diabetes Clinic for Children and Adolescents, Muenster, Germany, [4]Academic Department of Diabetes & Endocrinology, Queen Alexandra Hospital, Portsmouth, [5]University of Southampton, UK, [6]Internistisches Fachaerztezentrum, Langen, [7]Baseline Statistics GmbH, Mannheim, Germany, [8]Roche Diagnostics, Indianapolis, USA.

Background and aims: Use of multiple daily insulin injection (MDI) therapy is efficacious in achieving and maintaining optimal glycemic control. MDI therapy requires patients to appropriately utilize a number of parameters, including insulin-to-carbohydrate ratios (I:CHO), insulin sensitivity factors (ISF), target blood glucose (bG) range and current bG values, to determine their appropriate insulin dosages. Although correct use of these factors is essential for accurate bolus insulin calculations, patients' inability to accurately and consistently estimate planned CHO intake can adversely impact glycemic control in patients treated with MDI. We assessed the impact of using an automated bolus advisor on patients' CHO counting competence.
Materials and methods: We assessed the CHO counting competency of 218 diabetes patients who participated in the Automated Bolus Advisor Control and Usability Study (ABACUS), a large, 26-week, multi-national, prospective, randomized, controlled trial. The trial evaluated the use of an automated bolus advisor in suboptimally controlled MDI-treated type 1 diabetes and type 2 diabetes patients with baseline HbA1c 8.9 (1.2)%. Patients randomized to the control group (CNL) used a standard bG meter and manual bolus calculation; whereas, patients randomized to the intervention group (EXP) used the Accu-Chek® Aviva Expert meter, which provides an integrated automated bolus advisor to calculate insulin dosages. At entry and study end, patients were asked to assess the CHO content (grams) of 10 standardized meals (using life-size photographs), from which two scores were calculated. The mean meal error (MME) score was an indicator of accuracy, with "0" being a perfect score. The mean meal absolute error (MMAE) score was an indicator of variability, indicating the average range (number of CHO grams) above and below patients' MME. All patients then received refresher training and CHO reference materials prior to randomization. Patients were followed for 6 months, with regular reviews by their healthcare team. The CHO counting assessment was repeated at the end of the study.
Results: At study end, there was a significant improvement in MMAE: from 15.2 (9.0) grams to 12.4 (7.3) grams, $p < 0.01$; and a trend towards improvement in MME: 1.0 (10.1) grams to 0.3 (7.1) grams, p = NS in the EXP group but no change in MME or MMAE among CNL patients.
Conclusion: Our findings suggest that use of a bolus advisor may improve competency in CHO counting by providing frequent feedback on patient accuracy in estimating the CHO intake. Thus, automated bolus advisors may serve as educational tools that can improve the effectiveness of diabetes self-management in patients treated with MDI therapy.

Use of an automated bolus advisor improves multiple outcomes in patients treated with multiple daily insulin injections: results from ABACUS

D.A. Cavan[1], R. Ziegler[2], I. Cranston[3], K. Barnard[4], C.G. Parkin[5], W. Koehler[6], B. Petersen[7], I. Vesper[7], M.A. Schweitzer[7], R.S. Wagner[7];
[1]Bournemouth Diabetes and Endocrine Centre, UK, [2]Diabetes Clinic for Children and Adolescents, Muenster, Germany, [3]Academic Department of Diabetes & Endocrinology, Queen Alexandra Hospital, Portsmouth, [4]University of Southampton, UK, [5]CGParkin Communications, Inc., Boulder City, USA, [6]Baseline Statistics GmbH, Mannheim, Germany, [7]Roche Diagnostics, Indianapolis, USA.

Background and aims: Calculating bolus insulin dosages is challenging for many people with diabetes who use multiple daily injection (MDI) therapy. These calculations must take into account carbohydrate (CHO) intake, current blood glucose level, insulin sensitivity and insulin-to-carbohydrate ratios. This requires complex mathematics and, as a result, many patients rely on empirical estimates, which may increase the risk of hypoglycemia or hyperglycemia.
Materials and methods: The Automated Bolus Advisor Control and Utility Study (ABACUS) was a large, prospective, 26-week, randomized, multi-national study of patients with type 1 and type 2 diabetes who were treated with MDI therapy but maintained suboptimal diabetes control (HbA1c ≥ 7.5% / 58 mmol/l). The study enrolled 218 diabetes patients (202 type 1, 16 type 2), with mean (SD) baseline HbA1c 8.9 (1.2)%, age 42.4 (14.0) years, BMI 26.5 (4.2) kg/m^2 and 17.7 (11.1) years duration of diabetes. Patients randomized to the control group (CNL) used a standard blood glucose meter and manual bolus calculation; whereas, patients randomized to the intervention group (EXP) used the Accu-Chek® Aviva Expert meter, which provides an integrated automated bolus advisor to calculate bolus insulin dosages. Blood glucose measurements in both groups were downloaded during study visits and used to amend bolus parameters where appropriate and to record the frequency of hypoglycemic values. Frequency of bolus advice sought was recorded from the Expert meters; bolus calculations by CNL patients were reviewed from three 3-day intensive monitoring periods during the study. HbA1c, CHO counting accuracy and scores from the Diabetes Treatment Satisfaction Questionnaire (DTSQ) were recorded at the beginning and end of the study. The goal of the ABACUS trial was to achieve HbA1c reductions of >0.5% in all patients.
Results: Significantly more EXP than CNL patients achieved HbA1c reduction of >0.5% (56.0% vs. 34.4%, $p<0.01$); this difference was greater in patients aged <30 years (52.6% vs. 15.0%, $p<0.05$). The mean (SD) HbA1c reduction among all patients who achieved the study goal was 1.2 (0.5)%. Frequency of reported hypoglycemia and of severe hypoglycemia from self-monitored glucose measurements was similar in both groups during the study. EXP patients significantly improved their CHO-counting ability and experienced a significantly better improvement in DTSQ score by study end. EXP patients sought bolus advice for 73.5% of their average 3.8 daily boluses; whereas, CNL patients performed an average of 4.0 bolus calculations per day, of which up to 75% were incorrect. EXP and CNL patients performed similar frequency of blood glucose measurements per day at baseline and over the course of the study.
Conclusion: Use of the Accu-Check Aviva Expert meter supports insulin-treated patients in improving glycemic control, while improving CHO-counting ability, with no increase in hypoglycemia, insulin usage or blood glucose testing frequency.

Evaluating the patient experience in the Asian Treat to Target Lantus Study (ATLAS): a 24 week randomised, multinational study

I.R. Jarek-Martynowa[1], N. Freemantle[2], K. Admane[3], A. Koroleva[4], ATLAS Study Group;
[1]Endocrinological Research Center, Ministry of Health of Russian Federation, Moscow, Russian Federation, [2]Department of Primary Care and Population Health, University College London, UK, [3]Sanofi, Paris, France, [4]Sanofi, Moscow, Russian Federation.

Background and aims: Approach to dose titration in patients initiating basal insulin, whether led by the physician or the patient themselves, may impact

diabetes management overall, particularly in terms of treatment satisfaction and quality of life. The ATLAS study was designed to evaluate titration of insulin glargine in insulin-naïve, Asian patients who were uncontrolled on 2 oral antidiabetic drugs. This analysis aimed to examine treatment satisfaction and quality of life in these patients, based on physician- or patient-led insulin titration.

Materials and methods: A total of 552 patients were randomised into patient-led (n=275) and physician-led (n=277) insulin titration. Insulin dose was adjusted using identical algorithms to achieve a target FBG of 110mg/dL.

Results: The ATLAS study demonstrated superiority of patient-led compared with physician-led insulin titration. The overall scores for the Diabetes Treatment Satisfaction Questionnaire status (DTSQs) and change (DTSQc) were similar in the 2 groups. For the patient-led titration group, the LS mean change in DTSQs score from baseline to 24 weeks was significant (mean Δ: 5.34; 95% CI: 4.48-6.20, p<0.001); the same was shown for the physician-led titration group (mean Δ: 5.05, 95% CI: 4.21-5.90, p<0.001). LS mean change in DTSQc score from baseline to 24 weeks was also significant for the the patient-led (mean Δ: 12.92; 95% CI: 12.32-13.52, p<0.001) and physician-led (mean Δ: 13.19; 95% CI: 12.60-13.78, p<0.001) titration groups. Between-group differences were not significant, and there were no differences in any DTSQc item. Health utility elicited with the EuroQol EQ-5D was high at baseline, despite the need for insulin initiation. Baseline mean utility was 0.86 (95% CI: 0.83-0.88) and 0.88 (95% CI: 0.85-0.90) for the patient-led and physician-led groups, respectively. At 24 weeks, the LS mean change from baseline in the EuroQoL-5D was not significant for either the patient-led (mean Δ: 0.021, 95% CI: -0.006-0.047, p=NS) or the physician-led (mean Δ: 0.018; 95% CI: -0-008-0.045, p=NS) titration group; between-group differences were not significant. Baseline EuroQoL-5D scores were similar between country-randomised groups, but different between countries. Russian patients had the lowest health utility (mean: 0.73, 95% CI: 0.68-0.78), while Japanese patients had the highest (mean: 0.94, 95% CI: 0.91-0.96). No systematic differences between country-randomised groups existed in the end of study utility.

Conclusion: The ATLAS results confirm that Asian patients initiating basal insulin with a self-titration plan may do so without compromising health-related quality of life or treatment satisfaction.

A Smartphone for adjustment of basal insulin dose and for coaching: benefits in terms of glycaemic control for type 2 diabetes patients

A. Daoudi[1], M. Joubert[2], S. Franc[3,1], C. Fagour[4], P.-Y. Benhamou[5], Y. Reznik[2], M. Rodier[6], B. Boucherie[1], E. Benamo[7], P. Schaepelynck[8], B. Guerci[9], D. Dardari[1], A. Penfornis[10], G. Charpentier[3,1], TELEDIAB2 Study Group;
[1]CERITD, Evry, [2]CHU de Caen, [3]Centre Hospitalier Sud Francilien, Corbeil-Essonnes, [4]CHU de Fort-de-France, [5]CHU de Grenoble, [6]CHU de Nimes, [7]Centre Hospitalier Henri Duffaut, Avignon, [8]CHU de Marseille, [9]CHU de Nancy, [10]CHU de Besancon, France.

Background and aims: The introduction of basal insulin is recommended in type 2 diabetes (T2D) when HbA1c exceeds 7-7.5%, despite well-titrated oral agents. Nevertheless, the insulin dose is often too low, chiefly due to fear of hypoglycemia.

Materials and methods: We have developed a smartphone modeled on the DIABEO system specifically for use by T2D patients. This system was tested in telediab 2 study, a large multicentre National Study that compared the use of the smartphone vs the use of the interactive voice server (IVS) and vs standard care. The smartphone incorporates algorithms that should help patients achieve their optimal insulin dose. Similar algorithms were used for the interactive voice server (IVS) utilized as a control. In addition, the smartphone includes educational coaching functions that allow patients to act on their blood glucose values where daytime BG values fall outside the target range. It also transmits data to the physician to enable remote telemonitoring. Patients were randomized to 3 groups (G1: control group: 1 face-to-face consultation every 3 months; G2: interactive voice server (IVS) group: IVS with phone consultations until M4 and then 1 face-to-face consultation every 3 months until M13; G3: smartphone group with 1 phone consultation every 2 weeks until M4, followed by 1 phone consultation per month until M13. The main evaluation criterion comprised HbA1c values at M4 in G2 and G3 vs. G1.

Results: This 13-month, open-label, parallel-group, multicenter study included 190 adult patients (64% male) with T2D (>1 year), BMI 29.5±4.9 Kg/m^2, age 58.7±9.6 years, diabetes duration 13.1±7.6 years, and HbA1c 8.9±1.1% despite oral agents (>6 months). The 4-month reduction in HbA1c was greater in G2 (-1.44%) and G3 (-1.48%) than in G1 (-0.92%) (p=0.0017 for G2 vs. G1 and G3 vs. G1 comparisons), but did not differ between the intervention groups. Basal insulin detemir was initiated at a mean dosage of 11.7±6.2 U/d and subsequently titrated. The insulin dosage was 35±24 (G1), 44±35 (G2) and 50±35 (G3) U/d. The percentage number of patients with normal fasting blood glucose levels was much higher in G2 and G3 than in G1 (82.5% and 82.7% vs. 41.8%, p<0.001 for both comparisons). No severe hypoglycemia occurred and the incidence of mild hypoglycemia was similar in all groups during the initial 4-month period.

Conclusion: At 4 months, the reduction in A1c was greater both with the IVS and the PDA than with standard care in T2D patients with poor glycemic control. This result appears to be due to more active titration of basal insulin without any increase in hypoglycemia. The potential benefits of the smartphone (i.e. coaching functions, telemonitoring allowing teleconsultations) will be assessed during the study extension phase (smartphone vs. standard care from M4 to M13) and presented during the session.

Determinants of insulin dosing decisions made by diabetes care providers: a vignette study

N. Peek[1], A.C.R. Simon[2], J.E. Schopman[2], J.B.L. Hoekstra[2], A. Abu-Hanna[1], V.E.A. Gerdes[2], F. Holleman[2];
[1]Medical Informatics, [2]Internal Medicine, Academical Medical Center, Amsterdam, Netherlands.

Background and aims: Many patients with type 2 diabetes require insulin to maintain adequate glycaemic control. Many options exist for implementing insulin therapy and little is known about strategies that are followed by care providers in practice. The objective of this study was to explore the decision making behavior of care providers regarding insulin dose adjustments.

Materials and methods: In the light of current guidelines and research, we postulated that certain patient characteristics (level of FPG and HbA1c, occurrence of hypoglycaemic events, demographics, medical history and insulin dose) influence the decision making behavior of care providers with regard to insulin dose adjustments. We constructed nine narrative vignettes presenting a fixed set of characteristics of patients using basal insulin. To test the effect of each characteristic, each vignette described one additional characteristic, which varied among two versions of an otherwise identical vignette. Each respondent received one set of nine vignettes. For each vignette respondents were asked to indicate whether they would advise to change the basal insulin dose, and if so, by how many units. 520 paper questionnaires were distributed among general practitioners, diabetes nurses in secondary care, nurse practitioners in primary care and internists. Multivariate linear and logistic regression analyses were performed.

Results: Of all distributed questionnaires, 190 (37%) were returned. Each additional 1 mmol/L FPG and each additional 1% HbA1c resulted in an average increment in insulin dose of respectively 1.28 IU and 1.25 IU. The occurrence of a hypoglycaemic event led to a decrement of 1.19 IU. In case of severe compared to mild hypoglycaemic events, care providers were nearly five times (odds ratio [OR] 4.77; 95% confidence interval [CI] 1.65 to 13.75) more likely to decrease the insulin dose. Also, care providers were almost eight times (OR 7.88; 95% CI 2.96 to 20.99) more likely to increase the insulin dose if a patient's FPG was between 5.5 and 7.0 mmol/L, than if a patient's FPG was

below 5.5 mmol/L. When the current insulin dose was low (30 IU) compared to a high insulin dose (90 IU), care providers were more than six times (OR 6.38; 95% CI 3.04 to 13.37) more likely to increase the insulin dose. There were no differences in insulin dose (OR 1.76; 95% CI 0.73 to 4.29) if a patient experienced symptoms of hypoglycaemia and measured plasma glucose (PG) > 3.9 mmol/l compared to PG ≤ 3.9 mmol/l. A history of cardiovascular disease did not trigger care providers to strive for less intensive glucose lowering (OR 1.17; 95% CI 0.56 to 2.43).

Conclusion: A substantial number of care providers strive for FPG target of 5.5 mmol/L, probably reflecting implementation of treat-to-target algorithms. Relative hypoglycaemic events and high insulin doses were barriers for intensifying insulin dose, although this has no scientific foundation. In contrast, a patient history of myocardial infarction did not restrain care providers from increasing the dose, although the ACCORD study suggests less intensive treatment among patients with known vascular disease. We recommend that titration guidelines should mention cut-off values for hypoglycaemia and give recommendations on coping with high insulin doses. Furthermore, awareness for the risk of intensive treatment in heart disease patients should be increased.

Asian Treat to Target Lantus Study (ATLAS): a 24 week randomised, multinational study

K. Admane[1], S. Garg[2], M. Odawara[3], ATLAS Study Group;
[1]Sanofi, Paris, France, [2]Barbara Davis Center for Diabetes, University of Colorado School of Medicine, Aurora, USA, [3]Department of Diabetology, Metabolism, and Endocrinology, Tokyo Medical University, Japan.

Background and aims: Self-adjustment of insulin dose and patient empowerment have been effective in achieving better glucose control. The ATLAS study evaluated titration of insulin glargine in insulin-naïve Asian patients uncontrolled on 2 oral antidiabetic drugs.

Materials and methods: A total of 552 patients were randomised to 2 titration arms: 275 patient-led, 277 physician-led. Insulin dose was adjusted using identical algorithms to achieve a target FBG of 110mg/dl in both arms. The primary objective was non-inferiority of change in HbA1c at 24 weeks from baseline.

Results: Baseline demographics and HbA1c were similar in both groups. At 12 weeks, LS mean change in HbA1c was significantly decreased in both the patient-led (-1.27%) and physician-led (-1.16%) titration groups compared with baseline (both $p < 0.001$). At 24 weeks, HbA1c decreased further in both groups (-1.40% and -1.25%, respectively) from baseline (both $p < 0.001$). The between-group difference of the LS mean change from baseline (patient-led minus physician-led) was -0.15 (95% CI: -0.29 to -0.00; p=0.04), showing superiority. Proportions of patients with HbA1c < 7.0% without severe hypoglycaemia were not significantly different between the patient-led and physician-led titration groups (32.0% versus 26.0%, respectively; $p = 0.11$). Hypoglycaemia rates were low. Compared to physician-led titration, severe hypoglycaemia was similar, but nocturnal (p=0.002) and symptomatic hypoglycaemia (p=0.02) were higher in the patient-led titration group. Mean ± SD insulin daily dose was 8.2 ± 2.7 U at baseline and 24.4 ± 16.5 U at week 24, with a greater increase in the patient-led titration group ($p < 0.001$). Few unrelated serious adverse events (2.6%) were reported.

Conclusion: We conclude that insulin glargine titration, whether patient or physician-led, is safe and effective in achieving near-target glucose control in Asian patients uncontrolled on oral antidiabetic drugs. Contrary to common belief, Asian patients titrated up their insulin dose effectively when guided, similar to patients in the West. ´

The SimpleMix study with biphasic insulin aspart 30: a comparison between subject-driven titration vs investigator-driven titration

B. Saboo[1], C. Luquez[2], J. Råstam[3], H. Andersen[3], Y. Gao[4];
[1]Dia Care-Diabetes Care & Hormone Clinic, Ambavadi, Ahmedabad, Gujarat, India, [2]Centro Medico Luquez, Cordoba, Argentina, [3]Novo Nordisk, A/S, Bagsværd, Denmark, [4]Department of Endocrinology, Peking University First Hospital, Beijing, China.

Background and aims: Facilitating self-management of diabetes can help patients improve glycaemic control. SimpleMix was a 20-week, randomised, open-labelled, two-arm, parallel-group comparison of twice-daily subject- vs. investigator-driven (SD vs. ID) titration of biphasic insulin aspart (BIAsp) 30 in subjects with type 2 diabetes inadequately controlled with basal insulin analogues. The primary objective was demonstration of noninferiority of SD vs. ID titration of twice-daily BIAsp 30 assessed by change in HbA_{1c}.
Materials and methods: Subjects (n=348) were recruited from five countries (Argentina, China, India, Poland and the UK) and randomised 1:1 to treatment groups. BIAsp 30 was administered as two equal daily doses, before breakfast and dinner, (+metformin). BIAsp 30 starting dose was subject's previous basal insulin analogue dose split into two equal doses. The SD arm had five clinic visits and the ID arm had eight clinic visits. Phone contact could be made following changes to insulin dose and at any other time deemed necessary. No inferiority of SD vs. ID titration, assessed by HbA_{1c} change, was determined using a 0.4% noninferiority limit.
Results: Baseline data were comparable between titration groups (Table). During the first 12 weeks of treatment, HbA_{1c} reduction was similar between groups. By week 20, mean HbA_{1c} had decreased to 7.57 % in the SD titration group and 7.32 % in the ID group (difference 0.25%, 95% CI [0.04;0.46]). At the end of the trial (EOT) the proportion of patients achieving HbA_{1c} <7 % was 28.7% (SD) vs. 38.5% (ID), (OR 0.59, 95% CI [0.37;0.95]; p=0.032). For patients achieving HbA_{1c} ≤6.5 % at EOT the proportion was 12.1% vs. 20.7%, respectively (OR 0.50 [0.27;0.91]; p=0.022). Mean fasting plasma glucose (FPG) was similar in both groups (Table). Rate of hypoglycaemic episodes was slightly higher in the ID than the SD group (Table), but this was not statistically significant. Significantly higher weight gain was observed in the SD vs. ID group after 20 weeks (difference 0.68 kg, 95% CI [0.03;1.32]; p=0.041). Few serious adverse events were reported.

Table. Baseline characteristics and clinical outcomes at 20 weeks.

	Subject-driven	Investigator-driven
Demographic data, Mean (SD)		
Age, years	58.9 (9.8)	58.0 (9.5)
Female/Male, %	47.7/52.3	50.0 (50.0)
Duration of diabetes, years	9.3 (5.8)	10.6 (6.8)
Baseline, Mean (SD)		
HbA_{1c}, %	8.3 (0.9)	8.3 (0.9)
FPG, mmol/L	9.1 (2.7)	8.8 (2.8)
Weight, kg	81.0 (16.2)	77.9 (14.9)
Study outcome data*		
HbA_{1c}, % *		
Change at Week 12	−0.71 (0.07)	−0.82 (0.07)
Change at Week 20	−0.70 (0.08)	−0.97 (0.08)
Week 20 (LOCF)	7.57 (0.08)	7.32 (0.08)
FPG, mmol/L (LOCF) *		
Week 20	8.04 (0.21)	7.91 (0.22)
Change from baseline	−0.94 (0.21)	−1.07 (0.22)
Weight, kg (LOCF) *		
Week 20	82.6 (16.7)	78.6 (15.4)
Change from baseline	1.57 (0.24)	0.9 (0.25)
Mean dose, U/kg/day		
Week 1	0.37	0.37
Week 20	0.69	0.69
Hypoglycaemia, episodes/subject-exposure/year		
All episodes	9.59	12.08
Minor or severe episodes	3.90	4.47
Nocturnal episodes	0.80	1.09
*LS-Means (SE)		

Conclusion: Noninferiority of SD vs. ID titration with regards to change from baseline to EOT HbA_{1c} could not be confirmed. SD titration was as effective as ID titration in reducing FPG. There was no statistically significant difference between the groups in occurrence of overall, minor + severe or nocturnal hypoglycaemic episodes. 12-week HbA_{1c} results suggest a clinic visit ~12 weeks after BIAsp 30 initiation or intensification may benefit subjects' SD titration results. Overall, treatment with twice-daily BIAsp 30 was effective, safe and well tolerated.

Glycaemic control and quality of life: Is there any relationship in young patients with type 1 diabetes?

E.V. Surkova, O.G. Motovilin, A.Y. Mayorov, J.A. Shishkova;
Diabetes, National Research Centre for Endocrinology, Moscow, Russian Federation.

Background and aims: To analyse the relationship between quality of life (QoL), emotional state and glycemic control in young patients with type 1 diabetes (T1D).
Materials and methods: We enrolled 140 T1D patients aged of 18-28 years (m/f - 46/94, mean age 22,6±3,2 years, duration of diabetes 12,3±5,6 years, HbA1c level 9,4±2,2%). Patients were evaluated by The Audit of Diabetes Dependent Quality of Life (ADDQoL), The Short Form (36) Health Survey (SF-36), The Well-Being Questionnaire, 12- Item (WB-Q12), The State-Trait Anxiety Inventory (STAI) (the Spielberger's scale), The Centre for Epidemiologic Studies - Depression scale (CES-D), The Hospital anxiety and depression scale (HADS). Statistical analysis: Spearman correlation tests.
Results: Patients with better glycemic control had a higher QoL. HbA1c level had a negative correlation with 3 scales of SF-36: bodily pain (rs=-0.341, p<0.001), social role functioning (rs=-0.211, p<0.05), physical role functioning (rs=-0.207, p<0.05) and with 6 scales of ADDQoL: generic QoL (rs=-0.184, p<0.05), impact of diabetes on QoL (rs=-0.296, p<0.001), physical appearance (rs=-0.198, p<0.05), motivation (rs=-0.175, p<0.05), finances (rs=-0.206, p<0.05), living conditions (rs=-0.191, p<0.05). Better glycemic control was also associated with better emotional state. There was a correlation between HbA1c level and anxiety scale of HADS (rs=0.209, p<0.05), state and trait anxiety scales of STAI (rs=0.184 and 0.208 respectively, p<0.05), level depression according to CES-D (rs=0.183, p<0.05) and negative well-being scale of WB-Q12 (rs=0.230, p<0.01).
Conclusion: There is a relationship of glycemic control with QoL and emotional state in young T1D patients. Better glycemic control is associated with less bodily pain, better social role functioning and physical role functioning, according to SF-36, better satisfaction of physical appearance, motivation, finances, living conditions, according to ADDQoL, and lower level of anxiety and depression, according to HADS, STAI and CES-D.

Factors affecting non-adherence to drug, diet and physical activity advices among type 1 diabetic subjects

B. Banu[1], Z. Rizvi[1], A. Basit[2], L. Ali[3];
[1]Health Education & Health Promotion, Bangladesh University of Health Sciences, Dhaka, Bangladesh, [2]Baqai Institute of Diabetology and Endocrinology (BIDE) Baqai Medical University, Karachi, Pakistan, [3]Biochemistry & Cell Biology, Bangladesh University of Health Sciences, Dhaka, Bangladesh.

Background and aims: Nonadherence to drug, diet and physical activity advices has been identified as a major problem in the management of type 1 diabetes mellitus (T1DM). Factors for nonadherence among diabetic subjects vary from population to population due to difference in lifestyle, culture, knowledge and beliefs. No study has yet been conducted regarding nonadherence to drug, diet and physical activity advices among T1DM patients in Pakistan. The current study was designed to determine the proportion as well as factors affecting nonadherence to these advices among T1DM subjects attending a tertiary care hospital in Karachi.
Materials and methods: An observational analytic study was conducted among 194 T1DM subjects [Age in yrs mean (±SD), 17.9± (6.4)]. Data were collected through pre-tested semi-structured questionnaire and face to face interview with respondents. Information on sociodemographic and clinical

characteristics, health care delivery system, and proportion of nonadherence were collected. Drug, diet and physical activity history were collected by recall method and a standardized scoring system, based on adherence to respective advices by the educators, were developed. For drug advices a subject was marked as 'Nonadherent' if s/he did not attain 100% of the adherence score. For dietary and physical activity advices, the cut-off value for 'Nonadherence' was 60%. Data were analyzed by univariate as well as multivariate statistics.
Results: The proportion of nonadherence was found to be high for drug (88.1%) and dietary (58.5%) advices; on the other hand it was relatively low (42.3%) for physical activity advices. On logistic regression analysis, factors which were found to have significant effect on drug nonadherence were: briefing of prescription other than respondent's own language by prescriber (p=0.04), negative family history for type 2 diabetes mellitus (p=0.04) and low maternal education (p=0.04). Factors significantly associated with dietary nonadherence were less attendance to diabetic clinic (p=0.05) and diabetic education programs (p=0.01), and large family size (p=0.01). Fear of hypoglycemia (p=0.05), respondent's low level of knowledge regarding their diabetes (p=0.03), maternal occupation status as housewife (p=0.02) and high monthly family expenditures (p=0.03) were the determinants which significantly contributed to nonadherence with their physical activity advices.
Conclusion: An alarmingly high proportion of Pakistani T1DM subjects are nonadherent to drug and dietary advices and a substantial proportion of them are also nonadherent to physical activity advices. The major factors for these nonadherences are communication barrier between patients and physicians, negative family history of T2DM, less apprehension for their disease, behavioral characteristics regarding their treatment, lack of parental support, poor maternal education status, large family size, high monthly expenses, and fear of hypoglycemia. These factors need to be specifically addressed in the management plan of T1DM subjects.

Empowerment and motivation affects HbA_{1c} in subjects with low medical adherence and poor diabetes control

G. Andrésdóttir, L. Jelstrup, F. Persson, A.R. Varming, E.H. Petersen, G. Engelund, P. Rossing;
Steno Diabetes Center, Gentofte, Denmark.

Background and aims: Studies have shown that only around 50% of medications prescribed for the long-term treatment of chronic diseases are used as prescribed. Poor medical adherence (MA) contributes to suboptimal control and poor clinical outcomes. Moreover, very little knowledge of appropriate interventions exists. The aim of our pilot-study is to use new methods for individual empowerment to treat patients with type 2 diabetes and poor MA including poor glycaemic control. The end-points are change in HbA_{1c} at the end of the intervention in addition to six months later and medical possession rate during these 6 months.
Materials and methods: For all patients with HbA_{1c} of 63.9 mmol/mol or above from a single outpatient clinic, data from the Danish drug prescription database (Medicine Profile), were used to assess MA for oral hypoglycaemic agents, acetylsalicylic acid, lipid lowering drugs and liraglutide during the year 2010. A consultation program was developed and offered to 2/3 of patients with MA below 80%, the remaining 1/3 was used as a control group. The intervention consisted of three consultations and a phone call, and focused on facilitating empowerment, enhancing motivation and providing systematic, goal-oriented support, using tools to enhance dialogue, participation and informed patient decisions.
Results: We calculated MA for 172 patients, 105 (61%) had MA below 80% for at least one of the aforementioned drugs. Patients participating in other studies or not self-sufficient were excluded, thus 89 eligible patients remained. Altogether, 34 patients did not accept to participate and 11 patients died or migrated before or during the study and were excluded, resulting in 22 participants and 22 controls. At baseline the participants median HbA_{1c} was 69.5 (63-77) compared to 71.5 (62-80) mmol/mol in the control group (p=0.60). The participants showed a median decline in HbA_{1c} of 2 (IQ range -1 to 3) during the study compared to an increase of 2.5 (-2 to 4.5) mmol/mol (p=0.041) in the control group. The median decline from start to end of follow-up was 4 (-6 to 8) versus 0 (-8 to 7) mmol/mol for participants and controls respectively (p=0.45). Improvement in HbA_{1c} from start to end of intervention was seen in 64% of participants and 35% of controls (p=0.12), whereas from start to end of follow-up HbA_{1c} improved for 64% of participants compared to 48% of controls (p=0.36). At baseline participants were noncompliant for a mean of 1.3 (0.8) prescriptions whereas the same number was 1.4 (1.0) at follow up. The corresponding numbers for the control group were 1.6 (0.7) and 1.5 (1.0). There were no significant differences in mean change when the groups were compared (p=0.70). As were there no significant changes in total MA (p=0.95), or in mean MA for hypoglycaemic drugs (p=0.51).
Conclusion: In our pilot study, the intervention resulted in a decrease in HbA_{1c} of approximately 3 mmol/mol during the study period, with sustained effect 6 months after the intervention. When compared with the control group the differences were significant only at the former point in time. The intervention did not show improvement in medical possession rates for selected peroral drugs and liraglutide. This is in accordance with the patient's own goals that were more focused on improving glycaemia than MA. However, many participants improved their insulin routine which is not reflected in the estimated MA.

1068

Early utilisation of daily SMBG in insulin treated type 2 diabetes patients is associated with greater improvement in glycaemic control: results from the COMPASS study

Q. Su[1], L. Ji[2], B. Feng[3], Z. Shan[4], R. Hu[5], X. Xing[6], Y. Xue[7];
[1]Xin Hua Hospital, Shanghai, [2]Peking University People's Hospital, Beijing, [3]Tongji University Oriental Hospital, Shanghai, [4]The First Hospital of China Medical University, Liaoning, [5]Huashan Hospital, Shanghai, [6]Chinese Academy of Medical Sciences & Peking Union Medical College, Beijing, [7]Nan Fang Hospital, Guangdong, China.

Background and aims: While self-monitoring of blood glucose (SMBG) is generally deemed essential in the management of insulin-treated type 2 diabetes (IT T2DM), not many IT T2DM patients in China perform SMBG on a daily basis. In the COMPASS study, we evaluated the effect of introducing a recommended SMBG regimen on glycemic control and SMBG behaviour in IT T2DM patients. The introduction of the SMBG regimen resulted in a substantial increase in daily SMBG utilization among the patients observed. In this sub-analysis, we examined the association between timing of daily SMBG utilization and glycemic control in poorly controlled IT T2DM patients in China.
Materials and methods: The COMPASS study is a multi-centre, observational study. Daily SMBG was introduced according to a recommended SMBG regimen. 820 patients who had been on insulin for at least 3 months and had poor glycemic control (HbA1c>8%) were followed up for 6 months. Patients were trained on how to individually respond to their SMBG readings by lifestyle changes and self-adjustment of insulin doses. Glycemic control and therapy regimen were assessed during quarterly physician visits. Retrospectively, we grouped the 820 patients into 4 quartiles, first according to duration of T2DM (<4.12 yrs; 4.12-9.19 yrs; 9.20-13.81 yrs; >13.81 yrs) and then according to duration of insulin therapy (<8.87 mths; 8.87-30.25 mths; 30.26-66.60 mths; >66.60 mths). We then compared glycemic control between the groups according to duration of T2DM and duration of insulin therapy respectively.
Results: Mean (SD) baseline HbA1c according to duration of T2DM (<4.12 yrs; 4.12-9.19 yrs; 9.20-13.81 yrs; >13.81 yrs) were 10.38(2.00)%, 9.51(1.30)%, 9.56(1.41)% and 9.38(1.18)%, respectively. Mean (SD) baseline HbA1c according to duration of insulin therapy (<8.87 mths; 8.87-30.25 mths; 30.26-66.60 mths; >66.60 mths) were 10.33(1.86)%, 9.53(1.43)%, 9.62(1.60)% and 9.37(1.06)%, respectively. According to the duration of T2DM, the mean (SD) HbA1c changes from baseline were -2.92(2.47)% (p<0.0001), -1.50(1.49) % (p<0.0001), -1.57(1.53)% (p<0.0001) and -1.28(1.42)% (p<0.0001) respectively at month 3 and -2.82(2.59)% (p<0.0001), -1.41(1.50)% (p<0.0001), -1.56(1.45)% (p<0.0001) and -1.24(1.54)% (p<0.0001) respectively at month 6. According to the duration of insulin therapy, the mean (SD) HbA1c changes from baseline were -2.93(2.38)% (p<0.0001), -1.70(1.60)% (p<0.0001), -1.55(1.57)% (p<0.0001) and -1.03(1.23)% (p<0.0001) respectively at month 3 and -2.88(2.39)% (p<0.0001), -1.54(1.68)% (p<0.0001), -1.47(1.58)% (p<0.0001) and -1.10(1.36)% (p<0.0001) respectively at month 6.
Conclusion: In this cohort of poorly controlled IT T2DM patients who were introduced to a recommended SMBG regimen and trained on individual therapy adaptation, which resulted in daily SMBG utilization, HbA1c improvements tended to be greater in patients with shorter duration of T2DM and with shorter duration of insulin therapy. This suggests that early adoption of daily SMBG in IT T2DM is associated with greater improvement in glycemic control.

Correlates of patient barriers to medication taking in type 2 diabetes: the BENCH-D study

M. Rossi[1], F. Pellegrini[1], S. Gentile[2], G. Lucisano[1], G. Marra[3], B. Pintaudi[1], S. Skovlund[4], G. Vespasiani[5], A. Nicolucci[1], BENCH-D Study Group; [1]Clinical Pharmacology and Epidemiology, Consorzio Mario Negri Sud, S. Maria Imbaro (CH), [2]Clinical and Experimental Medicine, Federico II University, Naples, [3]NovoNordisk SpA, Rome, Italy, [4]Novo Nordisk A/S, Bagsværd, Denmark, [5]Diabetes Unit, Madonna del Soccorso Hospital, San Benedetto del Tronto (AP), Italy.

Background and aims: Compliance to medication is a key point for the achievement of a good metabolic control and, consequently, for a better quality of life. In the context of the BENCH-D study, an integral part of the DAWN-2 initiatives in Italy, we evaluated socio-demographic, clinical and humanistic characteristics associated with patients' perceived barriers to taking their medication as scheduled.
Materials and methods: The study was conducted in 28 diabetes outpatient clinics in Italy. In each center, a random sample of patients filled in the Barriers to Medication (BM) questionnaire. Additional instruments were: WHO-5 well-being index, Problem Areas in Diabetes questionnaire (PAID-5), Patients Assessment of Chronic Illness Care (PACIC) questionnaire, Health Care Climate Questionnaire (HCCQ), Patient Support (PS) questionnaire, Diabetes Self-care Activities (DSCA) questionnaire, Global Satisfaction for Diabetes Treatment questionnaire (GSDT) and Diabetes Empowerment Scale (DES). For all the instruments higher values indicate a higher level of the dimension measured. Clinical data were extracted from computerized medical records.
Results: Overall, 2434 patients with T2DM were evaluated (mean age 65.0±10.2 years, diabetes duration 13.8±15.2 years, 59.9% males, 48.6% treated with oral agents, 25.3% treated with insulin+oral agents, 24.3% treated with insulin). When compared with patients in the lower quartile of the BM score, patients in the upper quartile (i.e. highest level of perception of barriers) had higher HbA1c levels (8.0±1.0% vs. 7.6±1.5%, p<0.001), showed significantly lower scores for WHO-5, PACIC, HCCQ, PS, GSDT (p<0.001 for all the scales), and DES (p=0.015), and higher diabetes distress (PAID-5; p<0.001). A higher perception of barriers to medication was associated with poorer adherence to diet and medication taking and higher adherence to blood glucose self-monitoring (DSCA; p<0.0001 for all the items). No association with type of diabetes treatment emerged. At multivariate analysis, adjusted for socio-demographic and clinical characteristics, the risk of presenting a BM score in the highest quartile increased for increasing values (by 5 score points) of PAID-5 (OR 1.07; 95%CI 1.04-1.10).
Conclusion: Higher perceived patient barriers to medication taking is associated with poorer metabolic control, higher levels of diabetes related distress, poorer quality of life and lower levels of satisfaction with care. Addressing perceived barriers should represent a key component of any educational activity in the context of patient-centered care.

Correlates of patients' attitudes to check their feet as a diabetes self-care activity: the BENCH-D study

B. Pintaudi[1], G. Lucisano[1], S. Gentile[2], G. Marra[3], F. Pellegrini[1], M. Rossi[1], S. Skovlund[4], G. Vespasiani[5], A. Nicolucci[1], BENCH-D Study Group; [1]Clinical Pharmacology and Epidemiology, Consorzio Mario Negri Sud, S. Maria Imbaro (CH), [2]Clinical and Experimental Medicine, "Federico II" University, Naples, [3]NovoNordisk SpA, Rome, Italy, [4]Novo Nordisk A/S, Bagsværd, Denmark, [5]Diabetes Unit, Madonna del Soccorso Hospital, S. Benedetto del Tronto (AP), Italy.

Background and aims: Compliance with proper foot care reduces the incidence of foot ulcers and other serious complications. Optimum foot self-care practices include daily inspection of feet. In the context of the BENCH-D study, an integral part of the DAWN-2 initiatives in Italy, we evaluated socio-demographic, clinical and humanistic characteristics associated with patients' attitudes to inspect their feet.
Materials and methods: The study was conducted in 28 diabetes outpatient clinics in Italy. In each center, a random sample of patients filled in the Diabetes Self-care Activities (DSCA) questionnaire. Additional instruments were: WHO-5 well-being index, Problem Areas in Diabetes questionnaire (PAID-5), Patients Assessment of Chronic Illness Care (PACIC) questionnaire, the Health Care Climate Questionnaire (HCCQ), the Patient Support (PS) questionnaire, Barriers to Medication (BM) questionnaire, Global Satisfaction for Diabetes Treatment questionnaire (GSDT) and Diabetes Empowerment Scale (DES). For all the instruments higher values indicate a higher level of the dimension measured. Clinical data were extracted from computerized medical records.
Results: Overall, 2434 patients with T2DM were evaluated (mean age 65.0±10.2 years, diabetes duration 13.8±15.2 years, 59.9% males, 48.6% treated with oral agents, 25.3% treated with insulin+oral agents, 24.3% treated with insulin). When compared with patients in the upper quartile of the DSCA-Feet score, patients in the lower quartile (i.e. poorest compliance with foot monitoring) were more often male, had less diabetic complications, shorter duration of disease, showed significantly lower scores for PACIC, HCCQ, DES, PS, DSCA-subscales, and GSDT (p<0.001 for all the scales), and higher scores for BM (p=0.003). At multivariate analysis, adjusted for socio-demographic and clinical characteristics, the risk of presenting a DSCA-Feet score in the lowest quartile was higher in men (OR=2.4; 95%CI 1.7-3.6), in individuals taking oral agents as compared to those treated with insulin (OR=2.3; 95%CI 1.5-3.5), and decreased for increasing values of WHO-5 (OR 0.96; 95%CI 0.92-0.99; by 5 score points) and PACIC (OR 0.87; 95%CI 0.80-0.95; by 5 score points).
Conclusion: Poor adherence to foot monitoring is associated with lower perceived accessibility to chronic illness care-based services and lower levels of psychological well-being. Promoting patient-centered care and ensuring adequate psychological support are key elements to improve self-care activities in individuals with type 2 diabetes.

My Diabetes My Way: an electronic personal health record for people with diabetes

S.G. Cunningham[1], D.J. Wake[2], A.D. Morris[2], A. Waller[3], J. Walker[4]; [1]Clinical Technology Centre, [2]Medical Research Institute, [3]School of Computing, University of Dundee, [4]St. John's Hospital, NHS Lothian, Livingston, UK.

Background and aims: Diabetes prevalence in Scotland is increasing at ~4.6% annually, with figures currently reaching 247,278 (4.7%). My Diabetes My Way (MDMW - www.mydiabetesmyway.scot.nhs.uk) is the official NHS Scotland information portal, containing validated educational materials for people with diabetes and their carers. Internet-based interventions have the potential to enhance self-management and shift the balance of power towards the patient, with electronic personal health records (ePHRs) identified as an ideal method of delivery. In December 2010, a new service was launched within MDMW, allowing patients from across Scotland access to their shared electronic medical record. We analysed the first two years of usage and uptake.
Materials and methods: We developed a diabetes-focused, population-based ePHR for NHS Scotland based on data sourced from primary, secondary and tertiary care via the national shared-electronic record, Scottish Care Information - Diabetes Collaboration (SCI-DC). The system includes key diagnostic information; demography; laboratory tests; lifestyle, foot and eye screening results; prescribed medication and clinical correspondence. Changes can be tracked over time using 'history' graphs and tables, data items link to detailed descriptions, explaining why they are collected, what they are used for and what 'normal' values are, and tailored information links refer individuals to further facts related to their condition.
Results: At the end of the second year of live use, 2601 individuals had registered to access their data (61% male; 30.4% with type 1 diabetes); 1297 had completed the enrolment process and 625 had accessed the system (most logins=346; total logins=5167; average=8.3/patient; median=3). Audit trails show 59599 page views (95/patient), with laboratory 'test results' proving the most popular (11818 accesses; 19/patient). The most utilised history graph was, unsurprisingly, HbA1c (2866 accesses; 4.6/patient). Feedback: "It is great to be able to view all of my results so that I can be more in charge of my diabetes".
Conclusion: The system is now a useful additional component for the self-management of diabetes in Scotland. Although there are other patient access systems available worldwide, the MDMW system is unique as it offers access to an entire national population and provides access to information collected from all available diabetes-related data sources. Although the system has been developed for, and by, stakeholders from across Scotland, it has the potential to connect to any electronic medical record. The current project is expected to reach over 5000 patients by the end of 2013.

PS 088 Self blood glucose monitoring: utility and metrics

1072

Introduction of a recommended SMBG regimen improved glycaemic control in poorly controlled Chinese patients on insulin therapy: results from the COMPASS study

L. Ji[1], Q. Su[2], B. Feng[3], Z. Shan[4], R. Hu[5], X. Xing[6], Y. Xue[7];
[1]Peking University People's Hospital, Beijing, [2]Xin Hua Hospital, Shanghai, [3]Tongji University Oriental Hospital, Shanghai, [4]The First Hospital of China Medical University, Liaoning, [5]Huashan Hospital, Shanghai, [6]Chinese Academy of Medical Sciences & Peking Union Medical College, Beijing, [7]Nan Fang Hospital, Guangdong, China.

Background and aims: Self-monitoring of blood glucose (SMBG) is deemed integral in the management of insulin-treated type 2 diabetes (IT T2DM). In China, utilization of SMBG among IT T2DM patients is low. Even among those who perform SMBG regularly, the daily testing frequency falls short of those recommended in clinical guidelines. We examined the effect of introducing a recommended SMBG regimen on testing frequency and glycemic control in IT T2DM patients in China.
Materials and methods: The COMPASS study is a 2-phase, multi-centre, observational study. The first phase evaluated the current state of SMBG practice, types of insulin therapy used and glycemic control in IT T2DM patients. The second phase evaluated the effect of introducing a SMBG regimen on glycemic control in poorly controlled IT T2DM patients. Inclusion criteria for the second phase included patients who were enrolled in the first phase, had poorly controlled diabetes (HbA1c>8%) and had been on insulin therapy for at least 3 months. At the start of this second phase, patients received a blood glucose meter and a paper tool to record SMBG readings. They were introduced to and advised to follow a SMBG regimen. They were also trained on how to respond to SMBG readings via lifestyle changes and insulin dose self-adjustment. During the 6-month follow-up period, physician visits were scheduled at the end of month 3 and 6. Physicians assessed glycemic control based on HbA1c and SMBG records, and gave further advice on lifestyle changes, medication adjustment and SMBG regimen, if applicable. Endpoints included (1) daily SMBG frequency; (2) HbA1c baseline change at month 3 and 6; (3) proportion of patients who achieved glycemic control (HbA1c<7%) at month 3 and 6; and (4) proportion of patients who self-adjusted insulin dosage based on SMBG reading.
Results: Of the 3,006 patients participated at 120 centres in China in the first phase, 820 patients (age 55±9.8 yrs, 50% females, BMI 24.9±3.6) met the inclusion criteria of the second phase and were enrolled (baseline HbA1c 9.7±1.6%, T2DM duration 9.8±7.1 yrs, insulin therapy duration 45.4±46.8 mths). At baseline, 30% of the patients reported performing SMBG daily (12% once, 12% twice, 3% thrice, 3% four times). At month 3 and 6, 99.8%/99.1% of the patients reported performing SMBG daily (20%/20% once, 64%/65% twice, 11%/10% thrice, 4%/4% four times), and 70%/74% of the patients reported having self-adjusted their insulin dose based on SMBG readings. HbA1c decreased substantially from baseline at month 3 [mean ΔHbA1c -1.88%, p<0.0001] and month 6 [mean ΔHbA1c -1.85%, p<0.0001]. 36% and 40% of the patients achieved good glycemic control (HbA1c<7%) at month 3 and 6, respectively.
Conclusion: In this Chinese cohort of poorly controlled IT T2DM patients, introducing a recommended SMBG regimen substantially contributed to an improved HbA1c. Based on the results, we hypothesize that training on how to interpret and respond to SMBG readings together with daily SMBG enable patients and physicians to better manage diabetes.

Use of structured 3-day glycaemic profiles impacts glucose control in diabetes patients treated with multiple daily insulin injection therapy: results from ABACUS

C. Vogel[1], D.A. Cavan[2], R. Ziegler[3], I. Cranston[4], K. Barnard[5], J. Ryder[6], C.G. Parkin[7], W. Koehler[8], I. Vesper[9], B. Petersen[9], M.A. Schweitzer[9], R.S. Wagner[9];
[1]Internistisches Fachaerztezentrum, Langen, Germany, [2]Bournemouth Diabetes and Endocrine Centre, UK, [3]Diabetes Clinic for Children and Adolescents, Muenster, Germany, [4]Academic Department of Diabetes & Endocrinology, Queen Alexandra Hospital, Portsmouth, [5]University of Southampton, [6]Royal Bournemouth Hospital, UK, [7]CGParkin Communications, Inc., Boulder City, USA, [8]Baseline Statistics GmbH, Mannheim, Germany, [9]Roche Diagnostics, Indianapolis, USA.

Background and aims: Recent studies have shown that use of structured self-monitored blood glucose (SMBG) regimens positively influences health behaviors in non-insulin treated diabetes, leading to improvements in glycemic control and other measures. We examined the effect of using 3-day, 7-point glycemic profiles in patients treated with multiple daily insulin injection (MDI) therapy.
Materials and methods: Data were drawn from 194 patients enrolled in the Automated Bolus Advisor Control and Usability Study (ABACUS) trial, a large, 26-week, prospective, randomized multi-national trial. The trial evaluated the use of an automated bolus advisor in suboptimally controlled MDI-treated type 1 diabetes and type 2 diabetes patients with baseline HbA1c 8.9 (1.2)%. Patients randomized to the control group (CNL) used a standard blood glucose (bG) meter and manual bolus calculation; whereas, patients randomized to the intervention group (EXP) used the Accu-Chek® Aviva Expert meter, which provides an integrated automated bolus advisor to calculate insulin dosages. All patients were asked to perform 7-point bG testing (pre-/postprandial, at bedtime) for 3 consecutive days prior to randomization and prior to 3 additional clinic visits. We compared bG levels obtained on profile days with values from non-profile days.
Results: All patients had significantly (p <0.01) lower mean bG values (Table) and a higher percentage of bG values within target range (70-180 mg/dL / 3.9-10 mmol/L) on more profile days than non-profile days. Glycemic variability (MAGE) was significantly (p <0.01) lower with significantly fewer bG values in the hypoglycemic range (<50 mg/dL / 2.8 mmol/L) and hyperglycemic range (>300 mg/dL / 16.7 mmol/L) on most profile days compared with non-profile days. No significant between-group differences were seen in these parameters.
Conclusion: Recent studies of non-insulin treated diabetes have demonstrated that use of structured SMBG as a basis for close collaboration between patients and their healthcare team facilitates therapy optimization. Our study suggests that performing periodic 3-day, 7-point bG profiles may be an effective stand-alone intervention to optimize glycemic control for patients treated with MDI therapy.

Table. Comparison of bG values on profile days vs. non-profile days (Intent-to-Treat cohort, n=194)

Profile Days	Mean bG on Profile Days (mg/dL / mmol/L)	Mean bG on Non-Profile Days (mg/dL / mmol/L)	P Value
Baseline	173.7 (39.6) / 9.7 (2.2)	181.9 (42.4) / 10.1 (2.4)	< 0.01
Visit 5	175.1 (39.1) / 9.7 (2.2)	183.5 (40.6) / 10.2 (2.3)	< 0.01
Visit 7	173.9 (38.7) / 9.7 (2.2)	184.8 (40.7) / 10.3 (2.3)	< 0.01
Visit 9	176.0 (37.1) / 9.8 (2.1)	179.8 (39.6) / 10.0 (2.2)	NS

Colour record in self-monitoring of blood glucose improves glycaemic control for insulin-treated type 2 diabetes patients

A. Nishimura[1], I. Honda[1], S. Harashima[2], Y. Shimizu[1], K. Hosoda[1], N. Inagaki[2];
[1]Department of Human Health Science, [2]Department of Diabetes and Clinical Nutrition, Kyoto University, Kyoto, Japan.

Background and aims: We conducted a clinical research study to evaluate the effect of two color-indication methods used in SMBG, color display (CD)

and color record (CR), on glycemic control in insulin-treated type 2 diabetes patients.

Materials and methods: This was a prospective, 24-week, single center, comparison study. One hundred twenty outpatients of our University hospital were randomly allocated to four groups by two-by-two factorial design (Table). Group A used One Touch® Ultra Vue™ (Vue) with black and white indicator and recorded their blood glucose levels manually in black pencil. Group B observed a red or blue indicator light on the color Vue when their glucose levels were 160 mg/dl or greater, or less than 70 mg/dl, respectively, and recorded them manually in black pencil. Group C used the Vue with black and white indicator and recorded their blood glucose levels in red or blue pencil under the same glycemic conditions. Group D used both color display and color record. The primary endpoint was difference in HbA1c reduction in 24-week between CD (B+D) and non-CD (A+C) groups and between CR (C+D) and non-CR (A+B) groups. Secondary endpoints were differences in self-management performance change evaluated by the Summary of Diabetes Self-Care Activities Measure (SDSCA) and the Profile of Mood States (POMS) change.

Results: Demographics of subjects were almost the same among the 4 groups. Nine subjects (15.0%) in non-CR, 10 (16.7%) in CR, 9 (15.5%) in non-CD, and 10 (16.1%) in CD groups were dropped because of hospitalization for diabetes and comorbidities. Change in HbA1c in 24-week was -0.11% in non-CD group and -0.13% in CD group with no significant difference. However, change in the score on the exercise subscale of the SDSCA in 24-week was significantly improved by 0.50 points in CD group compared to that in non-CD group, suggesting that color display is favorable for an increase in physical activity. On the other hand, HbA1c levels at 24-week were significantly decreased in CR group by -0.28%, but were increased by 0.03% in non-CR group. Difference in HbA1c reduction in 24-week between the 2 groups was -0.31%, which was a significant difference. In addition, scores on diet and exercise subscales of SDSCA in 24-week were significantly increased by 0.44 points and 0.50 points, respectively, in CR group compared to those in non-CR group, implying that color record is helpful for improvement both in physical activity and in diet. There were no significant different in changes in scores on the POMS among the groups.

Conclusion: Color record has a favorable effect on self-management performance without any influence on psychological stress, resulting in improved glycemic control in insulin-treated type 2 diabetes patient.

Table. Two-by-two factorial design and subject number

n = 31 No color display No color record (A)	n = 29 Color display No color record (B)	Subtotal n = 60 No Color Record group (non-CR)
n = 27 No color display Color record (C)	n = 33 Color display Color record (D)	Subtotal n = 60 Color Record group (CR)
Subtotal n = 58 No Color Display group (non-CD)	Subtotal n = 62 Color Display group (CD)	Total n = 120

ExAct study: Integrated strip-free SMBG technology (Accu-Chek® Mobile) improves patient adherence to recommended testing frequency and patterns and glycaemic control

A. Maran[1], D. Tschoepe[2], M. Di Mauro[3], W.A. Fisher[4], K. Loeffler[5], I. Vesper[6], O. Mast[6], S. Bloethner[6], J. Weissmann[6], I. Amann-Zalán[7], I. Cranston[8];
[1]Department of Medicine, University of Padua, Italy, [2]Heart and Diabetes Center Nordrhein-Westfalen, Bad Oeynhausen, Germany, [3]Department of Medical and Pediatric Sciences, Policlinico 'G. Rodolico', Catania, Italy, [4]Department of Psychology, University of Western Ontario, London, Canada, [5]Accovion GmbH, Eschborn, [6]Roche Diagnostics GmbH, Mannheim, Germany, [7]Roche Molecular Systems, Inc., Pleasanton, USA, [8]Portsmouth Hospitals NHS Trust, Queen Alexandra Hospital, Cosham, UK.

Background and aims: Current guidelines recommend a self-monitoring of blood glucose (SMBG) at least 3-4 times daily for diabetes patients on prandial insulin regimen. Patient adherence to this recommendation is often suboptimal, non-adherence is often device-related. Integrated strip-free SMBG technology has been developed to reduce testing barriers. This study investigates the impact of integrated strip-free SMBG technology on testing frequency and glycemic control of non-adherent patients.

Materials and methods: 478 non-adherent patients (<3.25 tests/day at baseline) were enrolled into this multicenter, prospective, cluster-randomized study with sites randomized to either "integrated strip-free" or "any single-strip" SMBG technology. Testing frequency and HbA1c were measured at baseline, after 3, and after 6 months. Changes from baseline were investigated using generalized linear mixed models.

Results: 332 patients were eligible for efficacy analysis. Three months after baseline, testing frequency increased by 0.48 measurements/day in patients using integrated strip-free technology. The average testing frequency was 0.37 measurements/day higher in "integrated strip-free" compared to "any single-strip" patients (p=0.007). Glycemic control improved with the 2 technologies, with a greater HbA1c reduction in patients using strip-free technology (mean difference 0.22%, p=0.04). Changes in test frequencies and HbA1c concentrations are represented below. A detailed analysis of daily measurement patterns revealed: Testing frequency at lunch (11am-2pm) and dinner time (5pm-8pm) in "integrated strip-free" patients increased from 12.3 to 16.6 and from 12.6 to 16.9 measurements/hour/100 patients, respectively, after 6 months. No change in testing frequency was found in "any single-strip" patients. (Figure)

Conclusion: Integrated strip-free SMBG technology resulted in a significant increase in testing frequency towards guideline recommendations. The change was associated with a clinically relevant HbA1c decrease in previously non-adherent patients. Examination of daily patterns revealed an increase in testing frequency in patients using the integrated strip-free technology before lunch and dinner time, resulting in a relatively large HbA1c impact given the small increase in daily testing frequencies.

Changes in test frequency and HbA1c in the two study groups over the 6 month observational period

System accuracy evaluation of blood glucose monitoring systems for point of care testing and self monitoring

G. Freckmann[1], A. Baumstark[1], M. Link[1], S. Pleus[1], E. Stolberg[1], C. Haug[1], J. Sieber[2];
[1]Institut für Diabetes-Technologie Forschungs- und Entwicklungsgesellschaft mbH an der Universität Ulm, [2]Sanofi-Aventis Deutschland GmbH, Frankfurt am Main, Germany.

Background and aims: Blood glucose (BG) monitoring systems for professional use only and systems designated for self-monitoring of BG (SMBG) are used for point of care testing (POCT) by health care professionals. These systems are often used interchangeably for capillary glucose monitoring, thus raising the question for comparability of measurement quality.

Materials and methods: In this study, we evaluated the accuracy of a BG system for self-monitoring based on dynamic electrochemistry (BGStar, Sanofi) and six different, commonly used systems for professional use (HemoCue Glucose 201+, HEMOCUE AB; StatStrip, nova biomedical; ACCU-CHEK Inform II, Roche Diagnostics; BIOSEN C_line, EKF-diagnostic; HITADO SUPER GL compact, Dr. Müller Gerätebau; GLUKOMETER PRO, BST Bio Sensor Technology). Investigational procedures were performed following the international standard ISO 15197:2003. Capillary blood samples of 100 subjects were measured and the results were analyzed according to the ISO/DIS 15197 by calculating the percentage of results within ±10%/±15% or within ±10 mg/dL/±15 mg/dL of the reference measurement results for BG concentrations above or below

100 mg/dL, respectively. Glucose oxidase was used as comparison method (YSI 2300 STAT Plus, YSI Life Sciences, USA). Two devices and one lot of reagents or test strips were used for each POCT system, except for the SMBG system BGStar, for which three reagent lots were evaluated separately.
Results: For all evaluated systems 99% to 100% of the measurement results were within ±15 mg/dL or ±15% of the reference method results. When applying more restrictive limits of ±10 mg/dL or ±10% larger differences between the evaluated systems were observed (82% to 98% of the results within these limits). For three POCT systems for professional use and for the three lots of the system for self-monitoring more than 95% of the measurement results were within these more restrictive limits.
Conclusion: In this study, the BG system for self-monitoring based on dynamic electrochemistry and the POCT systems for professional use fulfilled the accuracy requirements of the new ISO/DIS 15197 standard measuring capillary glucose values. Furthermore this study demonstrated that BG systems for self-monitoring which have to fulfil strict requirements prior to market launch can achieve similar system accuracy as POCT systems for professional use.

Measurement error in estimated average glucose: a new approach
M.J. O'Kane[1], J.E. Given[2], B.P. Bunting[3], V.E. Coates[2];
[1]Clinical Chemistry Laboratory, Altnagelvin Hospital, Londonderry, [2]Institute of Nursing Research, University of Ulster, Coleraine, [3]Psychology Research Institute, University of Ulster, Londonderry, UK.

Background and aims: Estimated average glucose (eAG) has been suggested as a way to link daily self monitoring blood glucose (SMBG) directly to long term glycaemia. However variation in hemoglobin A1c (HbA1c) and mean plasma glucose (MPG) determinations due to measurement error (ME) may mean that people with the same HbA1c have different eAG values. The aim of this study was to explore the impact of measurement error on the determination of an HbA1c derived eAG.
Materials and methods: SMBG data from the 'Efficacy of self-monitoring of blood glucose in patients with newly diagnosed type 2 diabetes' (ESMON) study were used to explore the relationship between HbA1c and MPG, in order to determine an eAG regression equation (with and without correction for ME) for this population. Monitoring data from 1, 6 and 12 weeks before HbA1c measurement were available for 73 individuals, with an average 18.5 SMBG values for each HbA1c measurement. Linear regression and structural equation modelling (SEM) were used to explore the impact of ME on the eAG regression equation.
Results: The correlation between weekly SMBG values and HbA1c ranged from 0.51-0.62, p<0.001, improving to 0.71, p<0.001 when all three weeks' SMBG data were combined. This is the same principle behind multiple sampling, the usual method to control for ME in MPG. The regression equation produced, eAG=1.5xHbA1c - 2.28 was close to that from the A1c Derived Average Glucose study (eAG=1.59xHbA1c -2.59) When structural equation modeling was used to correct both HbA1c and MPG for ME the correlation improved to 0.87, p<0.001, with eAG (mmol/L) = 2.06 x HbA1c.
Conclusion: Ignoring ME in the estimation of MPG leads to an attenuated correlation and a regression equation which gives an artificially low eAG for any given HbA1c value. When combined with other sources of variation in the HbA1c/MPG relationship the clinical usefulness of eAG is drawn into question.

An innovative metric objective evaluation of glucose profiles
E. Salzsieder, P. Heinke, L. Vogt, P. Augstein;
Institute of Diabetes, Karlsburg, Germany.

Background and aims: Glucose monitoring (CGM or SMBG) has a high potential to improve significantly diabetes care and management. However, an easy, objective and practicable tool to evaluate the quality of measured glucose profiles is missing. It was the aim of our study to develop and to verify an easily to handle evaluation score (Q-score) that considers all important aspects of measured glucose profiles.
Materials and methods: 1495 registered glucose profiles provided the database for this study. First, a factor analysis addressing all parameters affecting glucose profiles (mean sensor glucose, intra- and inter daily variability, time and area above or below target range) was performed to identify factors with major impact on the measured profiles. For each factor one parameter was selected and used for the development of the Q-score.
Results: This study resulted in a Q-score for objective evaluation of glucose profiles. To verify the Q-score two diabetes specialists (DS) diagnosed independently 729 and 194 glucose profiles of type 2 diabetic patients, respectively. The results were analysed for the inter-individual variation as well as correlated with parameters to describe glucose profiles such as mean sensor glucose, ±SD, MAGE, -MODD. There was a high correlation between the Q-score and the results of both DS (Kendalls-Tau= 0.766 and 0.719; p<0.001). Both DS showed a high correspondence with the Q-score (Kendalls-Tau=0.763; p<0.001), although one DS seems to give a better diagnosis (McNemar-Bowker-Test p<0.001). To establish an easily to handle and practicable diagnostic tool, the Q-score was tested for categorisation of glucose profiles. 729 profiles were categorised by one DS in very good (Q-score: 3.4±0.8), good (4.9±1.2), satisfactory (7.1±1.6), borderline (10.0±1.9) and not satisfactory (13.8±2.6) and compared with the result obtained from the evaluation of the same glucose profiles by applying the Q-score. The Q-score was significantly correlated with the results obtained by the evaluation of the DS.
Conclusions: The Q-score combines all essential quality parameters to describe glucose profiles in only one parameter. The Q-score is independent of subjective opinions and can be used therefore for automated evaluation of glucose profiles. The Q-score has the potential to become a practical tool in diagnosis and therapy of type 2 diabetic patients.

Robustness of dynamical real-time estimation of HbA_{1c} using routine self-monitoring of blood glucose (SMBG) data
M. Breton[1], F. Flacke[2], J. Sieber[2], B. Kovatchev[1];
[1]University of Virginia, Charlottesville, USA, [2]Sanofi Diabetes, Frankfurt, Germany.

Background and aims: While A1c is the gold-standard marker for average glycaemia in diabetes, routine laboratory A1c results are only available to patients every few months. In studies, real-time estimation of A1c using self-monitoring of blood glucose (SMBG) data has shown improved glycaemic control and increased patient motivation. In a companion presentation, we introduce a new dynamical method for real-time *estimation of A1c* (*eA1c*) that tracks changes in average glycaemia in type 2 diabetes (T2D) patients. *eA1c* is shown to produce highly accurate estimates of A1c from SMBG. In this analysis, we study the robustness of the *eA1c* methodology.
Materials and methods: The data originated from a phase 3b trial of insulin-naïve subjects with T2D. The dynamical method was developed using a training data set (N=379 patients with T2D, who collected 17,925 fasting SMBG readings, 7-point profiles, and reference A1c values); then all model parameters and formulas were fixed. Robustness of the method was studied on an independent test data set (N=375 subjects; 17,925 fasting SMBG readings; 2314 7-point profiles; and 1628 reference A1c values; mean of 48 days of data/individual). We analysed: (1) robustness to reference A1c stratification; (2) robustness to initialisation comparing the first reference/eA1c pair for each subject to the rest of the data; (3) robustness to missing fasting SMBG, and (4) robustness to mislabelled profile SMBG (e.g. pre-post meal mislabelling). Analyses (3-4) were performed by randomly removing or mislabelling an increasing percentage of SMBG, assessing performance 10 times at each level.
Results: Stratifying the data by reference A1c, the dynamical method was most accurate in the 7% to 8% A1c range, with no bias and 4.48% MARD. Within the reportable A1c range of 6% to 10%, the bias of *eA1c* was always < 1% A1c; MARD < 10% (see Table). Stratifying the data by *eA1c*, the method was stable between 6% and 10% (bias:-0.23% to 0.19%; MARD: 6.74% to 7.24%). Performance at the initial *eA1c* for each subject was similar to overall performance (MARD 7.0% vs. 6.8%). Neither missing fasting SMBG (MARD 6.9% with 75% missing fasting SMBGs vs. 6.8% overall), nor mislabelling (MARD 7.0% with 75% mislabelled profile SMBGs vs. 6.8% overall) significantly altered *eA1c* performance when the method entry criteria were met (with increasing missing values the entry criteria are met less often).
Conclusion: The dynamical estimation procedure provides robust and accurate real-time estimation of A1c from self-monitoring data. Consistently achieving MARD < 10% in any strata defined by reference A1c, indicates that the model is capable of providing accurate tracking of changes in average glycaemia over time. The limited effect of missing or mislabelled SMBG values

supports that the algorithm is appropriate for field use. In addition, the computational requirements of the method are minimal; thus it is readily applicable into devices with limited processing power, such as home SMBG meters.

	HbA1c < 6	6= HbA1c < 7	7= HbA1c < 8	8= HbA1c < 9	9= HbA1c = 10	HbA1c > 10

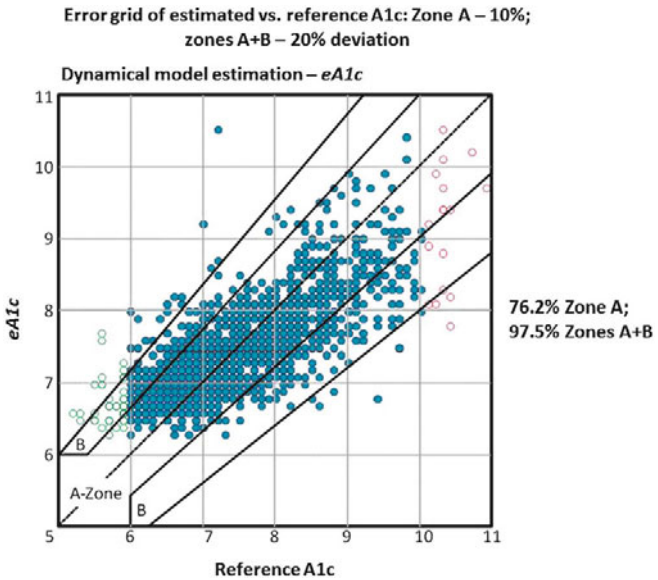
Accuracy of dynamical real-time estimation of HbA_{1c} using routine self-monitoring of blood glucose (SMBG) data

B. Kovatchev[1], F. Flacke[2], J. Sieber[2], M. Breton[1];
[1]University of Virginia, Charlottesville, USA, [2]Sanofi Diabetes, Frankfurt, Germany.

Background and aims: Although A1c is the gold-standard marker for average glycaemia in type 1 and type 2 diabetes (T2D), laboratory A1c assays are typically done only every few months. Self-monitoring of blood glucose (SMBG) offers the possibility for real-time estimation of A1c, which increases patients' motivation to improve diabetes control. We present a new dynamical method tracking changes in average glycaemia to provide real-time *estimation of A1c* (*eA1c*). The major advantage of this method is that it is designed to work with infrequent SMBG data typical in T2D - a setting in which previously introduced techniques would fail.

Materials and methods: Using compartmental modelling, a new 2-step algorithm was constructed that includes: 1) tracking average fasting glycaemia to compute *base eA1c* updated with every fasting SMBG data point; 2) calibration of the *base eA1c* trace with 7-point SMBG daily profiles taken approximately monthly, which uses a new factorial model to capture the principal components of blood glucose variability. Data originated from a multicentre phase 3b study of insulin-naïve subjects, 44.3% women (mean age 54 years) and 55.7% men (mean age 56 years); mean HbA1c 7.6%. A training data set (N=379 subjects; 17,863 fasting SMBG readings; monthly 7-point SMBG profiles; frequent reference A1c (n=1599 values); mean of 47 days of data/individual) was used to estimate all model parameters. The model was then fixed and applied without further modification to an independent test data set (N=375 subjects; 17,925 fasting SMBG readings; monthly 7-point profiles; frequent reference A1c (n=1628 values); mean of 48 days of data/individual). Accuracy was evaluated in the test data set by computing mean absolute and relative deviations (MAD, MARD) of *eA1c* from reference A1c; to visualise the results we also present HbA1c error-grid analysis (Figure 1).



Results: Test data set: MAD=0.51, MARD=6.8%; correlation between *eA1c* and reference A1c r=0.76. In comparison, the established ADA formula yielded MAD=0.98, MARD=13.1%, and r=0.73. In the HbA1c error-grid plot (Figure), 76.2% of all *eA1c* fell within 10% from reference A1c (Zone A) and 97.5% fell within 20% from reference (Zones A+B). If limited to a reportable A1c range (6%-10%), the accuracy of *eA1c* was 78.3% (Zone A) and 98.6% (Zones A+B).

Conclusion: A dynamical estimation model was developed using training data, then fixed and applied to independent test data, achieving accurate tracking of changes in average glycaemia over time (MARD <7%). This model is tailored to accommodate infrequent SMBG data typical for T2D, providing a new tool for A1c estimation on the patient level. Model accuracy is comparable to the accuracy of the original SMBG readings; thus, the model does not introduce bias in the estimate, beyond errors inherent with SMBG.

PS 089 New devices for glucose monitoring and insulin delivery

1081

Development of a novel microprobe array continuous glucose monitor: pre-clinical validation

A.H. El-Laboudi[1], S. Sharma[2], N. Oliver[1], H. Santhanam[2], A. Cook[2], J. Carton[3], T. Cass[2], D. Johnston[1];
[1]Diabetes, Endocrinology & Metabolism, Imperial College London, [2]Department of Chemistry & Institute of Biomedical Engineering, Imperial College London, [3]Histopathology Department, Imperial College Healthcare NHS Trust, London, UK.

Background and aim: Despite clinical benefits, continuous glucose monitoring (CGM) devices are invasive and can be uncomfortable, negatively affecting concordance and effectiveness. In addition, CGM sensor accuracy is suboptimal in the critical hypoglycaemic range. To overcome these challenges, a novel continuous glucose sensor has been developed based on microprobe technology. It consists of a small, wearable patch containing several microscopic projections (microprobes) that penetrate the stratum corneum to access interstitial fluid. Aim: Mechanical and functional validation of the sensor prior to in vivo clinical studies. Mechanical validation assesses the ability to penetrate the stratum corneum without mechanical failure, while functional validation assesses the current produced in response to changing glucose concentration and the effects of sterilisation and insertion.
Materials and methods: Each array had 64 microprobes arranged 8x8. Microprobe height is 1000 μm and tip diameter is 15 μm. Insertion tests were performed ex vivo in full thickness human skin. An Instron compression system was used to press the device into skin using forces of 7, 10, 15, 20 and 25 Newton. Skin penetration was confirmed by applying methylene blue dye to visualize created micropores and by histological examination. Fracture tests were performed in vitro using the Instron system to exert axial pressure against a metal probe using forces of 50, 100, 200, 300 and 400 Newton. Microprobes were examined using scanning electron microscopy before and after testing to detect failure and measure height reduction. To assess transverse fracture force, transverse pressure was exerted against one row of 8 microprobes till they fractured. Functional evaluation tests were performed in vitro by measuring the current generated in response to changing glucose concentration before and after gamma ray radiation and *ex vivo* skin insertion.
Results: Insertion tests (n=10) demonstrated successful penetration using forces as low as 7 N (equivalent to mild thumb pressure) without fracture. Axial fracture tests (n=10) have demonstrated the ability of microprobes to tolerate large forces without fracture of microprobes or base plate. There was reduction of microprobes' height between 4.1% for 50 N and 18 % for 400 N axial pressures. Transverse fracture tests (n=11) showed that the force required to fracture microprobes were 27 times higher than force required to penetrate the skin, implying a high safety margin of the device. Functional validation tests demonstrated the ability of the device to respond reproducibly to changing glucose concentrations in a linear fashion in the physiological range. This was not affected by either sterilisation or skin penetration. For glucose level ranging from 0 - 20 mM, currents measured (350 $x10^{-8}$ - 410 $x10^{-8}$ Amp) were approximately 250 times higher than those measured using a sensor licensed for clinical practice (1.0 $x10^{-8}$ - 16 $x10^{-8}$ Amp).
Conclusion: In vitro and ex vivo validation studies demonstrate a functional device, able to access the interstitial fluid compartment without mechanical failure, and the device can now be assessed in vivo. Glucose dependent responses are of high magnitude with a superior signal: noise to commercially available sensors in vitro.

Performance of a novel sensor during induced glucose swings

K. Obermaier[1], M. Schoemaker[1], J. Jager[1], G. Schmelzeisen-Redeker[1], G. Freckmann[2], E. Zschornack[2];
[1]Roche Diagnostics GmbH, Mannheim, [2]Institute for Diabetes-Technology, Ulm, Germany.

Background and aims: Continuous Glucose Monitoring (CGM) is expected to reduce the frequency and duration of hypoglycemic events. However, inaccurate CGM readings and associated high rates of false positive or missed warnings of hypoglycemic events diminish users' compliance of CGM sensor use. Sensor inaccuracy can be caused by a combination of erroneous or noisy sensor signals, mis-calibration of the sensor, physiological lag time between interstitial fluid (ISF) and blood glucose, physical lag time introduced by the CGM system and physiological effects at the sensor to tissue interface. Since the physiological lag time is an inherent element, efforts are being made to reduce the impact of the other factors.
Materials and methods: An early stage development CGM sensor (Roche Diagnostics, Germany) was investigated in an in-clinic setting. Two CGM sensors were worn in parallel for 7 days by 30 people with type 1 diabetes. The study design reflected some recommendations of the CLSI guideline POCT05-A Performance Metrics for Continuous Glucose Monitoring, especially regarding induced glucose swings. To obtain a wide range of glucose readings and rates of change, breakfast with a high glycemic index was given on two study days and the corresponding insulin bolus was slightly delayed and overdosed leading to a fast glucose rise followed by a glucose decline. Sensor accuracy was assessed by calculating MARD (Mean Absolute Relative Difference) between CGM value and self monitoring blood glucose (SMBG) measurements taken with a commercially available SMBG meter fulfilling the requirements of ISO 15197 (Accu-Chek Aviva, Roche Diagnostics, Germany). Precision between two sensors was assessed by calculating PARD (Precision Absolute Relative Difference). MARD and PARD were calculated over the complete data sets (7 days) as well as for the phases with induced glucose swings. Simulation of hypoglycemic warning thresholds was performed to estimate hypoglycemia detection rates.
Results: Rates of glucose change of up to ±6 mg/dL/minute were achieved. Overall MARD was 8.6% for the complete data sets (N=7039 paired values) and 10.6% for phases with induced glucose excursions (N=2250 paired values). Overall PARD was 7.6% for the complete data sets and 8.0% for phases with induced glucose swings. With a simulated hypoglycemic warning threshold set at 70 mg/dL, 97% of all hypoglycemic bG values ≤ 55 mg/dL would have been detected, with a threshold set at 65 mg/dL the detection rate would have been 92.7%.
Conclusion: The newly developed sensor showed high accuracy and precision in patients tested. During rapidly changing glucose levels the sensor followed the blood glucose concentrations very closely. Sensor precision during glucose excursions was comparable to the overall sensor precision.

1083

Presenting a truly non-invasive glucose monitor for home use

A. Gal[1], I. Harman-Boehm[2], E. Naidis[1], Y. Mayzel[1], N. Goldstein[1], K. Horman[1];
[1]Integrity Applications Ltd., Ashkelon, [2]Internal Medicine and the Diabetes Unit, Soroka University Medical Center, Beer-Sheva, Israel.

Background and aims: GlucoTrack® is a truly Non-Invasive device for self-monitoring of blood glucose at home and home-alike environment, combining three technologies: Ultrasonic, Electromagnetic and Thermal. The device comprises user friendly Main Unit (MU), as well as sensors per each technology, located at a Personal Ear Clip (PEC). The PEC is clipped externally to the earlobe for less than a minute, to conduct a real-time spot measurement, after individual calibration. Glucose readings are heard and displayed on the smartphone sized MU with a color touch screen, designed for diabetics' needs. The PEC must be replaced every 6 months, to be followed by a calibration.
Materials and methods: GlucoTrack performances were evaluated in various clinical trials, simulating home-alike environment, for subjects of diverse genders, BMI, diabetes types and ages (currently over 18 years). At the beginning of the trial, each subject was calibrated. The measurements taken throughout the trial were based on this calibration. GlucoTrack eligibility for home use was assessed according to calibration validity period, device learning curve of use and feedback analysis regarding device usability and user satisfaction. Evaluation was conducted based on two groups: Clinic group, where measurements were performed by a skilled medical team; Home Simulated (HS) group, where measurements were conducted by the subjects, after a brief training. Subjects participated in the trial for up to 6 months, in order to verify the calibration validity period (6 months).
Results: Clarke Error Grid pulled data analysis of 135 subjects (7912 points) over 6 months of operation shows 96.5% of the points in the clinically accepted A+B zones. Mean Absolute Relative Difference (MARD) of 30.2% was observed. No degradation in performance was noticed as a function of time elapsed from calibration. Furthermore, GlucoTrack performances were maintained across Clinic and HS groups as 96.6% and 96.1 % of the points in A+B zones, and MARD values of 30.1% and 30.9%, respectively. Feedback

analysis shows that 99% of the subjects found the device comfortable; 78% found the device easy to operate, 90% expressed willingness to use the device regularly and 84% declared they will use the device more frequently than the invasive one.
Conclusion: GlucoTrack is technically available to use. Its key benefits include 6 months of operation without re-calibration and ability to perform numerous spot measurements with acceptable accuracy. Furthermore, it provides pain-free and inexpensive use, without the need to be continuously worn; it is user friendly and demonstrates a short learning curve for use. These advantages emphasize GlucoTrack suitability for home use and can lead to better blood glucose monitoring adherence and tighter glucose control.

Six-month data from a clinical study of an implantable fluorescence-based glucose sensor
T. Whitehurst, J. Emken, P. Huffstetler, S. Tankiewicz, X. Wang, S. Rajaraman, M. Mortellaro, R. Rastogi, R. Rastogi, O. Chen, C. Mdingi, K. Lechleiter, A. Dehennis;
Senseonics, Inc., Germantown, USA.

Background and aims: A long-term implantable fluorescence-based glucose sensor has been developed. The small cylindrical sensor is designed to be implanted subcutaneously for at least 6 months. The outer shell of the sensor includes a polymer hydrogel containing a proprietary indicator molecule that becomes fluorescent when it binds glucose. The sensor includes a miniature fluorimeter for detection of the fluoresced signal. Prior clinical studies have demonstrated sensor functionality at one month post-implant. This study was designed to demonstrate functionality of the implantable glucose sensor while implanted over a 6-month period.
Materials and methods: In a pilot clinical study, 4 subjects were inserted with a single sensor in the upper arm. The sensors remained inserted for up to 6 months, and subjects came to the clinic every 14 to 28 days to have the sensors read for several hours. Blood samples were also taken every 15 minutes and processed using a YSI Blood Glucose Analyzer. A single blood glucose value from the beginning of each clinic day was used to calibrate each sensor for each session, and the sensor glucose values were calculated prospectively.
Results: The combined MARD for the 4 subjects is 13%, using an SMBG value twice daily (i.e., approximately once every 12 hours) for calibration and prospective calculation of the sensor glucose values. The percentage of remaining sensor fluorescence (relative to the fluorescence baseline at the time of implant) remains high after 180 days, suggesting that the sensor may last for more than 6 months after implant.
Conclusion: Clinical data from a 6-month pilot study of an implantable fluorescence-based glucose sensor has demonstrated that the sensor is able to maintain its fluorescence response and accuracy up to 6 months after implant.

1085

Catalytic protection from ROS using platinum nanoparticles: enabling a long-term, implantable glucose sensor
S.C. Puiu, M.A. Mortellaro;
Senseonics, Incorporated, Germantown, USA.

Background and aims: Reactive oxygen species (ROS) that are generated as a consequence of the acute and chronic immune response to an implanted medical device have been shown to be a primary cause of loss of device functionality and reduced *in vivo* longevity. The Senseonics implantable continuous glucose monitoring (CGM) system utilizes an abiotic, fluorescent glucose indicator containing glucose binding elements that may be oxidized. A 10 nm thick layer of platinum, sputtered onto the sensor glucose indicating polymer layer, has been shown to catalytically degrade ROS, prevent indicator oxidation and enable sensors implanted subcutaneously in human subjects to remain functional for six months in clinical trials. We now establish protection against ROS (i.e., hydrogen peroxide) oxidation, through *in vitro* experiments, using a surrogate catalytic protection strategy in which platinum nanoparticles embedded into the glucose indicating polymer layer replace the sputtered platinum layer. A combination of both a sputtered platinum layer and embedded nanoparticles is shown to provide increased protection against oxidation by hydrogen peroxide.
Materials and methods: Sensor blanks (units prepared without electronic and optical components) were used for all tests. Samples were prepared with and without embedded platinum nanoparticles and sputtered platinum layers. Catalytic rate of degradation of hydrogen peroxide in PBS was measured using a commercial spectrophotometric hydrogen peroxide assay kit. Activity was measured at t = 0, 1 and 2 months storage in PBS at 37°C. Glucose indicator protection against oxidation was determined by immersing samples into hydrogen peroxide solutions in PBS at 37°C and monitoring loss of fluorescence using spectrofluorophotometers.
Results: Platinum nanoparticle embedded indicator hydrogels catalytically decompose hydrogen peroxide at rates comparable to platinum sputter coated samples. No loss in catalytic activity was observed after 2 months storage in PSB at 37°C. In oxidation challenge tests using 20 mM hydrogen peroxide, samples prepared without platinum nanoparticles were completely oxidized in under 15 minutes, whereas at one hour, samples containing either sputtered platinum or nanoparticles lost ~ 50% fluorescence and samples prepared with both sputtered and nanoparticle platinum lost < 10% fluorescence.
Conclusion: Platinum nanoparticles embedded into the glucose indicating polymer layer catalytically degrade hydrogen peroxide and provide protection against oxidation. A combination of both a sputtered layer of platinum and embedded platinum nanoparticles displayed the greatest level of protection against a high concentration of hydrogen peroxide. This combined catalytic approach offers the possibility of increased protection against *in vivo* oxidation and thus increasing device longevity from six months to one year.

1086

Evaluation of drug efficacy using glucose area under the curve monitoring system without blood sampling
K. Kosugi[1], K. Sakamoto[1], K. Yoshiuchi[1], A. Ono[1], T. Sato[2], S. Okada[2], Y. Ohnishi[2], H. Koga[2], K. Tokunaga[2], H. Nakajima[3];
[1]Osaka Police Hospital, Osaka, [2]Sysmex Corporation, Kobe, [3]Osaka Medical Center for Cancer and Cardiovascular Diseases, Osaka, Japan.

Background and aims: HbA1c is widely used as an index of average blood glucose over medium- to-long-term periods; however, it is not suitable for short-term evaluation because of its slow dynamics. OGTT is used to evaluate drug efficacy over the short term, but the need for multiple blood samples is burdensome on the patients and medical staff. We have developed a glucose area under the curve (AUC) measurement system using minimally invasive interstitial fluid extraction technology (MIET) that allows convenient monitoring of postprandial glucose levels without blood sampling. In this study, we have applied this system to patients receiving incretin-related drugs to evaluate the efficacy of these drugs.
Materials and methods: Eleven type 2 diabetic inpatients aged 30-70 years old with a mean HbA1c of 9.9% ± 1.2% underwent OGTTs (75g) before and 4-7 days after receiving alogliptin, exenatide, or liragluitide. Plasma glucose (PG) levels were measured every 30 min for 2 h after glucose load to calculate the reference AUC (PG-AUC). Interstitial fluid glucose AUC (IG-AUC) was measured using MIET simultaneously. MIET consists of two steps. First, a plastic microneedle array is applied to the skin of the forearm as a pretreatment to enhance transdermal interstitial fluid (ISF) extraction. Second, hydrogel patches are placed on the pretreated area to collect ISF over a 2 h period. Accumulated glucose and sodium ion levels in the hydrogels are subsequently measured for calculating the IG-AUC at 2 h after glucose load.
Results: Before drug administration, fasting plasma glucose (FPG), 2-h PG, and PG-AUC were 108 ± 18 mg/dl, 310 ± 68 mg/dl, and 526 ± 85 mg•h/dl, respectively. After drug treatment, FPG was unchanged (113 ± 22 mg/dl), but 2-h PG and PG-AUC significantly reduced to 143 ± 74 mg/dl ($P < 0.01$) and 339 ± 123 mg•h/dl ($P < 0.01$), respectively. A good correlation between PG-AUC and IG-AUC ($R = 0.94$) was confirmed before and after the treatment. The reduction levels of IG-AUC by the treatment highly correlated with those of PG-AUC ($R = 0.92$), indicating that drug efficacy was precisely monitored by IG-AUC. Furthermore, the majority of patients reported neither pain nor discomfort from the MIET procedure.
Conclusion: The glucose AUC measured by MIET provided a good index for short-term monitoring of incretin-related drug efficacies without the need for blood sampling. The MIET system could be used for evaluating the efficacy of other drugs used to control postprandial hyperglycemia, such as other dipeptidyl peptidase-4 inhibitors, sodium-glucose co-transporter-2 inhibitors, alpha-glucosidase inhibitors, and glinides.

Very well controlled patients using InsuPad experience reduced insulin requirements and less hypoglycaemic events: results from the real world BARMER study

A. Pfützner[1], K. Funke[2], N. Hermanns[3], M. Derwahl[4], T. Forst[5], G. Bitton[6], R. Nagar[6], A. Karch[7], T. Haak[3];
[1]R&D, IKFE Institute for Clinical Research and Development, Mainz, [2]IKFE Potsdam, [3]Diabetes Research Center (FIDAM), Bad Mergentheim, [4]IKFE Berlin, [5]Profil Mainz, Germany, [6]Insuline Medical, Petach Tikva, Israel, [7]Barmer GEK, Mannheim, Germany.

Background and aims: The InsuPad device has been developed to enhance insulin absorption by standardized warming of the injection site after insulin administration. The primary objective of this prospective controlled trial was to investigate the impact of InsuPad use on prandial rapid acting insulin dose and glycemic control when studied under real world conditions.
Material and methods: This study was performed with 145 patients (51 female, 94 male, 13 type 1 and 132 type 2 patients, age: 61.6±8.4 yrs., disease duration: 16.6±7.2 yrs., HbA1c: 7.19±0.50 %, body weight: 105.7±18.6 kg). All patients were treated with multiple daily injections with insulin glargine and any of the existing short acting insulin analogs (aspart, glulisine, lispro). After a run-in treatment optimization and basal insulin stabilization period of up to 4 weeks, the patients were randomized to continue therapy for three months without (Control, n = 72) or with InsuPad (n = 73 patients). Only 3 visits at the site (screening, baseline, endpoint) were performed to ensure real-world conditions. Observation parameters included HbA1c, insulin dose, frequency of hypoglycemia, and body weight.
Results: During the run-in period, HbA1c decreased in the whole group from 7.2±0.5 % to 6.8±0.5 % ($p<0.001$), and further improved in both arms until study end (Control group: 6.3±0.5 % InsuPad: 6.2±0.5 %; both $p<0.001$ vs. baseline, n.s. between the groups). To achieve this glycemic control, patients in the control group needed an increase in the daily prandial insulin dose from baseline by 8 % (from 66±32 U to 71±38 U, $p<0.05$) with stable basal insulin requirements (47±20 U vs. 47±20 U, n.s.). Patients in the InsuPad group required significantly less prandial insulin to reach these HbA1c results (70±43 U to 55±34 U; -19 %, $p<0.001$) and a slight increase in the basal insulin dose (from 50±32 U to 52±36 U, $p<0.05$). In consequence, total daily insulin dose increased in the control group (+3.7 %) and decreased with InsuPad (-8.6 %, $p<0.001$ between the groups). The number of hypoglycemic events (blood glucose readings <63 mg/dL) during the observation period was significantly higher in the control group (6.2±9.9/patient) than in the InsuPad group (3.4±4.9/patient, $p<0.05$).
Conclusion: When treating patients to target with intensified insulin therapy, use of the InsuPad device for three months resulted in a significant lower frequency of hypoglycemic events and a significant reduction in insulin analog requirements as compared to a control group not using the device under real-world conditions. InsuPad may be useful to achieve treatment targets with a safer and more efficient basal bolus therapy in insulin-treated patients with type 1 and type 2 diabetes.

Proof of reliability of intradermal devices under extended wear basal/bolus infusion conditions

E.A. McVey[1], S.C. Keith[1], D.E. Sutter[1], K. Judge[2], J. Herr[2], R.J. Pettis[1];
[1]BD Technologies, Research Triangle Park, [2]BD, Franklin Lakes, USA.

Background and aims: Intradermal (ID) insulin administration provides faster onset of insulin action, increased early phase bioavailability, and a less invasive delivery interface than subcutaneous (SC) infusion. The primary objectives of this study were 1) to characterise an investigational ID insulin infusion catheter's ability to infuse placebo solution to ambulatory human subjects under extended wear basal/bolus conditions using commercial insulin pumps and 2) to characterise variations in pressure during infusion.
Materials and methods: This was a single-center, 2-arm, randomised, open-label study in 50 healthy, non-diabetic subjects in an inpatient setting. Diluent was infused at a basal rate of 1U/hr with three 10U boluses at meals and one before bed (1U = 10 μL). Each subject participated in one study arm consisting of four infusion sets of a single type (ID or SC) worn simultaneously. The ID arm consisted of two ID catheter sets (34G, 1.5 mm, stainless steel microneedles with different proprietary geometries) delivering via two commercial pump types (OneTouch®Ping® and MiniMed Paradigm®723). The SC arm included two commercial catheter sets (28G, 6 mm, stainless steel (SC-SS) & 24G, 6 mm, polytetrafluoroethylene (SC-PTFE)) with a single pump type (OneTouch® Ping®). Study endpoints addressed pump occlusion alarm occurrence, leakage, adhesion, tolerability, pain, and infusion pressure. A proprietary algorithm was used to characterise infusion pressure, measured by a commercial blood pressure transducer in-line between the pump reservoir and the infusion set. Effects of delivery route (ID vs. SC), ID set configuration, SC set type, and pump type (ID only) were tested with a generalised linear statistical model.
Results: Overall, ID delivery was successfully maintained over the 24 hour infusion period. The number of pump occlusion alarms was not significantly different based on delivery route or set type, but there was a significant difference between pump types ($p<.001$). For all SC and ID conditions, 85-95% of devices had no observable leakage or statistical differences among conditions. ID devices had less bleeding ($p<.05$), similar erythema, and less edema compared to SC ($p=.04$). Mean pain scores did not exceed 1 (on a 0-10 visual analogue scale) for any device, delivery route, or time point. Based on the proprietary infusion pressure algorithm, one ID catheter design had no significant difference in pressure endpoints compared to the SC-PTFE catheter. The percentages of total infusion time for which there was a flow interruption detected were 8.6% (SC-PTFE), 1.5% (SC-SS), 2.6% (ID-catheter A) and 11% (ID-catheter B).
Conclusion: This was the first study demonstrating that extended duration ID basal/bolus infusion is feasible in ambulatory human subjects. One investigational ID catheter showed flow performance similar to a commercial SC set, with equivalent tolerability. Commercially available SC infusion sets exhibited flow problems undetected by the pump, particularly in the first few hours after insertion. These flow anomalies merit additional investigation and study. Results suggest that ID infusion is biomechanically feasible for extended duration basal/bolus use. Further study on extended ID pharmacokinetics is underway.

Insulin therapy with a 4mm x 32G pen needle vs. larger needles in obese subjects, including those taking high doses and/or glargine

L. Hirsch[1], R. Bergenstal[2], E. Strock[2], D. Peremislov[2], V. Parvu[1], M. Gibney[1];
[1]BD, Franklin Lakes, [2]Internation Diabetes Center, Minneapolis, USA.

Background and aims: Pen needles (PN) as short as 4mm for insulin therapy have been shown to provide equal glycemic control, less pain, and are usually preferred by patients using pens. However, clinician hesitancy to use short needles remains, especially in obese patients and those injecting high doses and/or glargine.
Materials and methods: We performed a prospective, randomized, multicenter, crossover non-inferiority trial to compare glycemic control in obese

subjects with a 4mm x 32G PN vs two larger PNs (8mm x 31G and 12.7mm x 29G). Subjects with BMI ≥ 30 kg/m^2, HbA1c 5.5-9.5% and who injected insulin ≥ 2 months using only pens entered a 3-week wash-in period, using each study PN for one week. They were then randomized to either 4mm vs 8mm (N=127) or 4mm vs 12.7mm (N=147) PN study arms - order of PN use was also randomized. The 1° outcome was HbA1c after each 12-week study period; 2° outcomes included: pain by Visual Analog Scale (VAS), preference, ease of use, ease of insertion, injection anxiety, insulin leakage from skin, and safety. We also report on pre-defined subgroups - subjects taking high insulin doses (≥ one daily injection ≥ 40 units) or glargine, pooled across both study arms.

Results: Of 274 subjects randomized, 52% were male; 75% Caucasian, 18% Black; 92% T2DM. Mean age ± SD = 56.7 ± 11.0 yrs; BMI 37.0 ± 6.1, range 29.1-59.9 kg/m^2; insulin use duration 6.9 ± 7.7 years; total daily dose 78.4 ± 52.9, range 6-350 units; HbA1c 7.5 ± 0.9%; 226 subjects are included in the 1° A1c analysis. HbA1c with 4mm PNs was 0.08% lower (95% CI -0.21, 0.06) vs 8mm PNs, and 0.10% lower (-0.19, 0.00) vs 12.7mm PNs, both within the ± 0.4% equivalence margin. Median insulin dose changes were -2 to +5 units within study periods. Differences in perceived relative pain by 150 mm VAS were 12.4mm and 30.1mm lower for the 4mm vs the 8mm and 12.7mm PNs, respectively (both $p < 0.05$). Subjects preferred the 4mm vs the 12.7mm PN ($p < 0.05$), but NS vs the 8mm PN. The 4mm PN was rated superior for ease of use, ease of injection, and anxiety vs both larger PNs ($p<0.05$). Of ~131,000 injections, subjects reported skin leakage in 4.2%, 4.1%, and 4.3% of injections, respectively, with the 4mm, 8mm, and 12.7mm PNs (NS). Hyperglycemic (BG > 400 mg/dL) and hypoglycemic (BG < 50 mg/dL) event rates per 1000 patient days (1.9-3.0, and 8.0-9.9, respectively) did not differ between PNs. In the subgroup analyses, 118 subjects (43%) took high dose injections (mean total daily dose 113.5 ± 54.9, range 40 to 350 units), 174 (64%) used glargine (mean daily dose 77.5 ± 53.3, range 7 to 350 units), with 107 and 154 subjects completing the study, respectively. In high-dose subjects, HbA1c levels with the 4mm PN were -0.09% (95% CL -0.23, 0.05) compared to pooled 8mm and 12.7mm PNs and -0.08% (-0.16, 0.01) vs the longer PNs in the glargine group, both within preset HbA1c equivalence criteria (± 0.4%). The 4mm PN was rated significantly less painful than 8mm PNs in high-dose subjects, and vs 12.7mm PNs in the glargine subjects, both $p < 0.05$. Pain ratings trended similarly in the other subgroups but were NS. Reports of leakage for the three PN lengths were infrequent and NS, ranging from 3.4 to 5.1% in high-dose subjects, and 3.7 to 4.7% in glargine users.

Conclusion: For obese patients, including those injecting high insulin doses and/or glargine, the 4mm x 32G PN is safe, provides equivalent glycemic control, is less painful, better tolerated, and does not increase skin leakage, compared to larger pen needles.

Extra thin-wall pen needles: impact on thumb force, insulin flow, time-to-deliver, patient preference and confidence in dosing

R. Aronson[1], M.A. Gibney[2], K. Oza[2], J. Berube[2], K. Kassler-Taub[2], L. Hirsch[2]; [1]LMC Diabetes and Endocrinology, Toronto, Canada, [2]Becton Dickinson, Franklin Lakes, USA.

Background and aims: Pen needles (PNs) are an essential component of pen devices used to inject insulin and can significantly affect patients' injection experience. A new extra thin-wall needle (XTW) technology was evaluated in a laboratory study of thumb force, flow rate and time-to-dispense and in a clinical study that evaluated patients' injection experience in persons with diabetes injecting insulin with Lilly KwikPen™, sanofi-aventis SoloSTAR®, and Novo Nordisk FlexPen® insulin pens.

Materials and methods: Laboratory studies measured differences in thumb force, flow rate, and time-to-deliver medication between similar size, thin-wall PNs and XTW PNs using an Instron® Universal Testing Machine (Instron, Norwood, MA, USA). The clinical study was a prospective, randomized, 2-period open label crossover trial in subjects 35 to 80 years with T1 or T2 DM who injected insulin by pen ≥2 months. Subjects using 4 to 8 mm length PNs with 31-32G diameter were randomly assigned to use their current PN or the same/similar size XTW PN at home for ~1 week, followed by the other PN in the second week. Subjects completed several comparative 150 mm Visual Analog Scales (VAS) and direct questions at the end of Period 2 for overall patient preference, ease of injection, perceived time to complete the full dose, thumb button force to deliver the injection, dose delivery confidence and leakage/dripping. Both the lab and clinical studies included appropriate sample sizes to provide sufficient power to detect the impact of XTW PNs with each of the three insulin pens.

Results: Laboratory studies - XTW PNs showed thumb force reduced by 47% - 62%, increased flow rate by 108% - 149% and reduced time-to-deliver by 52% - 60% (all $p\leq0.05$). Clinical study - 216 subjects were randomized (80 SoloSTAR, 77 FlexPen, 59 KwikPen), 209 completed both periods; 198 were evaluable. Subjects were (mean (± SD)) 60.8 ± 9.3 years old; 50.5% female; 89.8% T2 DM; used insulin pens 4.3 ± 4.1 years; used 75.1 ± 52.3 U/day and 2.9 ±1.5 injections/day. Subjects rated the XTW PNs (mean (95% CI)) as more preferable than their current PN (68.2 vs 11.6%), requiring less thumb force (60.6 vs 7.1%), and giving more confidence of full dose delivery (51.5 vs 9.1%). XTW PNs were associated with less injection time (48.5 vs 4.5%), less pain (64.1 vs 9.6%), greater insertion ease (63.6 vs 6.1%), and more convenience (36.4 vs 4%) - all $p< 0.001$. Skin leakage and insulin dripping from the needle tip were rated as less frequent with the XTW PNs ($p<0.05$). There were no significant differences in reported AE's.

Conclusion: Extra thin-wall pen needles improve fluid flow, require less force and less time-to-deliver medication. Extra thin-wall pen needles were preferred overall, rated as requiring less time and less thumb force to inject, and provided greater confidence in completing a full dose in actual use, compared to usual needles.

PS 090 Closed loops and CGMS

1091

Inpatient evaluation of an automated closed-loop control-to-range system

H.C. Zisser[1,2], Control To Range Writing Group;
[1]Clinical Research, Sansum Diabetes Resaerch Institute, Santa Barbara,
[2]Chemical Engineering, University of California, Santa Barbara, USA.

Background and aims: The Control-to-Range (CTR) study was a multinational artificial pancreas study designed to minimise the time spent in the hypo- and hyperglycaemic ranges using continuous glucose monitoring (CGM) and subcutaneous insulin infusion in individuals with type 1 diabetes. The controller was challenged by over- and missed-bolused meals and a period of exercise (50% VO2 max). The study was designed to demonstrate that the closed-loop system met a set of pre-defined metrics for efficacy and safety with an attempt to keep the glucose between 70-180 mg/dl. The range controller used an average model with patient-specific tuning and was accompanied with a safety algorithm to minimize hypoglycaemia.
Materials and methods: We studied 53 individuals: 27 ≥18 y.o. (mean 41±11), 26 <18 y.o. (mean 15±1); mean duration T1D 25±11 years and 8±3 years, respectively; mean A1c 7.7±0.6 % and 8.1±0.9%, respectively. Subjects were studied in-clinic for approximately 54 hours on 2 or 3 separate sessions. Glucose values from 1 of 2 CGM sensors (Dexcom) inserted two days prior to each session were the input of the system. The subjects arrived at 7 AM and a study CSII pump (Insulet) was inserted. Plasma glucose was measured every 15-30 min (YSI). Day 1, the subjects ate, and bolused for 3 mixed meals (1 gm carbohydrate (CHO)/kg body wt, 100 g max). On the morning after the first admission, subjects ate a meal that was not announced to the controller (1 gm CHO/kg body wt, 50 gm max). Subjects returned for a second session, similar to the first except that the afternoon included 1 hour of moderate exercise and the second breakfast was over-bolused by 30%.
Results: During the blinded CGM wear prior to the admission, the median percentage of values 71-180 mg/dl was 56% for adults and 46% for adolescents. Overnight time in target was 59% and 50% respectively, and daytime time in target was 61% and 45% respectively. During the first day of closed-loop control (large meal challenges, but no exercise or mis-bolusing challenges), adults' mean percentage of values 71-180 mg/dl was 66% overall (95% Lower Confidence Limit (LCL) = 62%), 82% overnight (95% LCL=77%), and 59% during daytime (95% LCL=52%). The median mean glucose was 161 mg/dl. YSI values ≤70 mg/dl occurred in 48% of admissions, and YSI values >300 mg/dl occurred in 22%. The controller requested CHO treatment for anticipated hypoglycaemia in 70% of admissions. For adolescents during the first day of closed-loop control, the mean percentage of values 71-180 mg/dl was 62% overall (95% LCL=55%), 82% during overnight (95% LCL=75%), and 53% during daytime (95% LCL=44%). The median mean glucose was 163 mg/dl. YSI values ≤70 mg/dl occurred in 20% of admissions, and YSI values >300 mg/dl occurred in 32%. The controller requested CHO treatment for anticipated hypoglycaemia on 60% of admissions. There were no cases of severe hypoglycaemia or diabetic ketoacidosis.
Conclusion: Inpatient glycaemic control with the CTR system was safe and effective. An updated CTR system is being tested in the outpatient setting.
Clinical Trial Registration Number: NCT01271023

Tighter glucose control through a reduction of hyperglycaemia results from closed-loop intra-peritoneal vs subcutaneous insulin delivery in type 1 diabetes

E.M. Renard[1,2], A. Farret[1], J.J. Lee[3,4], J. Place[2], E. Dassau[4,3], M.-J. Pelletier[1], R.A. Harvey[4,3], F.J. Doyle III[3,4], H. Zisser[4,3];
[1]Endocrinology, Diabetes, Nutrition, Montpellier University Hospital,
[2]Institute of Functional Genomics, University of Montpellier, France,
[3]Chemical Engineering Department, University of California, Santa Barbara,
[4]Sansum Diabetes Research Institute, Santa Barbara, USA.

Background and aims: Closed loop insulin delivery aims at keeping blood glucose close to normal in patients with Type 1 diabetes (T1D) based on continuous glucose monitoring (CGM) and prediction of glucose levels according to a control algorithm. Faster insulin action from intra-peritoneal (IP) infusion is expected to improve control performance vs. subcutaneous (SC) delivery.
Materials and methods: Ten T1D patients (7M/3F, age: 49 +/- 11, BMI: 24 +/- 4, HbA1c: 7.7 +/- 1.0%, T1D duration: 29 +/- 14 years, insulin pump use: 8.5 +/- 7.8 years) underwent two 24-hour closed-loop insulin delivery trials in our Clinical Investigation Center: 1) with SC fast-acting insulin analogue infusion and 2) with IP regular insulin infusion after the implantation of a DiaPort system. For both trials, CGM was obtained from a Dexcom Seven Plus device and a zone-model predictive control-based algorithm was used. Control was evaluated based on ability to blunt glucose peak for large unannounced meals as well as the effect of pump suspensions to avoid hypoglycemia.
Results: Percentages of time (mean +/- SD) spent in 70-180 mg/dl and 80-140 mg/dl blood glucose ranges were both significantly increased with IP infusion: 65 +/- 9 vs. 42 +/- 14 (p=0.01) and 40 +/- 7 vs. 24 +/- 13 (p=0.02), respectively. Mean blood glucose levels (mg/dl) were also significantly lower with DiaPort use: 152+/- 11 vs. 192 +/- 31 (p=0.004). Tighter glucose control with IP infusion came from a significant reduction of time spent > 180 and 140 mg/dl: 32 +/- 9 vs. 54 +/- 17 (p=0.01) and 52 +/- 10 vs. 69 +/- 16 (p=0.02), respectively, while time spent < 70 mg/dl was similar: 2.8 +/- 3.3 (IP) vs. 4.4 +/- 5.4 (SC). Significantly higher daily units of insulin were infused with IP route: 46 +/- 17 vs. 35 +/- 11 (p=0.006).
Conclusion: This study comparing IP regular insulin vs. SC fast-acting insulin analogue infusions driven by the same CGM source and control algorithm design in the same patients supports the effectiveness of a faster insulin action thanks to DiaPort use in the reduction of post-meal excursions following unannounced meals. Besides, higher amounts of insulin can be delivered with IP route without impairing closed-loop safety through hypoglycemia.

Nocturnal glycaemic control with the MD-Logic artificial pancreas at type 1 diabetes mellitus patient's home

I. Muller[1], R. Nimri[1], E. Atlas[1], S. Miller[1], O. Kordonouri[2], N. Bratina[3], C. Tsioli[2], M. Avbelj Stefanija[3], T. Danne[2], T. Battelino[3,4], M. Phillip[1,5];
[1]The Jesse Z and Sara Lea Shafer Institute for Endocrinology and Diabetes, Schneider Children's Medical Center of Israel, Petah Tikva, Israel, [2]Diabetes Centre for Children and Adolescents, Kinder- und Jugendkrankenhaus, Hannover, Germany, [3]Department of Pediatric Endocrinology, Diabetes and Metabolism, University Medical Centre-University Children's Hospital, Ljubljana, [4]Faculty of Medicine, University of Ljubljana, Slovenia, [5]Sackler Faculty of Medicine, Tel Aviv University, Israel.

Background and aims: Inevitable hypoglycemic events are still the reality and a true concern for all patients with diabetes, especially at night. Several multicenter, multinational, randomized studies have shown that MD-Logic Artificial Pancreas (MDLAP) can improve glucose control and reduce nocturnal hypoglycemia. This study assessed the feasibility, safety, and efficacy, of the MDLAP during the night at patients' home, under real-life conditions.
Materials and methods: Presented is an interim analysis of an ongoing randomized, multinational, crossover, single-blinded trail. It is a two-arm study, each consist of 4 consecutive nights, comparing the MD-Logic ("closed-loop" arm) versus sensor-augmented pump therapy ("control" arm). 15 patients [age 19±10.4y, A1c 7.5±0.5%, diabetes duration 9.9±8.2y] were randomly assigned either as "Group A" (first "closed-loop", then "control" arm) or as "Group B" (vice versa). All overnight sessions were monitored via the internet to remote sites, investigators were masked to treatment intervention. Primary endpoints were the time spent with glucose levels below 70mg/dl (3.9mmol/l), and the percentage of nights, in which the mean overnight glucose levels were within 90-140mg/dl (5-7.8mmol/l). Study is expected to end by 6.2013.
Results: Time of glucose levels spent below 70mg/dl was significantly shorter under closed-loop versus control night [3.8 (0, 11.6) and 48.7(0.6, 67.9) min, median (interquartile range, IQR) respectively, P=0.003]. The percentage of individual nights, in which mean overnight glucose level was within 90-140mg/dl was 67 (IQR, 33 to 88), and 50 (IQR, 25 to 75), under closed-loop and control nights respectively. Secondary endpoints' analyses demonstrate significant improvements in hypoglycaemia parameters. No serious adverse events were reported.
Conclusion: The feasibility, safety, and efficiency of a closed-loop system are shown in home use, with smooth integration within patients' lives. Results of the entire study will be presented.

Performance of a new continuous glucose monitoring (CGM) system in youth with diabetes

L. Laffel[1], P. Chase[2], T. Bailey[3], B. Buckingham[4], D. Liljenquist[5], M. Daniels[6], K. Nakamura[7];
[1]Pediatric, Adolescent and Young Adult Section, Joslin Diabetes Center, Boston, [2]Pediatric Section, Barbara Davis Center for Diabetes, Aurora, [3]Advanced Metabolic Care and Research Institute, Escondido, [4]Pediatrics, Stanford, Palo Alto, [5]Rocky Mountain Diabetes and Osteoporosis Center, Idaho Falls, [6]Children's Hospital of Orange County, [7]Dexcom, San Diego, USA.

Background and aims: Data from the TID exchange shows that CGM use in children and adolescents has been very limited and some past assessments of pediatric users suggest dissatisfaction with CGM performance. We studied the performance of the new Dexcom G4 PLATINUM (DG4P) CGM system in 176 youth (age 2 - 17, mean 11.5, at 6 centers. Most youth (72%) used insulin pumps; mean A1C was 8.2±1.3%; zBMI was 0.5 (range -4.7 to 2.6).
Materials and methods: Youth wore 2 systems (1 blinded, 1 displayed) on either the abdomen and/or upper buttocks for 7 days of home use. Youth/parents performed CGM calibrations using SMBG twice daily. Each youth ≥ 6 years old (n=147) had a single in-clinic session lasting up to 6 hours on sensor days 1, 4, or 7 in which "arterialized" (via a heating pad over an arm IV) venous YSI reference samples were collected up to q15 minutes for comparison with SMBG and CGM data. The in-clinic session for the 29 youth < 6 years old only included a comparison of fingerstick SMBG with CGM results q30 minutes for 4 hours.
Results: Using capillary glucose obtained with SMBG as reference, the DG4P MARD was 15% in 16318 paired samples with similar results from the abdomen (14%) and buttocks (16%). There were no meaningful differences when supplemental topical adhesives were used to secure the sensor. The mean absolute realtive difference (MARD) was 17% in the 2-5 age group, 16% in ages 6-12, and 15% in ages 13-17. The MARD of the sensor decreased from 19% on day 1 to 12% on day 7. In a comparison of fingerstick SMBG to YSI "arterialized" glucose in 1296 paired samples, the MARD was 13%, higher than in previous adult studies. Consequently, since capillary glucose is used to calibrate the system, the DG4P MARD using YSI reference was 17% (N=2922), discrepant from the performance observed in comparison to capillary glucose. After adjustment for the bias of YSI and capillary glucoses values in simulated post-hoc analyses, the MARD of CGM to YSI reduced to 15%, similar to accuracy using capillary glucose as reference.
Conclusion: This is largest pediatric CGM performance study to date, and included young children 2-5. DG4P performance compared favorably to the CGM system currently approved for pediatric use. There were minor differences at wear sites and across age groups. Performance of SMBG and CGM in comparison to YSI was likely impacted by arterialization challenges in pediatric subjects. After adjustment, the DG4P performance to YSI was similar to SMBG.

Effect of repeated continuous glucose monitoring (CGM) profiles on glycaemic control of dialysis patients with diabetes: DIALYDIAB study

C. Fourmy[1], M. Joubert[1], P. Henri[2], J. Morera[1], A. Rod[1], Y. Reznik[1];
[1]Endocrinology Unit, [2]Dialysis Unit, University Hospital of Caen, France.

Background and aims: Diabetes mellitus (DM) is a frequent condition in dialysis patients and increases morbi-mortality. Metabolic control is particularly difficult in this population with low accuracy of HbA1c and increased glycemic variability due to dialysis. CGM reliability has been recently validated in this population. The aim of our study is to explore the impact of repeated CGM on glycemic control of dialysis patients with DM (any type), versus usual care with self monitoring blood glucose (SMBG).
Materials and methods: Dialydiab is a before-after monocentric 12 weeks pilot study in a dialysis unit. There are two periods of 6 weeks during this study : first period = SMBG period (6 weeks): 3-6 SMBG/day; second period = CGM period (6 weeks): 5 days CGM (covering days with or without dialysis) every 2 weeks. SMBG (first period) and CGM (second period) profiles are evaluated by a single diabetes expert (centralized procedure) who suggests diabetic treatment adaptations to the dialysis center. CGM data, HbA1c and treatment adaptations are evaluated before (T0), between (T1) and at the end (T2) of the two 6 weeks periods.
Results: Population: 15 DM patients (type 1 (n=2), type 2 (n=9) secondary (n=4)) ; age 60.9±14.8 years ; diabetes duration 19.2±8.5 years ; dialysis duration 6.5±6.9 years ; treatment (lifestyle (n=3), insulin (n=12)). At T0, T1 and T2 (respectively) : mean CGM glucose was 151.64±44.60, 148.70±29.54 and 140.12±28.66 mg/dl (p=0.048 T2 vs T0) ; area under curve (AUC) hyperglycemia was 16.18±25.24, 10.27±14.83 and 7.23±8.32 (p=0.035 T2 vs T0) ; MAGE was 109.62±40.76, 101.70±54.83 and 90.85±31.96 mg/dl (ns) ; AUC hypoglycemia was 0.4±0.84, 0.01±0.03 and 0.09±0.16 (ns T2 vs T0) ; HbA1c was 6.85±1.48, 6.61±1.24 and 6.46±1.49% (p=0.039 T2 vs T0). There were more treatment adaptations during the CGM period, compared to the SMBG period : 2.1±0.9 vs 1.4±1.0 adaptations/patient (p=0.022). Quality of life was not different between the two periods. CGM profiles were significantly different for days with vs without dialysis : all day mean CGM glucose was 138.09±18.43 vs 142.52±11.86mg/dl (p=0.0197) and dialysis period mean CGM glucose was 123.28±10.94 vs 136.44±14.53 mg/dl (p=0.0147), respectively. We found no difference in the CGM profiles during the 12 hours period following dialysis.
Conclusion: We show that repeated CGM profiles, compared to SMBG, significantly improve glycemic control of dialysis patients with diabetes : decrease of mean CGM glucose, decrease of hyperglycemia exposure, decrease of HbA1c, without increase of hypoglycemia. This improvement is the result of more frequent treatment adaptations during the CGM period, reflecting the unknown glycemic drifts with SMBG. The process of remote centralized interpretation of CGM profiles by a diabetes expert opens the field of telemedicine. The results of this pilot study encourage further studies : first, it would be important to define the CGM glucose targets for these patients. Then, larger and longer studies should explore the effect of repeated CGM on glycemic control and morbi-mortality in this population. Medico-economic evaluations would also be important in regard of the cost of CGM technology.

1096

A comparison of utilising SMBG vs CGM data to optimise glycaemic profiles and glucose control in patients with type 2 diabetes

R.M. Bergenstal, E. Strock, K. Thompson, M.X. Xi, M.L. Johnson, D. Wesley, S. Borgman, S. Borgman, R. Mazze;
International Diabetes Center, Minneapolis, USA.

Background and aims: Glycemic control in T2D is often judged by A1c and the rate of hypoglycemia. CGM better defines hypoglycemia and provides time in range and glucose variability. We report the first randomized, controlled, prospective study using CGM and A1c to compare the ability of structured SMBG testing (stSMBG) and real time CGM (rtCMG) to optimize glucose control.
Materials and methods: Subjects with T2D (N=114), age 59±0.9 yrs, duration 12±0.6 yrs, BMI 34±0.6 kg/m^2 used 2 wks of blinded CGM then were randomized to stSMBG [SMBG 4x /day and 3 x 7 point BG profiles (360 view) q2-4 wks] or rtCGM [CGM daily and CGM ambulatory glucose profile(AGP) report q2-4 wks] for 16 weeks. Therapy adjusted q2-4 wks. We evaluated if stSMBG or rtCMG led to improved glucose control and if one approach was safer or more effective based on a change in A1c and 2 wks of CGM in both groups (blinded CGM for stSMBG vs. rtCMG).
Results: See TABLE**:** Both stSMBG and rtCGM resulted in significant improvements in A1c, time in range and glucose variability (with no significant difference between groups). rtCGM resulted in a significant reduction in hypoglycemia compared to stSMBG, particularly in SU and insulin pts (not shown).
Conclusions: Collecting, analyzing and discussing structured SMBG or rtCGM (with AGP report) results in a significant improvement in glucose control and the glucose profile. CGM compared to SMBG also resulted in a reduction in hypoglycemia while improving glucose control particularly in SU and insulin treated pts.

Variables A1c & CGM data (14 days)	Baseline (Time 0)	Study End (16 weeks)	Change Baseline to Study End	Change within group p value	Change between groups p value

Improvement of metabolic control after three months use of RT-CGM in type 1 diabetics treated with insulin pump: the multicentre Greek DIAMOND study

A.C. Pappas[1], E. Anastasiou[2], C. Vasilopoulos[3], C. Zoupas[4], C. Manes[5], A. Tsatsoulis[6], N. Tentolouris[7], M. Benroubi[8], E. Pangalos[9], A. Gerasimidi-Vazeou[10], T. Didangelos[11];
[1]Diabetic Center, Venizelion Hospital, Iraklion, [2]Endocrinology Clinic, Alexandra General Hospital, Athens, [3]Endocrinology Department, Evaggelismos General Hospital, Athens, [4]Diabetes Center, Hygeia Hospital, Iraklion, [5]2nd Department of Internal Medicine, Papageorgiou General Hospital, Thessaloniki, [6]Endocrinology Department, University Hospital, Ioannina, [7]Diabetes Department, Laiko General Hospital, Athens, [8]Diabetes Center, Poliklinic General Hospital, Athens, [9]Diabetes Department, Thermi Hospital, Thessaloniki, [10]Diabetes Center, Panagiotis and Aglaia Kyriakou Children's General Hospital, Athens, [11]Diabetes Center, 1st Propedeutic Department of Internal Medicine, Medical School, "AHEPA" Hospital, Aristotle University, Thessaloniki, Greece.

Background and aims: To evaluate the efficacy of adding continuous glucose monitoring (CGM) for three months to insulin pump therapy (CSII) in patients with siabetes mellitus type 1 (DMT1) in a multicenter Greek study (THE DIAMOND STUDY).
Materials and methods: In total, 11 Diabetes Centers in Greece participated to the study. Forty three patients (24 female, 55.8%), with mean age 33.6±8.1, mean duration of T1DM 14.5±9.8 years and treated with continuous subcutaneous insulin infusion were enrolled prospectively. All patients were on CSII (MiniMed Paradigm) for three months at least before the use of CGM. Then all participants were instructed to wear the MiniMed Paradigm REAL-Time System (Medtronic Inc.), which integrates both CSII and RT-CGM functionalities, at all times throughout the study for the next three months. At the end of the study we evaluated the following parameters: HbA_{1c}, BMI, hypoglycaemic episodes (HYPO), total daily insulin requirement (TDI), total daily insulin for boluses (TDIBOL), number of daily boluses (NOBOL), total daily insulin basal (TDIBASAL) and percentage of total time use of sensor (PTTU).
Results: The mean PTTU was 74±17.0%. The results of the other examined variables were as follows [mean±1SD] in patients before and after the use of CGM: HbA_{1c} 8.3±1.2% vs 7.5±1.0% (p< 0.001), TDI 45.7±15.3 vs 50.8±23.9 (p= 0.018), TDIBOL 24.1±10.4 vs 28.3±19.0 (p= 0.033) and NOBOL 4.7±1.5 vs 6.3±2.4 (p< 0.001). No significant change observed in BMI, HYPO and TDIBASAL before and after the use of CGM. No ketoacidosis observed throughout the study. 44, 2% of the patients achieved HbA_{1c} targets (< 7%).
Conclusion: In the present study continuous glucose monitoring was associated significantly with improvement of glycaemic control without BMI and hypoglycaemic episodes change, in patients with type 1 diabetes using CSII. Better self-management and increase of the doses and units of insulin may have contributed to these beneficial effects.

Poor agreement of computerised calculators to calculate the mean amplitude of glycaemic excursions

J.B.L. Hoekstra, M.K. Sechterberger, J.H. DeVries;
Dept. of Internal Medicine, University of Amsterdam, Netherlands.

Background and aims: Glucose variability has been identified as a predictor of hypoglycaemia and is associated with intensive care unit mortality. A popular metric to quantify glucose variability is the mean amplitude of glucose excursions (MAGE). The 'ruler and pencil' approach to calculate MAGE is operator dependent and time-consuming for analysis of continuous glucose monitoring (CGM) data. Therefore, several computer software programs have been developed for the automated calculation of MAGE. The aim of our study was to evaluate the agreement of currently available MAGE calculators when applied to the same set of CGM traces.
Materials and methods: Four software programs for calculation of MAGE from CGM data were identified. The software programs were used to calculate MAGE of forty-two CGM traces from seven patients with type 1 diabetes. Correlation between the MAGE values obtained by the different MAGE calculators was evaluated by Spearman's correlation analysis. A correlation-coefficient (r) of at least 0.95 was considered a sufficient correlation, given the fact that the calculators aim at assessing the same metric. Lastly, between-group comparison of the median MAGE per calculator was performed using analysis of variance.
Results: Only one calculator was able to calculate a MAGE for all the provided CGM traces. The other calculators showed 1, 2 and 15 missing MAGE values. The correlation between the calculators ranged from 0.3899 to 0.8765 ($p < 0.05$ for all). Mean differences ranged from -0.68 to 1.76. Between-group comparison showed that overall median MAGE was statistically different (P=0.002).
Conclusion: Available computer programs developed to calculate MAGE agree poorly. Although software programs for the calculation of MAGE would seem attractive to assess glycaemic variability, their use is limited by widely different outcomes, in the absence of a gold standard.

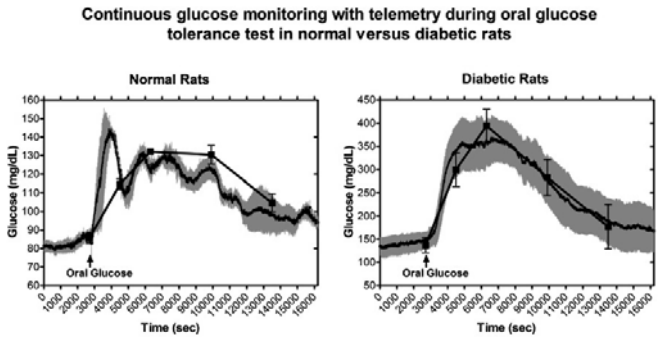
Continuous glucose monitoring via telemetry in rats

R. Brockway[1], T. Coskun[2], L.S. O'Farrell[2], P. Haefner[1], K. White[1], C.V. Jackson[3], R.G. Peterson[3];
[1]Data Sciences International, St. Paul, [2]Eli Lilly, Indianapolis, [3]PreClinOmics, Indianapolis, USA.

Background and aims: The current standard for routine glucose measurements in preclinical research is often glucometers and test strips. These pose significant limitations in terms of accuracy, animal stress, and frequency of sampling. Until now, continuous monitoring options for preclinical research have been very limited. The present study evaluates the use of a novel prototype device (Data Sciences International) for acute and chronic glucose measurements in rats.
Materials and methods: The device is 1.4cc and provides temperature, activity, and direct continuous blood glucose readings for 4 weeks or longer. The devices were evaluated in 4 diabetic and 4 normal Zucker fa/fa (ZDF) rats and in 10 Zucker diabetic/Sprague Dawley (ZDSD) rats. Each animal was surgically instrumented with glucose sensors in the abdominal aorta and the telemetry device placed in the intraperitoneal (ip) cavity. Continuous glucose readings were recorded for 5-7 weeks with periodic fasting GTTs (glucose, 2-3 g/kg, po or ip). Daily and GTT reference values were recorded with a StatStrip Xpress glucometer (Nova Biomedical).
Results: The glucose sensors provided high resolution data and demonstrated the ability to accurately assess chronic diurnal patterns matching with the feeding pattern of rats from 3 days up to 7 weeks after surgery.
Conclusion: These devices hold great potential for comparing physiologic processes associated with glucose regulation in normal and disease condition rats; monitoring diabetes progression and developing preventive treatments for type II diabetes.



PS 091 Insulin pumps in clinical practice

1100

Intermittent glucose monitoring in type 1 diabetics on insulin pump: is there difference in glycaemic control between real-time and retrospective analysis?

G. Petrovski, T. Milenkovic, B. Jovanovska, I. Ahmeti, I. Bitovska;
University Clinic of Endocrinology, Skopje, The Former Yugoslav Republic of Macedonia.

Background and aims: The aim of the study is to describe glycemic outcomes in type 1 diabetics using an insulin pump with intermittent Real-Time and Intermittent Retrospective continuous glucose monitoring (CGM).
Materials and methods: A total number of 57 type 1 diabetics using insulin pump therapy (Medtronic 7xx, Medtronic, Northridge, CA) for at least one year, used CGM in 6 sessions (each session was 7 days every month) in a period of 6 months. The patients were randomized in two groups: Intermittent Real-Time (IRT) CGM group, 29 patients using real-time CGM (Minilink with En-lite sensor, Medtronic, Northridge, CA), where patients could see the glucose value and respond adequately (Real Time CGM) and Intermittent Retrospective (IRS) CGM group, 28 patients using retrospective CGM (Ipro2 with En-lite sensor, Medtronic, Northridge, CA), where patients could not see the glucose value (blinded CGM). After each session (both Real-time and retrospective CGM), data was downloaded using specific software (Carelink Personal and Carelink Ipro, Medtronic, Northridge, CA) and specific instructions for optimization the pump therapy (basal and bolus insulin, education on food, physical activity and hypoglycemia/hyperglycemia) were given to the patients. HbA1c was obtained before, three and six months after the study.
Results: Both groups significantly improved glucose control (HbA1c) from 7.5±0.9% to 6.6±0.7% in IRT group and from 7.4±1.1% to 6.5±0.8% in IRS group, but there was no significant difference between both groups at the end of the study. There was no severe hypoglycemia in both groups. There was no significant difference in TDD of insulin and number of boluses.
Conclusion: Both intermittent real-time and retrospective CGM can improve glucose control in type 1 diabetics on insulin pump where our study showed no significant difference in decreasing of HbA1c using both methods. Further investigation on larger groups should be performed to confirm our findings.

1101

Quantitation of the roles played by the main determinants of meal glucose tolerance in patients with type 1 diabetes on insulin pump therapy

M. Trombetta[1], C. Brangani[2], L. Boselli[2], C. Negri[1], M. Dauriz[1], I. Rubbo[1], G. Ceradini[1], E. Bonora[1], R.C. Bonadonna[1];
[1]University of Verona and AOUI-Verona, [2]University of Verona, Italy.

Background and aims: The relative roles of each component of the glucose (G)/insulin (I) system in determining post-meal hyperglycemia in type 1 diabetes (T1DM) are still under debate. The use of Metabolic Control Analysis allows to compute the coefficients of control of G (CC_G), which quantify the control exerted by each component of the G/I system on G concentration. Aim of this research was to quantify the CC_G of the main components of the G/I system during a mixed meal test (MMT).
Materials and methods: 7 T1DM patients (age: 41±5 yrs; BMI: 24.3±0.6 $kg \cdot m^{-2}$; HbA1c: 7.9±0.2%) on I pump and continuous G monitoring (CGM) participated in 2 studies:1. Euglycemic I (240 $pmol \cdot min^{-1} \cdot m^{-2}$ BSA) clamp (duration: 120 min, M value: 1209±169 $\mu mol \cdot min^{-1} \cdot m^{-2}$ BSA) including CGM; 2. MMT (292 Kcal; 38.9 g complex CHO, 8.9 g lipids, 14 g proteins) with plasma I/G assessment and CGM for 300'. With our modeling strategy, data from both clamp and MMT are used to build an in silico replica ("virtual patient") of the G/I system of each patient (CGM included), which behaves as the real patient during the MMT. Virtual patients were used to compute the CC_G of both plasma G and CGM measured G.
Results: During the MMT, plasma G and I started from 9.5±1.8 mM and 75±8 pM and peaked at 12.2±1.4 mM (time: +90') and at 136±18 pM (time: +60') respectively. The CC_G of key components of the G/I system are in the Table. The apparent size of s.c. I depot had the highest CC_G ($p<0.01$ or less vs other CC_G). The CC_G of meal I bolus peaked at 300' ($p<0.01$ vs CCs at 30'-

60'). The CC_G of CHO transit time across the gut, including also absorption, was relevant in the first half and became negligible in the second half of the meal (p<0.01 CC_G 180-300' vs CC_G 30'-120'). The CC_G of CGM measured G were parallel, but not superimposable to CC_G of plasma G, with significant differences (p<0.03-0.01) in CC_G of gut CHO transit time.
Conclusion: In patients with T1DM on I pump therapy, after a MMT: 1. a primary determinant of plasma G may be the size of subcutaneous I depot; 2. pre-meal I bolus may be much more influential in the last 3 than in the initial 2 hours. These findings may have important implications for the development and the refinement of closed loop control of s.c. I delivery systems. Table. CC_G of meal carbohydrate (CHO) content, gut mean transit time (MTT) of meal CHO, rate of splanchnic CHO extraction (SGE), pre-meal I bolus, apparent size of s.c. I depot, meal I sensitivity (S_I) and G effectiveness (S_G) after the meal. The signs +/- indicate that an increase in the parameter causes an increase/decrease in plasma G.

HbA_{1c} and weight development one year after initiation of continuous subcutaneous insulin injection therapy in adult subjects
H.U. Andersen, E. Hommel, H.-C. Andersen, J.N. Christensen, K. Rytter, A. Hougaard, A. Grynnerup, M. Ridderstråle;
Steno Diabetes Center, Gentofte, Denmark.

Background and aims: The success of improvement in HbA1c after initiating or intensifying multiple daily injection (MDI) insulin therapy in subjects with diabetes is typically prevented by weight gain or hypoglycemia. Here we performed a retrospective observational analysis in adults with diabetes initiating continuous subcutaneous insulin injection (CSII) therapy in order to find out whether the effect of CSII is similar in clinical practice.
Materials and methods: All subjects initiating CSII at our Diabetes Center after year 2002 were analyzed for age at CSII initiation, HbA1c, weight and total insulin dose prior to and one year after pump initiation by non-parametric paired analysis and multiple regression analysis to find independent variables explaining the change in HbA1c or weight and adjust for relevant variables. Data are presented as mean ± SEM.
Results: 505 subjects had sufficient data to enter into the analysis, 184 males and 321 females; age at CSII initiation 40 ± 0.6 years (ns between males and females), weight before CSII 82.9 ± 1.1 and 70.0 ± 0.8 kg for males and females, respectively (p<0.0001), HbA1c before CSII 68.1 ± 0.6 mmol/mol (ns between males and females). At follow-up (after 312 ± 2.5 days) HbA1c had decreased significantly to 62.6 ± 0.9 mmol/mol in males and 60.6 ± 0.6 mmol/mol in females (p<0.05) with a significantly greater reduction in female patients (-7.6 ± 0.6 vs. -5.3 ± 0.7, p<0.05). While there was no significant change in weight for male subjects (-0.8 ± 0.6 kg), there was a slight but significant increase in weight for female subjects (+1.2 ± 0.4 kg, p=0.01 vs male subjects). The required total daily insulin dose decreased significantly in both males and females from 64 ± 6 to 46 ± 1 (p<0.0001) and 49 ± 1 to 38 ± 1 (p<0.0001) units, respectively, with a significant greater decrease in males compared to females in absolute (p<0.0001) but not in relative terms (ns). By univariate Spearman analysis a decrease in HbA1c was positively correlated with an increase in weight with no relation to the change in insulin dose whereas an increase in weight was negatively correlated to the decrease in insulin dose. Adjusting for relevant covariates by multiple regression analysis gender (p<0.05) and HbA1c prior to CSII (p<0.0001) were independent predictors of decrease in HbA1c (greater reduction for female sex and higher HbA1c) explaining 29% in the variability of change in HbA1c. Independent predictors for an increase in weight were HbA1c prior to CSII (p<0.05), weight prior to CSII (p<0.0001), and relative decrease in insulin dose (p<0.01) with no effect of gender (greater increase at lower HbA1c, lower weight, and lesser of a decrease in dose) explaining 17% of the variation in weight change.
Conclusion: Switching from MDI to CSII in adult patients with type 1 diabetes may lead to successful lowering of HbA1c in a clinical setting after one year. The HbA1c decrease is relatively greater in females with a higher starting HbA1c which is mirrored by an increase in weight in females compared to no change in males, despite the same relative reduction in total insulin dose. Meanwhile, the increase in weight in most cases was very marginal, particularly with regard to the observed substantial decrease in HbA1c (eq. to a 1.6 kg weight gain for every 10 mmol decrease in HbA1c). Gender differences may be important to consider when initiating CSII but neither this nor weight change appear to be significant barriers to a switch to CSII.

1103

Factors affecting glycaemic control in adult type 1 diabetic patients treated with personal insulin pumps
T. Klupa, B. Matejko, B. Kieć-Wilk, M.T. Malecki;
Department of Metabolic Diseases, Jagiellonian University Medical College, Krakow, Poland.

Background and aims: Continuous subcutaneous insulin infusion (CSII) improves glycemic control and quality of life as compared to conventional insulin therapies. However, it is not clear which factors play the most significant role in optimizing therapy in CSII treated patients. The purpose of this analysis was to investigate retrospectively variables affecting metabolic control in T1DM (type 1 diabetes) patients treated with personal insulin pump.
Materials and methods: Data from 145 patients treated with CSII were analyzed. Sources of information about the patients included: available medical records, memory read-outs from insulin pumps, blood glucose meter data, biochemical analysis results and questionnaires. Data from the last three years were used for this analysis. The Shapiro_Wilk test was performed as a test for normality. Correlation analysis was used to study the relationships between various variables. The difference between the groups was analyzed with the Student t test. Nonparametric tests were used when necessary. Additionally, a multivariate regression analysis was performed for mean HbA1c. We indicate a significant result when p<0.05. Statistica 10.0 software was used for statistical analysis.
Results: The mean age of the patients was 28.6, mean BMI 23.1 kg/m^2 with an average duration of diabetes of 13.4 years. Mean HbA1c level for the whole studied group was 7.3% (mean glycemia from glucose meter readings - 151 mg/dl). Negative correlations between HbA1c and age (r = -0.31, p = 0.0003), number of blood glucose measurements per day (r = -0.31, p = 0.0010) and number of hypoglycemic episodes per day (r = -0.48, p = 0,0000) were found. Mean glucose levels from glucose meter memory (r = 0.71, p = 0.0000), blood glucose variability measured with standard deviation from glucose meter data (r = 0.54), daily insulin requirement (r = 0.23, p = 0.0100), insulin requirement per kilogram of body weight (r = 0,25, p = 0,0050) and CSII duration (r = 0,24, p = 0,0065) correlated positively with HbA1c level. Patients with higher education were characterized by lower HbA1c (p = 0.0384). The use of an extended/dual wave bolus had no effect on metabolic control (p = 0.30). Both the Bolus Calculator (BC) (p = 0.0303) and Continuous Glucose Monitoring System (CGMS) (p = 0.0119) option was associated with lower HbA1c. In multivariate regression analysis, HbA1c significantly correlated with mean blood glucose, number of daily blood glucose measurements and insulin dose per kilogram of body weight. The adjusted coefficient of determination was 71%.
Conclusion: This study demonstrates that both patient-related and technology-related variables have a strong influence on glycemic control in CSII-treated individuals. Self monitoring of blood glucose and usage of some advanced pump options like BC and CGMS are associated with a better chance of achieving treatment goals, while extended/dual wave bolus functions have no significant impact. CSII-treated patients with higher insulin doses are characterized with poorer metabolic control.

1104

Carbohydrate-to-insulin ratio in type 1 diabetic patients treated with continuous subcutaneous insulin infusion therapy (CSII)

C. Gonzalez, I. Orellana, R. Corcoy, V. Alcantara, A. Chico;
Endocrinology, Hospital Sant Pau, Barcelona, Spain.

Background and aims: Patients with type 1 diabetes (T1DM) under CSII therapy usually calculate insulin boluses with the carbohydrate-to-insulin ratio (CH/IR), with the addition of a correction if pre-prandial blood glucose levels are above the objective. The initial calculation of the CH/IR is often done using the 500 formula (500/total daily doses of insulin-TDD). Some authors have suggested that the formula tend to underestimate this ratio and on the other hand the ratio is usually different along the day. The aims were to know the CH/IR used by T1DM patients under CSII therapy, the differences observed with the CH/IR obtained from the 500 formula, and also the differences of CH/IR along the day.
Patients and Methods: A total of 170 patients with T1DM under CSII therapy for at least 6 months and relatively good control were evaluated (132 women, age 45.5 ±10 years, diabetes duration 26.65 ± 10 years, CSII duration 9.15 ± 6 years, HbA1c 7.6 ± 0.8%). CSII indications were: non optimal glucose control with multiple daily injections (45%), optimization before pregnancy (29.8%), high glucose variability (8.2%) among others.
Results: The proportion of TDD as basal rate was 57.7 ± 13% and for boluses was 42.3 ± 12%. The table shows the CH/RI used in the main 3 meals, the CH/IR obtained with the 500 formula and the formula that should be used according to the real results obtained.

All patients	**Breakfast**	**Lunch**	**Dinner**
CH/IR	1.20±0.7 ui/10 g.	1.09±0.6 ui/10 g.	1.07±0.7 ui/10 g.
Calculation by 500 formula	1.55 ui/10 g.	1.55 ui/ 10 g.	1.55 ui/10 g.
Real calculation	507/TDD	460/TDD	455/TDD
Patients with HbA_{1c}<7%	**Breakfast**	**Lunch**	**Dinner**
CH/IR	1.2 ui±0.7 ui/ 10 g.	1.1±0.6 ui/10 g.	1.1±0.6 ui/10 g.
Calculation by 500 formula	1.6 ui/10 g.	1.6ui/10 g.	1.6 ui/10 g.
Real calculation	478/TDD	445/TDD	459/TDD

The CH/IR was significantly different between breakfast and lunch and between breakfast and dinner (p<0.05). Real CH/IR was also different that that obtained with the 500 formula in the 3 meals (p<0.05). CH/IR was higher at breakfast (p<0.05) that in the other meals.
Conclusions: The 500 formula for the calculation of CH/IR overestimate the real CH/IR used by T1DM patients under CSII therapy, especially for lunch and dinner. The CH/IR is higher at breakfast. A more approximate calculation can be obtained using the formula 480/TDD for breakfast and 450/TDD for lunch and dinner.

1105

Outcomes in people with type 1 diabetes transferring to insulin pump therapy after structured education

P. Mansell[1,2], R. Cullum[2], F. Cole[2], C. Taylor[3], D. Cooke[4], H. Murphy[5];
[1]Diabetes and Endocrinology, Nottingham University Hospitals, [2]School of Biomedical Sciences, University of Nottingham, [3]Diabetes and Endocrinology, Sheffield Teaching Hospitals NHS Foundation Trust, Sheffield, [4]School of Health & Social Care, University of Surrey, Guilford, [5]Clinical Biochemistry, University of Cambridge, UK.

Background and aims: In interpreting the results of studies of the use of Continuous Subcutaneous Infusion of Insulin (CSII) in people with Type 1 diabetes (T1DM), it can be difficult to disentangle the effects of education and of CSII per se on outcomes. Firstly, patients in such studies may not have attained optimal diabetes management through contemporary structured education before CSII is initiated. Secondly, those starting on CSII are necessarily provided with additional education and professional input, even in studies with a comparator group. Also, in many studies of the use of CSII, there is a paucity of data on psycho-social outcomes. We have therefore studied biomedical and psycho-social outcomes in people transferring to CSII compared to those remaining on Multiple Dose Insulin injections (MDI) after a one week UK Dose Adjustment For Normal Eating (DAFNE) intensive education course.
Materials and methods: The DAFNE research database is active in 10 UK diabetes centres and has ethical approval with patients required to give informed consent. Information on biomedical measures and from psycho-social questionnaires is collected at baseline and at 12 months after structured education. 1450 people with T1DM were registered on the database between January 2009 and June 2011.
Results: Of the above cohort, 938 people had paired baseline and follow-up data. Mean age was 44 (SD 14.0) years with duration of diabetes 20 (13.7) years. During 12 months follow-up, 57 (6.1%) patients transferred to CSII. At baseline, the Problem Area In Diabetes (PAID) score was higher in those that later transferred to CSII at 36.4 (19.9) compared with 28.3 (19.3) in those that remained on MDI (p=0.006). PAID scores of 21.7 (16.5) and 20.1 (17.0) respectively were similar at 12 months after structured education. At baseline, the frequency of severe hypoglycaemia was 1.31 events per patient year in those that transferred to MDI and 0.96 in those that continued on MDI (p=0.03). After DAFNE rates of SHE fell by approximately 75% overall and did not differ between groups at 12 months. In those that continued on MDI, HbA1c fell from 8.74 (1.53) % (72 mmol/mol) at baseline to 8.54 (1.49) % (70) at 12 months, and in those that transferred to CSII, was reduced from 8.79 (1.96) % (73 mmol/mol) to 8.20 (1.58) % (66 mmol/mol), with a greater fall in the latter (p=0.03).
Conclusion: In a group of people with T1DM undergoing structured education, those that subsequently transferred to CSII had normalisation of the higher levels of psychological stress (PAID score) and the increased rate of severe hypoglycaemia apparent at baseline and also had better overall glycaemic control at 12 months follow-up. Even after intensive structured education there remains a group of people with T1DM that gain additional benefits from CSII.

1106

Dose Adjustment for Normal Eating (DAFNE) structured education is associated with reduced progression to insulin pump among patients considered for pump before enrolment

T. Ray[1], P. Choudhary[1], P. Mansell[2], S. Heller[3], S.A. Amiel[1], D. Hopkins[1];
[1]Kings College Hospital, London, [2]University of Nottingham, [3]University of Sheffield, UK.

Background and aims: Current UK national guidelines recommend insulin pumps for people with type 1 diabetes suffering from 'disabling hypoglycaemia' or whose HbA_{1c} remains >8.5% on optimised multiple dose injection (MDI) regimens, but the meaning of 'optimised MDI therapy' is not clearly defined. Our aim was to determine if further training provided through the DAFNE (Dose Adjustment for Normal Eating) structured education programme could reduce the need for insulin pump therapy among patients already established on MDI.
Materials and methods: Retrospective study using a national database of participants attending DAFNE courses at 10 UK centres in 2009-10 being considered for insulin pump at time of enrolment. Baseline and one year data including treatment modality, HbA_{1c} , hypoglycaemia awareness status and severe hypoglycaemia prevalence (SH) were collected.
Results: 108 participants were considered for pump therapy at baseline. 34 proceeded to pump initiation after 202 ± 105 days. 69 remained on MDI after 384 ± 43 days follow-up; outcomes were unavailable for 5. Participants had mean and standard deviation age of 39 ± 13, diabetes duration of 20 ± 12 years and baseline HbA_{1c} 8.7 ± 1.8 %. 48% reported impaired hypoglycaemia awareness (IA) and 33% reported SH in the preceding year. 75% of patients enrolled for DAFNE who were considered for pump at enrolment fulfilled at least one criterion for pump, which fell to 60% at one year follow-up (p<0.05). Mean HbA_{1c} had fallen to 8.4 ± 1.5 % (p=0.04 vs. baseline) and there was a significant reduction in HbA_{1c} in participants who met insulin pump criteria based on HbA_{1c} (mean HbA_{1c} 10.2% at baseline vs. 9.4% at one year) (p<0.01). IA and SH prevalence reduced by 16% (p<0.001) and 20% (p<0.01) respectively.
Conclusion: Provision of DAFNE structured education was associated with reduction in proportion of participants meeting insulin pump criteria and prevalence of IA and SH, enabling 69% of patients being considered for insulin pump to remain on MDI. These findings strongly support optimisation of MDI through effective structured education prior to considering insulin pump as part of the treatment pathway for all patients with type 1 diabetes.

Comparison between individually and group-based insulin pump initiation by time-driven activity-based costing

M. Ridderstråle[1,2];
[1]Department of Clinical Sciences, Lund University, Malmö, Sweden, [2]Steno Diabetes Center, Gentofte, Denmark.

Background and aims: Controlling cost and increasing the precision of decision making is important for efficient and cost-effective delivery of health care. Time-driven activity based costing (TDABC) offers the possibility of absorbing costs in terms of activities and may be particularly suited for service businesses, not least where alternatives for the same service are available. Here we used TDABC to compare initiating insulin pump therapy in groups (GT) to individual treatment (IT) in adult subjects with type 1 diabetes.
Materials and methods: Activities and cost drivers were identified and routines timed or estimated at location. Medical quality and patient satisfaction were assumed to be equal or non-inferior and were not measured. Other quantitative data were obtained from departmental sources. Overhead costs were allocated differentially based on profession and manager(s). The alternatives were compared under different scenarios and conclusions adjusted for the net effect of alternate cost, cost of opportunity, and differential reimbursement.
Results: GT was about 30% less time-consuming and 17% less cost driving per patient per activity compared to IT. When analysed as a batch driver GT produced an upward jig-saw cost accumulating curve compared to the incremental increase incurred by IT. *Variable batch*, i.e. also taking into account the alternate cost that taking care of patients who did not attend group sessions, was less cost driving than IT already when only five out of 16 patients attended the sessions. Estimated cost accumulation curves for variable batch treatment and the cost of opportunity that was generated in comparison to IT converged already before filling the first session with 16 individuals suggesting that another group could be booked at no additional cost.
Conclusion: TDABC is an effective method for comparing treatment alternatives yielding estimates of the opportunity costs and the possibility to increase cost control and improve decision making. In this particular case, pump therapy initiation in groups was clearly favoured over an individual approach from a financial point of view.

Experience with V-GO insulin delivery device in clinical practice

J.-P. Lock, R. Powell, D.M. Harlan;
Medicine/Diabetes, University of Massachusetts, Worcester, USA.

Background and aims: V-GO is a disposable insulin delivery system providing set basal rates and bolus insulin on demand for 24 hours. We describe our early clinical experience with V-GO for the treatment of adults with suboptimally controlled type 2 diabetes (T2D).
Materials and methods: Adult T2D patients with suboptimal glycaemia control followed at a diabetes center were selected for insulin management using the V-GO device. Subjects were eligible for V-GO treatment if they demonstrated one of three difficult-to manage problems: 1) needle phobia limiting multiple dose insulin (MDI), 2) unwilling or unable to use conventional insulin pumps because of pump complexity, literacy/numeracy limitations, inability to carbohydrate count, or difficulty comprehending corrective insulin algorithms. 3) refractory hyperglycaemia despite self-reporting large daily insulin doses. All patients initiating insulin treatment with V-GO or transitioned from MDI to V-GO received either fixed basal doses of twenty (20) units, thirty (30) units or forty (40) units per day, with additional ability to receive 36 units of bolus insulin per day.
Results: Thirty six (36) patients with difficult-to-manage glycaemia issues received V-GO-based insulin treatment, twenty-one (21) continue to use the V-GO. Overall, fifteen (15) of the 36 have discontinued V-GO use; five (5) due to hypoglycaemia despite using the lowest basal V-GO device, three (3) due to skin irritation from the V-GO adhesive, four (4) withdrew for behavioral health reasons, one (1) withdrew as a result of resolved hyperglycaemia following diet/exercise, one (1) withdrew for discomfort, and one (1) for emergency surgery. Twenty one (21) are presently receiving insulin therapy as early V-GO adopters. Two (2) patients with severe needle phobia used the V-GO as their initial experience with basal/bolus insulin. Nineteen (19) patients with refractory hyperglycaemia despite self- reported high daily insulin requirements have all demonstrated a 40-60% decrease in their daily insulin need. Percentage of V-GO insulin users presently using V-GO 20 (which delivers 20 units basal insulin over 24 hours), V-GO 30, and V-GO 40 devices are (4/21) 19%, (5/21) 23% and (12/21) 57%, respectively. Our preliminary analysis of available A1C data from the 6 patients using the V-GO the longest (at least 8 weeks) finds a 17% improvement in A1C ; pre-V-GO A1c mean 9.8% (range 8.3 - 14.3%) with the post-V-GO A1c mean being 8.1% (range 7.1- 9.1%).

Patient	A1C Change (%)	Pre V-GO	Post V-GO
1	-43.90%	Lantus 140 units + Novolog 30 units, Januvia 100 mg, Metformin 2000 mg	V-GO 20, Metformin 2000mg
2	2.40%	Lantus 40 units + Humalog 24 units , 10 Glyburide mg, Metformin 2000 mg	V-GO 30, Metformin 2000 mg
3	-14.50%	Lantus 40 units + Novolog 25 units	V-GO 30
4	-19.10%	Lantus 60 units, Metformin 1500 mg	V-GO 40, Metformin 1500 mg
5	-11.70%	Lantus 70 units + Novolog 83 units, Victoza 1.8 mg	V-GO 40
6	-5.20%	Lantus 180 units + Humalog 125 units, Victoza 1.8 mg, Metformin 2000 mg	V-GO 40, Metformin 2000 mg

Conclusion: Our preliminary experience shows patients with suboptimally controlled T2D despite taking high daily dose MDI can be successfully transitioned to V-GO insulin delivery devices in clinical practice. Patients using the V-GO insulin delivery system experienced improved glycaemia control within the initial three month time framework, and required fewer medications and less daily insulin.

1109

A feasibility assessment of PaQ®, a simple 3-day basal/bolus insulin delivery device, in patients with type 2 diabetes

J.K. Mader[1], L.C. Lilly[2], F. Aberer[1], H. Kojzar[1], S. Korsatko[1], E. Strock[3], R. Mazze[3], P. Damsbo[2], T.R. Pieber[1,4];
[1]Internal Medicine / Endocrinology and Metabolism, Medical University of Graz, Austria, [2]CeQur Corp., Marlborough, [3]International Diabetes Center at Park Nicollet, Minneapolis, USA, [4]4HEALTH – Institute for Biomedicine and Health Sciences, Joanneum Research GmbH, Graz, Austria.

Background and aims: PaQ (CeQur, SA) is a simple patch-on device that provides preset basal rates and bolus insulin on demand. In this 6-week open-label single-arm study we assessed feasibility of use, transition from multiple daily injections (MDI), ability to maintain glycemic control and safety. The study was done in patients with type 2 diabetes (T2D) treated with PaQ.
Materials and methods: Twenty patients on a stable MDI regimen were enrolled (age 59 ±5 y, T2D duration 15±7 y, A1C 7.7 ±0.7 %). The study was comprised of three 2-week periods: baseline (MDI), transition to PaQ, and PaQ therapy. The first PaQ basal rate (dose/day) selected was ≤ the patient's basal MDI dose. There was no attempt to treat to target.
Results: Eighteen patients completed the study. All patients were able to assemble and use PaQ. No cannula site infections occurred and PaQ was well tolerated. At the end of PaQ therapy the mean total daily dose (TDD) was similar to baseline (57±15 U vs. 60.4 ± 19 U). Self-monitored blood glucose values (mean ± SD mg/dL) showed a trend towards better glycemic control pre and post breakfast and at bedtime compared to baseline values; pre- and post-breakfast; -10.7±28 (P=0.12), -13.0±34 (P =0.13), and bedtime -17.9±45 (P =0.12). Blinded continuous glucose monitoring (CGM) data revealed a trend towards improved glycemic control, with a mean change in average 24 hour glucose exposure of -190.3 mg/dL (P = 0.18) compared to baseline. The reduction in glucose exposure occurred overnight and during the day. CGM also revealed no episodes of severe hypoglycemia. The improved glucose exposure was consistent with a mean change in A1C of -0.3±0.4%.
Conclusion: MDI treated patients with T2D were easily and safely transitioned from MDI to PaQ. Despite similar TDD during MDI and PaQ study periods, there was a trend toward improved glycemic control with PaQ therapy. Future studies will assess long-term PaQ efficacy and safety.

PS 092 Delivering diabetes care

1110

Marked improvement of glycaemic control and insulin therapy associated problems of patients with diabetes mellitus after intervention in a diabetes day clinic

C.S. Kloos, C. Eckardt, G. Kramer, B. Milke, G. Wolf, U.A. Müller;
Internal Medicine, Klinikum für Innere Medizin III, Jena, Germany.

Background and aims: During the last decade diabetes care in Germany migrated from inpatient to now almost exclusively outpatient care. Health care associations´ more and more stringent stipulations after introducing the DRG system makes it nearly impossible to treat even complicated diabetes cases in hospitals. We evaluated, if therapeutic problems which could not be solved after repeated outpatient consultations on tertiary care level (university out-patient clinic) improved after intervention in a diabetes day clinic.
Population and methods: From 10/2010 to 09/2011 117 patients with diabetes mellitus (DM) had a problem orientated intervention in a diabetes day clinic (DDC) in a university out-patient clinic for Endocrinology and Diabetes. The intervention was performed by an experienced, specially trained diabetes nurse ("Diabetesberater") hand in hand with a diabetologist. All patients received problem orientated, structured education and training. After 11.9 months 93 (80%) of the patients had a follow-up examination, another 3 patients had died. Mean time of the intervention was 4.1 days. 26 patients had DM1 (age 58.3y.(SD15.2), BMI 27,8kg/m2(SD4.8), 54% male) and 67 DM2 (age 65.0y.(SD10.8), BMI 33.4kg/m2(SD5.9), 60% male). The HbA1c was measured locally with an HPLC-method (TOSOH G8) and DCCT adjusted (mean HbA1c 5.05%).
Results: Most frequent reasons for the DDC admission were for DM1 high Hba1c (19/26; 73%), extreme plasma glucose fluctuations (11/26; 42%) and frequent hypoglycemic events (5/26; 19%), for DM2, respectively, high HbA1c (47/67; 70%), optimization of insulin therapy (10/67; 15%) and initiation of insulin therapy 7/67; 10%). In DM1 patients HbA1c improved 0.6% (69.4±1.1 to 63.9±1.0 mmol/mol; p=0.001), the daily insulin dose decreased from 52.9±34.8 to 48.9±32.5 IE/d and the weight reduced 0.55 kg. Frequency of mild hypoglycemic episodes per week decreased from 1.75±1.8 to 1.23±1.6. In patients with DM2 the HbA1c improved 1.7% (83.6±8.3 to 65.0±1.3 mmol/mol; p=0.013), daily insulin dose increased slightly from 58.8±50.9 to 59.5±47.6 IE/d whereas weight decreased by 1.36 kg.
Conclusion: One year after a problem orientated intervention in a diabetes day clinic performed by a specially trained diabetes nurse and a diabetologist in patients with diabetes mellitus type 1 and 2 with therapeutic problems which could not be solved after repeated presentations in an outpatient setting beforehand, resulted in a marked and sustained improvement of glycemic control and hypoglycemic events with a reduced (DM1) or stable daily insulin dose (DM2) and reduced weight.

1111

How quickly do HbA_{1c} levels respond to a change in oral glucose lowering therapy? Results from a cohort study

J.A. Hirst, R.J. Stevens, A.J. Farmer;
Department of Primary Care Health Sciences, University of Oxford, UK.

Background and aims: A routine monitoring interval of 3-6 months for glycated haemoglobin (HbA1c) is recommended for people with type 2 diabetes. However, this recommendation is based on expert consensus with limited supporting empirical evidence. Using a prospective clinical research design, we measured how quickly HbA1c responds after a change in oral glucose lowering therapy (OGLT).
Materials and methods: In a 12-week cohort study, adults with non-insulin treated type 2 diabetes were recruited from 18 GP practices in the United Kingdom. Eligible participants had a diagnosis of diabetes for ≥ 3 months and were initiating or increasing dose of their OGLT. HbA1c was measured at baseline and 2, 4, 8 and 12 weeks after the medication change. Adherence to medication was recorded using the 8-point Morisky scale. High adherence was defined as a score of 0 at the final consultation. Results for change in HbA1c are presented for participants who have both a baseline and 12-week HbA1c result.
Results: A total of 94 eligible patients entered the study. Fifteen were excluded from the analysis because of changes to their diabetes medication during follow-up (n=7); the 12-week HbA1c was measured more than 3 days late or

early (n=7) and death from non-study related causes (n=1). Eighty-one patients have completed the study to date. The mean (SD) age of 56 per-protocol participants was 61.9 (11.0) years, BMI was 39.6 (8.1) kg/m^2, diabetes duration 5.9 (4.3) years and 36% were female. After 12 weeks 21 patients (38%) had achieved glycaemic control (defined as an HbA1c≤59mmol/mol), and 35 (63%) had not. Mean±SE change in HbA1c from baseline at 2, 4, 8 and 12 weeks was 1.0±0.4 (n=53) mmol/mol, 2.6±0.6 (n=53) mmol/mol, 3.6±0.9 (n=52) mmol/mol and 4.4±1.0 (n=56) mmol/mol (Figure). Twelve weeks after the medication change the change in HbA1c ranged from a reduction of 22mmol/mol to an increase of 13mmol/mol. In 26 patients with a Morisky score of 0, mean ±SE change after 2, 4, 8 and 12 weeks was 0.1±0.5, 1.6±0.6, 2.7±1.0 and 2.3±1.4 mmol/mol. Twenty-nine patients (52%) had a greater change in HbA1c at 12 weeks than at 8 weeks. However, in 27 patients the change in HbA1c by 8 weeks was as great as, or greater than, the change in HbA1c by 12 weeks; of these patients, two-thirds had not achieved optimal glycaemic control by the end of the study.

Conclusion: This preliminary analysis suggests that 8 weeks after a medication change the mean change in HbA1c was 82% of the 12 week change in all patients, and >100% of the 12 week change in the most adherent patients. Forty-eight percent of patients had achieved their maximum change in HbA1c within 8 weeks of their medication change but the majority still had sub-optimal glycaemic control. This data suggests that many patients would benefit from returning to their GP earlier than 12 weeks following a change in their medication to have their HbA1c checked and to review their medication adherence.

Use of sulfonylureas in patients with multiple risk factors for CV disease or those with existing CV disease - CREST Study: are we following current ADA/EASD guidelines?

S. Kachroo[1], H. Kawabata[2], S.A. Colilla[2], L. Shi[3], J. Liu[3], J. Mukherjee[4], V.A. Fonseca[3], U. Iloeje[4];
[1]Bristol-Myers Squibb, Nassau Park, [2]Bristol-Myers Squibb, Hopewell, [3]Tulane University, New Orleans, [4]Bristol-Myers Squibb, Wallingford, USA.

Background and aims: Current literature suggests increased risk of cardiovascular disease (CVD) and all-cause mortality with sulfonylureas (SU) use. The new ADA/EASD guidelines also recommend that SUs be avoided in patients with CVD risk. This study examines the use of SUs in a high risk population.

Materials and methods: A retrospective cohort study design was employed for this project. Records were obtained for 529,468 patients with at least 2 records of T2DM diagnosis. Data was obtained from a large administrative claims database from 01/01/2004 to 01/01/2011. High risk for a CV event was defined as: GROUP 1 (N= 97,762): having established CVD; and GROUP 2 (N= 151,700): having multiple risk factors for CVD but without established CV disease. Group 3 (N=280,006) included patients who neither had established CVD nor any risk factors. Frequency of SU use was reported as rate per 1,000 patient-years and as an aggregate use frequency (%). Chi-square tests were used to test the differences in the use frequency of SUs across the CV risk cohorts. As exploratory analyses, logistic regression models were used to examine the associations between baseline characteristics and use of SUs within each of the study cohorts.

Results: In all the three groups, approximately one-quarter of patients reported the use of SUs in the study period (Group 1: 26.9%, Group 2: 28.6%, Group 3: 26.0%). For SUs, the overall use frequency over the study period was 486.3/1,000 person-years for Group 1; 521.4/1,000 person-years for Group 2; and 396.5/1000 person-years for Group 3. Compared with Group 3, the frequency of use of SUs for Group 1 or 2 were significantly higher ($p<0.0001$) for overall (all ages) and within age groups: 55-64 years, 65-74 years, and ≥75 years. From 2004-2011, the overall number of patients on SUs declined 24.4%. There was a greater decline in SU use observed in the CV risk groups compared to the low risk group over this time period [Group 1 (-28.6%), Group 2 (-29.3%), Group 3 (-18.5%), $p<0.001$ for Group 1 vs 3 and Group 2 vs 3, respectively]. Using exploratory multivariate logistic regression, several baseline clinical factors were associated with the current use of SUs, compared to other anti-diabetic medications. Within each of the CV risk groups, the following factors were statistically significant: (OR [95%CI]) Group 1: nephropathy (1.55 [1.30-1.84]), congestive heart failure (CHF) (1.06 [1.03-1.11]), chronic kidney disease (CKD) (0.67 [0.62-0.72]), and obesity (0.88 [0.84-0.92]); Group 2: nephropathy (1.68 [1.39-2.02]), CHF (1.07 [1.01-1.14]), CKD (0.77 [0.70-0.84]), and obesity (0.80 [0.76-0.84]); Group 3: CKD (0.61 [0.55-0.68]), nephropathy (1.56 [1.33-1.84]), obesity (0.84 [0.81-0.86]) and hypertension (1.13 [1.11-1.15]).

Conclusion: This study highlights that in clinical practice the use of SUs has declined over time in all CVD risk groups, but the current use of SUs is still quite high and similar to patients who do not have established CVD or risk factors for CVD, despite recommendations against such use in the ADA/EASD guidelines. Future research examining the association between patient's co-morbidities at baseline and new SU prescriptions is needed as well as the impact of SU use on outcomes in high risk patients.

1113

National Diabetes Action Programme: a monitoring study regarding the Dutch care standard for diabetes among health care professionals and patients

L.G.M. Raaijmakers[1], M.K. Martens[2], A.E. Hesselink[2], I. de Weerdt[3], M.A. Jebbink[3], S.P.J. Kremers[1];
[1]Health Promotion, NUTRIM School for Nutrition, Toxicology and Metabolism, MUMC+, Maastricht University, [2]ResCon Research & Consultancy, Amsterdam, [3]Netherlands Diabetes Federation, Amersfoort, Netherlands.

Background and aims: The National Diabetes Action Program (2009-2013) was carried out with funding of the ministry of Health, Welfare and Sport. The main objective of the action program is the systematic implementation of the Care Standard (CS), an instrument for the content, organisation, quality and funding of diabetes prevention and care. The Netherlands can be regarded as unique in the use of the CS for prevention and care for diabetes. The CS is also translated for patients into the so called 'Zorgwijzer', describing what care should be provided. The aim of the present study was to suggest ways to optimise the implementation of the CS by examining the perceptions of Dutch health care professionals and diabetes patients regarding the CS and the delivery of care in accordance with the CS and the barriers to using it. In addition, we aimed to evaluate the efforts as part of the NAD until now.

Materials and methods: A cross-sectional questionnaire survey was conducted among health care professionals (N=1370) and diabetes patients (N=5650) between October 2012 and February 2013. In 2010 a similar study was conducted to monitor the action program. Two sample z-tests were conducted to assess the differences between both studies.

Results: In 2013, 43.7% of the professionals were in possession of the CS and 17.9% was unfamiliar with the CS. Only 18.1% of the professionals that were somehow familiar with the CS in 2013 perceived themselves as working completely in accordance with it. Professionals' familiarity with the CS has significantly improved compared to the monitor in 2010, when 37.6% was in possession of the CS. The majority perceived the CS as the norm for high quality diabetes care (92.6%), thought the CS made a major contribution to ensuring the quality of care (80.7%) and 78.7% judged the feasibility of working in accordance with the CS to be high. These scores were significantly higher compared to 2010. Logistic regression analyses showed significant differences in possession of the CS, working in accordance with the CS and appreciation of the CS between professional groups. The most important barrier professionals perceived was the care for groups that are difficult to reach, such as migrants or low SES patients. The majority of the professionals (80.4%) thought Dutch diabetes care has (strongly) improved since the past 2.5 years. Of the patients, 15.3% were in possession of the 'Zorgwijzer', while 40.4% was

unfamiliar with it. Patients were satisfied with their caregivers and perceived a high degree of autonomy support (M=4.1 (SD 0.8)) and self-management skills (M=4.1 (SD 0.7)) on a 5-point scale, but scored lower on perceived mastery (M=3.7 (SD 0.7)).
Conclusion: Overall, professionals were largely positive about the CS, although only a minority indicated that they were working completely in accordance with it. Professionals' perceptions regarding the CS have significantly improved compared to 2010 and the majority reported that diabetes care in general has improved in the past 2.5 years. Patients were generally satisfied with their care. Attention for the most important perceived barriers is however needed to further optimise the delivery of care and maintain the positive trend.

Differences in healthcare professionals' perceptions of diabetes healthcare provision in the DAWN2 study
R.I.G. Holt[1], K. Kovacs Burns[2], A. Forbes[3], N. Hermanns[4], S. Kalra[5], B. Kulzer[4], M. Massi Benedetti[6], A. Mayorov[7], N. Munro[8], A. Nicolucci[9], S. Skovlund[10], J. Wens[11], M. Peyrot[12], DAWN2 Study Group;
[1]Human Development and Health Academic Unit, University of Southampton, UK, [2]Edmonton Clinic Health Academy, Edmonton, Canada, [3]Kings College London, UK, [4]Diabetes Zentrum, Bad Mergentheim, Germany, [5]Bharti Hospital and BRIDE, Karnal, India, [6]UBF for International Health Research - HIRS, Perugia, Italy, [7]National Endocrinology Research Centre, Moscow, Russian Federation, [8]University of Surrey, Guildford, UK, [9]Consorzio Mario Negri Sud, Santa Maria Imbaro, Italy, [10]Novo Nordisk, Bagsværd, Denmark, [11]University of Antwerp, Belgium, [12]Loyola University Maryland, Baltimore, USA.

Background and aims: The 2nd Diabetes Attitudes, Wishes and Needs (DAWN2) study sought cross-country comparisons of healthcare provision for benchmarking of clinical practices. The study aimed to identify any differences in attitudes between different healthcare professional (HCP) disciplines towards diabetes healthcare.
Methods: 4785 HCPs (2066 primary care physicians, 1350 diabetes specialists, 827 nurses, 542 dieticians) from 17 countries across 4 continents completed an online questionnaire to assess healthcare provision, self-management and training between March and August 2012.
Results: There were significant differences between professional disciplines in most components of the survey. There was agreement, however, that people with diabetes needed to take more responsibility for their diabetes by becoming more active, maintaining a healthy weight and taking their medications as recommended. The greatest discrepancies between professions were in the areas of attendance for professional training in medical management of diabetes and healthcare organisation. The table shows the results to the survey questions by discipline where >5% of the variance in responses was explained by professional discipline - see Table: HCPs indicating this as an area of concern is shown as clustered mean, then % (95% CI). Nurses and dieticians expressed a greater need than GPs and specialists for better access to communication training and psychological care. Overall the rate of HCPs attending professional training for a better management of psychological aspects of diabetes was low, particularly for GPs. It was surprising that less than half of HCPs had attended training in the provision of diabetes self-management education. Members of all professional disciplines agreed that there was a need for better communication skills and better access to psychological treatments.
Conclusion: This survey has highlighted the similarities and differences in concerns of diabetes HCPs regarding diabetes healthcare provision, self-management and training. Understanding these differences in several areas will allow for better interdisciplinary working.

Table.

Question	Clustered mean	Specialists	GPs	Nurses	Dieticians	Variance explained by discipline
Healthcare organization: better access to psychologists	62.6	63.5 (53.5-72.4)	48.9 (38.8-59.0)	71.1 (61.8-78.9)	65.9 (55.9-74.7)	5%
Healthcare organization: formal training in effective communication	67.5	65.5 (55.2-74.6)	54.2 (43.4-64.5)	73.6 (64.2-81.2)	74.7 (65.4-82.2)	5%
% Attending professional training in provision of diabetes self-management education	35.4	41.1 (30.9-52.1)	23.8 (16.7-32.8)	45.8 (35.0-57.0)	32.9 (23.7-43.7)	6%
% Attending professional training in management of psychological aspects of diabetes	19.7	26.3 (18.2-36.4)	13.3 (8.7-19.8)	27.1 (18.8-37.4)	15.2 (9.9-22.7)	6%
% Attending no professional training	19.5	11.5 (7.2-18.0)	23.5 (15.5-34.0)	29.3 (19.7-41.0)	16.7 (10.6-25.5)	7%
% Attending professional training in medical management of diabetes	64.5	78.4 (59.7-89.9)	67.4 (45.7-83.5)	47.1 (26.6-68.6)	31.8 (15.9-53.5)	20%
% Attending professional training in dietary/ nutritional management of diabetes	57.1	58.1 (42.8-72.1)	42.6 (28.5-57.9)	49.4 (34.4-64.6)	75.6 (62.3-85.4)	11%

1115

Emergency medical identification use in adults with diabetes
P.L. Kapsner, H.P. Nguyen, C.A. Soller, J.P. Torres;
Internal Medicine/Endocrinology, University of New Mexico HSC, Albuquerque, USA.

Background and aims: Emergency medical identification (ID) is recommended for use by patients with diabetes. Prior studies show awareness of emergency medical ID and its importance among emergency providers. The purpose of this study is to characterize adherence of emergency medical ID use, types used, and reasons for non-adherence among adult patients with diabetes.
Materials and methods: Questionnaires were given to patients at a diabetes comprehensive care center in a university hospital. The survey was comprised of questions regarding the use of emergency medical ID, type used, if not used reasons why, and demographic information.
Results: The study population (N=185) were 57% female, 75% in the age range of 36-65 years old, 65% had type 2 diabetes, and 73% were on insulin therapy (Table). Most patients (87%) agreed with the importance of the use of emergency medical ID. Only 47% of patients carried or wore one, and only 25% were the jewelry type which would be more readily visible. Over half reported the barrier to use as lack of awareness with only 7% reporting concern for privacy. Cost was a factor in 19% of those patients who did not use emergency medical ID (Table). Patients with type 1 diabetes and patients on insulin therapy were more aware of the use of emergency medical ID and more likely to use it. In patients with type 1 diabetes, 64% reported using emergency medical ID compared to 42% of patients with type 2 diabetes, $p<0.05$. Visible emergency medical ID (jewelry) was reportedly used by 28% of patients with type 1 diabetes and only in 14% of patients with type 2 diabetes, $p<0.05$. In patients with type 1 diabetes, 29% reported no provider recommended the use of emergency medical ID as the reason for not using it, compared to 56% in patients with type 2 diabetes, $p=0.05$.
Conclusion: Medical providers and patients with diabetes agree as to the importance of the use of emergency medical ID. More patients with type 1 diabetes are aware of the recommendation to use emergency medical ID and are more adherent to the use of it, especially visible emergency medical ID (jewelry) compared to patients with type 2 diabetes. As unawareness of emergency medical ID use was the main reason for not using it, discussion of this with patients with diabetes may improve awareness and adherence to emergency medical ID use.

Table. Characteristics and medical ID use and reasons for non adherence in percentage (N=185)

	Characteristic	Any ID	Jewelry	No ID	Nobody Recommended it	Cost to much	Don't know where to buy	Don't want everyone to know medical problem	ID is important
All		47	25	53	53	19	21	7	87

Optimal target range for blood glucose in hyperglycaemic patients in a neurocritical care unit

P. Wang, Y.-J. Guo, Y. Zhou, S.-Y. Zhang, Q. Wei, Y. Huang, W.-Q. Xia, S.-H. Wang;
Affiliated ZhongDa Hospital of Southeast University, Nanjing, China.

Background and aims: Hyperglycemia is common among patients with critical neurological injury, even if they have no history of diabetes. The optimal target range for normalizing their blood glucose is unknown.
Materials and methods: Two groups were divided according to retrospective data, which were extracted from 890 hyperglycemic patients admitted to our neuroscience critical care unit (NCCU) with targeted blood glucose levels of 180 mg/dL: intensive control to ≤ 140 mg/dL, moderate control to 140-180 mg/dL. The groups were stratified according to the hyperglycemia type (pre-existing diabetes or stress-related). We defined the primary endpoint as death from any cause during NCCU admission.
Results: In the NCCU, tighter control of blood glucose at ≤ 140 mg/dL increased the mortality of the preexisting diabetic patients compared with moderate control (29 of 310 patients [9.4%] vs. 15 of 304 patients [4.9%], P =0.034). Patient age (adjusted odds ratio [OR] = 1.12; 95% confidence interval [CI] = 1.05-1.19; P < 0.001), level of glycated hemoglobin (adjusted OR = 1.24; 95% CI = 1.04-1.48; P = 0.017) and hypoglycemia (adjusted OR = 10.3; 95% CI = 2.92-36.6; P < 0.001) were positively associated with higher mortality. Death decreased among the stress-related hyperglycemic patients with tighter glucose controlled at ≤ 140 mg/dL (6 of 140 patients [4.3%] vs. 15 of 136 patients [11.0%], P = 0.035).
Conclusion: The blood glucose levels of hyperglycemic NCCU patients with pre-existing diabetes or stress-related hyperglycemia should be normalized at 140-180 or ≤ 140 mg/dL, respectively.

Table 1. Baseline Characteristics of the Study Patients

	Diabetic mellitus		Stress hyperglycemia	
	Intensive Glucose Control (n=310)	Conventional Glucose Control (n=304)	Intensive Glucose Control (n=140)	Conventional Glucose Control (n=136)
Age (year)	68.9±14.4	67.5±16.5	68.1±16.8	69.8±16.1
Hb_{A1c} (%)	10.8±2.7	10.7±3.0	5.4±0.7	5.3±0.6
NIHSS score (n)	13.5± 4.6 (278)	13.4±3.3 (273)	13.4±3.5 (126)	13.4±3.1 (122)
Treated with insulin (n, %)	276, 89.0**	189, 62.2	113, 80.7**	78, 57.4
Fasting blood glucose (During admission)	131±18**	164±21	124±19**	163±26
Infection with detectable septic focus (n, %)	94, 30.3*	117, 38.5	45, 32.1	57, 41.9
Severe hypoglycemia (n, %)	18, 5.8**	0	8, 5.7*	0
Death (n, %) During NICU admission	29, 9.4*	15, 4.9	6, 4.3*	15, 11.0
Death (n, %) During in-hospital admission	33, 10.6	20, 6.6	9, 6.4	18, 13.2

Data were presented as mean ± SD or frequencies. *P <0.05, ** P <0.001 compared with conventional glucose control of diabetic mellitus or stress hyperglycemia. NIHSS represents National Institutes of Health Stroke Scale score on admission.

1117

Predictors of medication usage for incident diabetes patients: a SUrveillance PREvention and ManagEment of Diabetes Mellitus (SUPREME-DM) study

J. Schmittdiel[1], J. Steiner[2], W. Dyer[1], P. O'Connor[3], J. Segal[4], L. Kirschner[5], E.B. Schroeder[2], G. Goodrich[2], M. Butler[6], M. Raebel[2];
[1]Kaiser Permanente Northern California Division of Research, Oakland, [2]Kaiser Permanente Colorado Institute for Health Research, Denver, [3]HealthPartners Institute for Education and Research, Bloomington, [4]Johns Hopkins University, Baltimore, [5]Geisinger Health System, Danville, [6]Kaiser Permanente Georgia Center for Health Research Southeast, Atlanta, USA.

Background and aims: Patients with diabetes use numerous medications to control blood glucose and treat comorbid conditions. However, no studies have documented the specific level and correlates of medication usage in the U.S. diabetic population, or trends in medication usage over time. By leveraging a large national sample of incident diabetic patients (the SUPREME-DM DataLink), this study aims to examine prescription drug usage pre- and post-diabetes diagnosis; determine patient-level correlates of drug usage; and examine if drug usage is changing over time.
Materials and methods: We analyzed data from a longitudinal, observational cohort study of 196,654 incident diabetes patients from 11 U.S. integrated health care delivery systems. Patients were included if they were ages 20 and above diagnosed with incident diabetes from January 1, 2005-December 31, 2010. We calculated overall medication usage using therapeutic classes defined by the American Hospital Formulary Services (AHFS) classification system for each patient in the 12 months prior to, and the 12 months following, their incident diabetes diagnosis date. We defined overall drug usage as the total number of therapeutic classes a patient had taken in each period. We also calculated the usage of 4 specific therapeutic classes: antihyperglycemic, antihypertensive, antihyperlipidemic, and mental health medications. A multivariate linear regression model was used to examine the relationship between the total number of therapeutic classes in the 12 months post-diabetes diagnosis and year of diagnosis; gender; age; race/ethnicity; baseline A1c value; and body mass index (BMI); and diagnosis of depression, hypertension, and/or hyperlipidemia within 2 years prior to diabetes diagnosis.
Results: Mean patient age was 58.6 years; 48% were female; 47% were white; and mean baseline A1c value was 58 mmol/mol. In the 12 months prior to diabetes diagnosis, patients used a mean of 5.72 drug classes, 0.35 mental health, 1.24 antihypertensive, and 0.39 antihyperlipidemic therapeutic drug classes. In the 12 months post-diabetes diagnosis, these averages increased to 7.97 total (including 0.60 antihyperglycemics), 0.39 mental health, 1.54 antihypertensives, and 0.74 antihyperlipidemic drug classes (p<.0001 for all pre vs. post comparisons). In the multivariate model, overall drug usage after diabetes diagnosis decreased by almost one therapeutic class (coefficient =-0.98, p<.001) between 2005 and 2009. Drug usage increased significantly with greater patient age, baseline A1c level, and BMI; and was lower for Hispanics, African-Americans, Asians, and Pacific Islanders compared to Whites.
Conclusion: Data from a large U.S. sample of incident diabetes patients suggests medication usage for these patients is high prior to diagnosis and increases substantially afterwards, primarily due to increases in antihyperglycemics and other cardiovascular disease risk factor medications. However, total drug usage appears to be decreasing over time.

Process- and intermediate outcome indicator results in the 2011 LOK survey (DUDE-2)

H.J.G. Bilo[1,2], M. Meulepas[3], A. Romeijnders[4], M. Klomp[5], S.T. Houweling[1,6], N. Kleefstra[1,2];
[1]Diabetes Centre, Isala Clinics, Zwolle, [2]Internal Medicine, University Medical Center Groningen, [3]Meetpunt Kwaliteit, Eindhoven, [4]Praktijkondersteuning Zuidoost-Brabant, Veldhoven, [5]Landelijke Organisatie Ketenzorg, Utrecht, [6]Medical Research Group, Langerhans, Zwolle, Netherlands.

Background and aims: In the Netherlands, professional health care organisations, patient organisations, insurance companies and regulatory agencies aim to assess the quality of diabetes care. The Landelijke Organisatie Ketenzorg (LOK (Dutch initiative for shared care organisations)) has initiated data collection over larger groups of subjects in the years 2010 and 2011, concentrating on subjects with type 2 diabetes (T2DM), treated in shared care

groups within a primary care setting. Information is collected (partly) based on the "kernset DM" ("core data set" (CDS)), which is supported by the relevant organisations mentioned above.
Materials and methods: All shared care groups were invited to voluntarily submit relevant information to the LOK; 66 out of a total of more than 100 did so with sufficient information to allow at least partial analysis of the known information. These 66 groups reported regarding 380,688 subjects with DM, as treated within the shared care environment, out of a grand total of 439,956 reported with DM. 54 groups also provided sufficient information regarding their total population (7,266,316). Data were analyzed as part of the DUDE-initiative (DUtch Diabetes Estimates).
Results: Results are observational and self-reported, which might lead to bias. Selection of main findings in 2011: in 380,688 subjects in 66 groups, HbA1c was measured in 91.7±6.7% (mean±SD, comparing groups), HbA1c was <7% in 68.5±7.6%; LDL < 2.5 mmol/l was reached in 52.7±6.3%, and lipid-lowering drugs prescribed in 63.6±14. Urine analysis was performed in 78.7±14.4%. BP could be traced in 92.5±5.8%, a BP<140 mmHg reported in 54.8±5.7%; fundus control in 74±14.8%, foot control in 68±15.9%. Part of the low score and high standard deviation in some items proved to be due to insufficient reporting.
Conclusion: In general, diabetes care within shared care groups is well organized, with overall good to excellent results. Still, improvement can be made both in actual care and noting down and properly reporting activities. LOK initiatives are ongoing to support lower-than-average performing groups in learning from better-than average performing groups.

1119

European vs non-European HCP attitudes and practices: results from DAWN2

S. Kalra[1], M. Comaschi[2], A. Forbes[3], R.I.G. Holt[4], E. Menéndez Torre[5], N. Munro[6], J. Salles[7], I. Tarkun[8], J. Wens[9], I. Willaing[10], M. Peyrot[11], DAWN2 Study Group;
[1]Bharti Hospital, Karnal, India, [2]ICLAS, Rapallo, Italy, [3]Kings College London, [4]University of Southampton, UK, [5]Hospital Central de Asturias, Oviedo, Spain, [6]University of Surrey, Guildford, UK, [7]Santa Casa de São Paulo Medical School, São Paulo, Brazil, [8]Kocaeli University, Kocaeli, Turkey, [9]University of Antwerp, Belgium, [10]Steno Diabetes Center, Gentofte, Denmark, [11]Loyola University Maryland, Baltimore, USA.

Background and aims: The 2nd DAWN (Diabetes Attitudes, Wishes, and Needs) study assessed healthcare provider (HCP) attitudes and practices regarding psychosocial issues faced by adults with diabetes across 10 European and 7 other (Algeria, Canada, China, India, Japan, Mexico, USA) countries.
Materials and methods: ≥4785 HCPs caring for people with diabetes - comprising general practitioners, specialist physicians (endocrinologists and diabetologists), diabetes nurses and dietitians - participated in an online survey; each country generated a parallel sample. Data were ranked across the nations to compare highest (rank = 1) and lowest (17) responses to each question and identify between-country variances.
Results: Highest between-country variance was for opinions related to healthcare organisation (HCO) (13-23%); least variance was for need for more training (2-7%). All numbers reported are relative ranking among the 17 nations. HCPs from European countries fared better than other countries in discussing emotional issues (France-1, Germany-3) and involvement and empowerment of people with diabetes (PWD; Poland-2, Netherlands-3). Healthcare organization was rated better in Europe (Netherlands-1, Denmark-3), as assessed by a lower perceived need for: more qualified nurses (Denmark-1, Netherlands-2); better communication between HCPs (Denmark-1, Netherlands-2, Germany-3); improved access to psychologists (Netherlands-2, Denmark-3). Involvement of PWD (Russia-1, Spain-2, Poland-3) and family members (FM; Russia-2, Turkey-4) by HCPs is rated higher in Europe. Societal discrimination against PWD was less in Europe (UK-2, Denmark-3); only Poland (15) reported high levels. European HCPs do not fare as well in postgraduate training (PT): Danish and German HCPs score 2 and 3 in attending PT, but Spain (17), Russia (14), France (12) and Italy (11) score lowest. Fewer European HCPs attend PT in the medical management of diabetes (only Denmark-1 figures in the top 3), nutritional management (only Poland-2 is in top 3), or provision of diabetes self-management education (SME; Denmark-2). PT for psychological management was more common in Europe (Poland-2, Netherlands-3), as was 'effective communication and motivation strategies to support long-term behavior change' (Denmark-1, Netherlands-2, Germany-3). Non-European countries may exemplify better attitudes and practices towards psychological support (India-1, Mexico-3). These countries, along with Turkey (2), also report more optimal SME; HCP collaboration and formal training; and involvement of FM. Availability of reimbursement is better in Canada (1) and China (3) than most European countries except Denmark (2).
Conclusion: These data may facilitate best practice sharing and help improve global diabetes care delivery. Other countries can learn from PWD and FM involvement in European HCO. European countries should work to improve support in providing psychological care, SME, HCP collaboration/formal training, and FM involvement.

PS 093 Type 1 diabetes education

1120

A randomised controlled trial of an internet-based mentoring programme for type 1 diabetes patients with inadequate glycaemic control

S. Suh[1], S.M. Park[2], T. Kim[2], S.M. Jin[2], J.C. Bae[2], K.Y. Hur[2], M.K. Lee[2], J.H. Kim[2];
[1]Division of Endocrinology and Metabolism, Department of Internal Medicine, Dong-A University Medical Center, Busan, [2]Division of Endocrinology and Metabolism, Department of Internal Medicine, Samsung Medical Center, Seoul, Republic of Korea.

Background and aims: This study is to determine whether an internet based mentoring program can improve glycemic control in subjects with type 1 diabetes mellitus (T1DM).
Materials and methods: Subjects with T1DM on intensive insulin therapy and with HbA1c ≥ 8.0% were randomized to mentored (glucometer transmission with feedback from mentors) or control (glucometer transmission without feedback) groups for 12 weeks. Five mentors were interviewed and selected. Two were T1DM patients themselves and three were parents of at least one child diagnosed with T1DM for more than 5 years ago.
Results: A total of 57 T1DM adult subjects with a mean diabetes duration of 7.4 years were recruited. The mentored group failed to show significant improvements in HbA1c levels or other outcomes, including quality of life, after completion of the study. However, the frequencies of blood glucose monitoring (1.41 vs. 0.30) and website logins (20.59 times vs. 5.07 times) were higher than in the control group.
Conclusion: A 12-week internet-based mentoring program for T1DM patients with inadequate glycemic control did not prove superior to the usual follow-up. However, the noted increase in the subjects' frequency of blood glucose monitoring may lead to clinical benefits.
Clinical Trial Registration Number: NCT01157611

Background and aims: The application of interactive telematic systems between the patient-healthcare team may improve the cost-effectiveness of healthcare programmes for the optimization of metabolic control in persons with diabetes. To evaluate the impact of the Medical Guard Diabetes® telematic system on the economic and clinical management of human resources and material used in a programme of optimization of metabolic control in patients with type 1 diabetes mellitus (DM1).
Materials and methods: This prospective, randomized, comparative, open, multicentre 6-month study included patients with DM1 >18 years of age receiving treatment with multiple insulin doses (MID) and HbA1c >8%. An intervention group (IG) (two face-to-face and 5 telematic appointments) was compared with a control group (CG) (7 face-to-face appointments). The variables studied were: 1) patient and healthcare team costs, 2) metabolic control 3) knowledge of diabetes 4) quality of life and 5) treatment self-care adherence.
Results: 118 (76.6 %) of the 174 patients included completed the study (IG: 54, CG: 64). The time (minutes) used by the patients to follow the programme in the CG was 823.7 ± 645.81 vs. 353.6 ± 222.2 in the IG (p <0.0001). Compared with the CG, the IG required less healthcare time from the professional (288 ± 105 vs. 232 ± 89, p=0.0001).

The following table shows the remaining variables studied in both groups:

Study Group	CG		p	IG		p
Months	0	6		0	6	
HbA1c (%)	9.1 ± 0.9	8.5±0.9	.000	9.1±1.4	8.6±1.5	.000
Knowledge (DKQ2)	24.7 ± 4.3	26.7±4.0	.000	24.7±4.4	26.3±4.5	.006
Quality of life (EuroQol)	67.1± 17.7	66.8± 17.3	.922	64.5± 17.9	69.9± 18.7	.904
Adherence (SCI-R) (%)	64.1 ± 10.7	69.8 ± 9.6	.000	61.2± 11.9	66.1± 11.0	.003

Conclusion: The use of interactive telematic appointments in subjects with DM1 treated with MID and inadequate metabolic control is an efficient strategy, providing comparable results to those of face-to-face appointments in relation to improvement in glycaemic control, acquisition of knowledge and treatment self-care adherence, with a significant reduction in the time used, especially by the patient, without a change in quality of life perception.

Evaluation of a 5 days education programme by regards to individualised patient target for patients with type 1 diabetes

M. Halbron[1], C. Sachon[1], T. Obadia[2], D. Simon[1], V. Quiniou[1], A. Grimaldi[1], A. Hartemann[1];
[1]Diabetes and Metabolic Diseases Department, AP-HP, Groupe Hospitalo-Universitaire Pitié-Salpétrière, Paris, [2]Unité de Santé Publique, INSERM/UPMC Paris 06, UMR-S 707, Paris, France.

Background and aims: The aim of our study was to see if the DAFNE model was adapted to the French clinical practice in routine health care delivery, and to evaluate if the same in-patient education training program in flexible intensive therapy (FIT) could achieve individualized therapeutic targets according to different typologies of patients.
Materials and methods: Prospective, observational monocentric study (Dec 2009-Dec 2010). All patients with type 1 diabetes participating in our educational FIT program were consecutively included.Patients have attended the same educational program (5 days) but were sub- divided in 3 groups according to their main goal: decrease HbA1c for patients with baseline HbA1c ≥ 7.5 % (58 mmol/mol) and no recurrent hypoglycaemia Group 1 (G1;n=74), improve diet flexibility and quality of life without worsening glycaemic control in patients with baseline HbA1c <7.5% (58 mmol/mol) and no recurrent hypoglycaemia Group 2 (G2;n=12) and decrease frequency of hypoglycaemia in patients who had recurrent hypoglycaemic episodes (≥ 2 severe hypoglycaemia in the preceding year or more than 5 episodes of minor hypoglycaemia per week) Group 3 (G3;n=35).Clinical data were collected at baseline and 12 months and quality of life and treatment satisfaction were evaluated with ADDQoL,DTSQs and DSTQc questionnaires at baseline and after 6 months.
Results: Baseline characteristics: 121 patients, mean duration of diabetes 19.7 ± 12.5 years,mean HbA1c 8.3± 1.5%(68 ± 16 mmol/mol).113 patients out of 121 had already a basal bolus insulin therapy with long acting analogue insulin or SCII therapy (n=17). In G1, mean HbA1c decreased significantly from 9.0 ±1,4 % (75 ± 15mmol/mol) to 8,4 ±1,4 % (68 ±15mmol/mol)(p=0.0004) and 53% of patients experienced a fall by 0.5% or more in HbA1c level. This decrease occurred without weight gain or more frequent hypoglycaemia. In the sub group of patients with at least a 0.5% decrease in HbA1c, global perception of quality of life assessed by overview I item (ADDQol) statistically improved between baseline and M6 (mean OvI Baseline= 0.46; mean OvI M6= 0.94; Δ=0.43; p=0.01) so did satisfactions treatment assessed with DSTQc score:2.04. Baseline HbA1c was the only predictable factor of success in G1 (OR=1.7 [1.08 ; 2.66] for an 1% increase). In G2, patients' satisfaction with treatment improved significantly after the program,DTSQc score: 2.17 [1.57;2.77] p<0.0001.The programme did not modify perception of dietary freedom. In G3, minor hypoglycaemia significantly decreased from 6.6 ± 4.7 to 3.2 ± 3 hypos/week p<0.001 and incidence of severe hypoglycaemia dropped significantly from 2.31 to 0.86 Ev/Patients/Year (E/P/Y) p<0,001. Among patients who had at least 2 severe hypoglycaemia in the past year, the rate of severe hypoglycaemic attacks significantly decreased from 4.6 ± 3.0 to 1.30 ±3.3 E/P/Y; p=0.0019.Patients felt more comfortable with their treatment and changes in perception of treatment were positive:DTSQc=1.91[1.5;2.3] p<0.0001.
Conclusion: Our study shows that the outcomes seen in DAFNE and Dusseldorf studies can be achieved in the clinical French routine hospital care, and that a patient-centered approach can solve different patient's problem and is appropriate even when patients with different primary outcome criteria attend the same FIT program.

Gender differences in the effect of motivational interviewing and cognitive behavioural therapy in Austrian adolescents with type 1 diabetes

G. Berger[1], F. Brunmayr[2], M. Muehlehner[1], T. Waldhoer[3], C. Wondratsch[1], M. Koenig[1], E. Horak[1], G. Wagner[2], M. Fritsch[1], T. Hoertenhuber[1], B. Rami-Merhar[1], E. Schober[1];
[1]Department of Pediatric and Adolescent Medicine, [2]Department of Child and Adolescent Psychiatry, [3]Department of Epidemiology, Medical University Vienna, Austria.

Background and aims: Living with diabetes is a challenge especially for chronically ill adolescents who are known to show decreased dedication to their diseases´ therapy during the period of adolescence. Deterioration of metabolic control is common and cannot only be explained by physiological changes in puberty, also psychological factors are contributing. The aim of our study was to assess the changes in metabolic control after a psychological intervention with elements of motivational interviewing (MI) and cognitive behavioral therapy (CBT) in adolescents with poorly controlled type 1 diabetes (T1DM) after 6 months of intervention in a randomized controlled trial
Materials and methods: 151 consecutive T1DM patients, age 13-20 years, diabetes duration >1 year and Hba1c >8% in the in the past year from 5 diabetes outpatient clinics in Austria were eligible to participate in this study. 39 refused participation, 37 could not be reached or did not attend their scheduled outpatient controls. 75 patients (male n=32) were included in the study. Participants were matched for age, sex and contributing clinic and randomly assigned to an intervention group (n=40) and a control group (n=35). In the intervention group (IG) 12 sessions of 45-60 minutes (4 sessions of motivational enhancement therapy, 8 sessions of cognitive behavioral therapy) and 10 supportive email exchanges performed by specially trained clinical psychologists were accomplished during a time span of 6 months. In the control group (CG) treatment as usual was performed with an additional offer of a fortnightly email contact. Hba1c was assessed before participation and within 4 weeks after completing the intervention. Groups were compared by using chi2-test, t-test and Wilcoxon test for statistical analysis.
Results: There was no significant improvement in metabolic control in either of the groups after intervention (IG 9.95% vs. 9.74%, p=.412; CG 9.25% vs. 9.18%, p=.978). When separated for gender, boys in the IG showed improvement in HbA1c after the intervention (9.74% vs. 9.14%, p=.017), girls did even slightly increase their HbA1c (10.09% vs. 10.14%, p=.475). The gender difference of the change of HbA1c in the IG was significant (p=.023) with -0.60% in boys vs. +0.05% in girls. In the CG and in refusing patients no significant change of HbA1c was found in either gender.
Conclusion: A six month intervention with MI and CBT showed different changes in metabolic control according to gender. While a moderate improvement was observed in boys, girls did not benefit directly after intervention. Long term effects will be observed.

Do young adults with poorly controlled type 1 diabetes benefit from a flexible nurse-led guided self-determination intervention? Results of a randomised controlled trial

V. Zoffmann, D. Vistisen, M. Due-Christensen;
Steno Diabetes Center, Gentofte, Denmark.

Background and aims: Psychosocial distress combined with impaired glycaemic control is common among young adults with type 1 diabetes (T1D). As these patients have poor prognosis due to early appearance of late complications and poor quality of life, health promoting and preventive interventions tailored young adults are needed. However, such interventions are difficult to implement as an integral part of clinical practice. As a solution we offered an autonomy supportive intervention, Guided Self-Determination (GSD), in a flexible nurse-led program for young adults with poorly controlled T1D. Eighteen months results available primo September will be presented.
Materials and methods: January 2010 - February 2012 we invited young adults with T1D (18-35 years, diabetes duration > 1 year and HbA1c ≥ 64 mmol/mol) at two diabetes clinics in the capital region of Denmark to participate in a waitlist trial randomized 2:1 to GSD immediately (intervention) or 18 months delayed (control). GSD advocates person-centred care using reflection sheets filled in by patients before appointments with GSD-trained nurses who use advanced communication skills in mutual problem solving of person-specific difficulties. Evidence of risks entailed to high and low blood glucose is translated to patients in a meaningful way enabling them to choose self-concordant goals in glucose-management. HbA1c was measured at baseline and every three months (primary outcome). Questionnaires with psychometric scales were answered at baseline before randomisation and again after 9 and 18 months (secondary outcomes). Analyses include repeated measurement analysis.
Results: 201 young adults (101 male) mean age 25.7(5.1), diabetes duration 13.7(6.8) were randomized to intervention (n=135) or control group (n=66). Overall at baseline participants had a mean HbA1c 81.3(15.1) mmol/mol/9.6(1.3) % and 30.3 % had complications. The patients' psychosocial functioning showed a mean of 24.8(6.5) in perceived competence in managing diabetes (PCD), 35.9(21.5) in burden experienced from diabetes-related problems (PAID), 28.4(5.8) in autonomy supportive climate with health professionals (HCCQ), 20.9(6.0) in self-esteem (RSES), 55.2(19.4) in well-being (WHO-5) and concerning amount and kind of motivation (TSRQ) mean 44.2(7.1) in autonomous, 37.1(10.8) in controlled and 9.9(5.1) in amotivation. Continuous Subcutaneous Insulin Infusion (CSII) was used by 15.9% and self-monitored glucoses (SMBG) were measured 23.4(21.7) times weekly in average. No baseline differences were seen between intervention and control groups concerning primary and secondary outcome measures. Among all participants significant differences were seen between men and women at baseline. Compared to men women perceived higher degree of burden from diabetes-related problems (PAID mean 43.2(22.2) vs. 28.7(18.2)), lower competence in managing diabetes, (PCD mean 22.9(6.7) vs. 26.6(5.8)) and lower self-esteem (RSES mean 19.1(6.1) vs. 22.7(5.4)) all p<0.001. Women more frequently used CSII and measured more SMBG weekly, 29.7(25.3) vs.16.6(14.2) both p<0.001.
Conclusion: Male and female young adults with poorly controlled type 1 diabetes are equally willing to participate in a nurse-led GSD program. Results will determine the effectiveness of such an intervention both concerning glycemic control and psychosocial functioning.

A cross country qualitative investigation of structured education programmes for adults with type 1 diabetes

M. O' Hara[1,2], M. Byrne[3], J. Lawton[4], U. Müller[5], N. Müller[5], F. Zillich[5], P. Mansell[6], I. Lawrence[7], S.R. Heller[8], S.F. Dinneen[1,2], E. O' Shea[9], for the Irish DAFNE Study Group;
[1]School of Medicine, Clinical Science Institute, NUI Galway, [2]Endocrinology and Diabetes Centre, Galway University Hospitals, [3]School of Psychology, NUI Galway, Ireland, [4]College of Medicine and Veterinary Medicine, The University of Edinburgh, UK, [5]Endocrinology and Metabolic Diseases, Internal Medicine III, University Hospital Jena, Germany, [6]School of Biomedical Science, University of Nottingham, [7]Department of Diabetes and Endocrinology, University Hospitals of Leicester NHS Trust, [8]Department of Human Metabolism, University of Sheffield, UK, [9]School of Business and Economics, NUI Galway, Ireland.

Background and aims: Type 1 diabetes (T1D) is associated with huge human and economic costs. T1D, its treatment and the skills necessary to self-manage are similar across the world but interventions and related outcomes are varied. Since the introduction of structured education programmes (SEPs) in Germany in the 1970s such programmes have been widely adopted. The aim is to explore differences and similarities in outcomes in relation to the self-management behaviours of people with T1D in 3 different cultures and healthcare systems to identify the "active ingredients" that lead to positive outcomes.
Materials and methods: Diabetes centres in Ireland (n = 7), the UK (n = 10) and Germany (n = 5) participated in this qualitative study which is embedded in a larger quantitative study, incorporating the Dose Adjustment for Normal Eating (DAFNE) programme in Ireland and the UK and the Insulin Training and Teaching Programme (ITTP) in Germany. Prior to completing a SEP, in-depth interviews were conducted with 16 patients and 4 educators in both Ireland and the UK and 13 patients and 2 educators in Germany. Repeat interviews were conducted 6 months after completing a SEP. NVivo, a qualitative software package was used to analyse the data.
Results: Patients' experiences around the time of their diagnosis appears to have an impact on their subsequent level of engagement with healthcare professionals and the health services. In some instances, patients described being initially misdiagnosed with type 2 diabetes or not being satisfied with the care

received from their diagnosing doctor, especially those who were diagnosed as children, particularly amongst UK participants. This led to many participants expressing feelings of "frustration", "bad first impressions" and "guilt". A pre-SEP knowledge difference is emerging among participants, with German participants expressing more in-depth understanding of their disease at baseline. Participants report dramatically increasing blood glucose (BG) diary usage, weighing foods and using BG corrections immediately following SEP. Many Irish and UK participants express a degree of frustration with this flexible intensive insulin approach, saying that while they enjoy more "freedom" they express a sense of loss to the more conventional fixed, "routine" approach. German patients by comparison were happier with the flexible approach.

Conclusion: Identifying differences across countries and understanding why these differences occur will help identify what are the "active ingredients" of a SEP to inform the development of more effective programmes and to help inform decision-makers of the most effective strategies to managing T1D.

Evaluation of a one day a week re-education course (EDWARD) for type 1 diabetes: 6-year follow up

E. Houghton[1], C. Soar[1], T. Cooper[1], S. Carr[2], W. Jeffcoate[1];
[1]Diabetes and Endocrinology, Nottingham University Hospitals Trust, [2]Academic Unit of Psychology, University of Southampton, UK.

Background and aims: To evaluate the EDWARD (Education for Diabetes without a Restrictive Diet) course. This structured education course was established in 2005 for people with Type 1 diabetes and who were already using a basal-bolus insulin regimen. One day group sessions were held weekly for four weeks, to allow consolidation of new knowledge between sessions. Topics focused on carbohydrate counting, with general information about diabetes and complications.

Materials and methods: Outcomes were examined in all those attending between 2005 and 2011, with follow-up to July 2012. Multiple measures were determined at baseline, 3, 6 and 12 months from completion of the course. HbA_{1c} was also determined annually for up to 6 years.

Results: (a) Follow-up over 12 months: Of 489 (52% male) who attended at least one session, median (range) age was 39 (17-77) years, and diabetes duration was 14 (<1-58) years. Median HbA_{1c} was 74 mmol/mol (8.9%) at baseline and 69 (8.5%) (2-tailed paired t-test, 70 (8.6%) and 72 (8.7%) at 3, 6 and 12 months (ANOVA p<0.00625). Between baseline and 12 months there was a fall in short acting insulin dose from mean 34 to 29 units/day in men, and from 23 to 19 units/day in women (both p<0.01), but none in the dose of basal insulin. Estimated mean daily blood tests rose by almost 50% (p<0.001). There was no change in BMI. The incidence of episodes of hypoglycaemia was not documented. There were significant falls in HADS scores for both anxiety and depression (p<0.001), although baseline results were within the normal range (anxiety baseline 5.52 men, 6.97 women; depression 3.41 and 4.07). There were similar falls in all domains of PAIDS, but also from a low baseline. (b) Follow-up over 6 years: Median HbA_{1c} values at 2 (n=290), 3 (n=206), 4 (n=165), 5 (n=135), and 6 (n=81) years after completion of the course were 68 (p=<0.0083, 2-tailed paired t with Bonferroni correction), 69 (p<0.0083), 69 (p=0.170), 68 (p=0.028) and 69 mmol/mol (p<0.0083).

Conclusion: These data indicate that this model of weekly structured education is associated with significant changes in both metabolic control and well-being at 12 months, and that the fall in HbA_{1c} is maintained for up to 6 years. Consideration may be given to introducing refresher courses at 3 years.

1127

Midterm impact of a specially designed therapeutic education programme in patients transferred from a paediatric to an adult diabetes unit

M. Giménez[1], M. Vidal[1], M. Jansa[1], C. Yoldi[2], A. Gómez[2], M. Torres[2], I. Conget[1];
[1]Diabetes Unit. Endocrinology Dpt, Hospital Clinic i Universitari, [2]Pediatric Endocrinology, Hospital Sant Joan de Deu, Barcelona, Spain.

Background and aims: Type 1 Diabetes (T1D) management in young patients is a challenge and troublesome in adolescence and emerging adults. In this period, T1D patients are usually transferred to adult Diabetes Units. We aimed to evaluate the mid-term impact of a specially transition therapeutic education program (TEP) on metabolic control, self-management and quality of life (QoL) 1-year after the transfer T1D patients from a pediatric to an adult diabetes Unit.

Methods: We included 189 subjects with T1D (aged 18.0±1.1 years, 92 women, disease duration 7.9±3.8 years) consecutively transferred (2005-2011). The TEP included a co-ordinated transfer between the Units, individual visits and group sessions. At baseline, we registered data on BMI, insulin dose, HbA_{1c} and the frequency of hypoglycaemia. For evaluation of the QoL and knowledge in T1D management, self-report questionnaires were assessed. After 12-months, all subjects were re-evaluated.

Results: Our TEP reduced HbA_{1c} from 8.6±1.4 to 8.0±1.4 (p=0.02) with a concomitant decrease in hypoglycemic episodes (severe events per subject year, from 0.31±0.46 to 0.07±0.25 (p<0.001) and frequency of > 5 mild episodes/week, 9,4% to 6.5 % (p=0.04). The TEP improved the knowledge in diabetes management (DKQ2 score from 25.0±4.1 to 27.7±4.0) and increased the frequency of SMBG (20.5±8.6 to 22.7±7.3 determinations7week, p<0.01). TEP was also associated with an improvement in some aspects of Qol (Diabetes-related issues worrying, 8.7±3.4 to 7.4±2.3). The significant increase in the proportion of subjects with $HbA_{1c} \leq 7\%$, (from 15.2 to 26.2 %, p=0.02) was related to a lower HbA_{1c} (7.2±1.1 vs. 8.6±1.5 %,p<0.001) at entry and less duration of the disease (5.9±1.6 vs 8.1±3.7 years,p=0.001).

Conclusion: The use of a specific transition TEP improves metabolic control, self-management abilities and some aspects of diabetes-related QoL of young T1D subjects transferred from pediatric care to an adult diabetes unit.

1128

Influence of basal insulin regimen on outcome from structured education in type 1 diabetes

H.E. Hopkinson[1], R.M. Jacques[2], I. Lawrence[3], S.A. Amiel[4], P. Mansell[5];
[1]New Victoria Hospital, Glasgow, [2]School of Health and Related Research, University of Sheffield, [3]University Hospitals, Leicester, [4]King's College Hospital, London, [5]Queen's Medical Centre, Nottingham, UK.

Background and aims: There is little evidence on whether the type or frequency of injection of basal insulin (BI) influences outcomes after structured education in flexible intensive insulin therapy in people with type 1 diabetes. Early successful programmes such as the German ITT course were designed with twice daily BI using NPH insulin, but more recently once daily basal regimens, often with analogues, have been introduced. In current UK programmes such as DAFNE, clinicians and patients choose a BI regimen which may include long-acting analogue insulin once daily. This study investigates the relationship between BI regimen and outcomes.

Materials and methods: We analysed baseline and 12 month follow-up data from 10 UK centres enrolled in the DAFNE Research Database Study. Outcomes were assessed in relation to BI type and frequency of injection; using a linear multiple regression model for HbA_{1c} and negative binomial models for hypoglycaemia and diabetic ketoacidosis (DKA) data. All models used population-averaged exchangeable correlation and robust standard errors to allow for clustering by centre.

Results: 558 pairs of complete baseline and 12 month data were identified. The cohort was 49.6% male, mean age 41.9 years (SD 14.2) and mean duration of diabetes 17.4 years (SD 14.0). At 12 months the proportions of people using NPH, detemir and glargine were 17.2%, 41.0% and 41.8%. The proportion using twice daily BI rose (40.3% to 61.1% CI: -24.6% to -17.0%, p<0.001). HbA_{1c} for the cohort fell from 8.68% (SD 1.50) to 8.55% (1.47) (-0.12, 95% CI: -0.22 to -0.03, p=0.012) but with significant fall only in those on twice daily BI (twice daily baseline HbA_{1c} 8.62% (SD 1.38), 12 month HbA_{1c} 8.42% (SD 1.37) difference -0.19, 95% CI: -0.31, -0.07, p=0.002 vs. once daily baseline HbA_{1c} 8.79% (SD 1.68), 12 month HbA_{1c} 8.77% (1.60) difference -0.02, 95% CI: -0.18, 0.14, p=0.802). In the multiple regression model at 12 months, use of twice daily BI was associated with significantly lower HbA_{1c} than once daily (-0.19, 95% CI: -0.34 to -0.04, p=0.012). There was no significant difference in HbA_{1c} at 12 months between analogue and NPH basal regimens (0.12, 95% CI: -0.14 to 0.39, p=0.369), nor between glargine and detemir (0.00, 95% CI: -0.20 to 0.20, p=0.997), and no significant interaction between type of basal insulin and frequency of injection. All associations were independent of age and duration of diabetes. Severe hypoglycaemia (SH) reduced from 0.74 to 0.21 events per patient per year, an estimated relative risk for SH of 0.28 (95% CI: 0.19 to 0.42, p<0.001). DKA episodes per patient per year reduced from 0.07 to 0.03, an estimated relative risk of DKA of 0.36 (95% CI: 0.18 to 0.71, p=0.003) with no significant difference in the relative risk of SH or DKA by type or frequency of BI.

Conclusion: Outcomes from structured education in flexible insulin therapy may be in part related to choice of BI regimen, with twice daily basal regimens offering lower HbA_{1c} and equal benefit in reduced risk of SH and DKA. There may be a potential for cost saving from the lack of apparent added benefit of basal analogue, although these data do not examine individual indications for either insulin. Optimising basal insulin regimen should be the subject of further investigation.

1129

Impact of ethnicity and social deprivation on uptake of structured education for type 1 diabetes in a multi-ethnic urban population
D. Hopkins[1], R. Foxcroft[2], D. Simpson[2], T. Evans[3], S. Thomas[4], A. Simonds[5], S. Amiel[6];
[1]Department of Diabetic Medicine, King's College Hospital NHS Foundation Trust, London, [2]Monitor Deloitte, London, [3]DENOVaRS Clinical Academic Group, King's Health Partners, London, [4]Department of Diabetes & Endocrinology, Guy's & St Thomas' Hospitals NHS Foundation Trust, London, [5]Novo Nordisk Ltd, Crawley, [6]Diabetes Research Group, King's College London School of Medicine, UK.

Background and aims: Structured education on flexible insulin therapy for is recommended by national guidelines for the management of type 1 diabetes (T1D) in the UK and is provided at no direct cost to patients and with sufficient capacity to meet demand. Despite this, overall uptake of structured education remains poor and a large proportion of patients do not receive formal training in insulin self-management. The aim of this study was to determine the factors influencing uptake of structured education in a cohort of patients attending two inner city London teaching hospitals serving a socially and ethnically diverse local population.
Materials and methods: We have conducted a retrospective analysis of combined biomedical (HbA1c), demographic (age, sex, diabetes duration, ethnicity and socioeconomic status) and health resource utilisation data collected over a 10 year period for a cohort of T1D patients (n=1365) resident in a defined geographical catchment area of London, UK, who attended one of two specialist diabetes clinics offering the DAFNE (Dose Adjustment For Normal Eating) structured education programme.
Results: 405 (29.7%) of the cohort attended DAFNE between 2001 and 2012. There were no differences in age (37±11 vs 38±13 yrs, p=0.05), duration of diabetes (15±12 vs 14+11 yrs, p=0.2) or baseline HbA1c (8.7±1.8 vs 8.6±2.0, p=0.5)) between those who received training and those who did not. However, ethnic minorities were under-represented among those receiving DAFNE (21.2 vs 30.5%, p <0.001) as were individuals residing in more socially deprived districts (mean index of multiple deprivation score 27.2 ± 9.8 DAFNE vs 30.3 ±9.6 others, p <0.001). Those who attended DAFNE achieved significantly better long-term glycaemic control (mean HbA1c at study end 8.1±1.2 vs 8.4±1.8 %, p=0.001, mean follow-up interval post-DAFNE 4.8 years) and a lower prevalence of severe hypoglycaemia requiring hospitalisation (1.7 vs 4.8%, p=0.006).
Conclusion: There are significant inequalities in uptake of structured education which impact on outcomes. The reasons for poor uptake by patients from ethnic minority and poor socio-economic backgrounds merit further study, with the aim of informing the development of specific targeted interventions for these groups and improving equality of care for type 1 diabetes.

NOTOS: an electronic questionnaire structures individualised diabetes management
B. Landers[1], J. Weissmann[2], L.C. Steinbrinker[3], U.A. Kraemer[4], S. Weinert[4], H.-J. Lüddeke[5];
[1]Diabeteszentrum IFLIA, Mayen, [2]Roche Diagnostics GmbH, Mannheim, [3]2hm & Associates GmbH, Mainz, Germany, [4]Roche Diagnostics Operations, Inc., Indianapolis, USA, [5]Diabetes Schwerpunktpraxis Dr. Lüddeke, München, Germany.

Background and aims: Successful individual management of patients with diabetes requires a multifactorial treatment to avoid and manage late complications. In addition, individualised goal setting - depending on disease progression and other individual risk factors - has become a standard of modern diabetes care. However, these approaches require careful data collection and consideration of appropriate therapeutic strategies and might be challenging for patient self-management. As active patient involvement is an important element to achieve outcome improvements, and as limited time budget and lack of patient engagement are major reasons for suboptimal achievement of therapy goals in diabetes, support for effective consultations can be useful. Electronic tools that include guidance on treatment have been shown to improve clinical outcomes. We developed a tablet based (iPad2, Apple), electronic questionnaire which is completed by the patient prior to a routine visit in the waiting room. The questionnaire covers quality of life, the patient's social environment, communication and disease knowledge issues, thereof generating a summary report on individualised patient needs and areas to be emphasized on. The report serves as basis for the subsequent consultation, may be used for documentation of goal achievement and therapy progress and serve as a self-management support by written documentation of the therapy goal.
Materials and methods: The evaluation quantitatively assessed handling and usefulness of NOTOS from a patient perspective. In brief, 63 patients (T1D and T2D) from two practices in Germany - one general practitioner and one diabetologist - who had previously used the NOTOS tool participated in an online survey on handling and usefulness of the tool. Questions were mainly answered as 5-point Likert-type scales and analyzed by descriptive statistics.
Results: 68% of the patients rated the tool as helpful for their diabetes therapy, with a high level of acceptance (average scores of 4,2 to 4,7). The majority of patients (83%) stated they would fill in such a questionnaire again in general, but only 35% would agree to fill in this type of questionnaire prior to every visit. A considerable share of the patients rated different aspects of the consultation to be better than usual consultations (20% mentioned a more target-oriented discussion, 24% felt motivated to put more effort into diabetes therapy, 25% rated the discussion to be more structured, 26% stated that it addressed additional important aspects). The share of patients who experienced a decrease in their motivation was below 2%. A share of 30% of patients recognized for themselves a beneficial behavioral change.
Conclusion: We demonstrated that application of the electronic, tablet based questionnaire on diabetes-related issues and the discussion of a subsequently generated individualized report with the physician was well accepted by patients with Diabetes, with a positive effect on a considerable share of patients in attitude towards the consultation and their awareness of the disease. Electronic consultation support tools as NOTOS might provide a way towards improved patient engagement in individualised diabetes management.

Information seeking behaviour of patients with diabetes mellitus: a cross-sectional study in an outpatient clinic of a university-affiliated hospital
K. Makrilakis[1], S. Kalantzi[1], P. Kostagiolas[2], G. Kachagias[1], D. Niakas[2];
[1]First Department of Propaedeutic Medicine, Athens University Medical School, [2]Faculty of Social Sciences, Healthcare Services Management, Hellenic Open University, Patras, Greece.

Background and aims: Self-care in diabetes mellitus (DM) is of fundamental importance for the successful management of this chronic disease. Informa-

tion behavior in diabetic patients is a relatively unexplored field of DM care. The purpose of this study was to examine the information behavior of patients with type 1 and 2 DM, including their stated needs for information, resources used, obstacles encountered and their degree of satisfaction regarding available possibilities for DM related information.
Materials and methods: The study was undertaken in a cohort of diabetic patients being followed-up in the outpatient diabetes and special diabetic foot clinic of a University-affiliated major hospital. The participants' related issues were assessed using a validated questionnaire that inquired into patients' information needs, resources, obstacles to information seeking and degree of satisfaction of their current ability to seek information.
Results: A total of 203 patients (M/F:110/93, DM type 2/1:172/29) completed the questionnaire. Patients identified diet (61.4%) and diabetic complications (41.9%) as "of great importance" as their needs of information. The treating physician (94.6%) and ophthalmologist (31.5%) were considered as of "extreme importance" as information resources, while internet importance and frequency of use ranked low (91.1% reported access of once a month or less). Main reported obstacles to information seeking were "lack of time" and "cost". Most patients (71.4%) stated they were "quite" or "very satisfied" with the current possibilities of information seeking.
Conclusion: Diabetic patients seemed particularly interested in diet and diabetic complications. Their main stated source of information was the treating physician and main obstacles to obtaining information were lack of time and cost. The results of this study could potentially have important implications in designing an information campaign for diabetic patients.

The art of creating dialogue and participation in patient education: health educator experiences using a person centred patient education tool kit

G. Engelund, R. Torenholt, U. Møller Hansen, I. Willaing;
Steno Diabetes Center, Gentofte, Denmark.

Background and aims: Participation and dialogue are core values in diabetes education, leading to increased likelihood of improved empowerment and improved action competence in persons with diabetes. Creating participation and dialogue as well as more participant-educator interactivity is shown to increase the effectiveness of self-management education programmes in diabetes. We tested the ability of a dialogue-based education tool kit to enhance participation and dialogue from a health educator perspective. The tool kit is designed for group-based sessions in chronic disease education and is part of an innovative health education concept called The Balancing Person including two theoretical models. It contains 24 different health education tools. The choice of how many and which tools to use is optional. We studied the dialogue between participants as well as the dialogue between health educators and participants.
Materials and methods: We tested the use of the tool kit in 49 chronic illness patient education settings in all parts of Denmark. We applied a mixed method approach drawing on questionnaires, observations, and interviews. Data was collected March-September 2012. Questionnaires about the experiences using the tool kit resulted in 432 responses. 19 observations and 18 interviews with health educators were performed in 12 selected settings. During observations we did 10 sec. interval coding to estimate the distribution of participant talk, educator talk, and group work. This gave an indication of the ability of the tool kit to support the creation of participation and dialogue. During interviews health educators were asked to complete in writing a number of unfinished sentences regarding their experiences using the tool kit. Data was analysed using descriptive statistics and meaning condensation.
Results: In all, 82% of the educators reported that the tools supported them in creating participation to a high or a very high degree. Furthermore, 75% of the educators reported that the tools enhanced dialogue between the participants, and 80% reported that the tools enhanced dialogue between educators and participants to a high or a very high degree. The 10 sec. interval coding demonstrated a higher degree of participant talk and group work in sessions where the tool kit was used compared to more traditional lecture inspired sessions showing a higher degree of educator talk. Additionally, data from the unfinished sentences suggested that the educators especially valued the flexibility of the tool kit and the ability of the tools to support the opening dialogue which appeared as a consistent theme throughout the analysis.
Conclusion: The health education tool kit constitutes a valuable approach for the health educators in creating participation and dialogue between participants as well as between educators and participants. Results indicate that the tool kit is especially well suited for establishing the initial contact and dialogue which is crucial to further learning during the entire educational programme. Furthermore, the flexibility enhances the use of the tool kit.

Motivation to change towards healthy diet and habitual physical activity in subjects with type 2 diabetes mellitus

A.S. Sasdelli, E. Centis, A. Mazzotti, G. Marchesini, the AMD-SID Interassociative Study Group on Physical Activity;
Medical and Surgical Sciences, University of Bologna, Italy.

Background and aims: Motivation to change is a critical issue for education to healthy lifestyles in patients with type 2 diabetes (T2DM). We aimed to check the level of motivation for change towards healthier diet and increased habitual physical activity in a cohort of patients with T2DM.
Materials and methods: In 1743 patients with T2DM (males, 879) recruited in 14 diabetes Italian centers, motivation to change was tested by the validated EMME 3 questionnaire, which assesses the stage of change (Precontemplation, Contemplation, Determination, Action, Maintenance) according to the model of Prochaska & DiClemente. The questionnaire derives from a previously validated tool for individuals with alcohol problems. It consists of two parallel sets of instruments (for diet and physical activity, respectively): an 18-item questionnaire (MAC 2) on a Likert scale from 0 (totally false) to 6 (totally true) and a set of 6 visual analogue scales (VAS) from 0 to 100, which also provide scores on Discrepancy, Self-Efficacy, Importance, Temptation, Readiness-to-change and Stabilization-of-change. Discrepancy refers to the contradiction between what one is or behaves like and what one aims to be or to behave like, related to personal "image of self", values, goals and expectations. Discrepancy (or internal fracture) reflects concern and dissatisfaction with the present situation (need for change) and the perceived importance of change (desire for change). Self-efficacy is the perceived confidence in attaining and maintaining the predefined goals of change. Importance and Temptation are defined as the importance attributed to the new lifestyle and the attractive value of the old lifestyle; finally Readiness-to-change and Stabilization-of-change offer a summary assessment of the stage of change. A third part of the test, containing 9 brief descriptions (PORTRAITS) of imaginary people, confirmatory of the same motivational components of the MAC 2 questionnaire, was not used in this setting. Data are reported as means [SD] and significance of differences (paired T-test).
Results: The scores on stage of change are different between diet and physical activity, with a much higher motivation to diet (P<0.0001). Men have higher scores in Maintenance and Self-Efficacy for Diet, while women have higher levels of Temptation to unhealthy habits in both questionnaires, despite higher levels of Determination for Diet and Contemplation and Internal Fracture for Physical Activity. The levels of Internal Fracture (in Diet) and Stabilization (in Physical Activity) are significantly higher in men. Finally, for both behavioral changes, most scores are dependent on time since the diagnosis of diabetes, in keeping with a progressive loss of motivation with time and/or comorbidities.
Conclusion: Data may be used to address tailored interventions in individual patients

Mean scores of changes for Healthy Diet and Habitual Physical Activity

	Healthy Diet	Habitual Physical Activity	P Value
Precontemplation	40 [22]	28 [22]	< 0.0001
Contemplation	57 [23]	60 [23]	ns
Determination	64 [24]	56 [28]	< 0.0001
Action	58 [24]	39 [31]	< 0.0001
Maintenance	59 [24]	46 [31]	< 0.0001
Internal Fracture	44 [25]	49 [26]	< 0.0001
Importance	81 [16]	78 [19]	< 0.0001
Self Efficacy	66 [20]	61 [24]	< 0.0001
Temptation	54 [27]	37 [26]	< 0.0001
Readiness-to-Change	63 [33]	61 [28]	ns
Stabilization	62 [35]	54 [29]	< 0.0001

Group-based diabetes self management education for refugees with type 2 diabetes in Sweden: an observational study on short term effects on metabolic control

E. Ridderstråle[1], K. Andersson[1], K. Balcker[2], T. Elgzyri[2], U. Jakobsson[1], M. Ridderstråle[2,3];
[1]Department of Nursing, Lund University, Lund, [2]Department of Clinical Sciences Malmö, Lund University, Malmö, Sweden, [3]Steno Diabetes Center, Gentofte, Denmark.

Background and aims: Refugees are faced with a number of difficulties in order to benefit from the opportunities provided by medical care. Very few published studies have investigated the special conditions that arriving to a new country and seeking asylum provokes in subjects with diabetes and the proper mode of health care delivery under these conditions. The purpose of this exploratory pilot study was to evaluate the effect of nurse-led group-based self-management education (SME) of refugees with diabetes compared to standard care based on individual visits (SC).
Materials and methods: We conducted a retrospective analysis of 134 refugees who were consecutively enrolled at a primary health care centre dedicated to refugee care in Malmö, Sweden, during 2007 and 2009. In addition to SC on an individual basis subjects were offered group-based structured nurse-led education sessions. Treatment effect and potential gender effects were investigated. HbA_{1c}, weight, type of treatment and other relevant clinical variables were recorded and compared by paired non-parametric analysis and multiple regression analysis was employed to identify independent predictors of treatment success. Data are mean ± standard error of the mean unless otherwise indicated. A p-value below 0.05 was considered statistically significant.
Results: A significant reduction in HbA_{1c} (from 7.63 ± 0.22 to 6.80 ± 0.16 %, $p = 0.0002$) was observed in the total patient population (mean duration of treatment 197 ± 13 days) resulting in subjects choosing SME no longer exhibiting an increased HbA_{1c} compared to those choosing SC alone. While improving metabolic control, a significant weight loss (BMI from 34.1 ± 1.9 to 32.5 ± 1.7 kg/m^2, p=0.005) was also seen in the group receiving SME which was not seen in patients receiving SC. When analyzed separately the decrease in weight was significant in female patients only ($p = 0.03$).
Conclusion: We conclude that SME may add significant value and benefits beyond what SC can offer to patients with diabetes in the particularly stressful circumstances of refugee/assylum seeking status. Alternatively, subjects that are willing to accept a group-based education setting under these circumstances are characterized by being able to improve metabolic control without the commonly associated weight gain. There may also be differences between the way males and females benefit from SME that need to be investigated further. Randomized studies are called for to address these important issues in a group of particularly vulnerable subjects.

Physical activity and life quality in patients with type 2 diabetes mellitus after therapeutic education in "diabetes school"

A.V. Petrov, D.V. Logutova, L.G. Strongin;
Endocrinology and Internal Medicine, Nizhny Novgorod State Medical Academy, Russian Federation.

Background and aims: Tolerance to physical exercise may be reduced in patients with diabetes as result of concomitant diseases, complications and deconditioning. Therapeutic education of patients is aimed to increase level of physical activity and tolerance to exercise may be changed as result which may be important for life quality. Aim of this study was to evaluate tolerance to physical activity, usual level of activity and their relation to life quality in patients with T2DM before and after educational course in "diabetes school"
Materials and methods: 40 patients with T2DM there included in open prospective study with evaluation of performance in 6-minute walk test (6MWT) at baseline and 3 and 6 months after therapeutic education program. Habitual physical activity was self-assessed by patient as total duration of exercise in a week. HbA1c, body weight, life quality using SF-12 questionnaire were also evaluated. 24 patients so far have finished 6-months observation. Statistical analysis was performed using Wilcoxon matched pairs test, Spearman correlation test.
Results: At baseline distance in 6MWT had significant negative correlations with HbA1c (R = -0.56 p=0.0001), diabetes duration (R=-0.44 p=0.005), BMI (R=-0.34 p=0.03). It was associated with better life quality on physical functioning (PF) and role-physical (RP) scales of SF-12 (R=0.46 and 0.43 p=0.003 and 0.005). Usual level of activity correlated with BMI (R=-0.37 p=0.028). After education patients had trend to decrease in HbA1c (7.4% baseline, 6.9% at 3 and 6 months p=0.08 and 0.06) with no change in BMI (30 at all visits). At 3 and 6 months after education patients had significant increase in average 6MWT distance (421 and 424 meters vs. 404 meters at baseline, p = 0.003 and 0.03). Increase in 6MWT distance from baseline for both 3 and 6 months correlated with diabetes duration (R=-0.57 and -0.42 p=0.0037 and 0.043), NSS neuropathy score (R=-0.43 and -0.44 p=0.033 and 0.035). Also there was increase in usual physical activity from 149 to 331 min/week (p<0.0001).
Conclusion: Education can be an effective way in improvement of physical performance in patients in T2DM which is an important contributor in physical component of life quality. Physical performance is dependent on diabetes compensation, obesity, diabetes polyneuropathy which all can be potential targets for interventions.

1136

Exploring diabetes education and information: perspectives of people with diabetes (DAWN2 study)

I. Willaing[1], M. Massi Benedetti[2], K. Kovacs Burns[3], M. Comaschi[4], M. Davies[5], M. Escalante[6], A. Forbes[7], N. Hermanns[8], B. Kulzer[8], R. Malek[9], A. Mayorov[10], N. Munro[11], M. Vallis[12], M. Peyrot[13], DAWN2 Study Group;
[1]Steno Diabetes Center, Gentofte, Denmark, [2]UBF for International Health Research - HIRS, Perugia, Italy, [3]University of Alberta, Edmonton, Canada, [4]ICLAS, Rapallo, Italy, [5]University of Leicester, UK, [6]University of Guadalajara, Mexico, [7]Kings College London, UK, [8]Diabetes Zentrum, Bad Mergentheim, Germany, [9]CHU Sétif, Algeria, [10]National Endocrinology Research Centre, Moscow, Russian Federation, [11]University of Surrey, Guildford, UK, [12]Dalhousie University, Halifax, Canada, [13]Loyola University, Baltimore, USA.

Background and aims: Diabetes education is essential for diabetes self-management and improved diabetes outcomes, quality of life and prevention of complications. The 2nd Diabetes Attitudes, Wishes and Needs (DAWN2) study assessed access to diabetes education/information among people with diabetes (PWD) in 17 countries.
Materials and methods: In each country, a sample of 500 PWD, stratified by diabetes type and treatment, completed a psychometrically and cross-culturally validated questionnaire in local languages. This incorporated access to diabetes education and information and validated scales, eg Problem Areas in Diabetes (PAID), Diabetes Empowerment Scale (DES), and Summary of Diabetes Self-Care Activities (SDSCA). Binary logistic regression models estimated factors explaining participation in education and use of diabetes information.
Results: 8596 patients completed the questionnaire: 16% with type 1 diabetes (T1DM), 84% with type 2 (T2DM). 68% of people with T1DM (N=934) and 58% with T2DM (N=4221) participated in education. Approx. 40% never participated in education, with higher nonparticipation for those with T2DM (OR 1.5 [1.4-1.7]). Participation rate between countries varied (range 27-86%) and was highest in Germany, Poland and Canada (80-86 %). Participation in education decreased with increasing age (p<0.0001), and was likely to be lower for people living in large cities (OR 0.5 [0.5-0.6]) whereas the participation rate was higher for people living alone (OR 1.5 [1.3-1.7]). Participation was associated with fewer psychological problems, better diabetes empowerment and better self-management (p=0.0001).The 79% of the patients who participated in education and found it helpful had fewer psychological problems, better diabetes empowerment and better self-management (p<0.01) compared to participants who did not find education helpful. Experiencing helpfulness decreased with increasing age (p=0.02). Preferences for future education included access to "printed information," "ongoing advice and support outside regular office visits" and "general health and diabetes websites." Preference for "printed information" decreased with increasing age (p<0.001). "Websites" were less preferred by males (OR 0.84 [0.76-0.93]), more preferred by people living in large cities (OR 1.31 [1.18-1.44]) and increased with increasing age (p<0.001).
Conclusion: PWD who access education find it valuable and have higher psychological well-being than those who have not accessed education. This multinational analysis has highlighted significant variations in access to education and identified groups of patients who may be less likely to participate. Best practices can guide improvements in access to diabetes education.

1137

Effect of individual patient education for people with type 2 diabetes mellitus in Bangladesh

M.S. Bukht[1], K.R. Ahmed[2];
[1]Health, Nutrition and Population Program, BRAC, [2]Health Education & Health Promotion, Bangladesh University of Health Sciences (BUHS), Dhaka, Bangladesh.

Background and aims: Diabetes patient education has long been recognized as a vital and integral component of successful diabetes care. Education that increases patients' understanding of diabetes can prevent or delay complications and reduce the number and duration of hospitalizations, which in turn can improve quality of life. To the best of our knowledge, there are no other studies addressing to conduct patient education to make its present health care services more comprehensive in Bangladesh. The aim of the study was designed to assess the effectiveness of individual patient education on metabolic control, diabetes knowledge and psychosocial outcomes through intervention.
Materials and methods: An Intervention study was conducted with one thousand newly diagnosed type 2 diabetic patients (aged ≥18 years) who were randomly selected from a tertiary care Diabetic hospital. Subjects were divided into a control group (500) and an intervene group (500). A structured questionnaire in simple understandable local language was used to collect socio-demographic history by face to face interview. Subjects in intervene group were visited every month; along with standard care and structured intervention especially self-care education was given. Control group were visit twice (0 and 6 month) and given only the standard care. Anthropometric measurement was done by standard techniques. Diabetic profile (HbA1c) and total cholesterol (TC) were examined by high-performance-liquid chromatography (HPLC) and enzymatic-endpoint method. Data were analyzed by univariate as well as multivariate analysis.
Results: Among the intervene group HbA1c was reduced significantly compared to control group. The weighted mean difference (WMD) of HbA1c was 0.8% with a trend to favour individual patient education (95% CI 0.3 to 1.3, P = 0.0007). There was no significant decrease in BMI at 0 to 6 months with a WMD of -0.2 BMI units (95% CI -1.0 to 0.6, P = 0.62). Intervene group with individual patient education had no significant effect on total cholesterol compared with control group with a WMD of -0.03mmol / L (95% CI -0.2 to 0.10, P = 0.66). There was a significant reduction in the number of participants who quit or reduced the amount of smoking in those receiving individual education versus control group (16.7% versus 5.7%, P = 0.031).
Conclusion: Individual education appears to be a significant effect among the intervene group compared to control groups. Repeated reinforcement of health education and strong motivation are needed in self-care practices with regard to diabetes control for the control groups as well as all diabetic subjects.

PS 095 Psychosocial aspects of diabetes

1138

Socioeconomic differences in families of children with well and poorly controlled type 1 diabetes

B.M. Zdunczyk[1], K. Piechowiak[2], A. Szypowska[3];
[1]Clinical Pediatric Hospital, [2]Department of Clinical Diabetology and Pediatrics, Clinical Pediatric Hospital, [3]Warsaw Medical University, Warsaw, Poland.

Background and aims: Numerous studies show that the achievement of near-normoglycaemia reduces the development of chronic complications of diabetes. The management of type 1 diabetes always poses a challenge, particularly in prepubertal children. The treatment completely depends on the parents' decisions and presents a unique set of problems. Difficulty in achieving glycemic targets in this age group stems both from children developmental stage and parents themselves; incorrect eating habits, family stress, fear of hypoglycaemia, parental depression, problems in insulin dosage, frequent infections and unpredictable physical activity affect glycaemia. Family socioeconomic status is also found to play a role in diabetes treatment. Our clinical experience shows that some parents manage to adhere to the treatment requirements while others constantly have problems with achieving good metabolic control in their children. The aim of the study was to identify the family factors affecting metabolic control of type 1 diabetic children under nine years of age.
Materials and methods: During the routine visit in the outpatient clinic 104 parents of type 1 diabetic children under nine years of age were asked to fill in Beck Depression Inventory, Quality of Life Questionnaire, a 58-item questionnaire, based on DCCT Quality of Life Measure, and a questionnaire specially prepared for this study on psychological, social, demographics and disease-related topics. 16 participants were rejected due to incomplete data. Out of the remaining 88 (84%) 45 were completed by mothers and 43 by fathers. At the same time other data was collected: sex of a child, age, diabetes duration, HbA1c, BMI, daily insulin dose. Families were divided into two groups depending on children metabolic control: HbA1c<7% and HbA1c≥7%.
Results: 36% (32/88) of children had HbA1c≥7%. There was no difference between groups with HbA1c<7% and HbA1c≥7% in age (6,8±1,8 vs. 6,5±2,0 yrs; p=0.51) and diabetes duration (2,6±1,6 vs. 2,9±1,9, p=0,448); respectively. The poorly controlled children had higher HbA1c 8,1±0,6% than the well controlled ones 6,6±6,5% (p<0.0001). In comparison with well controlled subjects, in families of children with HbA1c≥7% parents had lower education (p<0,05), more parents were employed as physical than office workers (p=0,004) and family income was lower (p=0,013). In the group with HbA1c≥7% there were more single parent families than in families of well controlled subjects (p=0,008). Parents of children with HbA1c≥7% had more problems with extra feeding by other family members (p=0.0008). Surprisingly we didn't find any difference in reported depressive symptoms (p=0.7824) and quality of life (p=0.6978). Children in both groups didn't differ in BMI (p=0.0545) or daily insulin dose (p=0.6456).
Conclusion: Our results show that families of prepubertal children with poorly controlled type 1 diabetes come from a disadvantage group. These families may require particularly careful screening for social and psychological problems. Additional help, including financial and psychological support, more re-education should be individually tailored according to each patient's needs.

1139

Association of personality traits with diabetes-related distress and psychosocial factors in subjects with long duration of type 1 diabetes

A. Duda-Sobczak, D. Zozulinska-Ziolkiewicz, B. Wierusz-Wysocka;
Department of Internal Medicine and Diabetology, Poznan University of Medical Sciences, Poland.

Background and aims: Type 1 diabetes is a chronic irreversible disease. Proper diabetes management is multidimentional and comprises issues of insulin therapy, prevention of chronic complications, psychological support, motivation and patient empowerment and is performed by a therapeutic team. The aim of this study was to assess the impact of particular personality

traits on diabetes-related distress and psychosocial factors in subjects with long history of type 1 diabetes.
Materials and methods: 255 subjects (138 women), aged 42.8±10.7 years, type 1 diabetes duration 27.1±6.2, HbA1c 8.2±1.5% were included. Personality was assessed using NEO-FFI (Neurotism-Extraversion-Openness Five Factor Inventory). Additionally Problem Areas in Diabetes Questionnaire (PAID) assessing diabetes-related distress, Beck Depression Inventory (BDI) and Multidimensional Fatigue Symptom Inventory- Short Form (MFSI-SF) were completed. Data on social, economic and lifestyle factors were collected. Metabolic control expressed by HbA1c, lipid profile and chronic complications was assessed via medical chart review.
Results: The main results are shown in Table 1. There was no correlation of personality traits to HbA1c, lipid profile or microvascular complications.
Conclusion: The results of this study may be useful in patient-centered, individualized therapeutic approach. Although there was no relationship of personality traits with metabolic control of diabetes, we indicated the association of several personality traits with psychosocial status. This may enable therapeutic team to better delineate the treatment plan and adjust it to patient's needs and behaviours.

Table 1. Correlation of personality traits to psychosocial status and diabetes-related issues in studied group. *p<0.05, **p<0.001

Socio-economic status - combination of occupation, education and income level - and diabetes risk: the Hoorn study
A. Koopman[1,2], F. Rutters[1,2], S. Rauh[1,2], P.J. Kostense[1,2], S.D.M. Bot[3,2], C.A. Baan[3,2], C.D. Stehouwer[4], P. Elders[3,2], G. Nijpels[3,2], J.M. Dekker[1,2];
[1]Department of Epidemiology and Biostatistics, VUMC, Amsterdam, [2]EMGO+ Institute for Health and Care Research, Amsterdam, [3]Department of General Practice, VUMC, Amsterdam, [4]Department of Internal Medicine and Cardiovascular Research Institute Maastricht (CARIM), Maastricht University Medical Centre, Netherlands.

Background and aims: Low socio-economic status (SES) is associated with increased risk of type 2 diabetes. Most studies however only include 1 indicator of SES: education, income or occupation. The aim of our study is to evaluate the strength of the association between education, income, occupation or the combination of all 3 SES indicators and diabetes risk in the general population.
Materials and methods: Design, setting, patients**:** The Hoorn study; a population-based cohort study among older men and women, who had a physical examination at baseline in 1989 and after 6y follow-up. Main outcome measure**:** Incident diabetes based on WHO Consultation criteria for fasting plasma glucose levels, 2h plasma glucose levels and HbA1c levels.
Results: We included 1162 participants (46% male; 59.9 ± 6.8 years). At follow-up, 106 (9.1%) participants had developed type 2 diabetes. Low levels of education (7-level scale), occupation (5-level scale) and income (3-level scale) were all associated with increased diabetes risk; however, only the association with income was statistically significant. When we combined the 3 SES indicators into 1 score, we observed that compared to the highest tertile, the age and sex adjusted HR (with 95% CI) for diabetes incidence for the middle and lowest tertile were 1.65 (1.01-2.67) and 1.62 (0.98-2.68). Adjustment for BMI and waist-to-hip ratio explained part of this increased risk.
Conclusion: The combined SES score of income, occupation and education level better predicts the increased risk of type 2 diabetes in those with low SES status, compared to the separate scores of the SES indicators in an elderly population-based cohort.

1141

Low self-efficacy and insulin resistance in a Swedish population: a cross-sectional study
M. Eriksson[1], C.A. Larsson[1,2], L. Råstam[3], U. Lindblad[1];
[1]Department of Primary Health Care, Institute of Medicine, Sahlgrenska Academy, University of Gothenburg, [2]Division of Social Medicin and Global Health, Department of Clinical Sciences, Malmö, Lund University, Malmö, [3]Department of Clinical Sciences/Community Medicine, Lund University, Clinical Research Centre, SUS, Malmö, Sweden.

Background and aims: The high prevalence of insulin resistance and depressive symptoms is well documented. The underlying psychological mechanisms and interactions are interesting both in prevention and treatment. The aim of the present study was to investigate the association between the self-efficacy and insulin resistance in men and women.
Materials and methods: A random sample of 2816 men and women from the municipalities of Vara and Skövde in South-western Sweden, were invited to a health survey in 2002-2005 (participation-rate 76%). After excluding participants with missing information on any of the study variables, 2564 subjects (1286 women and 1278 men) remained for the present study. Information on self-efficacy was assessed by the question "Do you believe you can do something yourself to maintain a good health", with the three answer alternatives "Yes, I believe that one's own effort is very important"; "Yes, I believe that one's own effort has some importance"; and "No, I do not believe that one's own effort has any importance". Information on leisure-time physical activity (LTPA), smoking, and education was also collected by questionnaires. Glucose metabolism (OGTT), insulin resistance (HOMA-ir), blood pressure, and BMI were measured using standard methods.
Results: Among men, 294 (22%) reported low self-efficacy, while corresponding findings in women were 280 (21%). In a linear regression model, there was a significant association between insulin resistance and low self-efficacy in both men (regression coefficient (ß): 0.042, 95% CI:0.005-0.079, p=0.025, Beta 0.042) and women (ß: 0.048, 95% CI: 0.010-0.086, p=0.013, Beta 0.067). When differences in BMI, LTPA, smoking and educational level were accounted for, these associations remained in women (ß: 0.033, 95% CI:0.001-0.065, p=0.043, Beta 0.047), but not in men (ß: 0.012 95% CI:-0.020-0.045, p=0.466, Beta 0.017).
Conclusion: Screening for self-efficacy related to the ability to sustain good health may be a way to target women who would benefit most from interventions to prevent impaired glucose metabolism, including type 2 diabetes.

Societal discrimination and emotional well-being in people with diabetes: results from DAWN2
J. Wens[1], A. Nicolucci[2], S. Kalra[3], B. Kulzer[4], M. Massi Benedetti[5], N. Piana[6], F. Pouwer[7], S. Skovlund[8], M. Peyrot[9], DAWN2 Study Group;
[1]Primary and Interdisciplinary Care, University of Antwerp, Belgium, [2]Consorzio Mario Negri Sud, Santa Maria Imbaro, Italy, [3]Bharti Hospital and BRIDE, Karnal, India, [4]Diabetes Zentrum, Bad Mergentheim, Germany, [5]UBF for International Health Research - HIRS, Perugia, [6]University of Perugia, Italy, [7]Tilburg University, Netherlands, [8]Novo Nordisk, Bagsværd, Denmark, [9]Loyola University Maryland, Baltimore, USA.

Background and aims: Suffering from a chronic condition such as diabetes may still be a reason for societal discrimination. The second Diabetes Attitudes, Wishes and Needs (DAWN2) study assessed perceptions of being

discriminated against because of having diabetes in persons with diabetes (PWD) across 17 countries within 4 continents. Data from DAWN2 allow exploration of correlates between perceptions of being discriminated against and psychosocial distress.
Materials and methods: All country samples comprised ~500 PWD (~80 type 1 [T1DM] and ~420 type 2 [T2DM], of which ~150 were insulin treated). Survey questionnaires, developed using new items as well as items adapted/modified from existing validated measures, were designed to assess self-management, attitudes/beliefs, health-related quality of life (QOL), social support and priorities for improving future diabetes care. Questionnaires were administered online, by telephone or in person. Comparisons between PWD who reported being discriminated against (or not) were made for various scales including WHO-5 Wellbeing index, Problem Areas in Diabetes (PAID-5), WHO-QOL-BREF (% of PWD reporting their QOL as poor/very poor), Impact on Life Dimensions, a support scale and Diabetes Empowerment Scale (DES). Data were analyzed using multilevel analysis (patients clustered within countries).
Results: 1368 adults with T1DM and 7228 with T2DM completed questionnaires in local languages. Overall, 19.2% of PWD reported being discriminated against because of diabetes, with wide country variation [11.1- 30.1%]. After adjusting for clustering effect, discriminated against PWD had a significantly lower WHO-5 score (-5.0; p<0.0001), a higher PAID-5 score (+12.4; p<0.0001), a 67% higher likelihood of reporting poor/very poor QOL (OR 1.67; 95% CI 1.43-1.92), lower perceived support (-1.6; p<0.0001), and higher empowerment (+9.6; p<0.0001). PWD who reported being discriminated against reported a negative impact on several life dimensions: financial situation (OR 1.44; 95% CI 1.28-1.62); relationship with family, friends or peers (OR 1.99; 95% CI 1.75-2.26); leisure activities (OR 1.42; 95% CI 1.26-1.59), work or studies (OR 1.76; 95% CI 1.55-2.00); and psychological well-being (OR 1.19; 95% CI 1.06-1.33).
Conclusion: Perceptions of being discriminated against because of diabetes are common in PWD and should be taken seriously. These perceptions are associated with negative impacts on emotions and well-being, coping strategies and different aspects of living with diabetes during work as well as leisure activities and with friends or relatives. Almost half of PWD with perceptions of discrimination also reported a negative financial impact of diabetes. It is not clear why discrimination was associated with higher empowerment.

1143

Psychosocial stress is associated with higher mortality: the Hoorn study
F. Rutters[1,2], S. Pilz[3], A. Koopman[1,2], S. Rauh[1,2], C. Stehouwer[4], P. Elders[5,2], G. Nijpels[5,2], J.M. Dekker[1,2];
[1]Department of Epidemiology and Biostatistics, VUMC, Amsterdam, Netherlands, [2]EMGO+ Institute for Health and Care Research, Amsterdam, Netherlands, [3]Department of Internal Medicine, Medical University of Graz, Austria, [4]Department of Internal Medicine and Cardiovascular Research Institute (CARIM), Maastricht University Medical Centre, [5]Department of General Practice, VUMC, Amsterdam, Netherlands.

Background and aims: Psychosocial stress is associated with chronic disease. Experiencing stressful life events may lead to premature mortality, by inducing behavioural, endocrine and metabolic changes. The aim of our current study is to evaluate whether in the general population (the number of) stressful life events are associated with all-cause and cause-specific mortality, and whether this relationship is mediated by behavioural, endocrine and metabolic disturbances.
Materials and methods: *Design, setting, patients*: The Hoorn study; a population-based cohort study among older men and women. *Main outcome measure*: Stressful life events experienced during the previous 5 years were assessed by questionnaire. We calculated Cox proportional hazard ratios (HRs) for all-cause and cause-specific mortality during follow-up for those who experienced no stressful life events compared to those who did.
Results: We included 2385 participants (46% male; 61.6 ± 7.4 years). During 20 years of follow-up 834 (35%) participants died, of whom 239 (28.6%) died of cardiovascular disease and 235 (28.2%) of cancer. Compared to the group with no stressful life events, the age and sex adjusted HRs (with 95% confidence intervals) for all-cause mortality for those who had 1 event, 2 events, 3 events and ≥ 4 events were 0.92 (0.75-1.11), 1.02 (0.83-1.25), 1.29 (1.01-1.65) and 1.51 (1.15-1.99), respectively. Adjustment for prevalent obesity, diabetes and cardiovascular disease and deleterious behaviour partly explained the increased risk. Similar results were observed for cardiovascular mortality and cancer mortality.
Conclusion: Having 3 or more stressful life events is associated with a significantly increased risk for all-cause mortality, cardiovascular mortality and cancer mortality in an elderly population-based cohort. This association is presumably mediated by behavioural, endocrine, behavioural disturbances, resulting in obesity, cardiovascular disease and diabetes.

1144

Qualitative insights into diabetes psychosocial needs and strategies from the perspective of healthcare professionals in DAWN2
H.L. Stuckey[1], K. Kovacs Burns[2], H. Ishii[3], S. Kalra[4], A. Kokoszka[5], C. Mullan-Jensen[6], A. Nicolucci[7], S. Skovlund[6], M. Vallis[8], J. Wens[9], I. Willaing[10], M. Peyrot[11], DAWN2 Study Group;
[1]Medicine, The Pennsylvania State University, Hershey, USA, [2]University of Alberta, Edmonton, Canada, [3]Tenri Hospital, Tenri, Japan, [4]Bharti Hospital and BRIDE, Karnal, India, [5]Medical University of Warsaw, Poland, [6]Novo Nordisk, Bagsværd, Denmark, [7]Consorzio Mario Negri Sud, Santa Maria Imbaro, Italy, [8]Dalhousie University, Halifax, Canada, [9]University of Antwerp, Belgium, [10]Steno Diabetes Center, Gentofte, Denmark, [11]Loyola University Maryland, Baltimore, USA.

Background and aims: To identify professionals' perceptions of the needs, challenges and wishes for people living with diabetes, the second Diabetes Attitudes, Wishes and Needs (DAWN2) study surveyed 4785 healthcare professionals (HCPs) who care for people with diabetes (PWD) in 17 countries across 4 continents. These included 2066 PCPs/GPs, 1350 diabetes specialists, 827 nurses and 542 dietitians.
Materials and methods: Qualitative data were drawn from responses to open-ended survey questions about challenges and successes in managing diabetes, and wishes for improvement in support for PWD. Emergent coding with input from multinational collaborators identified thematic content about psychosocial aspects of diabetes care, and yielded 30 macro-level (parent) codes, and 114 micro-level (child) codes.
Results: Two common challenges are not having time or support to help PWD manage the disease; that is, to "make time to think about things from the patient's perspective." PWD access to support groups and psychologists is limited. HCPs find a challenge in knowing how to listen to patients, understand causes of depression and find solutions. They state PWDs are not aware of complications, and "think that diabetes is nothing more than elevated blood sugar." Strategies considered successful in helping PWD achieve better outcomes include reducing the fear of taking insulin, and involving families and patients in goal-setting. Providing encouragement is helpful, such as giving hope that people can manage the disease and verbal reinforcement to raise motivation. One HCP encourages patients to "write down your thoughts, fears and experiences about diabetes." Across all countries, HCPs wish for psychological support for PWD "since there are personal and behavioral problems for which we don't have the ability to take action." This also includes helping PWD overcome depression. HCPs wished for more time with PWD and proper reimbursement, as well as learning motivational strategies to improve A1C. HCPs also wish for new advances in affordable oral medications with fewer side effects.
Conclusion: The narratives indicate that changes are needed to give HCPs enough time to assist PWD and to provide psychological assistance for the effective treatment of comorbid depression. The results highlight the psychosocial needs and strategies of HCPs globally to improve care and support for PWD.

1145

A psychological support programme for patients with nonalcoholic fatty liver disease (NAFLD)
L. Montesi, C. Caselli, E. Centis, C. Nuccitelli, S. Moscatiello, A. Suppini, G. Marchesini;
Unit of Metabolic Diseases & Clinical Dietetics, University of Bologna, Italy.

Background and aims: Lifestyle changes towards healthier diet and physical activity (PA] are mandatory in nonalcoholic steatohepatitis (NAFLD), but PA is more difficult to implement in the population. We aimed to determine the clinical effectiveness of an intense psychological support to PA in NAFLD.
Materials and methods: In a pilot study, 22 NAFLD cases were enrolled into an individualised motivational and psychological support to exercise (PA group], chaired by a psychologist and tailored to their motivational needs. Patients were helped to identify their preferable leisure activities (such as going for a walk or riding the bike) and then supported in developing a weekly schedule and implementing that plan. The sessions were then

focusing on how to deal with common psychological barriers to physical activity and on the importance of self-monitoring. Defined and reasonable goals for physical activity were set during the sessions. Only one hour was devoted to nutritional counselling. The effects on weight, body fat and physical fitness were compared with the data of 44 NAFLD subjects enrolled in a cognitive-behavioural program for weight loss (CBT group], consisting of 13 weekly group sessions, 120 min each (approx. 15-20 subjects), chaired by physicians, dieticians, psychologists, education experts. Education focuses on the alimentary pyramid, size of portions and regular eating, calorie counting, and marginally on physical activity. Physical fitness was measured by the 6-min walk test, VO2max and the PA rating questionnaire (PA-R]; body fat by the fatty liver index (FLI) and the visceral adiposity index. Measurements were performed at baseline, at 4 months and at 1-year follow-up. Data were adjusted for propensity score, based on baseline clinical characteristics.

Results: The two groups were well balanced at baseline, without significant differences in socio-economic, anthropometric and clinical data. The PA program produced a larger effect of physical fitness, the CBT program a larger effect on body weight. After adjustment for propensity, weight loss > 7% was associated with CBT (odds ratio (OR], 2.52 (95% confidence interval, 0.60-10.53] at 4 months and to 6.21 (1.23-31.30] at one year. By contrast, the probability of PA-R >3 was significantly associated with PA group (OR, 10.31; 2.02-52.63]. Liver enzymes and body fat similarly decreased in the groups, without significant differences at 4 months and 1-year follow-up.

Conclusion: An intensive psychological counselling for PA produces effects on the liver similar to those of a standard CBT, improving physical fitness independently of weight loss. Strategies aimed at promoting exercise are worth implementing in motivated patients.

Parameters at baseline and follow-up (mean or % [SD])

	PA Group			CBT Group			ANOVA (time x treatment)
Parameter	Baseline	4 months	12 months	Baseline	4 months	12 months	P Value
BMI (kg/m2)	30.4 [5.0]	29.3 [4.4]	29.7 [4.6]	32.4 [3.9]	30.3 [3.7]	30.4 [3.7]	=0.005
Waist circum. (cm)	99 [15]	97 [15]	98 [15]	105 [10]	100 [10]	99 [10]	< 0.001
ALT (U/L)	68.5 [28.5]	45.0 [20.1]	46.2 [21.0]	64.1 [32.2]	39.5 [15.9]	40.8 [20.7]	=0.983
Fatty Liver Index (%)	77.0 [23.7]	65.5 [26.8]	69.7 [25.1]	84.7 [14.8]	71.0 [20.9]	70.8 [20.6]	=0.083
Visceral Adiposity Ind. (%)	2.84 [1.83]	2.38 [1.66]	2.27 [1.32]	2.79 [1.54]	2.29 [1.16]	2.26 [1.34]	<0.001
6-Min Walk Test (m)	521 [92]	660 [112]	---	497 [82]	540 [76]	---	<0.001

Eating disorders and food anomalous behaviour in type 2 diabetes adults

A. Larrañaga, J. Garcia-Soidan, R.V. Garcia-Mayor, Traconal Study Group; Biomedical Foundation of University Hospital of Vigo, Spain.

Background and aims: It is well-known that Eating disorder (ED) and other anomalous eating behaviours (AEB) in young diabetics are associated with anomalies in their metabolic control. These anomalies occur more commonly in youth with type 1 diabetes than their non-diabetic peers. However, ED and AEB, have not been well studied in adults with type 2 diabetes. The aims of the present study were to determine the rate of ED and AEB in type 2 diabetes adults and to determine whether the presence of ED or AEB influences on patients metabolic control.

Materials and methods: Adult (over 40 years) patients with type 2 diabetes of both sexes from three Primary Care Centers in Southern Galicia, Spain, without previous selection and adult non-diabetic aged sex and BMI matched as controls from the same population were included. It is a prospective, case-control, multicenter and observational study of 1 year duration. This project was approved by the Research Ethics Committee of Galicia. All patients were submit to two self-administered, validated, psychological questionnaires to assess the presence of ED, the Bulimic Investigatory Test Edinburgh (BITE) to assess bulimic symptomatology, and Questionnaire of Eating and Weight Patterns-Revised (QEWP-R) to diagnose Binge Eating Disorder (BED) and Bulimia Nervosa (BN), followed for a structure interview on eating patterns. The study variables were ED and AEB rates, glycosylated hemoglobin (HbA1c), and body mass index.

Results: The rate of ED for diabetics and controls were similar, 4.8% and 3.9% respectively. Statistical significance differences were no found for the rates of BN (0% vs. 1.3%), BED (0.8% vs. 0%) and eating disorder not otherwise specified (3.9% vs. 3.8%) for patients and controls respectively. Picking at foods and dissatisfaction with body weight or shape were significantly more frequent rates of ED were observed. Table 1.

Table 1. Comparison of AEB rates between patients and controls

Rates (%)	DM2 (N=230)	CONTROLS (N=177)
Binge eating	4.8	5.2
Skipping meals	3.9	3.8
Picking at foods	28.7*	19.5
Dissatisfaction with body weight or shape	34*	15.6
Food addiction	16.1	15.6

*p<0.05 vs. controls

The mean values of HbA1c (%) were 7.0±1.3; 8.0±1.5** and 7.2±1.3** for the group of patients non ED and AEB, patients with ED and the group of patients with AEB. **p<0.05 vs. patients non ED and AEB.

Conclusion: These findings highlight the importance of evaluating type 2 diabetes over 40 years for the presence of AEB and ED.

Study on the support of compatibility between work and medical care and of return to work in diabetic patients in Japan

E. Nakashima[1], T. Sano[1], A. Watarai[2,1], T. Kawamura[1], H. Ishikawa[1], M. Omura[3], M. Nomura[4], Y. Yamamoto[5], K. Yaga[6], K. Kaneko[7], H. Yatsuya[8], N. Hotta[1];
[1]Diabetes and Endocrinology, Chubu Rosai Hospital, Nagoya, [2]Aichi Medical University School of Medicine, Nagoya, [3]Yokohama Rosai Hospital, [4]Osaka Rosai Hospital, Sakai, [5]Wakayama Rosai Hospital, [6]Yamaguchi Rosai Hospital, Sanyo-Onoda, [7]Kumamoto Rosai Hospital, Yashiro, [8]Department of Public Health, Fujita Health University, Nagoya, Japan.

Background and aims: Many previous reports showed that the increasing prevalence of lifestyle-related diseases (i.e. diabetes mellitus (DM) is one of the major factors leading to a decline in the working population. Therefore the prevention of DM is the most important issue for public and labor health in Japan. From 2000, the Ministry of Health, Labor and Welfare (MHLW) has been promoting measures against lifestyle-related diseases in Japan (Healthcare Japan 21th Century). But in a recent report of this plan in progress from MHLW, the population of DM and pre-DM patients is still increasing and is now more than 20 million in Japan. In another MHLW report in 2009, less than 25% of diabetic patients had received medical care. Patients without medical care and the condition of these workers are not clear.

Materials and methods: To clarify the problem for the compatibility between work and DM treatment, we conducted surveys in the form of a questionnaire. The surveys were conducted with 1184 employees with DM and with the health management staff in 800 companies in Japan. We used SPSS ver. 19.0 for statistical analyses, and set P<0.05 as significance level.

Results: Patient questionnaire results showed that the average of HbA1c adjusted by age and sex in employees working at companies that provide industrial physicians is significantly lower than for employees who do not have access to such physicians (7.5% vs. 7.2%, p=0.002). Similarly, the prevalence of diabetic retinopathy (P=0.046) and that of nephropathy (P=0.014) in employees at companies with industrial physicians (IPs) are significantly lower than those without IPs. In multiple regression analysis, existence of IPs is an independent factor for less prevalence of diabetic nephropathy after adjusting for age, gender, duration of diabetes, body mass index, HbA1c, existence of hypertension and dyslipidemia (odds ratio 0.51, 95% confidence interval 0.27-094, P=0.032). In questionnaire results from the companies, the age-adjusted prevalence rate of DM at small (employee number<50) companies is significantly higher than that at large (employee number<300) and medium-sized (50<employee number<300) companies (p=0.04). This tendency can be seen regardless of category of business. The questionnaire results of the survey conducted with health management staff in companies also showed that the prevalence of DM patients adjusted by age and sex in employees working at companies that provide full-time IPs tends to be lower than part-time or

nonscheduled IPs (38.2, 46.0, and 59.4 diabetic patients / 1000 employees, p=0.062).
Conclusion: Our results suggest that the IPs play an important role in DM management for employees and the quality of its management depends on the size of companies and type of employment of IPs. The goal of this study is to establish a system of cooperation among DM patients, medical doctors, and company through the adaptation of new guidelines prepared from our results.

PS 096 Good news for depression in diabetes?

1148

Multiple analysis of risk factors for depression in Chinese type 2 diabetic patients
M. Jia[1], B. Xie[1], X.L. Ye[1], Y.C. Tu[2], N. Yang[2], Z.L. Sun[1];
[1]Department of Endocrinology, Zhongda Hospital, Institute of Diabetes, Medical School, Southeast University, [2]Medical School, Southeast University, Nanjing, China.

Background and aims: Depression is common in patients with type 2 diabetes. Different studies have showed contradictory results on the risk factors for the depression in type 2 diabetic patients. A multiply factors analysis is needed for the a system study on the all-scaled factors affecting depression in diabetes patients. This study we first using multiply factors analysis to find the risk factors for depression in patients with type 2 diabetes in China.
Materials and methods: A total of 397 patients with type 2 diabetes were recruited from July 2012 to September 2012 in Nanjing. Depression was evaluated with the nine-item Patient Health Questionnaire (PHQ-9). Classification criteria for depression: <=4 points, normal group; 5-9 points, mild-depression group; 10-14 points, moderate-depression group; 15-19, moderate-to-major-depression group; 20 points or higher, major-depression group. While the demographic data (gender, age, education, marriage, income, way of payment, insulin injection and diabetic duration), metabolic data (fasting plasma glucose, postprandial blood glucose, HbA1c, triglyceride, total cholesterol, low density lipoprotein, high density lipoprotein, BP, BMI and obesity index) and chronic complications related to diabetes (diabetic angiocardiography, diabetic cerebrovascular disease, diabetic neuropathy, diabetic oculopathy, diabetic nephropathy and diabetic pedipathy) were collected, diabetic knowledge and self-management behaviors were also investigated by using Deborah scale and Diabetic Knowledge Test scale. Correlation tests were conducted between depression and all these potential factors. The risk factors associated with depression were screened by logistic regression.
Results: Of all the 397 patients with type 2 diabetes (137 males, 260 females, age 68.16 +/- 7.84 years, disease duration 9.43 +/- 6.53 years), a total of 94 (24.2%) patients were categorized as having depression, including 16.8% with mild, 5.8% with moderate, and 1% with moderate-to-major depression. Compared with the normal group, depression was correlated with gender (P=0.000), economic income (P<0.05), diabetes duration (P<0.05), economic income (P<0.05), tryglyceride (P<0.05), high density lipoprotein (P<0.05) and obesity index (P=0.000) in patients with type 2 diabetes. Although there was no significant relationship between depression and the number of chronic diabetic complications, the depression symptom was more severe in patients with diabetic pedipathy (P<0.05). Multiply logistic regression showed that obesity (OR=1.57), long diabetic duration (OR=1.37), diabetic pedipathy (OR=1.48), and female (OR=1.21), were risk factors for depression, while hight high density lipoprotein (OR=0.72) showed a protective effect on depression.
Conclusion: More attention should be paid on depression symptoms in patients with obesity and diabetic pedipathy especially the females with long diabetic duration. High density lipoprotein may act as a protective factor for depression in patients with diabetes and further research on the mechanism for this relationship is necessary.

Depression and the metabolic control of type 2 diabetes mellitus
L. Diaconu[1,2], B. Timar[1,2], S. Popescu[2], R. Timar[1,2];
[1]"Victor Babes" University of Medicine and Pharmacy, [2]Emergency County Hospital, Timisoara, Romania.

Background and aims: Depression is a frequent co-morbidity in patients with diabetes mellitus (DM), especially in those with chronic diabetic complications. It was estimated that half of depression cases in DM are undiagnosed and untreated. The aims of this study were to estimate the prevalence of depression in persons with type 2 DM and to evaluate the impact of depression on the metabolic control of type 2 DM.
Materials and methods: The study included 364 patients with type 2 DM, 180 men and 184 women, with mean age 54.2 ± 3.8 years. For the screening

of depression, all patients filled the questionnaire PHQ-9 (The 9-item Patient Health Questionnaire) and those identified with depression were subsequently subjected to psychiatric evaluation. For each subject we determined the waist circumference (WCF), body mass index (BMI), systolic blood pressure (SBP) and diastolic (DBP). Laboratory analyzes included: fasting plasma glucose, insulin, HbA1c, total cholesterol (TC), triglycerides (TG), HDLc. Insulin resistance was estimated using HOMA-IR index.
Results: The prevalence of depression in persons with type 2 DM was 22.8%. Of subjects with type 2 DM affected by depression only 38.5% were previously diagnosed with depression and were under psychiatric antidepressant treatment. Patients with type 2 DM and depression had poor glycemic control. The goal of HbA1c < 7% was achieved only in 13.7% of type 2 diabetics with depression previously undiagnosed, in 34.3% of those with previously known depression (under antidepressant treatment), and in 45.1% of patients without depressive symptoms. Depressed diabetics had significantly higher values of BMI, WCF, TG, SBP, DBP and insulin resistance than those without depression (Table 1).

Table 1. Characteristics of patients with type 2 DM with and without depression

Parameter		type 2 DM + depression previously undiagnosed	type 2 DM + previously diagnosed depression	type 2 DM without depression	P (ANOVA)
N		51	32	281	-
Men / women		24/27	15/17	142/139	-
Age (years)		54.7 ± 3.2	54.5 ± 3.1	54.1 ± 3.6	0.475
Duration of diabetes (years)		6.2 ± 1.8	6.5 ± 1.4	6.1 ± 1.3	0.292
WCF (cm)	M	106.5 ± 5.1	101.3 ± 5.2	96.6 ± 4.7	<0.001
	W	94.7 ± 4.9	89.3 ± 4.6	85.4 ± 4.1	<0.001
BMI (kg/m^2)		30.4 ± 3.8	28.9 ± 3.5	27.2 ± 3.4	<0.001
TG (mg/dL)		211.4 ± 22.9	182.7 ± 20.5	164.3 ± 21.4	<0.001
TC (mg/dL)		207.2 ± 23.3	210.6 ± 21.5	204.8 ± 22.7	0.341
HDLc (mg/dL)	M	34.8 ± 4.7	37.2 ± 4.2	40.5 ± 5.1	<0.001
	W	41.9 ± 4.8	42.7 ± 4.5	48.5 ± 4.6	<0.001
SBP (mmHg)		141.6 ± 9.8	136.9 ± 10.5	132.6 ± 11.2	<0.001
DBP (mmHg)		92.3 ± 5.6	88.4 ± 6.1	85.5 ± 6.8	<0.001
HOMA-IR		7.4 ± 1.2	6.5 ± 1.1	4.6± 0.9	<0.001
HbA1c (%)		8.1± 0.7	7.5 ± 0.9	7.3 ± 0.8	<0.001
HbA1c < 7% n(%)		7 (13.7)	11 (34.3)	127 (45.1)	

Conclusions: Depression negatively influences the management and the prognosis of type 2 DM, being associated with poor glycemic control, with an adverse cardiovascular risk profile and, subsequently, with an increased risk of chronic diabetic complications. Recognition and treatment of depression in type 2 DM patients is imperative, in order to achieve better adherence to diabetes management plan, in particular to lifestyle optimization measures, and consecutively to improve their prognosis and quality of life.

Diabetes and depression among pregnant women in Bangladesh: a hospital based study

K. Natasha[1,2], A. Hussain[1];
[1]Community Medicine, Institute of Health and Society, Faculty of Medicine, Oslo, Norway, [2]Public Health, Diabetic Association of Bangladesh, Dhaka, Bangladesh.

Background and aims: Diabetes (DM) is increasing worldwide along with gestational diabetes mellitus i.e.; GDM (1-4%)[1] and Depression is an alarming disease which ranks 4th among worldwide disease burden. In Bangladesh the prevalence rate of depression in adult population is only 4.6%[2]. Both depression and GDM are common in the antenatal period and result in serious consequences for mother and foetus. However there has been little research specifically examining the association between them in pregnancy, revealing that depression is more common in GDM cases with much complicacy [3,4,5]. To our knowledge data regarding this issue in South Asia are inadequate. Till date we could not find any single study in Bangladesh. This study was the 1st one in this aspect, designed to find out the prevalence of depression and associated factors, among GDM subjects and to compare with Non GDM.
Materials and methods: A total of 745 pregnant women participated in the case control study. They were followed up from their 1st visit (not included after 13th week) to 1st week after delivery for at least 4 checkups. Blood glucose was measured on every visit following WHO criteria; GDM was diagnosed within 24th to 28th weeks. Depressive symptoms was scored following MADRS scale (0-12=not, 13-19=mildly, 20-34 moderately, 35-60=severely - depressed). Semi structured questioner was used to assess their socio-demographic status and clinical history. BP, Height, weight was measured on each visit. Birth weight and APGAR score were assessed for the neonate.
Results: 382 subjects found to have GDM while 363 were without glucose abnormality. Prevalence of depression among pregnant women was 12.69%. The rate was higher in GDM subjects (21.73%) with mean age 28.34 years than NGDM subjects (7.73%) with mean age 27.17 years. Depression was more common in Middle aged group (26-35years, 22.53%). Surprisingly depression was found more in higher educated group. Occupation and habit of physical exercise do not seem to have any influence over depression but ove DM. Financial status may have an effect on depression, as the total income had a significant association with depressive symptoms (OR.18.5, 95%CI, 2.4, 9.6, P<0.001). Interestingly, though most of the participants were housewives, depression was more common in working women but with low income. Multipara women were more prone to both the diseases. FBS had some significant association with depression. Depression did not seem to have any association with neonatal status like APGAR and Birth weight but more analytical study is recommended to confirm it. Table 1: Prevalence of Depressive symptoms by age

Age	Non Depressive (MADRS<13)		Depressive (MADRS>13)		Prevalence of Depression (% and 95% CI)		
	NGDM	GDM	NGDM	GDM	NGDM	GDM	Total
≤15		3		1	na	25.00 (0.47, 0.37)	25.00 (0.48, 0.37)
16-25	131	81	10	21	7.09 (0.04,0.03)	20.59 (0.09, 0.07)	12.76 (0.04, 0.04)
26-35	196	196	16	57	7.55 (0.03, 0.02)	22.53 (0.06, 0.04)	15.70 (0.03, 0.03)
36-45	8	19	2	4	20.00 (0.13, 0.13)	17.39 (0.17, 0.14)	18.18 (0.14, 0.11)
Total	335	299	28	83	7.73 (0.03, 0.02)	21.73 (0.04, 0.03)	12.69 (0.02, 0.02)

Conclusion: The study confirmed again that depression boosts up in diabetes of all type and status. But the important finding of this study was the elevated prevalence rate of depression in pregnancy which was greater than assumed. Developing countries do not focus much on mental health but it is becoming ultimate necessity for future.

Diabetologist perceived barriers to addressing psychological matters in diabetes consultations

C.B. Johansen, R. Torenholt, E. Hommel, M. Wittrup, I. Willaing;
Steno Diabetes Center, Gentofte, Denmark.

Background and aims: In approximately two out of three cases health professionals working with diabetes fail to identify psychological problems and disorders in their patients. This has potential serious clinical implications: 1) diabetes is associated with an increased risk of psychological disorders, such as depression and anxiety; 2) the co-existence of psychological disorders and problems and diabetes are associated with poor diabetes outcomes, for example treatment adherence, higher HbA1c, and higher mortality; 3) psychological problems, such as diabetes distress and low quality of life, have clinical relevance in their own right. Diabetologists report poor psychological health to be widespread among patients with diabetes. This indicates a considerable gap between clinician awareness and clinical practice. It seems important to explore why hospital-based diabetologists fail to identify their patients' psychological problems. This study aims at identifying barriers as perceived by diabetologists to addressing psychological matters in diabetes consultations.
Materials and methods: We conducted a qualitative study based on individual semi-structured interviews with 12 diabetologists from four diabetes specialist clinics. The interviews lasted 50-60 minutes and were audio taped. The interview guide consisted of themes such as the individual physician's

definition of psychological problems and perceived barriers to addressing psychological problems in their patients. All interviews were transcribed verbatim. Analysis was performed according to the method of systematic text condensation (STC) formulated by Kirsti Malterud. The procedure consisted of four steps: 1) identification of preliminary themes 2) identification of meaning units related to previously identified themes 3) condensation and 4) synthesizing.
Results: Some diabetologists defined psychological problems as exclusively psychological pathology, for example depression or eating disorders whereas others perceived psychological matters more broadly, including problematic challenges of everyday life with diabetes. The barriers reported fell in three categories: system-related barriers, patient-related barriers and physician-related barriers. System-related barriers included perceived limited time and demands of time consuming documentation in the consultations. Patient-related barriers included the seriousness of patients' psychological problems and patients' apparent indifference to their diabetes. Physician-related barriers included perceived lack of skills in the field of psychology, lack of skills in opening and closing dialogue about psychological problems and the feeling of being powerless against the psychological burden of patients.
Conclusion: We identified several barriers, potentially amendable, for addressing patients' psychological problems in diabetes consultations. Diabetologists emphasized lack of time as a major barrier. However, the individual diabetologist receive very little guidance, and the organizational structure of consultations appears to exclude psychological health and problems from the systematic agenda for diabetes consultations. There seems to be a huge challenge in the trade-off between time for including diabetes health, psychological health and written documentation in diabetes consultations.

1152

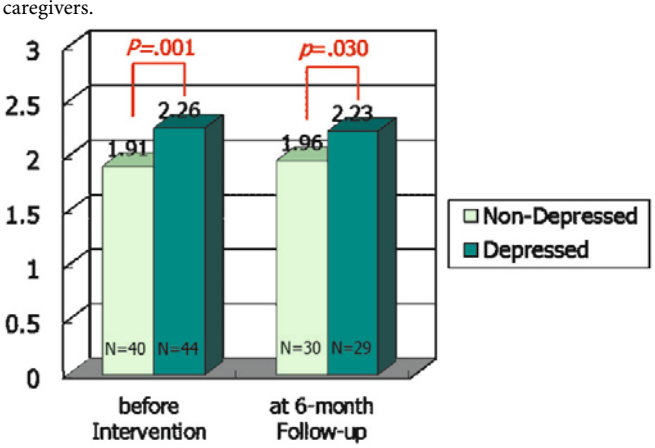
Depression in diabetes: the role of diabetes-related distress on incidence and recovery
D. Ehrmann, N. Hermanns, B. Kulzer, N. Bergis, B. Maier, T. Haak;
Research Institute Diabetes Academy Mergentheim (FIDAM), Bad Mergentheim, Germany.

Background and aims: Prevalence of depression in diabetic patients is nearly twice as high as in the non-diabetic population. As recent meta-analytic findings suggest, diabetes seems to be a risk factor for the incidence of depression or at least for elevated depressive symptoms. Mechanisms linking the diagnosis of diabetes to the development of depression are unknown. This study prospectively investigates the role of diabetes-related distress on incident depression and recovery in diabetic patients.
Materials and methods: Participants completed the CES-D and the Problem Areas in Diabetes Scale (PAID) at baseline and at a 6-month follow-up. Elevated depressive symptoms were indicated by a CES-D score of ≥16. A PAID score of ≥30 indicated moderate diabetes-related distress. Logistic regression analyses were performed with recovery from and incidence of depressive symptoms as dependent variables. Independent variable was diabetes-related distress adjusted for possible demographic (age, gender) and medical confounders (diabetes type, diabetes duration, HbA1c, BMI, late complications and intensification of treatment).
Results: Data from 370 patients with insulin therapy were analysed (age 53.9 ±14.2 yrs.; 47% female; 46% type 2 diabetes; diabetes duration 16.6 ±11.1 yrs.; HbA1c 8.5 ±1.4%; BMI 29.9 ±6.3 kg/m²; 57% with late complications; 4.2 ±1.7 injections/day). At baseline, 145 patients (39.2%) reported elevated depressive symptoms and 37 of these patients (25.5%) recovered 6 months later. Out of the 225 patients without elevated depressive symptoms, 35 (15.6%) had elevated depressive symptoms 6 months later. If diabetes-related distress was not present at baseline the chance to recover from elevated depressive symptoms was 2.8 times higher than if diabetes-related distress was present (OR=2.8; p=.017; 95% CI 1.2-6.6). Furthermore, if diabetes-related distress was present at baseline but could be reduced (PAID-score<30) at follow-up, the chance to recover from elevated depressive symptoms was substantially increased (OR=8.8; p=.003; 95% CI 2.1-37.0). In addition, the chance for incident depressive symptoms was reduced by 73% if diabetes-related distress was not present at baseline in contrast to present diabetes-related distress (OR=0.27; p=.003; 95% CI 0.11-0.64). For all analyses, none of the confounders reached a significant Odds Ratio.
Conclusion: This prospective study demonstrates that elevated diabetes-related distress is a risk factor for the incidence of elevated depressive symptoms and influences the reduction of depressive symptoms. These effects are independent and not mediated by demographic or medical confounders. One limitation of this study is the fact that depressive symptoms were assessed via a self-report questionnaire and not via interviews according to ICD-10. Nevertheless, the diagnosis of diabetes does not seem to be a risk factor for depression per se but the perception of diabetes-related distress seems to be much more important. Future research should address intervention strategies to reduce diabetes-related distress and the effect on depression to corroborate the findings presented. The findings suggest that it seems to be a promising approach to reduce depressive symptoms by reducing diabetes-related distress at first.

1153

Impact of comorbid depression on glycaemic control and family functioning in treatment-resistant Japanese patients with type 2 diabetes: a 6-month follow-up study
T. Saeki[1,2], M. Takaishi[3], S. Yamawaki[3], K. Ishida[4], T. Komo[5], S. Tazuma[1];
[1]General Medicine, Hiroshima University Hospital, [2]Palliative Medicine, Municipal Miyoshi Central Hospital, Miyoshi, [3]Psychiatry and Neurosciences, Graduate School of Biomedical Sciences, Hiroshima University, [4]Diabetes Metabolism Internal Medicine, JA Hiroshima General Hospital, Hatsukaichi, [5]Diabetes Internal Medicine, Medical Corporation Ichiyo-kai Harada Hospital, Hiroshima, Japan.

Background and aims: Depression in patients with diabetes is associated with poorer adherence and worse health outcomes. However, evidence for the efficacy of treating depression in improving glycemic control was mixed. The aim of the study was to investigate the impact of depression on glycemic control and quality of life including family functioning among treatment-resistant Japanese patients with type 2 diabetes and their caregivers.
Materials and methods: Ambulatory patients with type 2 diabetes were drawn consecutively from the treatment-resistant inpatient population participated in a two-week educational intervention program at two general hospitals affiliated with our university. Those who could have cognitive impairment were cautiously excluded. Among 123 out of 159 patients who gave written informed consent, we enrolled 84 patients living with his/her caregiver in the study to focus on family functioning. Before and after the intervention program, and also 6 months later, the subjects and their caregivers completed the Zung Self-rating Depression Scale(SDS), the Zung Self-rating Anxiety Scale, and the Problem Areas In Diabetes scale. Family functioning was assessed by the Family Assessment Device before the program and 6 months later. This study was approved by the Institutional Review Board and the Ethics Committee of those two hospitals and our university.
Results: "Depressed Patients" (N=44; SDS score at baseline >= 40) perceived significantly worse diabetes-related quality of life including family functioning than "Non-Depressed Patients" (N=40; SDS score at baseline < 40) before the intervention. At the 6-month follow-up after the intervention, Depressed Patients apparently improved in their mood, quality of life including family functioning, but still showed significantly worse general health, inappropriate familial communication and higher HbA1c values than Non-Depressed Patients.
Conclusion: The findings of the short-term longitudinal study suggested that, as for treatment-resistant patients with diabetes, depression at baseline might predict worse quality of life, less effective family functioning, and worse glycemic control afterward. Consequently, diabetes care professionals should devote attention to taking care of mood status of patients, and intervene to promote more effective communication among patients and their caregivers.



Gap between „Communication" scores by the Family Assessment Device (the higher score, the worse functioning): No improvement even at 6-month follow-up.

Low prevalence of depression and burden by diabetes mellitus at secondary care level in Germany
N. Kuniß, G. Kramer, N. Müller, C. Kloos, G. Wolf, U.A. Müller;
Dept. Internal Medicine, University Hospital Jena, Germany.

Background and aims: The importance of psychosocial factors for the treatment of diabetes mellitus is accentuated in the recommendation of all guidelines. A recent survey showed that every third patient with diabetes mellitus (DM) suffers from depressive disorders. Furthermore, it is suspected to be a trigger for diabetes complications. To detect diabetes-related burden and depression the PAID questionnaire ("Problem Area In Diabetes") provides a valid and reliable instrument.
Materials and methods: From 01.11.2012 to 31.01.2013 we assessed diabetes related burden and depression in 785 patients with DM (24.6% type 1, mean HbA1c 7.9%, age 54.3 years, diabetes duration 22.6 years, blood pressure 154/84 mmHg, BMI 27,0 kg/m2, 80/89 without retinopathy and 97/170 without neuropathy; 75.4% type 2, HbA1c 7.6%, age 66.6 years, diabetes duration 15.6 years, blood pressure 146/85 mmHg, BMI 32.8 kg/m2, 252/289 without retinopathy and 252/535 without neuropathy) with the PAID questionnaire in an university outpatient department for endocrinology. A PAID score <40 was considered as no increased risk of depressive disorders. As confounders of the "diabetes mellitus" effect on mental health we checked age, gender, type and duration of diabetes, method of treatment (with or without insulin), HbA1c and marital status. The department takes part in the disease management programme DM, therefore half of the patients are in permanent care. Patients attend the clinic usually every three months, or more often according to clinical needs. Participation in at least one of the following five structured patient education programmes, given by trained diabetes nurses and a diabetologist, is part of the standard treatment of all patients. If necessary patients got refresher courses. This is mainly the case in patients on insulin therapy.
Results: The main PAID score was 17.1 (DM1 17.8 vs. DM2 16.8, p=0.42). 91.1% of all responders had no diabetes-related signs of depression (score <40). There was a negative correlation with respect to the age of the patients (r=-0.205, p<0.001). The older the patients, the lower was the burden of diabetes. Metabolic control was associated to the PAID score, as we found a positive correlation with HbA1c (r=0.168, p<0.001). In contrast to age we did not found a correlation with duration of diabetes (r=-0.017; p=0.63). Furthermore, there were no significant differences regarding PAID score between patients with type-1 and type-2 (17.8±15.7 vs. 16.8±14.9; p=0.42), as well between patients with or without insulin (17.3±15.4 vs. 16.5±15.4; p=0.55). But there were significant differences between women and men (19.0±16.6 vs. 15.6±13.6; p=0.002). The marital status (living alone vs. married/cohabitee) had no effect (16.5±14.8 vs. 17.3.±15.2; p=0.51).
Conclusion: In contrast to a recent survey in a German inpatient diabetes centre with 30.8% of patients scored 40 or more in the PAID questionaire, less than 10% of our outpatients with DM showed a suspicion of depressive mood or high burden of diabetes. Beside the patients selection in an inpatients setting, possible reasons for the low prevalence of depression in our sample could be the participation in the disease management programme for outpatients and the high percentage of patients with permanent care in the department, as we could show recently social inequalities of diabetes care disappeared after care in our centre.

1155

Depression, anxiety, cognitive impairment and their correlations with clinical and demographic variables in people with type 2 diabetes: a 4-year prospective study
M. Trento[1], M. Raballo[1], M. Trevisan[1], P. Passera[1], F. Schellino[1], L. Charrier[2], P. Berchialla[2], F. Cavallo[2], M. Porta[1];
[1]Medical Sciences, Laboratory of Clinical Pedagogy, [2]Public Health and Pediatric Sciences, University of Turin, Italy.

Background and aims: Depression is at least twice as common among people with type 2 diabetes (T2D) as in the general population. The prevalence of depression, anxiety and cognitive impairment and their associations with clinical and socio-demographic variables were investigated in a 4-year follow up study in a population with T2D.
Patients and methods: 498 consecutive T2D patients were investigated, 249 Non Insulin-Treated (NIT) and 249 Insulin Treated (IT), aged 40-80 years. Demographic and clinical variables, depression, anxiety and cognitive impairment were measured at baseline and after 4 years by the Zung Self-Rating-Depression-Anxiety-Scale and Mini-Mental-State-Examination (MMSE).
Results: At baseline NIT patients were younger and had shorter disease duration (p<0.001, both). The IT did more blood glucose monitoring (BGM) and had higher blood glucose and HbA1c (p<0.001, both). The mean scores for depression were lower among the IT (p=0.006) with no differences for anxiety or MMSE. After 4 years, 72 patients were lost to follow-up, of whom 18 had died. The latter were older (p=0,0003), did more frequent BGM (p=0,019), smoked more (p=0.02) and had higher prevalence of microalbuminuria (MA) (p=0.03) than the survivors. The remaining 171 NIT had improved their fasting glucose (p=0.006), total cholesterol (p<0.0001), triglyceride and HbA1c (p=0.0006). Although the prevalence of MA and diabetic retinopathy (DR) had increased (p<0.0001, both), there was a small improvement in depression (p=0.04) and MMSE (p=0.0007). 41 NIT had been switched to IT and increased BMI (p=0.004), blood pressure (p<0.001), DR severity (p=0.03) and MA (p=0.0045), but did not change depression, anxiety or MMSE scores. The remaining original 214 IT patients increased the prevalence and severity of foot ulcers (p=0.03), DR (p<0001), MA (p=0.0047) and numbers treated for hypertension (p<0.0001). They had worse depression (p=0.0005) and anxiety (p<0.0001) but MMSE improved slightly (p=0.0002). Multivariate analysis showed that women with lower education had higher levels of anxiety but no difference in depression.
Conclusion: Depression and anxiety are associated with T2DM but not modified by time or switching to insulin therapy. Anxiety is associated with female gender and low schooling. Depression and anxiety are likely to worsen when complications become more severe.

Simple self-reported anger and memory loss as risk factors for the development of type 2 diabetes in Japanese individuals
A. Suzuki[1], Y. Heianza[2,1], Y. Arase[3,4], S. Hara[3,4], S. Hsieh[3,4], T. Yamada[1], K. Fujihara[1], K. Saito[5,1], S. Kodama[1,6], O. Hanyu[1], H. Sone[1];
[1]Department of Internal Medicine, Niigata University Faculty of Medicine, Niigata, [2]Department of Internal Medicine, University of Tsukuba Institute of Clinical Medicine, Tsukuba, [3]Health Management Center, Toranomon Hospital, Tokyo, [4]Okinaka Memorial Institute for Medical Research, Tokyo, [5]Center for Medical Sciences, Ibaraki Prefectural University of Health Sciences, Ibaraki, [6]Mito Kyodo General Hospital, Mito, Japan.

Background and aims: Although behavioral symptoms or psychological stresses can be considered as novel markers for risk of future type 2 diabetes, whether responses to simple statements on the presence of one or more of such factors would be effective in screening individuals at high risk of type 2 diabetes remains uncertain. We tested the hypotheses that a simple self-report questionnaire on negative behavioral or psychological characteristics including perseverance, anger, memory loss or sleep disorders would be predictive of the development of type 2 diabetes, and that the association would be independent of metabolic factors including fasting plasma glucose (FPG) and HbA1c concentrations in Japanese individuals.
Materials and methods: We investigated 2869 non-diabetic Japanese individuals. At the baseline examination, behavioral or psychological factors were assessed using a questionnaire. Firstly, individuals were asked as to whether they gave a positive answer to items on lack of perseverance, anger (testy, or easily annoyed), memory loss or sleep disorder. Cumulative incidence rate and hazard ratios (HRs) for the development of T2DM over 7-13 y were evaluated according to the presence of anger, lack of perseverance, memory loss or sleep disorders.
Results: Results of Cox regression analysis showed that anger, (age-sex-adjusted HR 1.71 (95% CI: 1.20, 2.42) or memory loss (1.49 (1.13, 1.96)) was predictive of the development of type 2 diabetes. Even after adjustment for metabolic factors including fasting plasma glucose and HbA1c concentrations, the two factors were significantly associated with an increased risk of future type 2 diabetes. We found that individuals with both anger and memory loss had a 2.44 (95% CI: 1.50, 3.97) times increased risk of type 2 diabetes than those without those two symptoms.

Conclusion: Responses to a simple self-report questionnaire as to whether individuals were aware of anger or memory loss could predict new onset of type 2 diabetes independent of traditional predictors. Using this easy-to-implement instrument might be an adjunctive screening method for detection of individuals at high risk of future type 2 diabetes.

Psychological, behavioural and biological changes following treatments of subsyndromal depression in people with type 2 diabetes
M. Pibernik-Okanovic[1], M. Vucic Lovrencic[2], D. Ajdukovic[1], M. Sekerija[3], N. Hermanns[4];
[1]Clinic for Diabetes Complications, Vuk Vrhovac University Clinic for Diabetes, Zagreb, [2]Department of Laboratory Medicine, Merkur University Hospital, Zagreb, [3]Croatian National Institute of Public Health, Zagreb, Croatia, [4]Forschungsinstitut Diabetes-Akademie Bad Mergentheim, Germany.

Background and aims: Research on clinical benefits of treating subsyndromal depression is scarce. This study aimed to determine the effects of three behavioural treatments -psychoeducation, physical exercise and diabetes re-education- in type 2 diabetic patients with mild depressive symptoms.
Materials and methods: A sample of 209 type 2 patients with subsyndromal depression (aged 57±6 yrs, 54% female, with diabetes duration of 11±8 yrs, 32% insulin treated, with HbA1c of 7.3%±1.2 and BMI of 30±5 kg/m2) were randomly assigned to either psychoeducation, physical exercise, or the control arm. The interventions were aimed at enabling patients to alleviate depressive symptoms. Psychoeducation was focused on cognitive-behavioural skills, and physical exercise on physical activation. The interventions comprised 6 weekly group sessions. The control arm consisted of one patient-centred re-educational session. The assessments of depressive symptoms, diabetes distress, diabetes self-care and health-related quality of life (QoL) were made by using validated questionnaires. Metabolic status was assessed by HbA1c and lipid panel (triglycerides, total-, HDL- and LDL-cholesterol). Leukocytes (total, neutrophils, lymphocytes and mononuclears), myeloperoxidase index (MPXI) and CRP, and plasma uric acid were used as endogenous inflammatory and antioxidant markers. The same psychological and laboratory measures were repeated after the completion of the interventions, and after a 6-month follow-up period. Repeated measures ANOVA was used to determine within- and between-group differences at follow-ups.
Results: Psychological outcomes including depressive symptoms, diabetes distress, subjective health, emotional roles and mental health improved after the interventions and remained so after six months, regardless of the group assignment (all time effects' $p<0.001$). Diabetes diet improved after the treatments ($p<0.001$) but deteriorated at six months follow-up ($p=0.01$). Physical exercise, self-monitoring blood glucose and foot care demonstrated stable improvement (all time effects' $p<0.001$). Glycaemic control was slightly improved in all groups (HbA1c : 7.24%±1.13 vs 7.09%±0.97 vs 7.08%±0.89 $p=0.002$). A significant drop in total cholesterol was found after the treatment ($p=0.01$), but this was not maintained after 6 months in any of the groups. CRP was not changed, whereas leukocyte-, neutrophil- and lymphocyte-counts significantly decreased (all $p<0.001$) throughout the follow-up period. MPXI recovered to baseline levels after a significant post-treatment drop ($p<0.001$). Plasma uric acid remained unchanged in males, but increased significantly at follow-up ($p<0.001$) in females in all three groups.
Conclusion: The employed behavioural interventions had comparable positive effects on 6-month-outcomes including depressive symptoms, diabetes distress, health-related QoL, diabetes self-care, glycemic control, and markers of chronic inflammation. Treating subtreshold depressive symptoms in type 2 diabetic patients by even minimal behavioural intervention has favourable clinical implications.

Defining the health economic value of avoiding weight gain and hypoglycaemia in type 2 diabetes mellitus
A. Lloyd[1], V. Foos[2], P. McEwan[3], D.M. Grant[4], M. Lamotte[5], J. Palmer[2];
[1]Health Economics and Outcomes Research, IMS Consulting Group, London, UK, [2]Health Economics and Outcomes Research, IMS Health, Basel, Switzerland, [3]Centre for Health Economics, Swansea University, Cardiff, [4]Health Economics and Outcomes Research, IMS Health, London, UK, [5]Health Economics and Outcomes Research, IMS Health, Vilvoorde, Belgium.

Background and aims: Treatment algorithms for the medical management of people with type 2 diabetes mellitus (T2DM) are based on a combination of glucose lowering efficacy and other important clinical effects such as the avoidance of weight gain and hypoglycaemia. Based on glucose lowering potential only, the addition of a sulphonylurea or basal insulin in those uncontrolled on metformin mono-therapy is considered the most effective and cost effective treatment strategy. From the patient perspective, weight gain and hypoglycaemia can negatively impact quality of life, treatment satisfaction and the attainment of glycaemic goals. The objective of this study was to assess the economic value associated the three key components of T2DM: changes in HbA_{1c}, hypoglycaemia and body mass index (BMI).
Materials and methods: This study utilized the IMS CORE diabetes model (CDM) to model four profiles associated with managing type 2 diabetes; Treatment 1: -0.5% HbA_{1c}; Treatment 2: -0.5% HbA_{1c} and BMI -1 Kg/m^2; Treatment 3: -0.5% HbA_{1c}, BMI -1 Kg/m^2 and 2 non-severe hypoglycaemia (NSHE) avoided; Control: no effect. Lifetime analyses were conducted using patient level data (NHANES) to populate the modelling. Health dis-utilities of -0.0052 and -0.0038 were applied to each NSHE and 1 unit increase in BMI respectively. Discounting was applied at 3.5% and GBP 2011 costs were used.
Results: Compared to Control (no effect), Treatments 1, 2 and 3 were associated with discounted gains in lifetime quality adjusted life expectancy (QALE) of 0.05, 0.107 and 0.233 respectively. Each unit decrease in NSHE and BMI were associated with similar gains in QALE associated with a 0.5% HbA_{1c} reduction. The maximum annual therapy specific costs (to remain cost effective at a willingness to pay threshold of GBP 20,000) for treatments 1, 2 and 3 were GBP 109.4, GBP 205.4 and GBP 428.6 respectively.
Conclusion: The health utility gains associated with weight reduction and avoidance of NSHE impact patients in the short-term and are therefore subject to less discounting within health economic models; in contrast to changes in HbA_{1c} that impact the probability of a future cardiovascular or microvascular event. Consequently, treatment strategies that avoid weight gain and hypoglycaemia exhibit favourable cost effectiveness profiles compared to improvements in glycaemic control only.

1159

Health-related of quality of life using EQ-5D in patients with type 2 diabetes
F. Saleh[1], F. Ara[1], S.J. Mumu[2], M.A. Hafez[3], F. Khan[4], L. Ali[5];
[1]Community Nutrition, Bangladesh University of Health Sciences (BUHS), Dhaka, [2]Epidemiology, [3]Biostatistics, BUHS, Dhaka, [4]Specialty Business Unit, Sanofi-Aventis Bangladesh, Dhaka, [5]Biochemistry & Cell Biology, BUHS, Dhaka, Bangladesh.

Background and aims: Diabetes is a lifelong disease that affects a patient's general health and well-being in various ways. Consequently, diabetes management requires a fundamental change in the patient's lifestyle and the one of the important outcome criteria in this view is quality of life. The aim of the study was to assess the health-related quality of life (HRQoL) and to examine the factors associated with HRQoL.
Materials and methods: An analytical cross-sectional study was conducted among 500 type 2 diabetics (age>25 years and diabetes duration >1 year), who were selected conveniently from the OPD of Bangladesh Institute of Health Sciences Hospital (BIHSH). Data were collected by a pre-tested, interviewer-administered questionnaire. HRQoL was assessed by an adapted and validated Bangla version of the EQ-5D (EuroQol Group, 2009) questionnaire which has five domains- mobility, self-care, usual activities, pain/discomfort

and anxiety/depression and three levels on each dimension. In addition, the Euroqol visual analogue scale (VAS) was used for assessing patients' overall actual health state where 0 represents the worst imaginable health state and 100 indicate perfect health.
Results: Mean age of the patient was 54.2 (±11.2) years; About 50.2% were females. Most of the patients (92.2%) belonged to middle to upper-middle age group; 41% had completed high school and 50.8% were from lower-middle income family. Mean BMI was 26.1(±6.7) kg/m2 and about 78.8% were overweight or obese according to Asian BMI cut-off value. About 49.6% patients had no problem in mobility, 71.8% in self-care, and 52.4% in usual activities though 57.8% had some problem in pain/discomfort and 59.4% in anxiety/depression. The mean ±SD EQ VAS score was 65.4(±18.3). The EQ VAS score of the female patients was significantly lower than the male patients (60.4±17.6 vs 70.5±17.5, p<0.0001). In binary logistic regression, age (OR 1.05; 95% CI 1.02 to 1.07), gender (OR 4.87; 95% CI 1.48 to 15.99), taking of OHA & insulin (OR 1.62; 95% CI 1.02 to 2.59) and lower-middle income group (OR 2.51; 95% CI 1.08 to 5.85) were significantly associated with mobility. Self-care was significantly related with age (OR 1.03; 95% CI 1.01 to 1.06), family history of DM (OR 0.43; 95% CI 0.26 to 0.73) and duration of DM (OR 1.05; 95% CI 1.01 to 1.08). Gender (OR 4.79; 95% CI 1.45 to 15.78), family history of DM (OR 0.46; 95% CI 0.28 to 0.74) and lower-middle income group (OR 2.67; 95% CI 1.13 to 6.29) had significant association with usual activities. Pain/discomfort was significantly associated with age (OR 1.05; 95% CI 1.02 to 1.07), taking of OHA & insulin (OR 1.75; 95% CI 1.04 to 2.93), lower-middle income (OR 2.89; 95% CI 1.25 to 6.64) and upper-middle income group (OR 2.54; 95% CI 1.12 to 5.79). Higher education (OR 0.24; 95% CI 0.08 to 0.68) was significantly related to anxiety/depression.
Conclusion: Around half of the patients have problem in mobility, usual activities,pain/discomfort,anxiety/depression and majority in self-care. Age, female gender, lower-middle & upper-middle income group, higher education, taking of medication, family history of DM and duration of DM are important factors associated with HRQoL in patient with type 2 diabetes.

Flexible insulin dosing improves health-related quality of life (HRQoL): a time trade-off survey
B. Chubb[1], M. Evans[2], H.H. Jensen[3], M. Bøgelund[3], J. Gundgaard[4], K. Khunti[5];
[1]Novo Nordisk Pharma Ltd, Crawley, [2]Llandough Hospital, Cardiff, UK, [3]Incentive, Holte, [4]Novo Nordisk A/S, Søborg, Denmark, [5]Department of Health Sciences, University of Leicester, UK.

Background and aims: The rigidity of insulin regimens may negatively impact on health-related quality of life (HRQoL) and therapy adherence, with the requirement for basal insulin dosing at the same time every day being a significant contributing factor. We examined the HRQoL impact of both flexible timing of the basal insulin injection and the number of basal insulin injections, in basal and basal-bolus regimens using time trade-off (TTO) methods.
Materials and methods: HRQoL was examined via an online TTO survey in the UK, Canada and Sweden with separate analyses of 2,465 respondents from the general population, and 265 and 392 people with type 1 (T1D) and type 2 diabetes (T2D), respectively. HRQoL was measured on a utility scale: 0 (dead), 1 (perfect health). Respondents traded off length of life for improving HRQoL in described health states. Respondents evaluated health states with diabetes and basal injections that were once-daily time-flexible, once-daily time-fixed and twice-daily time-fixed injections as part of a basal or a basal-bolus regimen.
Results: A time-flexible basal injection was associated with 0.016 (95% CI 0.011; 0.022) and 0.013 (95% CI 0.007; 0.019) higher utility vs. a fixed time of injection for basal-only and basal-bolus regimens, respectively, as evaluated by the general population (Table 1). The diabetes respondents confirmed the basal-only results, but the difference in utility was small and insignificant for basal-bolus. Once-daily injections had significantly higher utility compared with twice-daily injections for basal (0.039 [95% CI 0.032; 0.046] and basal-bolus (0.022 [95% CI 0.016; 0.028]) regimens, as evaluated by the general population. These results were confirmed by the respondents with diabetes.
Conclusion: Flexible dosing and fewer injections have a positive HRQoL impact, which may enhance therapy adherence and potentially contribute to improved long-term outcomes. The impact of flexibility is greater in people treated with basal-only insulin regimens, and diminishes if bolus injections are part of the treatment regimen.

Table 1: Utility differences from the time trade-off survey

	Basal-only				Basal-bolus

Economic models of diabetes mellitus: Are we making decisions on the best available evidence?
K. Norrbacka[1], W.J. Valentine[2], K.S. Boye[3], B.H. Curtis[3], J.P. Bae[3], L. Timlin[4], R.F. Pollock[2], J. Smith-Palmer[2], B. Hunt[2], D. Kendall[3];
[1]Eli Lilly, Helsinki, Finland, [2]Ossian Health Economics and Communications, Basel, Switzerland, [3]Eli Lilly, Indianapolis, USA, [4]Lilly UK, Windlesham, UK.

Background and aims: It is almost a decade since a number of important computer simulation models of diabetes mellitus were published. Several regulatory agencies have recently raised concerns that models based on historic clinical data may have limited relevance as care patterns and therapeutic choices change over time. This concern was echoed in a recent validation study, which reported limitations in the UKPDS Outcomes Model in predicting endpoints such as stroke, amputation, heart failure, and death from any cause. As the global economic crisis further restricts healthcare resources, accurate economic evaluation and prediction (and its influence on clinical decisions in diabetes care) will be increasingly important. To understand how models perform in predicting outcomes in the current diabetes care environment, a systematic literature review was undertaken to identify publications on diabetes models, clinical data relevant to complications, disease progression and mortality risk.
Materials and methods: In October 2012, literature searches including studies of both type 1 and type 2 diabetes were performed based on Medical Subject Heading terms in the PubMed and Cochrane Library databases. Hand searches of health technology assessment databases and landmark trial websites were also performed. Searches were limited to publications in 2004 or later. Abstracts were screened to exclude studies that did not provide longitudinal data, had follow up of less than 1 year, or study populations of fewer than 100 subjects. Full-text review of all remaining publications was performed to understand the capabilities of current diabetes models and identify opportunities for improvement.
Results: The literature searches identified a total of 12,405 hits for screening since 2004. Screening identified a total of 523 publications in type 2 diabetes and 53 papers in type 1 diabetes that met criteria for full-text review. Little has been published to validate the performance of diabetes models in recent years, or to describe how recent clinical observations have been integrated into models. In type 2 diabetes, data from meetings (e.g. Mount Hood) indicate that, although modeled estimates of relative risk between interventions may be acceptable, estimates of absolute risk represent an opportunity for improvement (comparison with CARDS, ASPEN, ADVANCE and ACCORD). The review identified many type 2 diabetes studies that may provide valuable information in terms of risk adjustment since publication of the models themselves. In type 1 diabetes, there are few data validating model performance in recent years. Long-term follow-up data from longitudinal studies (EDIC and Pittsburg EDC) may offer potential to update models of type 1 diabetes.
Conclusion: Literature review has demonstrated that there is a paucity of studies relating to the validation and ongoing development of existing models of diabetes. There may be an opportunity to incorporate data, where appropriate, from recent clinical approaches to management in both type 1 and type 2 diabetes to ensure that economic models reflect current practice and can best inform cost-benefit decisions for care.

Acute coronary syndrome patients with type 2 diabetes had higher healthcare costs vs patients without diabetes in the US population from 2006 to 2011

Y. Xu[1], M.J. Cziraky[2], R. Luthra[2], M.D. Fisher[2], K. Wilhelm[1], T.P. Power[3], V.S. Reddy[1];
[1]Genentech Inc., South San Francisco, [2]HealthCore Inc., Wilmington, [3]AIM Specialty Health, Deerfield, USA.

Background and aims: Acute Coronary Syndrome (ACS) contributes significantly to morbidity and mortality and represents an enormous economic burden to society. T2D has been recognized as one of the major risk factors for ACS; however, there are limited published data quantifying the impact of T2D on healthcare costs, especially the long-term costs following ACS. This study evaluated the total and cardiovascular (CV)-related healthcare costs for ACS with T2D versus patients without diabetes.
Materials and methods: Patients with ≥ 1 ICD-9 code for acute myocardial infarction (MI) (410.xx) or unstable angina (411.1x) during hospitalization were identified from the HealthCore Integrated Research Database (HIRD^{SM}) between 01/01/2006 and 09/30/2011. The first ACS hospitalization date was defined as the index event date. T2D patients were selected if ≥ 2 claims for T2D (250.x0, 250.x2) at least 30 days apart; or ≥ 1 claim for T2D and ≥ 1 claim for oral or injectable anti-diabetics; or ≥ 2 prescriptions of oral anti-diabetics or glucagon-like peptide 1 medications. Those with no evidence of a type 1 or 2 diabetes diagnosis claim (250.xx) in the study period were identified as ACS patients without diabetes. Patients with < 12 months' plan eligibility pre- and post-index ACS or age < 18 years were excluded. Total and CV-related healthcare costs following the index ACS event were evaluated in patients with T2D and without diabetes, for 1, 2 and 3 years, respectively, adjusting for baseline differences including demographic characteristics, co-morbidities, treatment utilization and index ACS characteristics.
Results: Of the 140,903 ACS patients identified, 38,553 (27%) and 81,845 (58%) patients have been selected into the ACS with T2D and without diabetes cohorts, respectively. Patients with T2D vs. without diabetes were older (mean age 68.2 vs. 65.6 years, respectively) and had higher mean baseline comorbidities (Deyo-Charlson Index score 3.15 vs. 1.11, respectively). Mean (median) length of stay of the index ACS hospitalization was longer in patients with T2D vs. without diabetes (7.62 [4.00] versus 5.20 [3.00] days, respectively). Adjusted mean (median) 1-, 2-, and 3-year post-index total and CV-related costs for T2D cohort were significantly higher than those without diabetes (Table). After adjusting for baseline differences, compared to non-diabetes, ACS patients with T2D had significant 14.4%, 16.2% and 14.8% increased total annual costs at 1, 2 and 3 years, respectively.
Conclusion: T2D patients have increased total and CV-related healthcare costs at 1, 2 and 3 years post-ACS event as compared with non-diabetes patients. These results provide further confirmation that new therapies directed specifically at T2D patients with ACS are needed to not only improve the quality of care, but also to help reduce the cost of care.

Table: Comparison of total and CV-related adjusted annual healthcare costs at 1, 2 and 3 years following an ACS event in patients with type 2 diabetes versus without diabetes

		With T2D			Without diabetes			P-value
		Mean	SD	Median	Mean	SD	Median	
Total costs, $	1-year	37,728	62,159.0	19,617	29,976	54,815.2	16,470	< 0.0001
	2-year	24,728	37,866.9	14,137	18,379	32,038.6	10,850	< 0.0001
	3-year	19,887	29,392.8	12,132	14,174	22,455.5	8,776	< 0.0001
CV-related costs, $	1-year	28,659	58,322.4	11,032	23,963	50,362.8	10,220	< 0.0001
	2-year	16,653	30,600.8	6,902	13,205	27,632.3	5,679	< 0.0001
	3-year	12,292	21,964.1	5,475	9,452	17,367.2	4,336	< 0.0001

Cost predictors in type 2 diabetes mellitus: a retrospective claims database analysis

R. Ionescu-Ittu[1], M. Bron[2], D. Latremouille-Viau[1], A. Guerin[1], J. Samp[2], E. Wu[1];
[1]Analysis Group, Inc., Boston, [2]Takeda Pharmaceuticals International, Deerfield, USA.

Background and aims: This study aimed to identify cost predictors in type 2 diabetes mellitus (T2DM) patients using oral antidiabetic therapies (OADs).
Materials and methods: Adult patients with T2DM using OADs were identified in the Truven Health Analytics MarketScan® databases (2004-2010). Patients with 4 or more HbA_{1c} tests within 1 year were classified into cohorts based on quartiles (Q) of the distribution of total 12-month diabetes-related costs following a randomly selected OAD prescription date (i.e., index date). Diabetes-related costs were defined as the sum of costs for medical services with a diagnosis for diabetes and antidiabetic (AD) medications. Patient demographics, comorbidity profile, AD use, HbA_{1c} level, and resource use were measured over the 12-month pre-index period and compared between cohorts with the highest costs (i.e., Q4) and lower costs (i.e., Q1-Q3). Multivariate logistic regression was used to identify predictors of the highest diabetes-related costs.
Results: Among the 3,921 selected patients with HbA_{1c} tests (i.e., 5% of the eligible T2DM patients using OADs), the average 12-month diabetes-related cost was $12,623 for the highest cost cohort (N=981) and $1,871 for the lower cost cohort (N=2,940). Compared to the lower cost cohort, during the pre-index period, fewer patients in the highest cost cohort were female and achieved the glycemic goal (HbA_{1c} <7%), more patients used insulin, and patients had a higher comorbidity burden, in particular microvascular diabetic complications, hypertension, and lipid disorders (all $p<0.01$). The main predictors (by greatest ORs) of the highest diabetes-related costs include insulin use (OR=3.08), coronary artery disease (OR=2.27), endocrinologist visit (OR=1.69), number of AD classes used (OR=1.56), diabetic retinopathy (OR=1.53), neuropathy (OR=1.44), and lipid disorder (OR=1.43) (all $p<0.05$).
Conclusion: In a sample of T2DM patients receiving OADs, the main predictors for high diabetes-related costs included factors suggesting greater T2DM severity and diabetic complications.

Trends in the management of type 2 diabetes and its prescription drug costs in Greece (2006 and 2012)

S. Papaoikonomou[1], A. Melidonis[2], A. Papazafiropoulou[3], M. Michael[1], A. Ganotopoulou[2], K. Ntinos[1], S. Bousboulas[3], A. Xilomenos[1], V. Vazintari[2], N. Katsilambros[1], S. Pappas[3], S. Liatis[1];
[1]1st Department of Propaedeutic and Internal Medicine, University of Athens, Medical School Laiko General Hospital, Athens, [2]Diabetes Center, Tzaneio Hospital, Piraeus, [3]Diabetes Center, Nikaia Hospital, Piraeus, Greece.

Background and aims: We had previously reported that cardiovascular risk (CVR) management of patients with type 2 diabetes (T2D), treated by diabetes specialists improved significantly in 2006 as compared to 1998. This finding was associated with a considerable increase in the prescription cost. Shortly thereafter, incretin-based medications launched and acquired a substantial market share. At the same time a major economic crisis emerged in Greece, leading to health system reform and consecutive reductions in drug prices. Aim of the present study, was to compare CVR factor control and prescription drug cost in patients with T2DM between the years 2006 and 2012.
Materials and methods: Medical files of all patients with T2D treated in three diabetes centers, located in Athens and Piraeus, during 2006 and 2012, were examined. Only patients with at least six months of follow-up prior to the recorded visit, were included. The prescription cost was calculated in € per patient/year (PY) according to the official Greek market prices. All comparisons were performed after adjustment for age and duration of T2D.
Results: 938 medical files from 2006 and 1015 from 2012 were included. Patients in the 2012 group were older (67.4±9.6 vs. 64.5±10.5 years, p<0.001), and had longer duration of T2D (13.9±8.1 vs 10.4±8.3, p<0.001). In 2012 a significantly higher proportion of T2D patients used glucose-lowering, lipid-lowering and antihypertensive medications, while no significant difference was observed for antiplatelet agents. The use of sulfonylureas, glitazones, glinides and acarbose decreased significantly. There was no change in the use of insulin, while a significant increase in the use of metformin occurred. In 2012, 34.7% of patients were treated with DPP-IV inhibitors and 3.8% with GLP-1 agonists. There was no significant difference in HbA1c, systolic blood pressure and HDL-cholesterol between 2012 and 2006 (7.0% [7.0-7.1] vs 7.0% [6.9-7.1], 134.1 mmHg [133.0-135.4] vs. 135.2mmHg [134.0-136.9] and 47.7mg/dl [46.8-48.7] vs. 48.4mg/dl [47.4-49.5] respectively). Significant reductions were observed in LDL-cholesterol (97.0mg/dl [94.9-99.0] vs. 112.6mg/dl [110.4-114.9]; p<0.001), triglycerides (138.8mg/dl [134.1-143.5] vs. 150.6mg/dl [145.4-155.7]; p=0.001) and diastolic blood pressure (DBP) (75.8mmHg [75.5-76.8] vs. 77.6mmHg [76.6-77.9]; p=0.03). The cost of prescriptions against hypertension declined slightly in 2012, while no significant difference was observed regarding the cost of lipid-lowering and antiplate-

let agents. A highly significant cost increase was found for glucose-lowering (615.6€PY [593.2-638.1] vs 391.2€PY [364.8-417.6]; p<0.001) and for total prescriptions (1309.4€PY [1272.61353.0] vs 1122 [1080.0-1164.0]; p<0.001).
Conclusion: In 2012, the lipid profile of T2D patients improved significantly, glycemic control remained stable and DBP slightly decreased. Despite a government-derived, overall decrease in medication prices, the glucose-lowering and total prescription cost increased, mainly due to intensification of CVR management and the introduction of new glucose-lowering medications.

1165

Cost of diabetes care and its determinants: a hospital based study in Bangladesh

A. Afroz[1], S.G. Choudhury[2], M.A. Hafez[1], L. Ali[3];
[1]Department of Biostatistics, [2]Department of Health Informatics, [3]Department of Biochemistry & Cell Biology, Bangladesh University of Health Sciences, Dhaka, Bangladesh.

Background and aims: Diabetes is creating a major socio-economic burden on individual, societal and state levels, and cost-effectiveness of interventions against this disorder is a high priority particularly in developing countries. Primary evidence on these issues are scarce even in developed world and these are almost absent in the developing countries. The present study was undertaken to assess the cost analysis of diabetes and its determinants in a Bangladeshi type 2 dietetic population.
Materials and methods: A cross-sectional study was conducted among 496 registered participants (aged ≥30 years) of Out-Patient Department of the central hospital of Diabetic Association with more than 1 year duration of diabetes. All treatment related records of the last 1 year were collected from patients' guide books. The degree and extent of complications like cardiopathy, retinopathy, nephropathy and vasculopathy were recorded and direct, indirect & incremental cost of the management of diabetes and complications were calculated from consumers' point of view. Direct cost included outpatient visits, drugs, laboratory testing and other medical services. Indirect cost included opportunity cost of participants and his/her attendance calculated by human capital approach.
Results: Among 496 patients 46% were males and 54% were females with mean±SD duration of diabetes 8.8±6.8 years. The average annual cost of care was US$ 313 (direct US$ 283 & indirect US$ 31) per patient. Drugs accounted for the largest share of direct cost US$ 193 (67%), followed by laboratory investigations US$ 27 (13%) and consultation fees US$ 23 (12%). Correlation analysis showed that average annual cost increases with increasing age (p=.018), duration of diabetes (p=.001) and increasing blood sugar level (p=.001). Participants with both cardiopathy-nephropathy had 1.8 times, with both cardiopathy-retinopathy had 2.3 times and with both nephropathy-retinopathy had 3.4 times higher cost of care compared to participants without complications. The annual medical costs of participants increased with increase in the number of complications/co-morbidities. Without complications/co-morbidities participants spent US$ 268, but the cost increased to US$ 303 with one/two and US$ 417 with more than two complications/co-morbidities (F=13.7, p=.001). Multiple regression analysis showed that blood sugar level (p=.001), number of complications/co-morbidities (p=0.01) and duration of diabetes were significant (p=0.01) explanatory variables of annual cost of care (R^2=0.21; F=32.5, P<0.001).
Conclusions: The average annual cost of diabetes care per patient in Bangladesh is US$ 313. With an estimated 9.5 million diabetic patients in the country the total annual burden will be US $ 2973.5 million which is huge for a developing country like Bangladesh. Better metabolic control should be in focus which can help in controlling complications and thus lead to substantial saving in the cost diabetes care.

The cost of type 2 diabetes: a population-based study in Catalonia

I. Vinagre[1], M. Mata-Cases[2,3], J. Franch-Nadal[4,3], M. Casajuana[3], R. Morros[3,5], E. Hermosilla[3], F. Fina[3], C. Castell[6], B. Bolivar[3,5], D. Mauricio[7];
[1]Endocrinology and Nutrition, Diabetes Unit, Hospital Clinic, Barcelona, [2]Primary Care Center La Mina, Gerencia d'Ambit d'Atencio Primaria Barcelona Ciutat, Institut Catala de la Salut, Barcelona, [3]Institut Universitari d'Investigacio en Atencio Primaria Jordi Gol, Barcelona, [4]Primary Care Center Raval, Gerencia d'Ambit d'Atencio Primaria Barcelona Ciutat, Institut Catala de la Salut, Barcelona, [5]Universitat Autonoma de Barcelona, [6]Public Health Management Agency, Generalitat de Catalunya Health Department, Barcelona, [7]Endocrinology and Nutrition, Hospital Germans Trias i Pujol, Badalona, Spain.

Background and aims: To estimate the direct cost of care associated to type 2 diabetes (T2DM) in patients with the disease compared with non-diabetic subjects in a population-based primary care database during 2011.
Materials and methods: Retrospective analysis of resource consumption (ambulatory care and in-patient care, laboratory tests, pharmacy, strips and disability days) during 2011, from the SIDIAPQ database, including 1.878.816 persons assigned to the Institut Català de la Salut in Catalunya. For each patient with T2DM (age 30-90 years), one control matched for age, sex and managing physician was randomly selected. Data on the diagnostic and procedure codes for outpatient and in-patient care were obtained. All costs were based on the official prices provided by the local Health Care Authority.
Results: We compared the costs of 126,811 T2DM patients (53.5% male, mean age 67.7 years, mean disease duration 7.2 years and mean HbA1c: 7.14%) with 126,811 patients without diabetes. The annual average of visits was 16.3 for diabetic and 10.1 for non-diabetic patients. Mean days of hospitalization were 8.2 and 6.7, respectively and those of temporary incapacity for work of 5.8 and 4.3, respectively. The annual average cost per patient was € 3,362.8 and € 2,156.5 for diabetic and non-diabetic subjects, respectively (difference € 1,206.3, i.e. 55.9% increased cost). The costs of in-patient care were € 1,226.6 and € 886.4 (38.4% increase in cost), pharmacy costs € 925.0 and € 489.2 (89.1% increase), and other costs of € 634.3 and € 412.4 (54.5% increase), in diabetic and non-diabetic subjects, respectively. Patients with poor control (HbA1c> 7%) had an average cost of € 3,631.7 vs € 3,119.5 for patients with good control. In the absence of macrovascular complications, average cost was € 2,925.2 for diabetic and € 1,950.9 for non-diabetic subjects, while the presence of any complication increased the cost to € 4,717.2 and € 3,478.7, respectively.
Conclusion: The direct costs of care were 56% higher in diabetic compared with non-diabetic subjects. Higher costs were associated with poor glycaemic control and diabetic complications.

Distribution of costs in patients with type 2 diabetes mellitus: a retrospective claims database analysis

M. Bron[1], A. Guerin[2], D. Latremouille-Viau[2], R. Ionescu-Ittu[2], C. Lopez[1], P. Viswanathan[1], E. Wu[2];
[1]Takeda Pharmaceuticals International, Deerfield, [2]Analysis Group, Inc., Boston, USA.

Background and aims: Patients with diabetes are known to have healthcare costs that are two to three times higher than the costs of the population without diabetes. This study aimed to describe the distribution of different cost components among adult patients with type 2 diabetes mellitus (T2DM), the most prevalent type of diabetes, receiving oral antidiabetic medications (OADs).
Materials and methods: Adult patients with T2DM using OADs and having records for HbA_{1c} tests were identified in the Truven Health Analytics MarketScan® databases (2004-2010), which cover a representative sample of employer-provided health insurance in the United States. Direct healthcare costs (2011 USD) were measured from a payer perspective over a 1-year period. Distribution of all-cause and diabetes-related costs were reported by cost components (Table, columns 1 and 2). Diabetes-related costs were defined as claims with a reported diagnosis for T2DM or an antidiabetic medication.
Results: Cost distribution of a total of 4,104 selected T2DM patients using OADs is detailed in the Table. Diabetes-related costs represented 34% of total costs (1-year means $13,548 versus $4,583, respectively). Medical costs accounted for the majority of all-cause and diabetes-related total costs (64%

and 60%, respectively), with outpatient services being the most costly component for all-cause medical costs (34%) and inpatient services being the most costly component of diabetes-related medical costs (30%). Less than 10% of the patients accounted for 50% of diabetes-related medical costs and antidiabetic medications accounted for 40% of diabetes-related total costs. Less than half of patients accounted for >80% of the total all-cause and diabetes-related costs (42% and 38%, respectively) and less than a quarter of patients accounted for >80% of the medical all-cause and diabetes-related costs (23% and 15%, respectively).

Conclusion: In a sample of T2DM patients receiving OADs, a small proportion of patients was found to incur most of healthcare costs, especially for the diabetes-related cost component. Identifying these costly patients is warranted to improve the health, enhance the understanding of cost drivers and reduce the economic burden of T2DM patients.

Cost type	Cost Component	Annual Cost Distribution (2011 USD)				
		Across Patients			Across Components	
		Mean±SD	Median (IQR)	P90	% of the Total	% of the Component

The effect of intensive insulin treatment on plasma level of LP-PLA2 and sPLA2 in patients with newly diagnosed type 2 diabetes

X.-H. Lin, M. Xu, F. Li, L. Mai, X. Wang, Y. Li, L. Yan;
Sun Yat-sen Memorial Hospital of Sun Yat-sen University, Guangzhou, China.

Background and aims: Recent studies have shown that lipoprotein-associated phospholipase A2 (LP-PLA2) and secretory phospholipase A2 (sPLA2) are closely related to chronic inflammation and atherosclerosis. In this study, we aimed to evaluate plasma level of LP-PLA2 and sPLA2 in patients with newly diagnosed type 2 diabetes mellitus (T2DM), and investigate the effect of short-term intensive insulin treatment on it.

Materials and methods: We enrolled 90 patients with newly diagnosed T2DM and 58 people with normal blood glucose, 30~60 years old, from Oct.2010 to Mar. 2012. Plasma LP-PLA2 and sPLA2 were determined in all subjects with an empty stomach. All the patients received continuous subcutaneous insulin infusion with an insulin pump for 10~14 days. IVGTT and OGTT were carried out before and after treatment.

Results: As to gender, age, body mass index, waist-hip ratio, blood pressure and lipid profile, there were no statistically differences between these two groups ($P > 0.05$). Plasma levels of LP-PLA2 and sPLA2 were significantly higher in diabetic patients ($P < 0.05$), especially in those with macroangiopathy ($P < 0.05$). After treatment, level of sPLA2 was significantly reduced ($P < 0.05$), while there was no statistically difference of LP-PLA2 ($P > 0.05$). Regarding to β cell function, AUC_{Ins} of IVGTT and OGTT, acute insulin response (AIR), $\Delta Ins_{30}/\Delta G_{30}$, modified beta cell function index (MBCI) and HOMA-β were all increased after treatment even when corrected by the influence of insulin resistance ($P < 0.001$). With respect to insulin resistance, HOMA-IR was lower after treatment, while insulin sensitivity index of Cederholm (SIM), IAI (1/(FBG*FIns)) and quantitative insulin-sensitivity check index (QUICKI) were higher ($P < 0.05$). Correlation analysis showed that LP-PLA2 and sPLA2 were positively correlated with HOMA-IR in all the subjects ($P < 0.05$). In a multiple linear regression analysis, LP-PLA2 and sPLA2 were independent correlative factors of HOMA-IR ($P< 0.05$).

Conclusion: We conclude that plasma level of LP-PLA2 and sPLA2 is closely related to T2DM, insulin resistance and macroangiopathy of diabetic patients. And we inferred that early intensive insulin therapy in patients with newly diagnosed T2DM might be helpful for the improvement of insulin resistance as well as the protection of diabetic macroangiopathy.

Intensification of antihyperglycaemic treatment with DPP-4 inhibitor: influence on body composition and adipokine level

I. Shmushkovich, O. Sukhareva, T. Chernova, A. Ilin, M. Shestakova, A. Aleksandrov, I. Dedov;
Endocrinology Research Center, Moscow, Russian Federation.

Background and aims: Obesity, insulin resistance and chronic inflammation are very serious problems in treatment of type 2 diabetes (DM 2). The aim of this study was to make a comparative analysis of the weight and body composition and adiponectin level in patients with DM 2 in a 6 months after the addition of inhibitor DPP-4 vildagliptin or sulfonylurea to basal metformin therapy.

Materials and methods: 50 patients with poor controlled DM 2 on basal metformin therapy (2000 mg/day) alone (mean age 55.1 y, mean duration of diabetes 2.5 years, mean HbA1c level 8.0 %) were divided into 2 groups. Group 1 (26 people): vildagliptin (100 mg/day) was added to metformin in stable dose for 6 months. Group 2 (24 people): sulfonylurea was added to metformin for 6 months with titration due to achieve fasting glycemia < 7.0 mmol/l. Group1 and 2 were comparable in basic glycemic control level, weight and adiponectin level (mean=5.04mcg/ml). HbA1c level, body weight, BMI, waist circumference, adiponectin level, body composition (2-energy X-ray absorptiometry DEXA Lunar Prodigy GE) were evaluated at baseline and after 6 months of combination therapy. Exclusion criteria: liver failure, GFR <60 ml/min/1,73m^2, BMI ≥ 40 kg/m$^{2/}$

Results: After 6 months of therapy improvement of glycemic control was comparable in both groups: HbA1c 6.7% [6.2, 7.0] vs 6.5% [6.1, 7.0] (p>0.05), but hypoglycemiae were significantly often in group 2. In group 1: adiponectin level was significantly improved (5.0[3.0; 8.8] vs 10.6 [7.1; 14.9] mcg/ml, p < 0.0001); weight decreased from 81.8 [81.3, 96.0] to 77.0 [73.4, 93.6] kg (p <0.0001); BMI decreased from 32.2 [29.2, 34.0] to 30.4 [28.1, 31.9] kg/m^2 (p <0.0001); waist circumference decreased from 105.0 [98.6, 118.0] to 98.9 [94.7, 108.6]cm, (p < 0.0001) and fat mass from 34128.0 [31850.5, 37805.1] to 29863.0 [29408.2, 34184.1] g, (p = 0.001), the percentage of tissues fat from 42.9 [33.8, 45.7] to 39.2 [33.9, 41.1]%, (p = 0.001) and the percentage of regional fat from 41.7 [32.6, 43.9] to 38.5 [32.7, 39.8]% (p = 0.001); lean body mass was not significantly changed (44910.2 [42738.0; 55189.5] vs 44798.2 [43056.2, 54933.5] g, p = 0.3). In group 2 adiponectin level was not significantly changed (5.1 [3.1; 7.5] vs 5.9 [3.2; 8.0]mcg /ml, p = 0.39); weight increased from 78.5 [73.0, 105.0] to 81.4 [74.1, 107.0] kg (p <0.0001); BMI increased from 31.4 [28.6, 36.7] to 32.2 [29.2, 34.0] kg/m^2, (p <0.0001) and waist circumference increased from 101.9 [105.0, 119.3] to 105.5 [100.1, 123.6] cm, (p <0.0001), and fat mass increased from 30648.0 [30081.5, 6572.0] to 33320.4 [31250.3, 35100.1] g, (p = 0.047). Changes in the percentage of tissues fat, lean body mass and the percentage of regional fat were NS.
Conclusion: Both combination therapies (metformin + vildagliptin and metformin + sulfonilurea) are effective in glycemic control. Well-known negative effect of addition of sulfonilurea as part of combination therapy is risk of hypoglycemia and increase of weight and body fat. However, combination of metformin and vildagliptin has additional positive effects, such as the reduction of total body weight, decrease of body fat (without reduction of lean body mass) and waist circumference (as surrogate marker of visceral obesity), and increase of adiponectin level (antiinflammation adipokine). These observations should be taken into account during intensification of diabetes therapy.

1170

Depression in newly diagnosed type 2 diabetes is associated with raised levels of systemic inflammatory markers

J.S. Laake[1], J.C. Pickup[2], S.A. Amiel[2], D. Stahl[3], F. Petrak[4], K. Ismail[1];
[1]Psychological Medicine, King's College London, Institute of Psychiatry, [2]Division of Diabetes and Nutritional Sciences, King's College London, School of Medicine, [3]Biostatistics, King's College London, Institute of Psychiatry, London, UK, [4]Clinic of Psychosomatic Medicine and Psychotherapy, Ruhr-University Bochum, Germany.

Background and aims: There is an increased prevalence of depression in type 2 diabetes mellitus (T2DM) which is associated with more frequent diabetes complications and increased mortality. T2DM and macrovascular disease are independently associated with raised levels of circulating inflammatory markers and in non-diabetes participants there is evidence that depression is linked with inflammation. Since inflammation may be the common antecedent of both T2DM and depression and may play a pathogenic role, we tested the hypothesis that patients with new-onset T2DM and depression have higher levels of circulating inflammatory markers than T2DM patients without depression.
Materials and methods: Adults with newly diagnosed T2DM recruited from primary care were assessed for depression using the Patient Health Questionnaire-9 (PHQ-9). Markers of inflammation were measured from fasting blood samples and included: high sensitivity C-reactive protein (hs-CRP), white blood cell count (WBC), interleukin-1 receptor antagonist (IL-1RA). Covariates included socio-demographic factors, adiposity, smoking and HbA_{1C}. Univariate analyses were used to determine relationships between depression and inflammatory markers and multiple linear regressions were used to adjust for covariates.
Results: 1489 data sets were available for analysis; mean [SD] age = 55.4 [11.2] years, 44.9% female, prevalence of depression = 14.7%. Depressed participants were younger at diagnosis (mean [SD] age = 52 [9.9] vs. 56 [11.2] years, p <0.001) but had similar HbA_{1C} (mean [SD] HbA_{1C} = 7.0 [1.5] vs. 7.2 [1.5] %). Inflammatory markers were significantly increased in depressed compared to non-depressed participants; median [IQR] hs-CRP = 3.4 [1.5 - 8.9] vs. 2.6 [1.1 - 6.2] mg/L, p=0.002; median [IQR] WBC = 7.1 [5.7 - 8.6] vs. 6.5 [5.3 -7.9] x10^9/L, p < 0.001; median [IQR] IL-1RA = 501.6 [334.6 - 786.3] vs. 435.4 [292.0 - 678.2] ng/L, p = 0.004. Associations between levels of inflammatory markers and depressive symptoms remained after adjusting for covariates: hs-CRP (standardised b = 0.10, p = 0.002), WBC (standardised b = 0.11, p < 0.001, IL-1RA (standardised b = 0.13, p < 0.001). After one year inflammatory markers remained significantly increased in participants who were depressed at baseline compared participants who were not depressed at baseline: median [IQR] hs-CRP = 3.5 [1.3 - 7.9] vs. 2.2 [0.9 - 5.0] mg/L, p < 0.001. This association also remained after adjusting for covaraites: hs-CRP (standardised b = 0.11, p < 0.001). In those who were depressed at baseline after twelve months there was no difference in levels of inflammatory markers between those with improved depressive symptoms and those without.
Conclusion: Circulating markers of inflammation are significantly elevated in T2DM participants with depression compared to non-depressed T2DM participants, these levels were still raised 12 months later. These consistently increased levels of inflammation and activated innate immunity observed in T2DM with depression may help to explain the persistent increased risk of complications and mortality in this group.

Relation of the obesity-related gene (FTO) polymorphism with depressive symptoms and quality of life in type 1 diabetic children treated with insulin pumps: a pilot study

A. Szypowska[1], B. Zduńczyk[1], J. Sendela[1], A. Ramotowska[1], A. Bossowski[2], W. Łuczyński[2];
[1]Medical University of Warsaw, [2]Medical University of Białystok, Poland.

Background and aims: A single-nucleotide polymorphism rs9939609 of fat-mass and obesity-associated (FTO) gene is associated with weight gain and obesity. The A allele of the FTO gene predisposing to obesity occurs in approximately 40% of the European population. Type 1 diabetic children who are carriers of the AA genotype of the FTO gene polymorphism (rs9939609) are at risk of more weight gain in the course of insulin therapy when compared to carriers of the TA and TT genotypes of this polymorphism. There is confirmed that obesity-related disorders are more often observed among people with depression than in general population. Moreover, depressive disorders are more common in children with type 1 diabetes. Some authors confirmed that polymorphisms in the FTO gene are associated with increased BMI in the depressive patients. There is also suggested that FTO rs9939609 A variant may be associated with a lower risk of depression independently of its effect on BMI. The aim of this study is to evaluate the frequency of depressive symptoms in type 1 diabetic children with AA genotype of the FTO gene polymorphism (rs9939609) and compared the results of youth the TA and TT genotypes of this polymorphism.
Materials and methods: The analysis included 277 children (93 girls) with type 1 diabetes diagnosed at least 1 year priori, treated with insulin pumps. The mean age was 13.1±2.9 years, the mean diabetes duration was 5.6±3.1 years and the mean HbA1c 7.5±1.1%. Gene polymorphism analysis in the extracted DNA were made with the real-time PCR method using TaqMan 7900 HT by Applied Biosystems. During the routine visit in the outpatient clinic children were asked to fill in Polish version of Children's Depression Inventory (CDI) by Maria Kovac. This self-report questionnaire is often used in clinical studies due to high coefficient of reliability (α-Cronbach between 0.81 - 0.89). Patients from age 11 and above were additionally asked to answer questions in 58-item Quality of Life Questionnaire, based on the DCCT Diabetes Quality of Life Measure. At the same time, other data was collected, including: sex, age, diabetes duration, HbA1c, BMI, daily insulin dose/kg body mass/24h (TDD).
Results: There were carriers of the genotype of the FTO gene polymorphism (rs9939609): AA (n=62), AT (n=139), TT (n=76). No difference between groups AA vs. AT vs. TT was observed depending on the results of: age (p=0.897), diabetes duration (p=0.601), BMI (p=0.968), TDD (p=0.388) and HbA1c (p=0.878). Fifteen percent (14 girls, 28 boys) of all participants reported depressive symptoms based on CDI scores ≥13. The percentage of children with depressive symptoms was slightly higher in the group TT (20.6%) in comparison to the groups AA (16.9%) and AT (16.8%), however without statistical significance (p=0.857). The quality of life was similar in all examined groups (p=0.803).
Conclusion: FTO gene polymorphism (rs9939609) had no impact on BMI, daily insulin dose, glycaemic control and quality of life in type 1 diabetic children treated with insulin pumps. The frequency of depressive symptoms was a little lower in children who were carriers of the A allele of the FTO gene in comparison to control subjects, however without statistical significance.

Is there a relationship between depression and inflammatory markers in people with type 1 and type 2 diabetes?

M. Carreira[1,2], M.T. Anarte[1,2], M. Guerrero[2,3], E. Rubio[2,3], N. Colomo[2,3], M. Domínguez-López[2,3], N. Sánchez[1], A. Machado[1,2], E. Varela[1,2], M.S. Ruiz de Adana[2,3];
[1]Department of Personality, Evaluation and Psychological Treatment, University of Malaga, [2]Biomedical Research Institute of Málaga (IBIMA), [3]Clinical Management Unit of Nutrition and Endocrinology. Carlos Haya University Hospital, Spanish Biomedical Research Centre in Diabetes and Associated Metabolic Disorders (CIBERDEM), Málaga, Spain.

Background and aims: Previous studies suggest a relationship between depression and increased inflammatory markers in the general population. In people with diabetes, depression is the most common mental illness, and the risk of depression twice that of the general population. The objective of this study is to analyse the relationship between depression and inflammatory markers in patients with type 1 and type 2 diabetes, and to analyze the influence of the main risk factors of both variables.
Materials and methods: The sample consisted of 190 patients with diabetes (type 1: 144 and type 2: 46). Sociodemographic and medical variables were collected by structured interview. Biological values: Glycosylated haemoglobin (HbA_{1c}), interleukin-6 (IL-6), tumor necrosis factor-α (TNF-α) and C-reactive protein (CRP) were collected through analytical blood. The assessment of depressive symptoms was performed with the Spanish version of the Beck Depression Inventory (BDI-II). To analyse the relationships between the variables was used Pearson correlation coefficient. To analyze differences between patients with depressive symptoms and without depressive symptoms an analysis of variance was performed (ANOVA). We used SPSS version 19.0.
Results: In the sample studied, 31.1% of patients had depression symptoms (type 1: 23.2%; type 2: 7.8%). After analysing the three inflammatory markers, only found significant relationships between depression symptoms and IL-6 marker. In this case, in type 1 diabetes the marker IL-6 was associated with: depression symptoms, age and complications of diabetes. Type 1 diabetes patients with depressive symptoms had higher values of IL-6 than those without depressive symptoms ($p = 0.037$). However, in type 2 diabetes were not differences. After controlling for age and complications of diabetes, there were still significant differences in the values of IL-6 in patients with type 1 diabetes between those with depressive symptoms and those without depressive symptoms ($p < 0.001$).
Conclusion: This study shows a relationship between depressive symptoms and IL-6 levels in type 1 diabetes. While in type 1 diabetes patients with depressive symptoms have higher values of IL-6 than patients without depressive symptoms, in type 2 diabetes does not occur. None of the variables associated in this study with elevated levels of IL-6 in type 1 diabetes patients (age and complications) explain this relation. Therefore, the results of this study highlight the role of inflammatory markers, specifically IL-6 marker as a biomedical indicator of depressive symptoms in patients with type 1 diabetes.

Insulin antibodies are associated with use of protaminated insulin, and the uncommon TNF -857T allele in subjects with type 2 diabetes mellitus

K. Takahashi, M. Masaya, T. Takahashi, M. Yamashina, T. Oda, R. Nakagawa, M. Ono, M. Matsui, K. Nagasawa, H. Homma, T. Kajiwara, H. Taneichi, Y. Takahashi, N. Takebe, J. Satoh;
Department of Diabetes and Metabolism, Iwate Medical University, Morioka, Japan.

Background and aims: The clinical significance of insulin antibodies (IA) cannot be ignored, even after the introduction of either recombinant human or analog insulin. We recently reported IA to be associated with use of protaminated insulin, as well as showing an independent positive association with diabetic retinopathy in type 2 diabetic subjects receiving recombinant human or analogue insulin therapy. Herein, we tripled the number of subjects, and endeavored to further assess the clinical features of IA-positive type 2 diabetic subjects. The genetic background for the emergence of IA was also examined, focusing on functional tumour necrosis factor (TNF) promoter polymorphisms.
Materials and methods: The study group was comprised of inpatients at our University Hospital. There were 247 females and 342 males, with a mean age of 58± 16 years, diabetes duration of 12± 9.8 years, and HbA1c of 13± 2.1%. After obtaining informed consent from all subjects, blood samples were collected. IA levels were measured with RIA kits for IA (Yamasa, Tokyo, Japan). TNF promoter polymorphisms at -857 and -863 were determined by sequencing the PCR products of the 5'-flanking region of the TNF gene. Statistical significance was analysed by the Mann-Whitney U test, or multiple linear regression analyses.
Results: One-hundred-nineteen of the 259 subjects (46%) receiving current or previous therapy with recombinant human or analogue insulin were IA positive (percent binding 10± 18%), whereas 92% of those without such therapy (n=330) were IA negative. Among the subjects treated with insulin, those with IA had significantly longer durations of diabetes (16± 8.1 vs 13± 9.5 years, P=0.013), and lower fasting CPR levels (1.5± 0.13 vs 1.9± 0.65 ng/ml, P=0.005). Multiple regression analyses revealed treatments with protaminated insulin to be the only significant explanatory variable for the percent binding with IA ($\beta=0.352$, $R^2=0.124$, P=0.000). Among the subpopulation of subjects genotyped for the TNF polymorphisms (n=43), the mutant -857T allele was found to significantly predict percent binding with IA ($\beta=0.433$, $R^2=0.187$, P=0.019). Diabetic retinopathy was predicted by the percent binding with IA ($\beta=0.214$, P=0.009), as well as by diabetes duration ($\beta=0.216$, P=0.011).
Conclusion: Our recent findings, the positive association of IA emergence with current or previous use of protaminated insulin, and with diabetic retinopathy, were reconfirmed after tripling the number of subjects. Our finding on protaminated insulin could be interpreted, based on previous observations, as indicating that protaminated proteins had augmented antigenicity. To our knowledge, this is the first report showing the -857T allele of the TNF promoter polymorphism, which may lead to a high TNF producer phenotype, to be positively associated with IA generation. This finding is in line with previous observations indicating that some functional TNF polymorphisms confer humoral immune responsiveness in settings of infectious immunity or autoimmunity. In conclusion, we propose that the emergence of IA and its concomitant adverse effects should be taken into account when starting insulin therapy in subjects with type 2 diabetes, and that the -857T allele of the TNF polymorphism could be a good marker for the emergence of IA.

Prevalence of albuminuria and reduced renal function in type 2 diabetes and its association with vascular co-morbidities in a Swedish primary care setting

M.K. Svensson[1], A. Bröijersén[2], L. Weiss[3], C. Östgren[4];
[1]Dept of Nephrology, Sahlgrenska University Hospital, Gothenburg, [2]Boehringer Ingelheim, Stockholm, [3]Department of Medicine, Karlstad Central Hospital, [4]Department of Medical and Health Sciences, Linköping University, Sweden.

Background and aim: To estimate the prevalence of chronic kidney disease (CKD) and albuminuria and it associations to prevalent cardiovascular co-morbidities in patients with type 2 diabetes in a primary care setting in Sweden.
Patients and methods: Cross-sectional data on demography, laboratory measurements, current medication, previous vascular disease and major events of hypoglycaemia during the last 12 months was consecutively recorded from 53 primary care centres. Stage of CKD was defined based on the presence of albuminuria and estimated glomerular filtration rate (eGFR) according to KDOQI. Albuminuria was measured using the urinary albumin-creatinine ratio.
Results: We included 362 men and 226 women aged 68.5±9.3 years, mean diabetes duration 9.9±7.2 years. 220 patients (37%) were categorized as having CKD stage 1-5, 105 subjects (18%) CKD 1-2, and 115 subjects (20%) CKD 3-5. Albuminuria was present in 155 subjects (26%), microalbuminuria in 128 (22%) and macroalbuminuria in 27 (5%) subjects. The proportion of patients (%) with prevalent micro- and macrovascular disease according to CKD stage (CKD 0-2 vs. 3-5) is shown in figure 1. The OR, adjusted for age and gender, for subjects with CKD 3-5 for having retinopathy was 2.71 (95% CI 1.14 to 6.25, p=0.02) and for myocardial infarction 1.91 (95% CI 1.04 to 3.45, p=0.03) compared with CKD 0-2. Severe hypoglycaemia was more common in CKD 3-5 (n=3; 2.6%) and OR for subjects in CKD stages 3-5 for having hypoglycaemia was 8.71 (95% CI 1.19 to 80.11; p=0.03) compared with CKD 0-2 (n=2; 0.4%). Levels of haemoglobin were lower (133 ±14 g/L vs. 143 ±12 g/L) in CKD 3-5 compared to CKD 0-2 (p<0.01). In addition, the prevalence of vascular disease (p=0.03) and ischemic stroke (p=0.02) were higher in subjects with albuminuria compared with individuals without albuminuria.
Conclusion: Chronic kidney disease is common in type 2 diabetes in a primary care setting and associated with prevalent vascular co-morbidities.

Figure 1 Proportion of patients (%) with prevalent micro- and macrovascular disease according to CKD stage (CKD 0-2 vs. 3-5) in study population included in PRIDE: Prevalence of Renal Impairment in Diabetes. Vascular disease; composite of myocardial infarction, ischemic stroke, CABG and PCA, CABG; coronary artery bypass graft, PCA; percutaneous coronary angioplasty

Albuminuria significantly predicts cardiovascular events in patients with type 2 diabetes independently from the baseline coronary artery state

A. Vonbank[1,2], D. Zanolin[3], P. Rein[1], C.H. Saely[1,2], H. Drexel[1,4];
[1]Academic Teaching Hospital Feldkirch, Austria, [2]Private University of the Principality of Liechtenstein, Triesen, Liechtenstein, [3]Vorarlberg Institute for Vascular Investigation and Treatment, Feldkirch, Austria, [4]Drexel University College of Medicine, Philadelphia, USA.

Background and aims: Albuminuria is an important indicator of cardiovascular risk. We have recently shown that it is also associated with angiographically determined coronary artery disease (CAD). Whether albuminuria predicts cardiovascular events independently of the baseline coronary artery state in patients with type 2 diabetes (T2DM) has not been investigated yet.
Materials and methods: We measured urinary albumin and creatinine concentrations in 211 consecutive patients with T2DM undergoing coronary angiography for the evaluation of suspected or established stable CAD. Albuminuria was defined as a urinary albumin to creatinine ratio (ACR) of 30 µg/mg or greater. Prospectively, we recorded vascular events over 3.2±1.4 years.
Results: During follow up, 24.6% of our patients suffered cardiovascular events. The cardiovascular event rate was significantly higher in patients with albuminuria (n=85) than in those with normoalbuminuria (35.3 vs. 17.5%; p = 0.003). Cox regression analysis adjusting for age, gender, BMI, smoking, systolic and diastolic blood pressure, LDL cholesterol, HDL cholesterol, eGFR, and use of ace inhibitors/angiotensin II antagonists confirmed that albuminuria significantly predicted cardiovascular events independently from conventional risk factors (adjusted HR 1.96 [1.11-3.46]; p=0.021). Further adjustment for the angiographically determined presence of CAD at baseline did not significantly attenuate the predictive power of the ACR (HR 1.84 [1.04-3.27]; p=0.037). Similar results were obtained when the ACR was entered into the final regression model as a continuous variable (standardized adjusted HR 1.30 [1.02-1.65]; p = 0.037).
Conclusion: Albuminuria significantly predicts cardiovascular events in patients with T2DM independently of established cardiovascular risk factors and of the baseline coronary artery state.

1176

Impact of morbid obesity on kidney function in type 2 diabetes

N. Belhatem[1,2], K. Mohammedi[1,2], F. Rouzet[2], N. Matallah[1,2], F. Travert[1,2], R. Roussel[2,3], M. Marre[1,2], D. Le Guludec[2], B. Hansel[1,2];
[1]INSERM, Research Unit 695, [2]Assistance Publique Hôpitaux de Paris, Bichat Hospital, [3]INSERM, Research Unit 872, Paris, France.

Background and aims: Type 2 Diabetes (T2D) and obesity are risk factors for kidney dysfunction (Glomerular Filtration Rate (GFR) and Urinary Albumin Excretion (UAE)). People with T2D are often obese. We looked on the separate effects of T2D and of obesity on kidney function.
Materials and methods: We enrolled consecutively in our clinic for kidney function 822 participants with various levels of obesity (of them 784 T2D). Their GFRs were assessed using the slope-intercept method derived from ^{51}Cr-EDTA plasma clearance, corrected or not for 1.73m^2 body surface area, and their UAE status (normo-, micro-, macro-albuminuria) from 3 consecutive urine collections. Obesity stages were classified as: absent (BMI < 25kg/m2), overweight (25 - < 30), obesity (30 - < 40), and morbid obesity (≥ 40). GFR was analysed by 2-factor ANCOVA (T2D yes/no; obesity stages, adjusted for age and sex), and UAE status by Cochran-Mantel-Haenszel test. Logistic regression analyses were used to determine the risk for micro- and macro-albuminuria in patients with obesity and morbid obesity compared to subjects with normal weight.
Results: There was an interaction between obesity stages and T2D on body surface-adjusted GFR (p=0.01). In non-diabetic subjects, GFR increased with obesity stages up to 40 kg/m^2 and declined over 40. For patients with T2D, a progressive decline of GFR was observed when crossing the whole obesity range (table 1). Results on unadjusted GFR were similar. The effects on UAE status were similar: diabetes-obesity interaction (p<0.0001), diabetes effect (p=0.0005) and obesity effect (p=0.001). The prevalence of normo-, micro- and macro-albuminuria according to morbid obesity was 38.1%, 42.9% and 19.0%, respectively. Regressive model indicated an increased risk of microalbuminuria (OR 2.86, 95%IC 1.55 - 5.17, p=0.0005) and macro-albuminuria (OR 2.22, 95%IC 1.40 - 3.55, p=0.0007) in patients with morbid obesity, after adjustment for sex, age and T2D status.

Conclusion: We found a strong interaction between obesity status and T2D with a reduced GFR and an increased UAE in patients with morbid obesity.

Table 1. Body surface adjusted GFR according to obesity stages and T2D status

		Normal (N=155)	Overweight (N=301)	Obesity (N=296)	Morbid obesity (N=70)	p*
Diabetes	Yes	91 ± 3	89 ± 2	88 ± 2	73 ± 4	0.0004
	No	93 ± 7	99 ± 7	115 ± 6	105 ± 5	0.04

Results expressed as means ± SEM. *ANCOVA adjusted for sex and age. Diabetes x obesity stages interaction: p=0.01.

1177

Heterogeneity of chronic kidney disease (CKD) phenotypes in patients with type 1 diabetes mellitus

E. Russo[1], G. Penno[1], M. Garofolo[1], D. Lucchesi[1], L. Pucci[2], V. Sancho Bornez[1], R. Russo[1], L. Giusti[1], R. Miccoli[1], S. Del Prato[1];
[1]Endocrinology and Metabolism, University of Pisa, [2]Institute of Agricultural Biology and Biotechnology, CNR, Pisa, Italy.

Background and aims: According to traditional paradigms, increased albuminuria precedes GFR loss in the progression to CKD. However, mainly in type 2 diabetes, but in type 1 too, recent findings demonstrate that GFR decline may occur also in longstanding normoalbuminuria. Indeed, in the DCCT/EDIC over 19 years 24% of type 1 diabetic subjects (T1DM) develops sustained eGFR <60 ml/min/1.73 m2 with no previous albuminuria. Furthermore, different sets of risk factors are related to albuminuria and eGFR suggesting they represent parallel phenotypes. Prevalence and correlates of different CKD phenotypes have been explored in 777 adults with T1DM consecutively recruited at our Outpatients Clinic between 2001 and 2009.
Materials and methods: We studied 408 males and 369 females (52.5/47.5%). Mean age (±SD) was 40.2±11.7 (IQR 32-47), duration of diabetes 19.4±12.2 (9-28) years. BMI was 24.8±3.6 kg/m2; HbA1c 7.83±1.17% (IQR 7.1-8.4); 29.6% were current smokers, 35.2% had hypertension, 19.4% were treated with anti-hypertensives (17.5% with RAS blockers). Diabetic retinopathy (DR) was detectable in 41.3% of subjects (25.7% background, bDR; 15.6% proliferative, pDR); peripheral polyneuropathy in 8.1%, major cardiovascular (CV) events occurred in 8.5%.
Results: Normoalbuminuria (nA, albumin to creatinine ratio, ACR <30 mg/g), microalbuminuria (μA, ACR 30-299) or macroalbuminuria (MA, ACR ≥300) were present in 91.6, 6.4 and 1.9% of subjects, respectively. Stage 1 (≥90), 2 (60-89) and ≥3 (<60 ml/min/1.73 m2) eGFR were present in 57.3, 39.0 and 3.7% of patients. Combining eGFR and ACR strata, 89.4% (n. 695) had no-CKD, while stages 1-2 and stages ≥3 CKD were detected in 6.8% (n. 53) and 3.7% (n. 29) of subjects. The albuminuric (Alb+) and non-albuminuric (Alb-) phenotypes were present in 17 (58.6%) and 12 (41.4%) of stages ≥3 CKD. Alb+ and Alb- showed similar age, duration of diabetes and gender distribution. Patients with nA were splitted in subjects with "normal albuminuria" (ACR <10 mg/g; 77.2%) and those with "low-microalbuminuria" (ACR 10-29 mg/g; 14.4%); patients with stage 2 eGFR were stratifed in 2a (75-89) and 2b (60-74 ml/min/1.73 m2). Also in 2b eGFR, nA (88.7%) and normal albuminuria (70.4%) were highly frequent. Prevalence of normal albuminuria was lower but still significant (35.7%) in stages ≥3 CKD. Prevalence of DR (37.3, 70.6 and 85.2%; pDR 11.4, 47.0 and 63.0%), polyneuropathy (5.8, 18.8 and 48.0%) and CV events (7.3, 11.3 and 34.5%) increased from no CKD to stages ≥3 CKD (p<0.0001). In logistic backward regressions (model 1), CKD 1-2 and CKD 3-5 (versus no CKD) were both independently associated with age (inversely in CKD 1-2), HbA1c, gammaGT, fibrinogen, hypertension and (model 2) also with pDR, but not with gender, BMI, smoking, HDL-C and triglycerides. CKD ≥3 Alb+ correlated with male gender, diabetes duration, HbA1c, HDL-C (inversely), fibrinogen but not with hypertension, while CKD ≥3 Alb- was associated with age, gammaGT, hypertension, but not with HbA1c.
Conclusion: Alb- CKD phenotypes are detectable in a significant proportion of T1DM subjects. These findings hardly can be due to a misclassification artifact and support the hypothesis of two distinct pathways (Alb+ and Alb-) that progress to advanced kidney disease in T1DM as also suggested by the observation that different sets of covariates are related to different CKD phenotypes.

1178

Diabetes increases renovascular impedance in patients with liver cirrhosis

G. Privitera, L. Spadaro, G. Fede, S. Calanna, A. Rabuazzo, F. Purrello;
University of Catania, Italy.

Background and aims: The increase of renal Doppler indices (pulsatility index, resistance index, PI- RI) in cirrhosis, has usually been associated to a higher risk of deterioration in renal function. An increase of PI-RI has also been reported in type 2 diabetes (T2DM). It's still unknown if T2DM modifies renal hemodynamics in cirrhosis.To compare renal Doppler indices in cirrhotics with and without type 2 diabetes (T2DM) and in diabetics without cirrhosis.
Materials and methods: We evaluated 89 consecutive patients with normal renal function: 37 cirrhotics with T2DM (CD-Group), 41 cirrhotics without diabetes (C-Group) and 11 diabetics without cirrhosis (D-Group). The kidney pulsatility index (PI) and the resistance index (RI) were measured with Doppler-ultrasound. Renal function was expressed as the estimated glomerular filtration rate (eGFR) using the Modification of Diet in Renal-Disease (MDRD) formula, the microalbuminuria (μAlb), was also evaluated.
Results: No significant differences were present regarding age, Child-Pugh's class and serum creatinine. The eGFR was weakly reduced in CD-Group compared to C-Group and D-Group, μAlb was present in 24.4% of the CD-Group and in 9% of the D-Group. The PI and RI were significantly increased in CD-Group and in D-Group compared to C-Group. Both PI and RI were significantly related to μAlb independently of age and Child-Pugh's class.
Conclusion: Diabetes is associated with an increase in reno-vascular resistance in cirrhotics that is related to μAlb values. The novel finding of this study was that DM impairs renal hemodynamics in cirrhosis.

1179

Poor glycaemic control is related with increased nitric oxide activity within the renal circulation of patients with type 2 diabetes mellitus

M.P. Schneider, C. Ott, S. Schmidt, I. Kistner, S. Friedrich, R.E. Schmieder;
Nephrology and Hypertension, University of Erlangen-Nurmberg, Erlangen, Germany.

Background and aims: Experimental studies have shown that glucose releases endothelial nitric oxide (NO), and that NO contributes to renal hyperperfusion in models of diabetes. To examine whether this translates into the *human* condition, we studied the relationship between glycemic control and renal NO activity in patients with type 2 diabetes.
Materials and methods: A total of 113 patients with type 2 diabetes mellitus and a wide range of glycated hemoglobin A1c (HbA1c) concentrations were included. Renal plasma flow (RPF) and glomerular filtration rate (GFR) were determined by constant infusion input clearance. Functional NO activity in the renal circulation was determined as change of RPF to infusion of the NO synthase (NOS) inhibitor N(G)-monomethyl-L-Arginine (L-NMMA, 4.25 mg/kg). As additional markers, we measured urinary excretion of NO (UNOx) and L-arginine/asymmetrical dimethylarginine (ADMA) ratio in plasma.
Results: Subjects within the highest tertile of HbA1c concentration had increased RPF (low, medium and high tertiles: 576±17 versus 585±22 versus 627±33 ml/min/m^2, P=0.05 by 1-way ANOVA), while GFR was similar across tertiles. The response of RPF to NOS-blockade was augmented in subjects with higher HbA1c levels (-55±7 versus -64±8 versus -86±8 ml/min, P=0.04 by 1-way ANOVA). Further, L-arginine/ADMA ratio and UNOx were increased in subjects with higher HbA1c levels.
Conclusion: In line with experimental evidence, we could demonstrate *in humans* that poor glycemic control is related with higher NO activity and hyperperfusion of the kidney. The renal NO system may thus be a novel therapeutic target for improving renal hemodynamics in patients with diabetes mellitus.

Haemodialysis-associated hypoglycaemia and inter-day glycaemic variability assessed by continuous glucose monitoring system in patients with type 2 diabetes

S. Popa[1], C. Vaduva[2], E. Mota[3], M. Mota[1];
[1]Diabetes, Nutrition & Metabolic Diseases, University of Medicine and Pharmacy, Craiova, [2]Nephrology, Clinical County Emergency Hospital Craiova, [3]Nephrology, University of Medicine and Pharmacy, Craiova, Romania.

Background and aims: The proportion of diabetic patients undergoing hemodialysis is rapidly increasing. Glucose control among such patients is difficult to assess, because hemodialysis seems to alleviate uremia-induced insulin resistance and is therefore likely to induce significant glycemic variability. The aims of the study were to assess the glucose variability in type 2 diabetic patients undergoing hemodialysis, using continuous glucose monitoring system (CGMS), and to perform a comparative analysis of CGMS glycemic curves in days with and without hemodialysis.
Materials and methods: We investigated 12 hemodialysed type 2 diabetic patients (HD DM; 6M/6F, 56±7.3 years, diabetes duration 8.6±3.9 years) and 11 type 2 diabetic patients without renal impairment (nonHD DM; 5M/6F, 57.6±9.5 years, diabetes duration 8.1±5.7 years). Subjects were monitored 48-h using CGMS (Medtronic MiniMed). The glycemic variability was quantified by mean interstitial glucose, percent of time with interstitial glucose >180mg/dl and <70mg/dl, coefficient of variation (%CV), mean amplitude of glycemic excursion (MAGE), fractal dimension (FD), mean of daily differences (MODD). SPSS 17 software was used for statistical analysis. The comparisons between different groups were performed using parametric tests.
Results: HbA1c levels were lower in HD DM patients than in non-HD DM controls (6.0±0.5 vs. 6.9±1.6%), but the differences did not rich statistic significance. The percent of time spent with glucose <70mg/dl was significantly higher, during the 1st day with dialysis session, in HD DM patients comparing with non-HD DM subjects during the equivalent 1st day (6.6±3 vs 0.7±0.2%, p<0.001). MODD was significantly higher in HD DM patients, comparing with nonHD DM subjects (36.2±10.3 vs 19.8±5.7, p=0.01), indicating the influence of hemodialysis on inter-day glycemic variability. Although there were no differences for indices of glycemic variability between the day with and without hemodialysis, hypoglycemia occurred predominantly in day on hemodialysis (6.6±3% vs 2.1±0.4% time with glucose <70mg/dl, p=0.03). There were no significant differences for indices of glycemic variability or time in hyper/hypoglycemia between the 1st and 2nd day, in nonHD DM subjects.
Conclusion: Our findings suggest that HbA1c was not as good marker of glucose control in hemodialysis and, according to the CGMS readings, hemodialysis seems to increase inter-day glucose variability and the risk of hypoglycemia. This study provides evidence that CGMS can be a useful tool in glycemic variability assessment in hemodialysed diabetic patients.

1181

Glucose profile in patients with type 2 diabetes and ESRD: comparison between haemodialysis sessions and inter-haemodialysis periods

A. Smagala[1], L. Képénékian[2], F. Chantrel[3], L. Meyer[4], L. Kessler[2];
[1]Pasteur Hospital, Colmar, [2]NUDE Pole, Strasbourg University, [3]Emile Muller Hospital, Mulhouse, [4]Ste Anne Clinic, Strasbourg, France.

Background and aims: The main difficulty to obtain adequate glycaemic control in diabetic patients with end stage renal disease (ESRD) treated by hemodialysis is due to the consecutive dialysis and inter-dialysis periods. In this population, glucose profile is not well documented. We aimed to analyze the glucose profile by continuous glucose monitoring (CGM) during consecutive dialysis and inter-dialysis periods in patients with type II diabetes and ESRD.
Materials and methods: CGM (Navigator, Abbott) was performed in 33 diabetic patients (14 female/19 male, age: 66±8yrs, diabetes duration: 23±11yrs, hemodialysis duration: 3.8±2.6yrs) during 54 hours, including 2 consecutive hemodialysis sessions at 0, 1 and 3 months with determination of the mean CGM glucose value, maximal glucose excursion, MAGE during consecutive dialysis and inter-dialysis periods. Comparisons were done using ANOVA for repeated measures. Each patient used a dialysate solution with a 100mg/dL glucose concentration.
Results: Mean glucose value of 78 CGM was 171±36 mg/dL with coefficient of variability: 34±9% and MAGE: 104±42 mg/dL. During dialysis sessions, mean glucose value was significantly lower: 136±46mg/dL vs. 171±35 mg/dL between two dialysis sessions (p< 0.001). Standard deviation, coefficient of variability and MAGE significantly decreased by 35±5mg/dL (p<0.001), 20±1% (p<0.001) and 58±7mg/dL (p<0.001) respectively. Percentage of glucose value < 60mg/dL increased significantly during dialysis: 4.4±9.6 % vs. 2.1±7.9% between two dialysis sessions (p<0.001) with a mean glucose value significantly higher: 49±10mg/dL vs. 37±24 mg/dL (p< 0.001).
Conclusion: During hemodialysis sessions, mean glucose CGM value and glucose variability are improved in patients with type II diabetes and ESRD. Hypoglycemic risk increases but low glucose values are less severe. The use of 100mg/dL glucose dialysate solution in all dialysis sessions may contribute to the decrease of glycaemic variability. The continuous glucose monitoring (CGM) allows documenting the glycaemic status in this group of patients with high cardiovascular risk.

PS 100 Nephropathy: clinical risk factors, markers and outcomes

1182

Socioeconomic risk factors for developing end stage renal disease in patients with childhood onset type 1 diabetes: a population based register study

C. Toppe[1], A. Möllsten[1], G. Dahlquist[1], S. Schön[2], The Swedish Childhood Diabetes Study group;
[1]Department of Clinical Sciences, Pediatrics, Umeå University, [2]Swedish Renal Registry, Jönköping, Sweden.

Background and aims: Sweden has one of the highest incidences of childhood onset type 1 diabetes. The aetiology of ESRD in diabetes mellitus is multifactorial. Well known risk factors are genetic traits, disease duration, metabolic control and high blood pressure. The latter two may be associated with psychosocial stress. Therefore the aim of the present study is to investigate the influence of some early social determinants on ESRD development.
Materials and methods: The Swedish Childhood Diabetes Registry (SCDR) covers almost all patients in Sweden with onset of type 1diabetes before 15 years of age since 1 July 1977. The SCDR was linked to the Swedish Renal Registry, which includes virtually all cases of ESRD in Sweden since 1991. Information on the patients and their parent's socioeconomic status was retrieved anonymised from Statistics Sweden. Age at onset was grouped in five year groups; 0-4, 5-9 and 10-14 years. In Cox regression analyses we analysed the effect of parental education (up to college / higher than college) and the family's use of income support (any / none) on the risk for ESRD in the proband, using follow up time from diabetes onset to ESRD.
Results: Out of 7836 patients with diabetes duration longer than 15 years, 129 (68 men, 61 women) developed ESRD due to diabetes. Mean duration of diabetes was 28 years for those who developed ESRD, 24 for those who did not. *Educational level:* In crude analysis, low maternal education was associated with almost three times higher risk of developing ESRD, HR=2.8 (95% CI 1.6-4.8). Low paternal education almost doubled the risk, HR=1.9 (1.1-3.2). When adjusting for sex and age at onset of diabetes, low maternal education was still significantly associated with increased risk, HR=2.8 (1.6-5.0). Stratifying for sex, low maternal educational level was more important in females, HR=3.6 (1.4-9.0), than in males, HR=2.3 (1.1-4.9). Adjusting for maternal educational level, paternal educational was not significant and not included in further analyses. *Income support:* In crude analyses, the risk of developing ESRD was increased if any of the parents had received income support, HR=2.6 (1.8-3.7). Adding age at onset and sex to the model, the effect of parental income support remained significant, HR=3.0 (2.1-4.2). In analyses stratified by sex the parents' need of income support was associated with ESRD in both sexes, females HR=1.9 (1.1-3.3), males HR=3.8 (2.3-6.3). Adding maternal educational level to the model changed the effect of income support, slightly reducing its importance (table 1).
Conclusion: Low maternal education and income support in the family of young patients with type 1 diabetes increases the risk of developing ESRD. Maternal education seems to be the stronger predictor for women, while income support in the family is a stronger predictor for men.

Smoking increases the incidence of diabetic nephropathy and end stage renal disease in patients with type 1 diabetes

M. Feodoroff, V. Harjutsalo, C. Forsblom, L. Thorn, J. Wadén, N. Tolonen, R. Lithovius, P.-H. Groop;
Biomedicum Helsinki, University of Helsinki, Folkhälsan Institute of Genetics, Helsinki, Finland.

Background and aims: We studied the effect of smoking on the development and progression of diabetic nephropathy (DN) in patients with type 1 diabetes.
Materials and methods: The study included 2,583 patients without DN at baseline participating the FinnDiane (Finnish Diabetic Nephropathy) study. 16 (0.75%) out of 2,135 normoalbuminuric (AER <20µg/min or <30mg/24h) patients and 81 (18.0%) out of 448 microalbuminuric (AER 20-200µg/min or 30-300mg/24h) patients developed DN during the follow-up of 16,112 person years. The AER was based on three 24h or overnight urine collections. Nephropathy was defined as macroalbuminuria (AER >200µg/min or >300mg/24h) or end stage renal disease (ESRD). Smoking status was based on baseline questionnaires and patients were considered as nonsmokers, ex-smokers and current smokers. To evaluate the effect of the cumulative smoking dose, current smokers were further divided in three different groups: less than 5 pack years, 5-19.9 pack years and more than 20 pack years. We also analyzed the cumulative risk of ESRD from the beginning of diabetes and included 4,074 patients with data of smoking history and follow-up data for ESRD. 563 patients developed ESRD during the 122,685 person years of follow-up. Patients were divided into never/ever-smokers and according to the smoked pack years. Cox-regression analyses were used to estimate the HRs for developing DN or ESRD. Sex, duration of diabetes, BMI, hypertension, HbA_{1c}, eGFR, HDL and triglycerides were used as covariates when analyzing the risk of DN. Sex and age at onset of diabetes were used in the multivariate model when estimating the risk of ESRD.
Results: In the univariate analyses, the HR of DN was 2.15 (95% CI 1.22-3.79) for ex-smokers and 4.12 (95% CI 2.60-6.51) for current smokers compared with nonsmokers. In the multivariate model the HR of DN was 1.55 (95% CI 0.85-2.84) for ex-smokers and 3.29 (95% CI 2.02-5.36) for current smokers. Current smokers had significantly higher risk of developing nephropathy compared with ex-smokers (data not shown). Patients who had smoked <5 pack years before baseline had a HR of 1.77 (95% CI 0.73-4.25), 5-19.9 pack years a HR of 4.66 (95% CI 2.77-7.84) and >20 pack years a HR of 5.89 (95% CI 3.11-11.15) compared with nonsmokers in the univariate model and the results remained similar in the multivariate model. Ever-smokers had a significantly higher risk of developing ESRD with a HR of 1.81 (95%1.53-2.15) in the univariate model and 1.75 (95% CI 1.48-2.08) when adjusted for sex and age at onset. The risk of developing ESRD increased with increasing pack years with HR of 1.44 (95% CI 1.08-1.93) for <5 pack years, 1.79 (95% CI 1.44-2.22) for 5-19.9 pack years and 1.98 (95% CI 1.56-2.50) for >20 pack years. When adjusted for sex and age at onset the HRs were 1.36 (95% CI 1.01-1.82), 1.70 (95%CI 1.37-2.11) and 2.05 (95% CI 1.60-2.62), respectively.
Conclusion: Smoking increases the risk of developing DN and ESRD. Smoking cessation has a beneficial effect on the development of DN. Increasing cumulative smoking dose is associated with an increasing risk of DNP.

Metabolic risk factors according to albuminuria and chronic kidney disease in apparently healthy Koreans

N. Kim, S. Kim, J. Ahn, J. Yu, H. Hong, H. Choi, Y. Kim, H. Yoo, H. Kim, S. Kim, K. Choi, S. Baik, D. Choi, C. Shin, N. Kim;
Internal Medicine, Korea University College of Medicine, Seoul, Republic of Korea.

Background and aims: Both high albuminuria and chronic kidney disease (CKD) represented by low estimated glomerular filtration rate (eGFR) are known risk factors for cardiovascular events and mortality. However, the differences of metabolic phenotypes according to albuminuria and CKD have not been investigated in apparently healthy adults.
Materials and methods: 2963 individuals aged over 40 years (mean age, 58.3 ± 7.2 years) from the Korean Genome and Epidemiology study were included in this cross-sectional analysis. CKD was defined as estimated glomerular filtration rate < 60 mL/min/1.73m^2. Albuminuria was defined as urinary albumin-to-creatinine ratio (ACR) ≥30 mg/g. All participants were divided into four groups according to the presence or absence of albuminuria and CKD. Body mass index (BMI), waist circumference (WC), percent body fat, and metabolic parameters including blood pressure, serum glucose, and lipid profile were all assessed.
Results: The mean eGFR was 74.2 ± 10.6 ml/min/1.73 m^2, and the median ACR was 4.7 mg/g (interquartile range, 2.90-8.86). Obesity measures including BMI and WC, serum triglyceride and high-density lipoprotein cholesterol levels were significantly correlated with both high ACR and low eGFR. Addi-

tionally, fasting plasma glucose and blood pressure were positively associated with ACR. Among four albuminuria/CKD categories, albuminuria with CKD group had the worst metabolic characteristics and the highest prevalence of diabetes. When comparing albuminuria without CKD and CKD without albuminuria groups, the former had higher BMI (26.3 vs. 25.4 kg/m^2, p=0.026), WC (86.1 vs. 83.5 cm, p=0.008), systolic blood pressure (123.3 vs. 113.1 mmHg, p<0.001), fasting plasma glucose (112.3 vs. 98.3 mg/dl, p<0.001), and higher prevalence of diabetes (51.6 vs. 40.3%, p=0.038) after adjusting for age and sex. This finding was similar in subjects with or without diabetes. In the logistic regression analyses, subjects with albuminuria and/or CKD had increased odds of metabolic syndrome compared to those without albuminuria and CKD after adjusting for age, sex, BMI, alcohol, smoking and cardiovascular disease [ORs, 2.32 (95% CI, 1.61-3.33), 1.76 (1.24-2.49), 3.26 (1.71-6.18) in albuminuria without CKD , CKD without albuminuria, albuminuria and CKD groups, respectively).

Conclusion: In apparently healthy population, those with albuminuria and/or CKD had metabolically unhealthier phenotypes than those without albuminuria and CKD. Albuminuria without CKD was more strongly associated with metabolic syndrome and its components compared to normoalbuminuric CKD.

1185

Genome-wide association scan for diabetes associated chronic kidney disease (CKD) in patients with type 1 and type 2 diabetes

N.W. Rayner[1,2], H. Desmukh[3], N. Sandholm[4,5], C. Ladenvall[6], E. Ahlqvist[6], Eurodiab, FinnDiane, SUMMIT;
[1]Wellcome Trust centre for Human Genetics, University of Oxford, [2]Oxford Centre for Diabetes, Endocrinology and Metabolism, University of Oxford, [3]University of Dundee, UK, [4]Folkhalsan Research Center, Helsinki, [5]Division of Nephrology, Helsinki University Central Hospital, Finland, [6]Lund University, Malmo, Sweden.

Background and aims: Diabetes is the leading cause of chronic kidney disease (CKD) and is associated with excessive cardiovascular morbidity and mortality. We conducted a genome-wide association study (GWAS) to identify susceptibility loci for CKD in Patients with type 1 and type 2 diabetes.

Materials and methods: We defined cases as CKD stages 3-5 with an estimated Glomerular Filtration Rate (eGFR), based on MDRD-4 formula, <60 ml/min/1.73m^2 or presence of End Stage Renal Disease (ESRD), defined as dialysis or renal transplantation. Controls had eGFR >=60 ml/min/1.73m^2 and duration of diabetes >= 15 years for T1D, >= 10 years for T2D. GWAS data from 4,207 European samples (1,299 cases, 2,908 controls) with T1D and 4,469 European samples (3,088 cases, 1,381 controls) with T2D were imputed to ~2.4 million single nucleotide polymorphisms (SNPs) with HapMap2 using IMPUTE. To test for association we used a logistic regression model, adjusting for age at onset, gender and duration of diabetes and in addition a meta-analysis using a fixed effects model in GWAMA. We also performed a combined meta-analysis of the T1D and T2D comprising 8,676 individuals (4,387 cases, 4,289 controls).

Results: In T1D CKD we observed the strongest association for rs12632850 (OR = 1.39, P = 1.1 x 10^{-6}, Effect Allele Frequency (EAF) = 0.8) on chromosome 3q25.33 between *SCHIP1* and *IL12A*. The strongest association for the T2D CKD analysis was rs2378013 (OR = 0.60, P = 9.1 x 10^{-8}, EAF = 0.92) a SNP close to the *TGFB2* gene encoding transforming growth factor beta 2. In the combined T1D + T2D analysis the strongest association was rs2231899 mapping to FIGN (OR = 1.25, P = 1.6x10^{-6}, EAF = 0.79). We did not see any significant association (P < 0.05) in previously published signals for non-diabetic CKD (*UMOD*, *PRKAG* or *SOX11*).

Conclusion: We have identified several putative loci for CKD in patients with type 1 or Type 2 diabetes. *TGF-β* has been previously shown to be an important mediator in the pathogenesis of CKD. Non-replication of known loci for CKD from population based GWAS studies in patients with diabetes suggests that the genetic background for non-diabetic CKD disease differs from that of diabetes associated CKD.

Urinary proteomics predict onset of microalbuminuria in a cohort of normoalbuminuric type 1 diabetic patients in the DIRECT 1 study

F. Persson[1], M. Lindhardt[1], P. Zürbig[2], A. Stalmach[3], H. Mischak[2], H. Lambers Heerspink[4], A. Sjoelie[5], R. Klein[5], T. Orchard[5], M. Porta[5], J. Fuller[5], R.W. Bilous[5], N. Charturvedi[5], H.-H. Parving[5], P. Rossing[1,6];
[1]Steno Diabetes Center, Gentofte, Denmark, [2]Mosaiques Diagnostics GmbH, Hannover, Germany, [3]University of Glasgow, UK, [4]University Medical Centre, Groningen, Netherlands, [5]The DIRECT Steering Group, Odense, [6]University of Copenhagen, Denmark.

Background and aims: Early prevention of diabetic nephropathy is not successful as early interventions have shown diverging results. Urinary proteomics has shown promise as an early indicator of future development of diabetic nephropathy and could guide need for treatment. In this study we investigate that ability in a large type 1 diabetic cohort with normoalbuminuria.

Materials and methods: In a post-hoc study of the DIRECT-Protect 1 study, a randomized, controlled clinical trial of candesartan for slowing the progression of diabetic retinopathy, we studied patients with type 1 diabetes and normoalbuminuria (n=783), followed for a mean of 4.5 years. We determined a previously defined CKD risk score based on proteomic measurement of 273 urinary peptides (CE-MS), selected from previous cross sectional case-control studies. A Cox regression model for progression of albuminuria was built. The primary endpoint was development of persistent microalbuminuria (MA) (3 out of 4 samples).

Results: Persistent MA developed in 40 patients (5.4%). At baseline the CKD risk score was able to predict development of MA during follow-up, independent of treatment (candesartan/placebo), age, gender, baseline systolic BP, baseline UAER, baseline eGFR, baseline HbA_{1c} and diabetes duration (HR 2.88 (95% CI 1.1-7.6), p=0.032). In the placebo treated group the HR was 4.9 (1.3-18.7) compared to 2.0 (0.5-8.9) in the candesartan group.

Conclusion: In this cohort of patients with type 1 diabetes and normoalbuminuria from a large intervention study, the urinary proteome-based CKD classifier was an independent predictor of MA. This may provide a better opportunity to select normoalbuminuric patients for early prevention of diabetic nephropathy as treatment with candesartan seems to mitigate this risk.

Alkaline phosphatase is independently associated with renal function in normoalbuminuric type 1 diabetic patients

T. Bulum, K. Blaslov, K. Zibar, L. Duvnjak;
Vuk Vrhovac Clinic for Diabetes, Endocrinology and Metabolic Diseases, University Hospital Merkur, Zagreb, Croatia.

Background and aims: Nonalcoholic fatty liver disease (NAFLD) is associated with an increased prevalence of chronic kidney disease in patients with type 1 diabetes. The aim of this study was to explore the relationship between markers of NAFLD and renal function in normoalbuminuric type 1 diabetic patients.

Materials and methods: Study included 313 normoalbuminuric type 1 diabetic patients without clinical evidence of cirrhosis or other causes of chronic liver disease and before any interventions with statins, ACE inhibitors or angiotensin II receptor blockers. Normoalbuminuria was defined as a urinary albumin excretion rate (UAE) <30 mg/24h. UAE was measured from at least two 24-h urine samples and determined as the mean of 24-h urine collections. Study included patients with glomerular filtration rate (GFR) >60 mlmin-11.73m-2 estimated using the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI) formula. Correlations and multiple logistic regressions analysis were performed to identify the relationships between UAE, estimated GFR, serum creatinine and NAFLD associated markers (aspartate aminotransferase (AST), alanine aminotransferase (ALT), alkaline phosphatase (ALK), γ-glutamyltransferase (GGT), ferritin and bilirubin).

Results: The mean age of our patients was 34±11 years, and 51.5% were males. Mean/median values of body mass index (BMI) (24 (15-37) kg/m2), waist to hip ratio (WHR) (0.81±0.07), HDL cholesterol (1.7±0.4 mmol/L), triglycerides (0.91 (0.3-4.1) mmol/L), AST (20 (10-146) units/L), ALT (19 (7-171) units/L), ALK (69 (11-229) units/L), GGT (16 (7-553) units/L), bilirubin (12 (5-103) μmol/L), ferritin (55 (5-697) μg/L), serum creatinine (71±14 μmol/L), UAE (11.0 (1.7-29.8) mg/24h) and eGFR (106±16 mlmin-11.73m-2) were within the normal range for patients with diabetes, with slightly elevated hemoglobin A1c (HbA1c) (7.4±1.6%) and LDL cholesterol (2.8±0.8 mmol/L)

levels. ALT, GGT, bilirubin and ferritin significantly correlated with serum creatinine (r=0.16, 0.18, 0.29, and 0.39, respectively, for all p<0.05), ALK and bilirubin with eGFR (r=0.23, and -0.12, respectively, for all p<0.05) and GGT with UAE (r=0.11, p<0.05). ALT, GGT, bilirubin and ferritin levels were significantly higher in subjects in the highest quartile of serum creatinine (≥80 μmol/L) compared to those in lowest quartile (<63 μmol/L) (21 vs 20 U/L, 18 vs 14 U/L, 14 vs 10 μmol/L, and 103 vs 25 μg/L, respectively, for all p<0.05). ALK levels were significantly higher in subjects in the highest quartile of UAE (≥16.6 mg/24h) compared to those in lowest (<6.8 mg/24h) quartile (71 vs 69 U/L, p=0.03), as well as in hyperfiltrating subjects (eGFR >125 mlmin-11.73m-2) compared to those with normal or mildly impaired eGFR (81 vs 68 vs 64 U/L, p<0.001). In a multiple logistic regression model adjusted for age, sex, duration of diabetes, HbA1c and BMI, only ALK levels were significantly associated with disturbances in serum creatinine and eGFR in our normoalbuminuric subjects (p≤0.007), with odds ratios of 0.98 to 1.02.
Conclusion: NAFLD associated markers, particularly ALK, are associated with renal function in normoalbuminuric type 1 diabetic patients. Whether the detection of elevated ALK levels in normoalbuminuric type 1 diabetic patients has predictive value for development of renal disease needs to be assessed in further follow-up studies.

1188

Circulating levels of adrenomedullin are elevated in type 1 diabetes with nephropathy and associated with outcome

P. Holmager[1], U. Pedersen-Bjergaard[2], J. Faber[1,3], C. Kistorp[1];
[1]Centre of Endocrinology and Metabolism, Herlev, [2]Department of Endocrinology and Kardiology, Hillerød, [3]Faculty of Health Sciences, Copenhagen, Denmark.

Background and aims: Endothelial dysfunction is associated with progression of diabetic nephropathy. Adrenomedullin is a 52 amino acid peptide, which is expressed in various tissues, including vascular endothelium. Circulating levels of the stable midregional fragment of the pro-adrenomedullin peptide (MR-proADM) is measured in plasma using a newly developed assay which reflects adrenomedullin levels. MR-proADM has potential as an endothelial biomarker. The aim of the present study was to examine if MR-proADM levels were elevated in T1D patients with increasing nephropathy, and to evaluate the prognostic value of this biomarker.
Materials and methods: A total of 264 patients with T1D (59.5 % men, mean age 44 years) were enrolled at baseline, and followed for a median of 12 years with respect to all-cause mortality. Measurement of plasma MR-proADM at baseline was available for all the patients. The median duration of diabetes was 19 years (11-28), and 54 (20.5%) of the patients received ACE-inhibitor or angiotensin II antagonist therapy. Twenty (7.6 %) patients had macrovascular complications whereas, 149 (56.4 %) had retinopathy. Mean HbA1c was 8.6 % (1.2 %), and mean BMI 25.1 kg/m^2 (3.7 kg/m^2). During follow-up 39 (14.8 %) patients died, 12 due to cardiovascular disease. Diabetic nephropathy defined as either elevated urinary albumin creatinine ratio (UACR) > 30 mg/g or creatinine levels above reference interval were present in 68 (%) of the patients.
Results: Median (interquartile range (IQR)) MR-proADM plasma levels were elevated in T1D patients with nephropathy 0.38 nmol/l (0.33-0.52 nmol/l) compared to T1D patients without nephropathy 0.35 nmol/l (0.28-0.42 nmol/l), P = 0.009. There was no association between MR-proADM levels and BMI or glycemic regulation measured as HbA1c. Baseline MR-proADM levels tended to be increased in the T1D patients who died during follow-up, 0.40 nmol/l (0.30-0.55 nmol/l) vs. 0.35 nmol/l (0.29-0.43 nmol/l), P = 0.054. Presence of nephropathy was not associated with significantly increased mortality risk (HR 1.8, P = 0.6) in the present population. We could not demonstrate a significant association between MR-proADM levels and all-cause mortality when performing a cox regression analysis, a two fold increase in MR-proADM levels was associated with a HR of 1.3 (0.8-2.2), P = 0.3.
Conclusion: T1D patients with nephropathy have increased plasma MR-proADM levels, which could possess prognostic implications. The relatively limited number of events in the present study should be considered. The prognostic value of MR-proADM in combination with urinary albumin excretion rate with respect to survival and progression of diabetic nephropathy should be evaluated in future studies.

1189

Renal depletion of the organic osmolyte, myo-inositol, in hypertension, diabetes and insulin resistance: therapeutic implications for chronic kidney disease

K.M. Loomes, H.-H. Chang, H.-N. Chao, B. Choong, C. Walker;
School of Biological Sciences, University of Auckland, New Zealand.

Background and aims: Depletion of the organic osmolyte, myo-inositol (MI), in the kidney is implicated in the pathogenesis of diabetic nephropathy. MI depletion was proposed to arise as a consequence of increased glucose metabolism through the polyol pathway and sorbitol accumulation in the kidney. However, MI depletion in diabetes persists despite normalization of sorbitol levels following treatment with an aldose reductase inhibitor. The origin of MI depletion in diabetes mellitus is therefore currently poorly understood as are the mechanisms linking it to the pathogenesis of renal complications. We hypothesized that renal depletion of MI was due to changes in metabolic pathways regulating its biosynthesis, reabsorption and catabolism in the renal cortex. Of special interest is the catabolism of MI through the renal-specific enzyme myo-inositol oxygenase (MIOX) and the glucuronate-xylulose (GX) pathway, which are implicated in oxidative stress and the pathogenesis of interstitial fibrosis in diabetes. We also surmised that MI depletion might occur not just in diabetes but in other metabolic states characterised by hyperosmotic conditions. We therefore examined the expression of genes regulating MI de novo biosynthesis, reabsorption, and catabolism and extended the analyses to animal models of diabetes, dietary-induced obesity, and hypertension.
Materials and methods: Analyses were investigated in kidneys derived from animal models of streptozotocin-induced diabetes (Wistar rats), dietary induced obesity (C57BL/6 mice), and hypertension (SHR vs. WKY rats). Gene and protein expression were measured using real time PCR, western blotting, and activity measurements. MI content in the kidney was analysed by GC/MS using deuterated MI as an internal standard.
Results: Renal MI depletion occurred in hypertensive and insulin resistant states as well as in diabetes. Compared to their respective controls, renal depletion of MI was most pronounced for hypertension with a 52% decrease ($N = 6$, $p < 0.01$) followed by a 35% decrease in diabetes ($N = 7$, $p < 0.01$) and an 18% decrease in dietary-induced obesity ($N = 6$, $p < 0.05$). Of all the genes and proteins analysed, MI depletion was positively correlated with increased MIOX activity across all three disease states compared with their respective controls. MIOX activity was increased by 144% fold in the hypertensive state, followed by 124% fold in diabetes mellitus ($N = 6$, $p < 0.01$), and 114% for insulin resistance ($N = 7$, $p < 0.05$). We also showed using immunohistochemistry that MIOX and the GX pathway were localized to the proximal tubules in the renal cortex where MI depletion occurs.
Conclusion: Oxidative stress is a common pathological component of chronic kidney disease. Our data indicate that renal MI depletion is a surrogate biomarker reflecting increased catabolism through MIOX and the GX pathway in the proximal tubules. Renal MI depletion is also a common feature of diabetes, insulin resistance, and hypertension, suggesting that the GX pathway could contribute to the respective associated nephropathies by promoting oxidative stress. Inhibition of MIOX and the GX pathway may therefore offer a new therapeutic strategy to target chronic kidney disease.

Mortality and requirement of renal replacement therapy in people with type 1 diabetes: a 30 years prospective observational study

M. Stadler[1,2], S. Peric[3], H. Strohner-Kaestenbauer[3], R. Kramar[4], K. Irsigler[5], T. Kaestenbauer[3], F. Kronenberg[6], R. Prager[2,3];
[1]Diabetes, King's College London, UK, [2]Hietzing Hospital, Vienna, [3]Metabolic Diseases and Nephrology, Karl Landsteiner Institut, Vienna, [4]Austrian Dialysis and Transplantation Registry, Wels, [5]Ludwig Boltzmann Institut, Vienna, [6]Division of Genetic Epidemiology, Department of Medical Genetics, Innsbruck, Austria.

Background and aims: We investigated long term mortality and requirement of renal replacement therapy (RRT) in an observational cohort study of 647 patients with type 1 diabetes to study risk factors for late complications and mortality.
Materials and methods: In 1982/83 we recorded the anthropometrical and laboratory data of all 647 patients (47% females) with type 1 diabetes mellitus

who attended the outpatient department of a tertiary referral centre in Vienna for their yearly diabetes review. In 2012 we investigated the two endpoints death and renal replacement therapy by record linkage with national registries. Furthermore all patients still alive were asked questionnaires regarding other endpoints (cardio- and cerebrovascular, blindness, limb amputation).
Results: During the 30-years follow up, 156 patients died [mortality rate: 860 (95%CI: 721-1000) per 100.000 person years] and 55 received renal replacement therapy [incidence rate: 335 (95%CI: 247-424) per 100000 person years]. Mortality was higher in males (p<0.02), but incidence of RRT was equally high in both genders.395 of the still alive patients returned their questionnaires (response rate 86%). These patients reported 56 cardiac events, 24 strokes, 13 limb amputations and 8 blindness due to diabetes. Patients in the highest baseline HbA1c quartile (HbA1c above 8.3%) had the highest mortality rate and incidence of RRT (p<0.05).
Conclusion: In people with established Type 1 diabetes who were observed over 30 years, the overall mortality was 24% and the overall incidence of renal replacement therapy was 8.5%. Patients in the higher HbA1c quartiles were burdened with an increased mortality risk and an increased risk to need renal replacement therapy.

Pitavastatin improves the estimated glomerular filtration rate (eGFR) in patients with type 2 diabetes and hypercholesterolaemia treated with sitagliptin
S. Kurioka;
Komatsu Hospital, Osaka, Japan.

Background and aims: Previous studies have shown that statins improve renal function in patients with chronic kidney disease. In this study, we examined the renal effect of pitavastatin in patients with type 2 diabetes and hypercholesterolemia, who had already been treated with or without the DPP-4 inhibitor sitagliptin.
Materials and methods: The subjects in this study were 81 patients with type 2 diabetes and hypercholesterolemia. Twenty-nine patients were treated with sitagliptin (SITA) and 52 patients were not (no-SITA). The patients were treated with 2mg pitavastatin for 6 months, and we evaluated the effects on eGFR, lipid profile, and glycemic control.
Results: Age (SITA 62±12 vs. no-SITA 63±10 years, p=0.71), male gender (55 vs. 56 %, p=0.96), body mass index (26.2±5.0 vs. 26.1±3.9 kg/m^2, p=0.90), smoking status (17 vs. 8%, p=0.20), systolic blood pressure (135±17 vs. 135±20 mmHg, p=0.88), fasting plasma glucose (FPG; 178±57 vs. 151±57 mg/dl, p=0.05), HbA1c (7.5±1.4 vs. 7.9±1.4%, p=0.21), total cholesterol (TC; 254±39 vs. 243±34 mg/dl, p=0.20), triglyceride (TG; 189±93 vs. 178±101 mg/dl, p=0.62), HDL-C (54±13 vs. 56±16 mg/dl, p=0.68), LDL-C (164±36 vs. 155±27 mg/dl, p=0.22), apolipoprotein B-100 (Apo B; 134±26 vs. 126±20 mg/dl, p=0.15), serum creatinine (Cr; 0.83±0.27 vs. 0.79±0.25 mg/dl, p=0.57), and eGFR (71.3±23.2 vs. 73.3±20.1 ml/min/1.73m^2, p=0.69) were not significantly different between the two groups. A significant increase of the eGFR was observed in the SITA group (71.3±23.2 to 84.2±22.7 ml/min/1.73m^2, p<0.001), but not in the no-SITA group (73.3±20.1 to 76.1±19.7 ml/min/1.73m^2, p=0.15), and the changes of Cr (-0.13±0.16 vs. -0.03±0.15 mg/dl, p=0.0079) and eGFR (+12.9±16.3 vs. +2.8±14.2 ml/min/1.73m^2, p=0.0049) were significantly different in the two groups after 6 months of pitavastatin treatment. Changes of TC (-78±36 vs. -64±37 mg/dl, p=0.09), TG (-25±138 vs. -1±132 mg/dl, p=0.43), HDL-C (+5±13 vs. +4±13 mg/dl, p=0.74), LDL-C (-73±35 vs. -64±34 mg/dl, p=0.26), Apo B(-46±27 vs. -34±19 mg/dl, p=0.05), FPG (-21±73 vs. -2±63 mg/dl, p=0.26) and HbA1c (-0.6±1.5 vs. -0.0±1.2 %, p=0.06) were not significantly different between the two groups.
Conclusion: These findings suggest that combination therapy of pitavastatin and sitagliptin may exhibit a renal protective effect in patients with type 2 diabetes and hypercholesterolemia.

PS 101 Nephropathy basic science: from profiling to targets

1192

Transcriptional profiling of kidney glomerulus in diabetic mouse models
G. Genové[1], J. Norlin[1], B. Lavina-Siemsen[1], E. García-Vaz[2], M.F. Gómez[2], C. Betsholtz[1];
[1]Medical Biochemistry and Biophysics, Karolinska Institute, Stockholm, [2]Clinical Sciences, Lund University, Malmö, Sweden.

Background and aims: Diabetic nephropathy (DN) is the main cause of chronic kidney disease, which is characterised by a gradual decline in renal function, eventually leading to a need for kidney replacement therapy -dialysis or transplantation. Almost 50% of all diabetes patients will develop DN. The pathogenesis of DN is unknown, but likely to be multifaceted, with the involvement of metabolic, endocrine, hemodynamic, and inflammatory factors. DN pathogenesis is thought to onset in the kidney glomeruli.
Materials and methods: Previously, we developed a novel method for the isolation and enrichment of kidney glomeruli in mice, yielding ≈97% purity of glomerular preparations. The high glomerular purity allowed us to generate a glomerular transcriptome profiling. Here we use diabetic mouse model strains such as db/db, Akita, and BTBRob/ob, to extract the kidney glomeruli at different time points (1, 2, 4, and 6 months), and perform microarray in order to compare the transcriptional profiling of the different models analyzed.
Results: Our preliminary data from the db/db model has already identified 14 transcripts that are up- or downregulated in all timepoints analyzed (p<0.05). Upregulated genes are Chi3l3, Ankrd1, Grp, Fn1, Frzb, P2rx1, Fkbp5, Sirpb1. Downregulated genes are Negr1, Cacna2d2, Car3, Keg1, Calca, 2210023G05Rik. Interestingly, we could detect alterations in these transcripts before the onset of hyperglycaemia in the db/db model. We are currently performing pathway analysis as well as preliminary comparisons with public human data. In addition, we are waiting for the microarray results from the BTBRob/ob and Akita models.
Conclusion: Our developed method for high-yield, high-purity glomerular extraction allows us to charting the glomerular transcriptional changes that occur before and during the onset of hyperglycaemia in diabetic mouse models. Our data will prove of high value in validating findings in human samples as well as in monitoring the changes in diabetic mouse models.

Electron and confocal microscopy of diabetic E1-DN mouse glomeruli revealed thickening of basement membrane and decreased nephrin expression
V. Dumont[1], M.E. Hyvönen[1,2], E. Lehtonen[1,3], J. Ustinov[4], J. Tienari[5], T. Otonkoski[2,4], P.J. Miettinen[2,4], S. Lehtonen[1];
[1]Department of Pathology, Haartman Institute, University of Helsinki, [2]Children's Hospital, University of Helsinki, [3]Laboratory Animal Center, University of Helsinki, [4]Biomedicum Stem Cell Center, University of Helsinki, [5]HUSLAB and Department of Pathology, Helsinki University and Helsinki University Hospital, Finland.

Background and aims: Currently available animal models for diabetic nephropathy recapitulate only partially the features of the human disease. The transgenic E1-DN mice express a kinase-negative epidermal growth factor receptor (EGF-R) in their pancreatic islets and are diabetic due to impaired postnatal growth of pancreatic islet β-cells. The mice survive without insulin treatment, and can be used to investigate the effects of long term exposure to hyperglycaemia. The aim of this study was to characterize the renal phenotype of E1-DN mice, focusing on glomerular injury.
Materials and methods: The transgenic mice in FVB background were generated previously. E1-DN homozygous (n=9), heterozygous (n=14) and wild-type (wt) (n=12) mice were followed up to the age of 40 or 50 weeks (wks). Blood glucose, urine volume and albumin excretion were measured. Homozygous male mice were selected for further analysis based on albuminuria. Mesangial matrix expansion was measured using PAS-staining. Thickening of the glomerular basement membrane (GBM) was measured using electron microscopy, and the difference in the glomerular expression level of nephrin was assessed by confocal microscopy.

Results: Increased albumin excretion rate (AER) in homozygous E1-DN mice was detected at both 10 and 20 wks of age ($p<0.01$, Mann-Whitney U-test). At 20 wks, some of the homozygous mice had developed massive albuminuria. In histological analysis, PAS-staining revealed mesangial expansion in E1-DN homozygous mice at 20 wks, and focal glomerular sclerosis was observed in the most albuminuric mice at 50 wks. Measurement of PAS staining intensity per glomerular area showed an increase in homozygous mice compared to wt mice (n = 70 glomeruli from 7 homozygous mice, age 20-50 wks; n=30 glomeruli from 3 wt mice, age 50 wks; $p<0.001$, Student's t-test). Electron microscopy analysis indicated thickening of the GBM in homozygous E1-DN mice at 40-50 wks compared to wt mice at 50 wks (370 µm in homozygous [n= 8 glomeruli] vs. 250 µm in wt [n= 3 glomeruli], $p = 0.025$, Mann-Whitney U-test). In addition, podocyte foot process effacement was observed in homozygous E1-DN mice. The expression level of nephrin was lower in glomeruli of E1-DN homozygous mice (n=15 glomeruli) compared to wt mice (n=10 glomeruli) at 50 wks ($p<0.001$, Student's t-test). Membranous and cytoplasmic localization of nephrin was analyzed by co-staining with ZO-1, but no significant difference in localization between diabetic and control mice was observed.
Conclusion: Hyperglycaemic E1-DN mice develop substantial albuminuria. The histological and structural changes in glomeruli include mesangial expansion, thickening of the GBM and podocyte foot process effacement, and resemble human diabetic nephropathy. In addition, nephrin expression is reduced. Altogether, our data indicate that E1-DN mice are a valuable model to study diabetic nephropathy.

Characterisation of transcriptional influences on the coagulation protease-activated protein C pathway in diabetic nephropathy
J.G. Schneider[1,2], E. Rybacka[1], T. Madhusudhan[3], K. Roomp[1], B.H. Isermann[3];
[1]Luxembourg Centre for Systems Biomedicine (LCSB), University of Luxembourg, Esch, Luxembourg, [2]Saarland University Medical Center, Internal Med. II, Homburg, [3]Laboratory Medicine and Clinical Chemistry, University of Magdeburg, Germany.

Background and aims: Recent data demonstrated the prevention of diabetic nephropathy by activation of the serine protease activated protein C (aPC) pathway. In an animal model of diabetic nephropathy nephroprotection was associated with inhibition of glomerular apoptosis and mitochondrial dysfunction. The mechanism how the extracellular protease aPC prevents glomerular apoptosis and mitochondrial dysfunction remains unknown, but in other disease models aPC has been linked with altered gene-expression
Materials and methods: microRNAs (miRNAs) have shown to play a role in diabetic nephropathy. Thus, we performed microarray based mRNA and microRNA expression analysis of kidney samples from mice with and w/o diabetic nephropathy using wild type mice and two different mutants with single mutations affecting aPC availability (TMPro/Pro, low aPC plasma levels; and aPChigh, high aPC plasma levels).
Results: miRNA profiling of the kidney cortex revealed that miR-34a-5p was significantly upregulated in all diabetic mice, regardless of the genetic background (i.e. in both diabetic mutant mice), as compared to controls ($p<0.05$). miR-192-5p was also an indicator of diabetic nephropathy, also less significantly. We did not identify differentially expressed miRs in direct comparison between both diabetic mutants, indicating that no direct post-transcriptional regulation with miR participation is likely to occur within aPC pathway. The analysis also demonstrated the highest number of differentially expressed miRs (n=13) in diabetic TMPro/Pro vs. TMPro/Pro control mice. Seven of the detected miRs showed differential expression exclusively in this comparison: miR-1224-5p, miR-2681, miR-494-3p, miR-5105, miR-5109 and miR-5126, and miR-7e-5p. MiR-26b-5p was the only miR upregulated in diabetic aPChigh vs diabetic WT mice, while miR-148a-3p, miR199a-3p, miR-31-5p and miR-342-3p were all found to be downregulated only in diabetic TMPro/Pro vs. diabetic WT. Validation experiments were used to confirm selected array results. We constructed two networks of genes de-regulated in diabetes, starting with DEGs from comparison between both diabetic mutants. Genes included in the networks interact directly with and are connected with DEGs from comparison of both mutants and are considered particularly important protection against diabetic nephropathy. The most pronounced changes in expression were in diabetic TMpro mice (from 27.8 to -25.3 fold change), followed by diabetic WT mice (from 7.02 to -3.22 fold change), and diabetic aPChigh mice (from 6.32 to -3.25 fold change). Twelve of the aggravations signaling network genes are potentially regulated by four miRs, found specifically deregulated only in diabetic TMPro/Pro mice: let-7a-5p, miR-494, miR-1224-5p and miR-2861. The most pronounced changes in expression were in diabetic TMpro mice (from 27.8 to -25.3 fold change), followed by diabetic WT mice (from 7.02 to -3.22 fold change), and diabetic aPChigh mice (from 6.32 to -3.25 fold change).
Conclusion: These findings indicate that a deregulation of specific miRs is associated with deactivation of the aPC pathway in diabetic nephropathy.

Experimental podocyte injury leads to reduced expression of CD2AP
S. Kuusela[1], P. Saurus[1], P. Räihä[2], T. Palmen[2], M. Saleem[3], H. Holthöfer[2], E. Lehtonen[1,4], S. Lehtonen[1];
[1]Dep. of Pathology, University of Helsinki, [2]Dep. of Bacteriology and Immunology, University of Helsinki, Finland, [3]University of Bristol, Southmead Hospital, Bristol, UK, [4]Laboratory Animal Centre, University of Helsinki, Finland.

Background and aims: Podocyte injury and loss play a central role in the development of glomerular diseases, such as diabetic nephropathy. Podocyte loss may occur by apoptosis or detachment from the glomerular basement membrane, and it leads to defects in the filtration function and proteinuria. CD2-associated protein (CD2AP) is critical to the structural and functional integrity of the glomerular filtration barrier as mice lacking CD2AP develop nephrotic syndrome with heavy proteinuria and effacement of podocyte foot processes. Here, we studied the role of CD2AP in podocyte injury and apoptosis by using cultured podocytes and a rat model of puromycin aminonucleoside (PA) -induced acute nephrosis.
Materials and methods: Rats and cultured human podocytes were treated with PA to induce podocyte injury and apoptosis. The expression level of CD2AP was analysed by RT-PCR and Western blotting. The localisation of CD2AP in the PA-treated rat glomeruli was analysed by conventional immunofluorescence microscopy and immunoelectron microscopy. Apoptosis of cultured podocytes was measured by flow cytometry, and the involvement of different signalling pathways associated with apoptosis was analysed by Western blotting.
Results: RT-PCR analysis revealed that in 3-day and 10-day PA-treated rats, the mRNA level of glomerular CD2AP decreased to about 50% and 40%, respectively, compared to controls. Immunofluorescence microscopy of 10-day nephrotic kidneys showed a dramatic decrease in glomerular CD2AP signal. Immunoelectron microscopy revealed a dramatic disappearance of CD2AP from the podocyte foot processes 10 days after PA-injection. Occasionally the remaining CD2AP signal associated with cytoplasmic electron dense material, apparently representing disorganized actin cytoskeleton. PA-treatment of cultured human podocytes induced apoptosis, and significantly reduced CD2AP protein level and disrupted the actin stress fibers. Overexpression of CD2AP was able to reduce PA-induced apoptosis in cultured podocytes. Analysis of the activity of different apoptotic pathways revealed that PA-treatment induced the expression of proapoptotic BAX protein and caspase-3 -mediated apoptosis. Additionally, PA-treatment reduced antiapoptotic BCL-2 protein expression and Akt phosphorylation, but overexpression of CD2AP rescued BCL-2 protein expression and Akt phosphorylation and reduced BAX expression in cultured human podocytes.
Conclusion: Our results show that the development of PA-induced acute nephrosis is associated with distinct changes in glomerular expression and distribution of CD2AP, and that these changes are apparent already before appearance of major albuminuria. Disregulation of CD2AP may thus have a pivotal role in the pathogenesis of proteinuria in acute nephrosis. Overexpression of CD2AP may rescue experimentally induced podocyte injury by modulating the expression of both pro- and antiapoptotic proteins.

Senescence marker protein-30 deficiency accelerates diabetic renal injury through tubulointerstitial fibrosis in a mouse model of type 1 diabetes

H. Okada, T. Senmaru, M. Asano, M. Yamazaki, M. Fukui, G. Hasegawa, N. Nakamura;
Endocrinology and Metabolism, Kyoto Prefectural University of Medicine, Graduate School of Medical Science, Kyoto, Japan.

Background and aims: Aging is a risk factor for the progression of diabetic nephropathy leading to end-stage renal failure. However, its mechanism has not been elucidated. Senescence marker protein-30 (SMP30) is abundantly expressed in renal tubular cells and decreases with aging. Our studies using SMP30 knockout mice have revealed that a reduction in SMP30 expression may contribute to age-associated deterioration of cellular function and the enhanced susceptibility to harmful stimuli in aged tissue. In this study, we investigated the effects of SMP30 deficiency on the pathogenesis of diabetic nephropathy.
Materials and methods: Diabetes (DM) was induced using streptozocin in male SMP30 Y/- mice (KO) and wild-type, SMP30 Y/+, mice (WT) at 7 weeks of age. Twelve weeks after the induction of diabetes, the mice were sacrificed for the study.
Results: Urinary albumin excretion was increased in KO compared to WT both in DM and non-DM condition ($P<0.05$). The proportions of cortical tubulointerstitial fibrosis area (Sirius red stain) were increased in KO compared to WT (1.02±0.20 vs 3.00±1.38%, $P<0.05$). In DM, this increase was markedly enhanced in KO (2.02±0.34 vs 19.34±6.10%, $P<0.05$). On the other hand, SMP30 deletion did not affect mesangial expansion (PAS stain). The changes in tubulointerstitial fibrosis were well associated with the expression of HIF-1α, not 4HNE, as assessed by immunohistchemistry. However, increase of HIF-1α mRNA was observed only in KO of non-DM condition ($P<0.05$). Similar to the HIF-1α protein expression, the mRNA expression of CTGF and MCP-1 were increased in KO both in non-DM and DM condition.
Conclusion: These results indicate that SMP30 deficiency deteriorates diabetic nephropathy through tubular injury. Stabilization of HIF-1α and following signaling may be mainly involved in these changes. The decrease of SMP30 could be a factor which explains the cross-talk between pathogenesis of various chronic kidney diseases, including diabetic nephropathy, and aging.

Methylglyoxal induced insulin resistance in podocytes contributes to diabetic kidney disease

L.A. Gallo[1], B.E. Harcourt[1], A.K. Fotheringham[1], D. McCarthy[1], S.A. Penfold[2], J.M. Forbes[1,3];
[1]Glycation and Diabetes Complications, Mater Research, Woolloongabba, [2]Diabetes Complications Division, Baker IDI Heart and Diabetes Institute, Melbourne, [3]School of Medicine, Mater Clinical School, University of Queensland, St Lucia, Australia.

Background and aims: The plasma concentration of the reactive carbonyl, methylglyoxal (MGO), is elevated in diabetes. Increased accumulation of MGO may contribute to insulin resistance at peripheral sites of glucose uptake. A deficiency in podocyte insulin signalling impairs podocyte function resulting in chronic kidney disease. Hence, we examined the effects of MGO accumulation on glucose trafficking and insulin signalling in podocytes.
Materials and methods: Human podocytes were exposed to MGO or an inhibitor of glyoxalase-1 (GLO-1), an enzyme considered to detoxify MGO. Podocyte glucose uptake was determined using 2-deoxyglucose. Podocyte insulin sensitivity was assessed using pAKT/AKT and membranous GLUT4 protein expression using Western immunoblotting. Male db/db mice (reminiscent of human type 2 diabetes) and db/H control mice were administered with GLO-1 on alternate days from weeks 6 to 9 of life (50mg/kg body weight) and renal function and glycaemic control were assessed.
Results: Human podocytes exposed to MGO or an inhibitor of GLO-1 showed a decline in insulin-dependent glucose uptake and reduced insulin signalling with lower pAKT/AKT ratios and GLUT4 membrane translocation. In the db/db mouse, serum cystatin C was elevated at 9 weeks, and this was exacerbated with GLO-1 inhibition. Peripheral insulin resistance in db/db mice however, was not different under the presence of GLO-1 inhibition. Decreased glucose uptake, insulin signalling and expression of GLUT4 in human podocytes exposed to MGO or an inhibitor of GLO-1 were consistent with the degree of renal dysfunction in diabetic mice.
Conclusion: The accumulation of the reactive carbonyl MGO in diabetes may contribute to renal impairment by adversely affecting podocyte insulin sensitivity.

Unexpected behaviour of aminoguanidine on human embryonic kidney cell (HEK293) exposed to glycated albumin

A.I. Serban[1], L. Stanca[1,2], O.I. Geicu[1,2], A. Dinischiotu[2];
[1]Preclinical Sciences, University of Agronomical Science and Veterinary Medicine, [2]Biochemistry and Molecular Biology, University of Bucharest, Faculty of Biology, Bucharest, Romania.

Background and aims: The accumulation of extracellular matrix proteins in the glomerular mesangium and tubular basement membranes is a hallmark of diabetic nephropathy. Advanced glycation end products (AGEs) and TGF-β1 seem to mediate critical steps that lead to this type of pathological modifications. Our aim was to investigate the role of AGEs receptor-RAGE in overexpression of collagen IV in HEK293 cells exposed to glycated BSA (AGE-BSA) and the pathway through which aminoguanidine (AG) could prevent these modifications correlated with diabetic nephropathy development.
Materials and methods: Cultured cells were treated for 12 and 24 hours with AGE-BSA or BSA (control) at concentrations between 50-200 μg/ml in the presence or absence of 10-100 μM AG. The levels of RAGE, TGF-β1 and procollagen α1 (IV) mRNAs were analyzed by quantitative real-time PCR whereas protein expression of RAGE from cell membranes and collagen type IV and TGF-β1 from culture media were assessed by Western blot analysis.
Results: All target genes mRNA relative expression ratios (R) increased with both time exposure and AGE-BSA concentration. After 12 hours of exposure to 200 μg/ml AGE-BSA the R of RAGE increased to 1.21+/-0.06, TGF-β1 increased to 1.25+/-0.1 and procollagen α1 (IV) was upregulated to 1.17+/-0.07. At the same AGE-BSA dose, after 24 hours the target genes RAGE, TGF-β1 and respectively procollagen α1 (IV) were further upregulated to 1.83+/-0.23, 3.4+/-0.09 and 4+/-0.12. The protein levels of RAGE, TGF-β1 and collagen were in good correlation with the mRNA expressions. After the 12 hour co-treatment with AG and 200 μg/ml AGE-BSA, the protein expression for all target proteins showed a proportional increase with AG level compared with the treatment in the absence of inhibitor. The lowest AG dose (10 μM) seemed to amplify the expression of the three genes, as their R reached the highest values of 2.27+/-0.18, 1.85+/-0.05 and 1.53+/-0.08 for RAGE, TGF-β1 and respectively procollagen α1 (IV). At 50 and 100 μM AG, R decreased for RAGE and TGF-β1 and remained nearly unchanged for procollagen α1 (IV), compared to treatment with 10 μM AG. After 24 hours, the treatment with 10 μM AG led to an additional increase of R for all target genes, whereas 50 and 100 μM AG concentrations downregulated the mRNA expression, but only at 100 μM AG, R had subunitary value for RAGE (0.84+/-0.09). In addition, the protein expression for all target proteins, had a downward trend, reaching at 100 μM AG subunitary values, compared to AGE-BSA treatment in the absence of inhibitor.
Conclusion: These results show that AGEs can interfere in collagen IV synthesis through RAGE receptor dependent pathway in which TGF-β1 could have a pivotal role. It seems that at short time intervals (<12 hours) and very low concentrations (<10 μM), not only that AG is unable to block AGEs binding to RAGE, but moreover, due its decomposition, it may have a pro-oxidant effect promoting ROS formations, which in turn, can induce RAGE activation. It is also possible that AG reacted with some albumin-bound dideoxyosones derived from Amadori products competing with arginine residues and thus generated new AGEs products. AG positive effects were observed after 24 hour at higher concentrations, when it could more effectively trap AGEs and inhibit the AGEs-RAGE pathway.

Anti-fibrotic peptide AcSDKP restores diabetes-suppressed microRNA-let-7 cluster and exhibits therapeutic effect on kidney fibrosis in diabetes

K. Kanasaki, T. Nagai, S.P. Srivastava, M. Kitada, M. Kanasaki, D. Koya;
Diabetes & Endocrinology, Kanazawa Medical University, Kahoku, Ishikawa, Japan.

Background and aims: Fibroblast play vital roles in organ fibrosis process, including kidney. Endothelial to mesenchymal transition (EndMT) has emerged as one of the important origins of matrix producing fibroblast. Endogenous anti-fibrotic peptide N-acetyl-seryl-aspartyl-lysyl-proline (AcSDKP) is degraded by angiotensin-converting enzyme (ACE) and ACE-inhibitor increased plasma levels of AcSDKP. microRNA let-7 family exhibits potential anti-EndMT effect.
Materials and methods: In vivo experiments were performed in streptozotocin (STZ)-induced diabetic CD1 mouse, the diabetes-associated kidney fibrosis model. Human umbilical vein endothelial cells (HUVEC) and human microvascular endothelial cells (HMVEC) were stimulated with transforming growth factor (TGF)-β2 or combination of TGF-β2, interleukin-1β and tumor necrosis factor-α with or without AcSDKP incubation. microRNA expression was analyzed by array and qPCR.
Results: Herein we found that AcSDKP inhibited EndMT and exhibited anti-fibrotic effects associated with microRNA let-7 family cluster alterations in vivo and in vitro. When analyzing the kidney fibrosis in STZ-induced diabetic CD1 mice, the conventional ACE-inhibitor plus AcSDKP add-on therapy significantly ameliorated kidney fibrosis in association with EndMT inhibition. In diabetic kidney, mmu-let-7 family cluster was suppressed when compared to non-diabetic kidney; anti-fibrotic and anti-EndMT effects of AcSDKP in diabetic kidney were associated with restored mmu-let-7 expression. TGF-β2 or cytokines combination induced HUVEC/HMVEC cells into spindle shapes and reduced endothelial markers CD31/VE-cadherin expression together with the induction of mesenchymal markers such as αSMA or SM22α expression, suggesting induction of EndMT. Such induced EndMT was restored by the co-incubation with AcSDKP in either HUVEC or HMVEC. In vitro anti-EndMT effect of AcSDKP was also associated with the hsa-let-7 family alterations.
Conclusion: These results suggest that AcSDKP is potential valuable endogenous anti-fibrotic molecule via partially inhibition of EndMT through microRNA let-7 alternations.

Theobromine cocoa prevents high glucose-induced extracelular matrix accumulation via activation of NAD+-dependent deacetylase sirtuin-1 in human mesangial cells

E.B.M. Peixoto, A. Papadimitriou, K.C. Silva, J.M. Lopes de Faria, J.B. Lopes de Faria;
Renal Pathophysiology Laboratory, Investigation on Complications of Diabetes,Faculty of Medical Sciences, University of Campinas (Unicamp), Brazil.

Background and aims: Oxidative stress is a critical underlying mechanism for microvascular complications of diabetes, including diabetic nephropathy (DN). Excess oxidative stress causes increased extracellular matrix (ECM) accumulation with progression to fibrosis and end stage renal disease. High polyphenol substances such as cocoa reduce oxidative stress. Surprisingly, we have observed that also cocoa with low amount of polyphenols ameliorated diabetes-induced oxidative stress and ECM accumulation in diabetic rats. HPLC and mass spectrometry analyses revealed that theobromine was an important component of the cocoa extract with low polyphenols. Sirt1 is a class III histone deacetylase with deacetylase activity, depending on intracellular NAD^+ concentrations. Activation or overexpression of Sirt1 is known to protect against oxidative stress, apoptosis and ECM accumulation in the diabetic kidney. The aim of the present study was to assess if theobromine is effective in reducing ECM accumulation induced by high glucose via Sirt1 activation in immortalized human mesangial cells (iHMCs).
Materials and methods: iHMCs were cultured for 24 h in normal glucose (NG; 5 mM), high glucose (HG; 30 mM) or hydrogen peroxide (H_2O_2; 10 μM), with or without theobromine treatment (44 nM), a blocker of NADPH-induced oxidative stress such as diphenyleneiodonium chloride (DPI; 50 nM), NAD+, or Sirt1 activity blocker (EX-527). Oxidative stress was assessed by measurement of reactive oxygen species (ROS) by H_2DCF-DA (2',7'-dichlorodihydro-fluorescein diacetate) and quantification of NADPH oxidase-dependent superoxide (SO) formation. NAD+ and Sirt1 activity levels were determined in total iHMC lysates by colorimetric and fluorometric kits, respectively. ECM accumulation was assessed via western blot for type IV collagen and fibronectin expressions. Immunoprecipitation assay was performed by immunoprecipitating total Smad3 and carrying out western blot for acetylated Smad3.
Results: In iHMCs high glucose or H_2O_2 increase ROS production (P<0.0001), mainly through NADPH oxidase pathway, and decrease NAD+ levels (P=0.0005) and Sirt1 activity (P<0.0001). These abnormalities were prevented by treatment with theobromine. Theobromine did not confer additional rise in NAD+ and Sirt1 activity when co-treated with DPI (P<0.0001) in comparison to DPI treatment alone (P<0.0001). Immunoprecipitation of total Smad3 followed by western blot for acetylated Smad3 showed that theobromine significantly reduced HG-induced acetylated Smad3 (P<0.0001) and this was reversed (P<0.0001) by blockade of Sirt1 with EX-527. Similarly, EX-527 reversed significantly (P=0.018) the ameliorating effect of theobromine in HG-induced rise in type IV collagen and fibronectin (P=0.02).
Conclusion: In summary, theobromine improves HG-induced ECM accumulation via reduction in NADPH-induced ROS production, rise in NAD+ and Sirt1 activity levels and reduction in acetylated Smad3.

***Cocoa* enriched in polyphenols is renoprotective in experimental diabetes mellitus by reducing transforming growth factor beta-1 (Tgfbeta-1) signalling**

A. Papadimitriou, E.B.M. Peixoto, K.C. Silva, A.M. Faria, J.M. Lopes de Faria, J.B. Lopes de Faria;
Renal Pathophysiology Laboratory, Investigation on Complications of Diabetes, Faculty of Medical Sciences, University of Campinas (Unicamp), Campinas, Sao Paulo, Brazil.

Background and aims: Oxidative stress (OS) has been implicated in the pathogenesis of diabetic vascular complications, including nephropathy. Cocoa enirched in polyphenols has been reported to be beneficial in endothelial dysfunction due to its antioxidative properties. The aim of the present study was to investigate the effect of cocoa enriched in polyphenols in nephropathy (DN) of diabetic spontaneously hypertensive (SHR) rats.
Materials and methods: Twelve-week-old SHR rats were rendered diabetic by intravenous injection of streptozotocin (60 mg/Kg), whereas control rats received citrate buffer. Blood glucose levels of ≥ 270 mg/L were considered diabetic. Diabetic SHR rats were randomized to receive or not treatment with cocoa enriched in polyphenols (Barry Callebout, Belgium, 24 mg/Kg b.w./day) by gavage. After 16 weeks of treatment, extracellular matrix (ECM) accumulation was evaluated by periodic acid-Schiff (PAS) staining, and western blot and immunohistochemistry for collagen IV (C-IV), fibronectin (F/N), phosphorylated Smad2 and Smad3. OS was determined by quantification of NADPH oxidase-dependent superoxide (SO) generation and by western blot and immunohistochemistry for nitrotyrosine (N/T) expression. For *in vitro* studies, immortalized human mesangial cells (iHMCs) were cultured for 24 h in normal glucose (NG; 5mM) or high glucose (HG; 30mM), or H_2O_2 or TGFβ-1 (5 ng/ml) with or without cocoa treatment (100 ng/ml) and blockers of OS such as N-acetyl cysteine (NAC; 1 mM) and diphenyleneiodonium chloride (DPI; 50 nM). OS was assessed by measurement of reactive oxygen species (ROS) by H_2DCF-DA (2',7'-dichlorodihydro-fluorescein diacetate) and NADPH oxidase-dependent SO generation. TGFβ-1 release was measured in the supernatants of iHMCs by a TGFβ-1 ELISA kit.
Results: Plasma glucose levels (P=0.0001) were higher in untreated and treated diabetic SHR rats than in nondiabetic group. Blood pressure levels and albuminuria were not modified by cocoa treatment. Cocoa treatment significantly reduced diabetes-induced mesangial matrix expansion (P=0.02), C-IV (P=0.0005), F/N (P=0.003), phosphorylated Smad2 (P<0.0001) and Smad3 expression (P=0.04). Cocoa also ameliorated diabetes-induced NADPH oxidase-dependent SO formation (P=0.016), and N/T levels (P=0.0001) in SHR rats. In *vitro* studies showed an inhibition in HG-induced ROS production (P<0.0001) and NADPH oxidase-dependent SO generation (P=0.003) by both treatment of cocoa and its major component, epicatechin, (41 nM) (P=0.0002). Collagen IV, F/N, phosphorylated Smad2 and Smad3 expression (P<0.0001) and TGFβ-1 release were significantly reduced by cocoa and epicatechin treatment under HG levels. Similar results with cocoa treatment were obtained when iHMCs were exposed to H_2O_2 or TGFβ-1 (P<0.0001).

Cocoa did not confer additional reduction when co-treated with NAC or DPI in HG-induced rise in F/N , C-IV, phosphorylated Smad2 and Smad3 and TGFβ-1 release in comparison to DPI or NAC alone (P<0.0001).
Conclusion: In summary, cocoa enriched in polyphenols and particularly epicatechin, improves DN by ameliorating TGFβ-1 signalling-induced ECM accumulation via inhibition of OS and particularly NADPH oxidase activity.

Silencing of a disintegrin and metalloproteinase (ADAM)17 enhances ACE2 protein expression and activity in COS7 cells
M. Di Fulvio, N.F. Kashkari, E.J. Shah, H.K. Somineni, H. Chodavarapu, M. Almiahuob, R. Singh, N. Grobe, K.M. Elased;
Pharmacology & Toxicology, Wright State University, Dayton, USA.

Background and aims: Diabetic Nephropathy (DN) is one of the most common complications of diabetes and a major cause of end-stage renal failure. Angiotensin converting enzyme 2 (ACE2) is conceded to play a renoprotective role by converting Ang II to Ang-(1-7). Administration of recombinant ACE2 is shown to ameliorate albuminuria and kidney function in animal models of diabetes. Indeed, loss of renoprotective ACE2 was observed in diabetic animal models due to increased ACE2 shedding mediated by a Disintegrin and Metalloproteinase (ADAM) 17. COS7, a robust and easily transfectable cell line derived from the kidney of an African green monkey are used to directly demonstrate and assess the role of ADAM17 on ACE2 shedding. The aim of this study was to demonstrate the presence of endogenous and functional RAS and ADAM17 in COS7 cells. We hypothesize that silencing of ADAM17 could be a potential target in the regulation of ACE2 expression and activity.
Materials and methods: RNAi-based silencing of ADAM17 in COS7 cells was done by stably expressing lentiviral constructs encoding short-hairpin RNAs (shRNAs) directed against ADAM17. Silenced cells were then grown to 90-100% confluency and GFP expression was used to screen stable transfectants. Western blot and immunohistochemistry were used to determine RAS components and ADMA17 at the protein level. ACE2 activity was measured using Mca-APK [Dnp] fluorogenic substrate.
Results: Immunoreactive bands for renin (41 kDa), ACE (195 kDa), ACE2 (90 kDa) and ADAM17 (93 kDa) were observed. Silencing of ADAM17 was confirmed using Western blot. Silenced cells demonstrated a significant increase of ACE2 activity in comparison with wild type cells (3.8 pmoles/hr/μg protein vs. 2 pmoles/hr/μg protein, $p<0.05$). In accordance with the activity, expression of ACE2 was also upregulated in the ADAM17 silenced cells.
Conclusion: This is the first report to demonstrate functional and endogenous expression of the RAS in COS7 cells and the crosstalk between ADAM17 and the regulation of ACE2. The transfectable nature of this cell line makes it an attractive *in vitro* model for manipulating components of the renal RAS.

Deletion of GIPR (glucose-dependent insulinotropic polypeptide receptor) in mice results in reduced blood pressure and changes in vascular contractility
L.M. Berglund[1], K. Swärd[2], Y. Seino[3], D.J. Drucker[4], L. Groop[1], M.F. Gomez[1];
[1]Clinical Sciences in Malmoe, Lund University, Malmoe, [2]Experimental Medical Science, Lund University, Lund, Sweden, [3]Kansai Electric Power Hospital, Osaka, Japan, [4]Dept of Medicine, Samuel Lunenfeld Research Institute, Mt Sinai Hospital, Toronto, Canada.

Background and aims: GIP and GLP-1 (glucagon-like peptide-1) are secreted after a meal to stimulate insulin secretion. In addition to their insulinotropic activity, a plethora of actions have been described in other tissues, including effects on the cardiovascular system. Evidence suggests a cardioprotective role of GLP-1, but less is known about GIP in this context. Previous studies demonstrated effects of GIP on splanchnic blood flow, with increased flow in the superior mesenteric artery and portal vein and decreased pancreatic and hepatic blood flow. These effects were suggested to be achieved by differential production of endothelin-1 (ET-1) and nitric oxide (NO) by endothelial cells. In the work presented here, we study the effect of GIPR deletion in mice on blood pressure and vascular contractility.
Materials and methods: GIPR knockout (KO) and wildtype (WT) littermate mice were used. Blood pressure was measured using tail-cuff plethysmography and vascular contractility was examined in small mesenteric resistance arteries and saphenous arteries by wire myography. Serum levels of ET-1 and

nitrate/nitrite (NOx) levels were determined by commercially available assays.
Results: In GIPR KO mice, we found significantly lower systolic blood pressure when compared to WT control mice (103.1 ± 1.8 vs. 113.5 ± 1.7 mm Hg, p=0.0009). We found no effect of acute stimulation with naturally occurring GIP(1-42) or the stable GIPR agonist D-Ala2-GIP(1-42) on contraction of small mesenteric resistance arteries or saphenous arteries from WT mice, nor did these peptides relax vessels pre-contracted with potassium (30 mmol/L). In contrast, the contractile response to depolarization by potassium (60 mmol/L) was significantly reduced in both small mesenteric arteries and saphenous arteries from GIPR KO mice, when compared to WT mice. Cumulative concentration-response curves using the selective α_1-receptor agonist cirazoline revealed greater force in saphenous arteries from GIPR KO mice compared to WT mice, which could reflect a potential upregulation of α_1-receptor signaling to compensate for the lower blood pressure. Pre-treatment with GIP(1-42) had no effect on cirazoline-induced force in WT mice. No differences in serum ET-1 or NOx levels were found.
Conclusion: Our data demonstrate a role for GIPR in the regulation of blood pressure and vascular contractility. Inhibition of GIPR signaling may have beneficial effects in hypertension and vascular disease.

Prevalence of hypertension and its determinants among Bangladeshi type 2 diabetic subjects
F. Jasmine[1], S. Hossain[1], H. Chowdhuri[2];
[1]Health Education and Health promotion, Bangladesh University of Health Sciences, [2]Biostatictis, Bangladesh University of Health Sciences, Dhaka, Bangladesh.

Background and aims: Hypertension, an important risk factors for cardiovascular diseases, is known to be more prevalent in diabetic patients; however the prevalence and its determinants vary substantially from population to population. The prevent study was undertaken to investigate the prevalence and determinants of hypertension in a group of Bangladeshi type-2 diabetes mellitus subjects. Aims: This study was aimed to investigate Prevalence of hypertension and its determinants among Bangladeshi type-2 diabetic subjects.
Materials and methods: A cross-sectional study was conducted among 18697 subjects 11917 diabetic and 6780 non diabetic purposively from selected 16 diabetic hospitals health centre located in the capital, Dhaka and in northern part of Bangladesh. Data were collected using a pre-tested, semi-structured questionnaire by face to face interview. Anthropometric measurement and biochemical analysis were done by standard techniques. Hypertension was diagnosed using IDF criteria for this population. Data were analyzed by univariate as well as bivariate analysis. Logistic regression was applied to estimate the odds ratio (OR) and corresponding 95% confidence intervals (CI) for the different explanatory variables.
Results: 42% of the subjects were male and 58% were female. The mean age (±SD), years the non diabetic and diabetic subjects was 46 (±14) and 57% respectively. The corresponding BMI values were 23.7(±3.8) and 25.4 (±3.9). The diabetic group had a substantially higher proportion of hypertensive subjects compare to the non diabetic group (38% vs 7%).On logistic regression analysis, hypertension was found to have strongly significant($p<0.001$) association with increasing age, urban resident, higher socioeconomic status, smoking, higher BMI and west hip ratio and high total cholesterol.
Conclusion: Bangladeshi type 2diabetis mellitus subjects are about 7 times were pron to hypertension compare to their no diabetic counter patient. Irrespective to the percent of diabetic age, urbanization, high-low economic status, generalized and central obesity and hypercholesterolemia an independent risk factors of hypertension in this population.

1205

Normal fasting glucose and HbA_{1c} levels and the development of hypertension in Japanese individuals
T. Yamada[1], Y. Heianza[1,2], S. Kodama[1,3], Y. Arase[4,5], K. Saito[6,1], A. Suzuki[1], S. Hara[4,5], O. Hanyu[1], H. Sone[1,4];
[1]Department of Internal Medicine, Niigata University Faculty of Medicine, Niigata, [2]Department of Internal Medicine, University of Tsukuba Institute of Clinical Medicine, Ibaraki, [3]Mito Kyodo General Hospital, Mito, [4]Health Management Center, Toranomon Hospital, Tokyo, [5]Okinaka Memorial Institute for Medical Research, Tokyo, [6]Center for Medical Sciences, Ibaraki Prefectural University of Health Sciences, Ibaraki, Japan.

Background and aims: Whether higher fasting plasma glucose (FPG) or HbA1c concentrations within normal range would independently predict hypertension remains unclear. Since the development of high blood pressure would coincide with the development of hyperglycemia, clarifying normal glucose or HbA1c concentrations as risk factors for the development of hypertension among normoglycemic individuals can be considered to be clinically important. We investigated whether FPG or HbA1c concentrations could help detect normoglycemic individuals at increased risk for future hypertension.
Materials and methods: We investigated 8786 individuals without known diabetes and hypertension (hypertension indicated by self-reported history of treatment, systolic blood pressure ≥140 mm Hg or diastolic blood pressure ≥90 mm Hg). Logistic regression analysis was performed using FPG or HbA1c as a continuous variable (1-SD increment) or quartile (Q) categories for the development of hypertension; odds ratios (ORs) and 95% CIs were calculated.
Results: We documented 1012 incident cases of hypertension at 5 y after the baseline examination. A multivariate model adjusted for age, sex, body mass index (BMI) and pre-hypertension showed a progressively increased risk of hypertension among individuals with FPG 89-93 mg/dL (odds ratio (OR) 1.38 (95% CI 1.11, 1.72)), FPG 94-99 mg/dL (OR 1.43 (1.15, 1.78)) or FPG ≥100 mg/dL (OR 1.87 (1.51, 2.33) than those in the bottom quartile (<89 mg/dL), P for trend <0.001). Further adjustment for parental history of hypertension and metabolic risk factors attenuated the association but the trend remained significant (P=0.001). No significant association was observed across quartile categories of HbA1c concentrations below pre-diabetic ranges and increased risk of hypertension. The joint effect of hyperglycemia and either overweight, older age or pre-hypertension resulted in substantially elevated ORs for hypertension than the absence of such an association.
Conclusion: Higher FPG levels within normoglycemic range rather than HbA1c levels were predictive of future hypertension among Japanese individuals. Elevated glycemic markers may help along with older age, BMI and pre-hypertension to identify apparently healthy individuals at increased risk for hypertension.

The effect of pre-measurement rest time on ankle systolic pressures in people with and without diabetes
V.H. Chuter, S.L. Casey;
Health Sciences, University of Newcastle, Ourimbah, Australia.

Background and aims: Systolic ankle pressures are routinely measured as part of an ankle-brachial index to screen for the presence of lower extremity peripheral arterial disease in people aged 50 years and over with diabetes and, in the general population aged 65 years and over. Despite widespread use of this measurement, the effect of pre-measurement duration of rest on the magnitude, or reliability of the ankle systolic pressure measurement is unknown. Similarly although diabetes has been associated with reduced reliability of brachial pressures and altered blood pressure control, possible disease-related effects on ankle systolic pressure and therefore the ankle-brachial index have not been investigated. The aim of this study was to assess the effect of pre-measurement rest duration on systolic ankle pressures on people with and without diabetes.
Materials and methods: One hundred and forty participants meeting current guidelines for screening for peripheral arterial disease including 64 participants with Type 2 diabetes volunteered for this study. Following 5 minutes of rest in the supine horizontal position, ankle systolic pressures from either the dorsalis pedis or posterior tibial artery of the left or right lower extremity

were taken using hand-held Doppler. Measurements were repeated at 10 and 15 minutes. Testing was repeated 7-10 days later.
Results: A significant drop in ankle pressure of 5.02 mmHg occurred between 5 and 10 minutes ($p<0.05$) however no significant change occurred between 10 and 15 minutes (mean change 0.15 mmHg, $p=0.99$). Presence of diabetes was associated with a smaller drop between 5 and 15 minutes (mean change 1.85 mmHg) and predicted 14% of the variance in change in ankle pressure (beta:-3.72, $p>0.05$). In the total population test-retest reliability after 5 minutes was excellent (Intraclass correlation coefficient [ICC]: 0.84, 95% confidence interval [CI]: 0.76 to 0.91) however increased for measurements taken at 10 and 15 minutes (ICC: 0.89 95% CI: 0.83 to 0.94 and 0.89 95% CI: 0.82 to 0.93 respectively). Diabetes was associated with a reduction in test re-test reliability at 10 minutes when compared to those without diabetes (ICC:0.82 95% CI 0.76 to 0.88 and ICC 0.90 95% CI: 0.85 to 0.94 respectively).
Conclusion: Results suggest ankle systolic pressures stabilise after 10 minutes of rest. Longer periods of pre-measurement rest did not improve reliability of the measurement significantly. Presence of diabetes is associated with an altered response of ankle systolic pressure to rest and a reduction in test-retest reliability.

Prognostic value of reading-to-reading blood pressure variability over 24 hours in 584 patients with diabetes from 11 populations

T. Hansen[1], L. Thijs[2], Y. Liu[2], K. Asayama[2], Y. Li[3], J. Boggia[4], K. Björklund-Bodegård[5], E. Dolan[6], T. Kuznetsova[2], K. Stolarz-Skrzypek[7], V. Tikhonoff[8], S. Malyutina[9], J.A. Staessen[2], on behalf of the IDACO Investigators;
[1]Steno Diabetes Center, Gentofte, Denmark, [2]Studies Coordinating Centre, Division of Hypertension and Cardiovascular Rehabilitation, Department of Cardiovascular Sciences,, University of Leuven, Belgium, [3]Center for Epidemiological Studies and Clinical Trials, Ruijin Hospital, Shanghai, China, [4]Centro de Nefrología and Departamento de Fisiopatología, Hospital de Clínicas, Universidad de la República, Montevideo, Uruguay, [5]Division of Cardiovascular Medicine, Department of Clinical Sciences, Danderyd Hospital, Karolinska Institutet, Stockholm, Sweden, [6]Cambridge University Hospitals, Addenbrook's Hospital, Cambridge, UK, [7]First Department of Cardiology and Hypertension, Jagiellonian University Medical College, Kraków, Poland, [8]Department of Clinical and Experimental Medicine, University of Padova, Italy, [9]Institute of Internal Medicine, Novosibirsk, Russian Federation.

Background and aims: Information on the predictive value of blood pressure (BP) variability recorded over 24-h in patients with diabetes is scarce.
Materials and methods: We followed health outcomes in 584 patients with diabetes (mean age, 62.0 years; 40.1 % women) randomly recruited from 11 populations. Diabetes was the use of antidiabetic drugs, a fasting blood glucose concentration of at least 7.0 mmol/L, a random blood glucose concentration of at least 11.1 mmol/L, a self-reported diagnosis, or diabetes documented in practice or hospital records. At baseline, we assessed BP variability from the standard deviation (SD) and average real variability (ARV24) in 24h ambulatory BP recordings. We computed standardized hazard ratios (HR), while stratifying by cohort and adjusting for 24h BP and other risk factors.
Results: Over 11.0 years (median), 165 deaths (85 cardiovascular) occurred. The incidence of a fatal or nonfatal cardiovascular event was 155, and 75 experienced a stroke. Higher diastolic ARV24 predicted ($P\leq0.002$) total (HR: 1.28) and cardiovascular (HR: 1.42) mortality as well as the combined cardiovascular endpoint (HR: 1.19, $P=0.040$) and stroke (HR: 1.38, $P=0.006$). Higher systolic ARV24 predicted cardiovascular mortality (HR: 1.27, $P=0.045$) but none of the other endpoints ($P\geq0.08$). Higher diastolic SD was significantly ($P\leq0.042$) associated with total (HR: 1.21) and cardiovascular (HR: 1.31) mortality and fatal and non-fatal stroke (HR: 1.42; $P=0.009$). Systolic SD did not predict any of the endpoints ($P\geq0.086$). While accounting for the 24-h BP level, ARV24 added <1% to the prediction of a cardiovascular event.
Conclusion: In patients with diabetes the BP variability assessed from 24-h ambulatory recordings was an independent predictor of mortality and of cardiovascular and stroke events. However, the proportion of the risk explained by the variability indices was low.

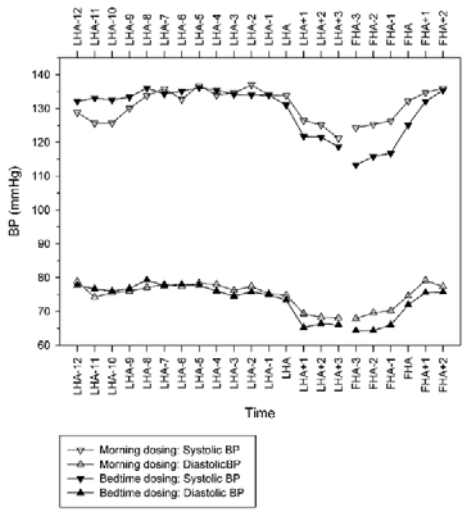
1208

Targeting nocturnal hypertension in type 2 diabetes: bedtime dosing of once-daily antihypertensive drugs reduces night-time BP and 24-h BP

N.B. Rossen[1,2], S.T. Knudsen[2], E. Ebbehøj[2], P.L. Poulsen[2], K.W. Hansen[1];
[1]Department of Medicine, Silkeborg Regional Hospital, Silkeborg, [2]Department of Endocrinology and Internal Medicine, Aarhus University Hospital, Aarhus, Denmark.

Background and aims: Several studies have suggested nighttime BP as an independent risk factor for cardiovascular disease, stronger than daytime BP. Therefore, new strategies to treat increased nighttime BP are warranted. In a population of type 2 diabetic patients with nocturnal hypertension, our aim was to investigate whether bedtime dosing of once-daily antihypertensive drugs will reduce nighttime BP without an increase in daytime BP.
Materials and methods: We included 41 type 2 diabetic patients with nocturnal hypertension (nighttime systolic BP (SBP) > 120 mmHg) in an open-label, cross-over study. Patients were randomized to 8 weeks of either morning or bedtime dosing of all once-daily antihypertensive drugs, followed by 8 weeks of switched treatment regimen. At baseline and after each of the two 8-week periods, patients underwent ambulatory blood pressure monitoring, measurements of arterial stiffness, and blood and urine testing.
Results: The median number of once-daily antihypertensive drugs was 3 (range 1-6). Nighttime SBP with morning dosing (MD) and bedtime dosing (BD) were 125.3±10.2 mmHg and 117.8±10.7 mmHg, respectively (difference 7.5±10.1 mmHg, $p<0.001$); daytime SBP with MD and BD were 134.2±9.8 mmHg and 133.0±12.1 mmHg, respectively (difference 1.3±8.5 mmHg, $p=0.336$); and 24-h SBP with MD and BD were 131.7±8.7 mmHg and 128.7±10.9 mmHg, respectively (difference 3.1±7.7 mmHg, $p=0.014$). The same pattern of significant decrease in nighttime and 24-h BP and insignificant decrease in daytime BP was found for diastolic BP, mean arterial pressure and pulse pressure. Morning surge was not significantly different between treatment regimens. Figure 1 illustrates the systolic and diastolic BP curves with morning and bedtime dosing for the 41 patients; the hourly averages have been fixed at each individual's last hour awake (LHA) and first hour awake (FHA). Pulse wave velocity and central BP parameters did not differ significantly between MD and BD. Analyses of renin-angiotensin-aldosterone parameters, markers of endothelial dysfunction, and urine albumin/creatinine ratio showed no significant changes. However, with BD urine sodium/creatinine ratio was significantly increased (MD: 14.3±6.7; BD: 18.8±6.4; difference 4.5±7.0, $p<0.001$) and urine osmolality was significantly decreased (MD: 563.5±191.8 mosmol/kg; BD: 509.4±172.2 mosmol/kg; difference 54.1±155.0 mosmol/kg, $p=0.031$).
Conclusion: We found a significant decrease in nighttime BP and, importantly, also a significant decrease in 24-h BP with BD. Despite lower nighttime BP, BD did not result in higher morning surge. Interestingly, the reduced nighttime BP with BD was associated with increased nocturnal natriuresis. In patients with type 2 diabetes and nocturnal hypertension, dosing of antihypertensive drugs at bedtime may be favorable.

Figure 1: Systolic and diastolic BP curves with morning and bedtime dosing for the 41 patients. The hourly averages have been fixed at each individual's last hour awake (LHA) and first hour awake (FHA)



Clinical Trial Registration Number: NCT01158625

1209

Arterial stiffness is associated with diabetic complications in type 1 diabetes and normalisation of albuminuria is associated with reduced arterial stiffness

S. Theilade[1], T.W. Hansen[1], P. Rossing[1,2];
[1]Steno Diabetes Center, Gentofte, [2]University of Copenhagen, Denmark.

Background and aims: We investigate the associations between diabetic complications and arterial stiffness in patients with type 1 diabetes.
Materials and methods: Cross-sectional study including 676 patients with type 1 diabetes. Arterial stiffness was measured by pulse wave analyses (PWA) (SphygmoCor (Atcor Medical, Australia)), as central pulse pressure (CPP), central aortic systolic pressure (CASP), heart rate adjusted augmentation index (AI75), augmentation pressure (AP) and pulse wave velocity (PWV). Patients were classified as normoalbuminuric if the urinary albumin excretion rate (UAER) persistently was <30 mg/24h, and micro- or macroalbuminuric if the UAER had ever been 30-299 mg/24h or ≥300 mg/24h, respectively, in two consecutive measurements in the absence of other kidney or urinary tract disease. History of cardiovascular disease (CVD) was myocardial infarction or stroke. Simple or proliferative retinopathy or blindness collectively defined retinopathy. Cardiac autonomic neuropathy was defined by a heart rate variability (HRV) <11 beats/minute.
Results: PWAs were available in 621 patients (mean age: 54.6 years; 54.8% men). Mean CPP, CASP, AI75, AP and PWV was: 43 mmHg, 118 mmHg, 17, 10 mmHg and 10.4 m/s, respectively. All measures were independently associated with presence of ≥1 diabetic complication (CVD, retinopathy and cardiac autonomic neuropathy) (p<0.05 for all) (adjusted for gender, diabetes duration, mean arterial pressure, heart rate, kidney function, HbA_{1c}, cholesterol and antihypertensive medication). Per SD increase, CASP was strongest associated with CVD and cardiac autonomic neuropathy (HR=3.5 and 4.6, p<0.001 for both) and PWV with retinopathy (HR=1.9, p=0.008). In adjusted analyses, all measures of arterial stiffness were similar in normoalbuminuric patients with low (<15mg/day) *vs.* high UAER at follow up and in previously microalbuminuric patients (30-299mg/day) with normalised *vs.* elevated UAER (≥30mg/day) at follow up (p≥0.083 for all). However, in previously macroalbuminuric patients (≥300mg/day), PWV was significantly lower in patients with normalised (<30 mg/day, n=35) *vs.* elevated UAER (n=129) at follow up (10.0±2.1 *vs.* 11.9±3.3 m/s (p=0.007). Although, all other measures of arterial stiffness were similar in the two groups.
Conclusion: In patients with type 1 diabetes, arterial stiffness is associated with complications. CASP and PWV showed the strongest associations. Patients previously diagnosed as macroalbuminuric with normalised UAER on reno-protective treatment had lower arterial stiffness than non-responders. Thus, maybe responders have lower arterial stiffness than non-responders, or arterial stiffness may be modifiable by reno-protective treatment. However, this needs to be confirmed in prospective studies.

1210

Blood pressure independent effect of renin angiotensin system blockade on soluble klotho levels in patients with type 2 diabetes and albuminuria

J. Karalliedde, G. Maltese, G. Viberti, L. Gnudi;
King's College London, UK.

Background and aims: Soluble Klotho is an anti-ageing phosphaturic protein associated with vascular-renal protection. In-vitro and in-vivo studies have demonstrated that renin-angiotensin-system (RAS) blockade increases soluble Klotho levels. The effect of RAS-blockers on soluble Klotho in patients with type 2 diabetes and albuminuria is unknown.
Materials and methods: Plasma soluble Klotho was measured in a secondary analysis of a randomised controlled clinical trial performed at a single university hospital centre. Seventy six patients with type 2 diabetes, systolic hypertension and albuminuria were studied at baseline and at 24- weeks (end of study), following randomisation to valsartan/hydrochlorothiazide (n=37) or amlodipine (n=39) treatment. All patients had an estimated glomerular filtration rate >45 ml/min/1.73 m^2. Aortic-pulse wave velocity (Ao-PWV) by applanation tonometry and albuminuria (from 3 timed urine collections) were also measured at baseline and 24-weeks.
Results: There were no significant baseline differences between the two groups. Valsartan/hydrochlorothiazide treatment significantly increased soluble Klotho mean±standard deviation, from 432.7±179 to 506.4±226.8 pg/ml, p=0.01 and reduced serum phosphate 1.05±0.38 to 0.84±0.31 mmol/l, p=0.04 compared to amlodipine (430.1±145.8 to 411.9±157.6 pg/ml and 0.95±0.18 to 0.87±0.49 mmol/l]. There was a significant between treatment group difference, mean (95% confidence interval), in soluble Klotho, 91.9 (19.9 to 162)pg/ml and serum phosphate levels -0.22 (-0.05 to -0.43)mmol/l with valsartan/hydrochlorothiazide treatment, p<0.05 for both. In the valsartan/hydrochlorothiazide group change in soluble Klotho was negatively correlated with change in phosphate (Pearson correlation R^2 -0.41 p=0.07). Attained blood pressure was similar in the two-groups and levels of soluble Klotho were not associated with Ao-PWV and albuminuria, variables which fell significantly only with valsartan/hydrochlorothiazide.
Conclusion: Treatment with valsartan, a RAS blocker, significantly increases soluble Klotho levels and reduces serum phosphate, effects which appear to be independent of its blood pressure lowering actions. These results suggest that elevations in soluble Klotho levels may at least in part contribute to the blood pressure independent benefits observed with RAS blockers in patients with type 2 diabetes and albuminuria.
Clinical Trial Registration Number: NCT00171561

Effect of direct renin inhibitor aliskiren on circulating endothelial progenitor cells number in patients with type 2 diabetes mellitus and arterial hypertension

M.C. Mazioti[1], K.P. Markakis[1], A.E. Raptis[1], E. Maratou[2], I. Ikonomidis[3], D.V. Vlahakos[1], A. Tsirogianni[4], S.A. Raptis[1,2], G.D. Dimitriadis[1];
[1]2nd Department of Medicine-Propaedeutic Clinic, Research Institute and Diabetes Centre, Athens University Medical School, Attikon University Hospital, Haidari, [2]Hellenic National Center for Research, Prevention and Treatment of Diabetes Mellitus and its Complications (H.N.D.C.), Athens, [3]2nd Department of Cardiology, Athens University Medical School, Attikon University Hospital, Haidari, [4]Department of Immunology-Histocompatibility, "Evangelismos" General Hospital, Athens, Greece.

Background and aims: Circulating endothelial progenitor cells (EPCs) derive from bone marrow and have the ability to differentiate into endothelial cells with high angiogenic potential. Diabetes mellitus has proved to have a strong impact to the number of EPCs which contributes to the development of vascular complications in diabetic patients. In the recent years, the ability of several treatments to achieve a favorable modification of EPCs population is under research. The aim of this study was to investigate the effect of renin inhibition on circulating EPCs population in patients suffering from type 2 diabetes mellitus and arterial hypertension.
Materials and methods: This open study enrolled 20 patients aged > 50 years with type 2 diabetes under stable glycaemic control and first diagnosed mild arterial hypertension. In phase A, patients received once-daily aliskiren 300 mg for 3 months. In phase B, once-daily hydrochlorothiazide 25 mg substituted for aliskiren for 3 more months. At baseline and at the end of phase A and phase B, the population of circulating EPCs was estimated by measuring of Dil-AcLDL+ / FITC-lectin+ cells in culture of peripheral blood mononuclear cells and also by quantification of CD34+/CD133+ cells in peripheral blood by flow cytometry. Endothelial function and arterial stiffness were also assessed by determination of brachial artery flow-mediated dilatation (FMD), augmentation index (AIx) and pulse wave velocity (PWV).
Results: After 3 months of treatment with aliskiren (n=18) mean sitting systolic BP (msSBP) and mean sitting diastolic BP (msDBP) were reduced by 8,8 mmHg and 5,9 mmHg respectively. The number of Dil-AcLDL+ / FITC-lectin+ cells and CD34+/CD133+ cells was increased by 40% (p < 0,05) and 31% (p < 0,05) respectively. FMD was increased by 87% (p < 0,001), while PWV and AIx were decresed by 16,8% (p < 0,05) and 10,2% (p < 0,05) respectively. At the end of phase B (n=12), msSBP and msDBP remained unchanged. Despite the similar control of msBP achieved with hydrochlorothiazide, the values of Dil-AcLDL+ / FITC-lectin+ cells and CD34+/CD133+ cells returned to baseline levels, exhibiting a reduction by 21% (p < 0,05) and 33% (p < 0,05) respectively compared to the corresponding values under treatment with aliskiren. In consistence with the effect on EPCs population, treatment with hydrochlorothiazide resulted in loss of the favorable effect of aliskiren on FMD, PWV and Aix.
Conclusion: Treatment with aliskiren resulted in increase of number of circulating EPCs, improved endothelial function and reduced arterial stiffness in type 2 diabetic patients. These effects were not observed with treatment with hydrochlorothiazide despite the similar blood pressure lowering. These results indicate a favorable effect of renin inhibition on EPCs, endothelial function and arterial stiffness beyond lowering msBP.

PS 103 Basic science retinopathy: novel in vitro and in vivo findings

The C57BL/KsJ-db/db mouse: an appropriate model for investigating diabetes-induced retinal neurodegeneration

R. Simó[1,2], P. Bodganov[1,2], L. Corraliza[1,2], A.R. Carvalho[1], C. Hernández[1,2];
[1]Institut de Recerca Hospital Universitari Vall d'Hebron, [2]CIBERDEM, Barcelona, Spain.

Background and aims: In recent years the C57BL/KsJ-*db/db* mouse has been used as a spontaneous diabetic model of type 2 diabetes to investigate the pathogenesis of diabetic retinopathy (DR). Several authors have reported the presence of retinal neurodegeneration (apoptosis, glial activation and retinal thinning) in this model However, the characterization of the retinal neurodegenerative process and its functional consequences in db/db mice is far from being completed. In addition, whether neurodegeneration could be attributed to genetic factors rather than to diabetes is a question which remains to be elucidated. On this basis the aim of this study was to characterize the sequential events that are taking place in retinal neurodegeneration in this murine model and to examine whether neurodegenerative features could be prevented or arrested by lowering blood glucose levels.
Materials and methods: A total of 72 C57BL/KsJ-*db/db* mice were divided into two groups: non-diabetic (db/+) and diabetic (db/db). To assess the chronological sequence of the abnormalities the analysis was performed at different ages (8, 16 and 24 weeks). The retinas were evaluated in terms of morphological and functional abnormalities [electroretinography (ERG)]. In addition, an interventional study to lowering blood glucose levels by using a GLP-1 agonist was performed. For this purpose db/db mice 8 weeks old received subcutaneous injections (300 µl/50 g body wt) of either vehicle (phosphate-buffered saline, pH 7.3-7.5) (n=8) or liraglutide (400 µg/kg) (n=8) once daily for 15 days. Eight non-diabetic mice matched by age served as control group. Statistical analysis: unpaired Student t-test. Levels of statistical significance were set at $p<0.05$.
Results: Glial activation was higher in diabetic (db/db) than in non diabetic (db/+) mice at 8, 16 and 24 weeks ($p<0.01$). The percentage of TUNEL positive cells in the retinal ganglion cell layer (RGC) was higher in db/db in comparison with db/+ at 8 weeks (30% vs.1%; $p<0.001$), and this differences were even higher at 16 weeks (35% vs. 1%) and 24 weeks (38% vs. 3%). Moreover, a significant reduction of neuroretinal thickness was also observed in db/db ($p<0.05$). Significant ERG abnormalities (increase in b-wave implicit time and decrease of b-wave amplitude; $p<0.01$) were present in db/db mice at weeks 16 and 24 but not at week 8. Overall all these findings are very similar than those found in the early stages of DR in diabetic patients. Diabetic (db/db) mice treated with liraglutide showed a significantly lower GFAP immunofluorescence and rate of apoptosis in GCL than db/db mice treated with vehicle ($p<0.05$). In addition, in treated db/db mice total the neuroretinal thickness (µm) was higher than in those treated with vehicle (215.9 ± 4.7 vs. 195.2 ± 4.0; $p<0.001$), and similar to that observed in age-matched non-diabetic control mice (215.9 ± 4.7 vs. 212.3 ± 3.1). Finally, a significant prevention in ERG abnormalities was also observed ($p<0.01$).
Conclusion: Our results suggest that the db/db mouse is an appropriate murine model for investigating the underlying mechanisms of diabetes-induced retinal neurodegeneration and for testing neuroprotective drugs. In addition, we provide evidence that neurodegeneration is prevented by lowering blood glucose levels and, therefore, diabetes rather than genetic factors is the primary reason accounting for retinal neurodegeneration in this model.

Connexin 43 (Cx43) upregulation rescues retinal endothelial cells from high glucose-induced apoptosis and excess permeability through amelioration of tight junctions

S. Roy, K. Barrette, T. Tien;
Medicine and Ophthalmology, Boston University School of Medicine, Boston, USA.

Background and aims: Intercellular communication is an essential process for maintenance of cellular function, homeostasis, and cell survival. In the retina, the predominant gap junction protein, Cx43, is abundantly expressed. Downregulation of Cx43 expression has been shown to promote apoptosis in retinal vascular cells, and contribute to the development of vascular lesions in the diabetic retina. In this study, we investigated if upregulation of Cx43 prevents high glucose-induced apoptosis and excess monolayer permeability in rat retinal endothelial cells (RRECs), and whether this is achieved through amelioration of tight junction protein expression.
Materials and methods: RRECs were grown in normal (5 mM glucose; N) or high glucose (30 mM; HG) medium for 7 days. In parallel, cells were grown in either N or HG medium, and transfected with plasmid pEGFPN1 containing full-length rat Cx43 cDNA conjugated to green fluorescent protein (GFP) using a lipofectamine reagent. Transfected cells were subsequently selected for stable colonies. To determine Cx43 upregulation in the transfected cells, Cx43 immunofluorescence microscopy (IF) and western blot (WB) analysis were performed. Additionally, cells were assessed for changes in gap junction intercellular communication (GJIC) using a scrape loading dye transfer (SLDT) assay, and tight junction proteins, ZO-1 and occludin, levels by IF/WB analyses. To identify cells undergoing apoptosis, differential staining using acridine orange/ethidium bromide was used, and an in vitro permeability assay (IVP) was performed to study changes in cell monolayer permeability.
Results: WB analysis indicated a significant increase in Cx43 expression in cells transfected with pEGFPN1compared to untransfected cells (152±13% of N; $p<0.05$), and IF identified most cells to contain the GFP conjugated Cx43 from the plasmid. Importantly, WB analysis showed that the inhibitory effect of HG on Cx43 expression (64±11% of control) was abrogated in transfected cells grown in HG medium (114±10% of N; $p<0.05$). Similarly, SLDT analysis indicated that HG-induced decrease in cell-cell communication (51.2±5%) was returned to near normal levels in cells transfected with pEGFPN1 and grown in HG medium (89±9%). As expected, cells grown in HG medium showed a significant increase in the number of apoptotic cells (225±17% of N). Interestingly, normalization of Cx43 expression resulted in (i) rescue of 50% of the HG cells from apoptosis, (ii) reduction in cell monolayer permeability by 40%, and (iii) upregulation of ZO-1 and occludin expression.
Conclusion: Findings from this study indicate that upregulation of Cx43 may rescue cells from HG-induced apoptosis by improving GJIC, upregulating tight junction protein expression, and reducing cell monolayer permeability in RRECs grown in high glucose condition. Thus, targeting abnormal Cx43 expression may prevent cellular demise and excess permeability associated with diabetic retinopathy.

Activation of cell proliferation and VEGF transcription by advanced glycation end-products in hydroquinone-treated human retinal pigment epithelial cells

H. Tsujinaka[1,2], A. Itaya-Hironaka[2], A. Yamauchi[2], S. Sakuramoto-Tsuchida[2], H. Ota[2], T. Fujimura[2], K. Nochioka[3], K. Shimoyama-Miyata[3], N. Ogata[3], S. Takasawa[2];
[1]Saiseikai Chuwa Hospital, Sakurai, [2]Biochemistry, Nara Medical University, Kashihara, [3]Opthalmology, Nara Medical University, Kashihara, Japan.

Background and aims: Age-related macular degeneration (AMD) is the commonest overall cause of irreversible blindness in patients aged 50 or over in the world. The disease has been traditionally classified into early and late stages with its dry and wet (exudative) forms. The dry form AMD was defined as progressive destruction of retinal pigment epithelial (RPE) cells. While, exudative form AMD is characterized by choroidal neovascularization which is led by some angiogenic cytokines such as vascular endothelial growth factor (VEGF). It is known that cigarette smoke and diabetes are important risk factors for both dry and exudative AMD. Advanced glycation end-products (AGE) are generated during diabetes and are correlated with the development of AMD. Hydroquinone (HQ), a toxic substance, is the most abundant quinone in cigarette tar. Here, we investigated effects of AGE on RPE cell proliferation and VEGF expression in HQ-damaged human RPE cells.
Materials and methods: ARPE-19 cells, a human RPE cell line, were treated with bovine serum albumin (BSA) (0-300 µg/ml), HQ (20 µM), AGEs-BSA (0-300 µg/ml), and HQ+BSA-AGE for 12 h. After the treatment, the viable cell numbers were measured by WST-8 cleavage assay. Apoptosis was measured by TUNEL method. Replicative DNA synthesis was measured by 5-iodo-2'-deoxyuridine (IdU) incorporation. Real-time RT-PCR of *VEGF* was performed using HQ, BSA-AGE, or HQ+BSA-AGE treated cell RNA as template. To investigate *VEGF* promoter activation, ARPE-19 cells were transiently transfected with the reporter plasmids consisting of a luciferase gene

under the control of human *VEGF* promoters, and luciferase activities were measured after the treatments of HQ, AGE, or HQ+AGE. VEGF secreted in the culture medium was measured by ELISA.
Results: WST-8 cleavage assay showed that the viable cell numbers were markedly reduced by HQ treatment, and the addition of AGE-BSA increased the HQ-treated cell numbers (P=0.0001) in a dose-dependent manner. We next examined apoptosis of ARPE-19 cells and found that HQ increased apoptosis (P=0.0002) and that the AGE-BSA addition did not reduce the apoptosis of HQ-treated cells (P=0.6112), suggesting that AGE-BSA stimulate cell proliferation. As expected, replicative DNA synthesis was stimulated by the addition of AGE-BSA in HQ-treated cells (P=0.0001), indicating that AGE increases cell number by activating HQ-treated cell replication. Real-time RT-PCR revealed that the level of *VEGF* mRNA was increased by HQ treatment and the addition of HQ+AGE-BSA resulted in a further increment of *VEGF* mRNA (P=0.0025). The reporter gene assay revealed that the *VEGF* promoter was activated by HQ (P<0.01), and further increment was observed in HQ+AGE-BSA-treated cells. The -358~+50 region was revealed to be essential for the *VEGF* promoter activation. The increase of VEGF in the HQ+AGE-BSA treated ARPE-19 cell culture medium (P=0.0064) was confirmed by ELISA.
Conclusion: HQ induces RPE cell apoptosis and AGE-BSA enhances *VEGF* transcription in HQ-damaged cells to stimulate proliferation. The secreted VEGF may act as an autocrine/paracrine growth factor to RPE and/or adjacent vascular cells, causing exudative form of AMD.

1215

Mesenchymal stem cell-derived microvesicles induce pericyte destabilisation in diabetic-like conditions
T. Lopatina, E. Beltramo, E. Berrone, M. Porta;
Dept Medical Sciences, University of Turin, Italy.

Background and aims: During angiogenesis, the stable association between pericytes and endothelial cells (EC) in pre-existing vasculature is disrupted, leading to EC proliferation. Recent findings suggest the existence of a novel way of intercellular communication, where the 'units' of information are microvesicles (MV), or exosomes, derived from different cells and containing biologically active proteins and RNA, that may promote phenotypic changes in other target cells. MV derived from injured cells may induce dedifferentiation of pericytes allowing their detachment from vessels. The literature on the molecular interactions between EC-derived MV and pericytes for the angiogenic switch is growing, but little is known about mesenchymal stem cells (MSC), a self-renewing cells that can be found in most tissues, to activate pericytes. Our study aimed at evaluating if MV produced by MSC in hypoxia and/or hyperglycaemic-like conditions are able to induce pericyte detachment and influence their survival.
Materials and methods: MSC from bone marrow and human microvascular EC were of commercial origin, while human retinal pericytes (HRP) were immortalized in our laboratory. MV were extracted from the supernatant of MSC or EC cultured in hypoxic and/or high glucose (HG) conditions and added to HRP cultured in physiological conditions both on plastic and EC-produced extracellular matrix (ECM). We evaluated HRP detachment after 2, 4, 6 and 24h exposure to MV by cell counts, as well as viability, cytotoxicity and apoptosis by an ELISA/fluorimetric assay. Motility and cell modifications were analyzed by a MicroImage analysis system.
Results: The number of attached HRP decreased in a time-dependent manner after addition to the culture medium of MSC-derived MV obtained in all the above-described conditions, the higher decrease occurring after 4h of MV exposure. HRP number on plastic after 4h: with MV obtained in physiological conditions (NG) -35.8% vs control (HRP not exposed to MV, p<0.05, n=5); MV in HG -27.1% (p<0.05), MV in NG+hypoxia -27.2% (p<0.05), MV in HG+hypoxia -37.0% (p<0.005). HRP number on EC-produced ECM after 4h: MV in NG -30.1% vs control (p<0.05); MV in HG -52.3% (p<0.005), MV in NG+hypoxia -40.3% (p<0.005), MV in HG+hypoxia -41.0% (p<0.005). Apoptosis and cytotoxicity did not change significantly. Trypan blue staining and TUNEL assay showed that detached cells were alive. Increased cell motility was observed in the presence of MV, reaching its maximum after 1h exposition of HRP to MV (+56.0% vs control, p<0.05), while microscopy observation showed evidence of cell contraction. Interestingly, EC-derived MV had no effects on pericyte viability/destabilization.
Conclusion: We conclude that MSC-derived MV induce HRP detachment, a possible indicator of destabilization. Diabetic-like conditions (hyperglycaemia and hypoxia) may play a synergistic role in influencing vessel destabilization during the stages of retinopathy that precede angiogenesis. Since this role seems to be MSC-specific, EC-derived MV having no effect, further studies are needed to better characterise MSC-HRP interactions.

$VEGF_{165}b$ reduces blood vessel dysfunction in diabetic retinas
N. Ved[1], R. Hulse[2,1], L.F. Donaldson[2], J.W. Bainbridge[3], D.O. Bates[1];
[1]Microvascular Research Laboratories, University of Bristol, [2]School of Physiology and Pharmacology, University of Bristol, [3]National Institute for Health Research Biomedical Research Centre for Ophthalmology at Moorfields Eye Hospital and UCL Institute of Ophthalmology, London, UK.

Background and aims: Diabetic macular edema (DME) is associated with vascular hyperpermeability as a consequence of pro-angiogenic vascular endothelial growth factor (VEGF) upregulation. $VEGF_{165}$ has been connected with the degradation of tight-junction proteins zona occludens 1 (ZO1) and occludin in vitro. This reorganisation of ZO1 and occludin is prevented in retinal pigmented epithelial (RPE) cells by co-treatment with $VEGF_{165}b$, an alternatively spliced anti-angiogenic isoform, suggesting that $VEGF_{165}b$ could abrogate retinal vascular hyperpermeability. The aim of this study was to determine whether $VEGF_{165}b$ reduces retinal vascular hyperpermeability in rats with streptozotocin-induced diabetes.
Materials and methods: Sprague-Dawley male rats (200g) were induced with diabetes using streptozotocin (50mg/kg). After 6 days, 5µl saline was injected into one eye of each diabetic rat, and 5µl 10ng/µl rh$VEGF_{165}b$ injected into the contralateral eye. Control rats had no injection in one eye, and 5µl saline in the contralateral eye. On day 7, Evans blue (45mg/kg) was injected i.v into anaesthetised rats. Plasma was collected every 15 minutes for 2 hours, after which, animals were sacrificed, eyes enucleated and retinas excised. Retinas were weighed and Evans blue was extracted using formamide, with Evans blue solute flux calculated from the amount of Evans blue, per wet weight of tissue, per hour relative to the mean plasma Evans blue level during the 2 hr perfusion.
Results: Increased solute flux in the retinae of rats with streptozotocin-induced diabetes was significantly reduced by intravitreal administration of rh-$VEGF_{165}b$ compared with vehicle-injected controls (P<0.05). Vehicle-treated eyes showed no significant difference in solute flux compared to uninjected eyes in control rats.
Conclusion: $VEGF_{165}b$ reduces hyperpermeability of retinal vasculature in streptozotocin-induced diabetic rats and may offer an effective therapeutic approach to diabetic retinopathy.

The role of macrophage migration inhibitory factor in a mouse model of diabetic retinopathy
J. Wang;
Fifth Medical Department, Medical Faculty Mannheim, Heidelberg University, Mannheim, Germany.

Background and aims: Diabetic retinopathy is the most common microvascular complication, of which the primary lesion is the formation of acelluar capillaries with no blood flow. The pathogenesis of diabetic retinopathy has not been completely defined. Several studies have shown that diabetic retinopathy shows features of inflammation, such as up-regulation of inducible nitric oxide synthase (iNOS), cyclooxygenase 2 (COX2), inter-cellular adhesion molecule 1 (ICAM-1), receptor for advanced glycation end products (RAGE), monocyte chemoattractant protein-1 (MCP-1), increased production of nitric oxide, prostaglandin E2 (PGE2), proinflammatory cytokines tumor necrosis factor alpha (TNF-a), interleukin-1 beta (IL-1ß) as well as increased capillary permeability and leucostasis. Macrophage migration inhibitory factor (MIF) is a pleiotropic proinflammatory cytokine involved in the regulation of inflammation and innate immunity. The aim of the study was to analyze the expression of MIF and its role in a mouse model of diabetic retinopathy.
Materials and methods: Wild type (C57BL/6) and MIF-knockout mouse were rendered diabetic by intraperitoneal injection of streptozocin (150mg/kg body weight) and maintained for 6 months. Blood glucose and body weight were monitored regularly and HbA1c was measured at the end of the study. The expression of MIF was assessed by immunofluorescence staining of the retina and western blot analysis of retinal protein extract. Vascular damage was quantitated in retinal digest preparations.

Results: We found that MIF is expressed in the neurons of the inner retina, mainly in the ganglion cell layer and inner nuclear layer. The protein levels of MIF were unchanged in the diabetic retinas. Both diabetic wild type and MIF-knockout animals developed significant increased acelluar capillaries, compared to their non-diabetic controls (Wild type: diabetic 34±7 acelluar segments/mm^2 of retinal area vs control with 24±5 acelluar segments/mm^2 of retinal area, $p< 0.01$; MIF-knockout: diabetic 40±6 acelluar segments/mm^2 of retinal area, vs control with 27±4 acelluar segments/mm^2 of retinal area, $p< 0.001$), while the deletion of MIF aggravated the vascular damage in diabetic retinas compared to their diabetic wild type controls (diabetic MIF-knockout 40±6 acelluar segments/mm^2 of retinal area, vs diabetic wild type 34±7 acelluar segments/mm^2 of retinal area, $p< 0.05$).
Conclusion: Our data demonstrate that MIF is expressed in the retinal neurons and appears to provide partial vascular protection in this mouse model of diabetic retinopathy. Since MIF appears unregulated in diabetes, the mechanism by which MIF deletion affects vasoregression in diabetes needs mechanistic workup.

S-nitrosoglutathione eye drop inhibits inducible nitric oxide synthase up-regulation by post-translational modification in experimental diabetic retinopathy

M.A.B. Rosales[1], K.C. Silva[1], D.A. Duarte[1], M.G. de Oliveira[2], J.B. Lopes de Faria[1], J.M. Lopes de Faria[1];
[1]Department of Internal Medicine, Faculty of Medical Sciences, State University of Campinas (UNICAMP), [2]Chemistry Institute, State University of Campinas (UNICAMP), Campinas, Brazil.

Background and aims: The rise of nitric oxide (NO) production in the retina, as a result of inducible nitric oxide synthase (iNOS) induction, is associated with inflammatory responses and increase of oxidative/nitrosative stress in an experimental model of diabetic retinopathy (DR). It has been shown that high glucose increase iNOS expression in retinal pigment epithelial (RPE) cells. Endogenous NO is unstable and most of its biological actions are mediated via nitrosothiols (SNO), the addition of a NO into thiol groups that contain a sulfhydryl group (SH) with specific cysteine residues. This process, known as S-nitrosylation, promotes post-translational modification of proteins affecting their activities. The purpose of this study was to assess the possible effects of S-nitrosoglutathione (GSNO) eye drop in preventing retinal damage in experimental DR through the post-translational modifications of i-NOS by S-nitrosylation and/or S-glutathionylation.
Materials and methods: Diabetes (DM) was induced by streptozotocin (60 mg/kg) in spontaneously hypertensive (SHR) rats with 4 week-old and randomized to receive vehicle only or a low (900nM) or high (10μM) dose of GSNO eye drop twice daily in both eyes. Similarly, non-DM rats received the same treatments. After 20 days, the animals were submitted to electroretinography (ERG), then euthanized and the retinas were collected for protein extraction or immunohistochemistry. To assess the mechanisms, human RPE cell lines (ARPE-19) were exposed to normal glucose (NG) or high glucose (HG) without or with GSNO 100nM.
Results: In DM animals, GSNO decreased iNOS expression and peroxynitrite formation, thus preventing glial dysfunction (GFAP) and restoring the electroretinogram potentials. In contrast, in the non-DM animals, GSNO induced oxidative/nitrosative stress ($p\leq0.05$). For the *in vitro* studies, ARPE-19 cells under HG+GSNO condition showed a decrease in the total intracellular reactive oxygen species (ROS) and NO levels, accompanied by iNOS down-regulation and decreased peroxynitrite formation ($p\leq0.05$), without any change in reduced glutathione (GSH) levels ($p=0.9$) and showed a tendency to increase GSNO reductase (GSNO-R) expression ($p=0.06$). To assess whether post translational modification could be involved in inhibition of i-NOS by GSNO treatment under HG condition, we addressed the S-glutathionylation of iNOS by immunoprecipitation of GSH/iNOS, which presented an increase of this complex ($p\leq0.05$). In contrast, in the NG condition, GSNO treatment promoted nitrosative stress by NO formation ($p\leq0.05$), but did not increase i-NOS expression ($p=0.7$).
Conclusion: In this study, a new pharmacological therapeutic modality (GSNO eye drop) targeting nitrosative stress by redox post-translational modification of iNOS is efficient against the early retinal damage in experimental DR. In normal conditions, either *in vivo* or *in vitro*, the exogenous GSNO promoted nitrosative stress probably by NO formation. This data shows the potential clinical implications of an S-nitrosoglutathione/glutathione system balance in the treatment of DR. The mechanisms involved in the post-translational modification of iNOS are currently under investigation.

Neuroprotective effect of fenofibrate on retinal neurodegeneration in an experimental mouse model of type 2 diabetes

L. Corraliza[1], P. Bogdanov[1], A. Rodrigues-Carvalho[2], J. García-Arumí[2], C. Hernández[1], R. Simó[1];
[1]Centro de Investigación Biomédica en Red de Diabetes y Enfermedades Metabólicas Asociadas (CIBERDEM), Diabetes and Metabolism Research Unit. [2]Ophthalmologic Research Laboratory, Vall d'Hebron Research Institute. Universitat Autònoma de Barcelona, Spain.

Background and aims: There is now consistent evidence from two major clinical trials (FIELD and ACCORD-Eye) that fenofibrate arrests the progression of diabetic retinopathy in type 2 diabetic patients. However, the underlying mechanisms of this beneficial effect remain to be elucidated. The aim of the study was to evaluate the potential effect of fenofibric acid (the active metabolite of fenofibrate) in preventing retinal neurodegeneration in an experimental mouse model of type 2 diabetes.
Materials and methods: A total of 24 diabetic mice (db/db) aged 8 weeks were randomly assigned to daily oral treatment (by gavage) with fenofibric acid (100 mg/Kg/day) (n=12) or vehicle (n=12) for one week. We measured the body weight, triglycerides and glucose levels. Ten non-diabetic mice (db/+) were used as control group. Retinal neurodegeneration was evaluated by measuring glial activation assessed by immunohistochemistry and western blotting against GFAP (Glial fibrillar acidic protein), and apoptosis was quantified using the TUNEL method. Functional abnormalities were assessed by electroretinography (ERG) before and after treatment. Statistical analysis: paired and unpaired Student t-test and the Mann-Whitney U test.
Results: At 9 weeks diabetic mice presented a significant higher glial activation and apoptosis in ganglion cell layer than non-diabetic mice. Treatment with fenofibric acid significantly prevented glial activation ($p< 0.001$) and neuronal apoptosis ($p< 0.05$). Moreover, db/db mice treated with fenofibric acid showed a dramatic improvement in ERG parameters (b-wave implicit time and oscillatory potentials amplitude). As expected, lower levels of triglycerides were detected in db/db treated with fenofibric acid in comparison with db/db treated with vehicle ($p=0.02$). No differences in blood glucose and body weight were detected between the groups.
Conclusion: Fenofibric acid prevents retinal neurodegeneration induced by diabetes. Our results suggest that neuroprotection could be added to the non-lipidic mechanism by which fenofibrate exerts its beneficial actions in diabetic retinopathy.

Epi-retinal membranes, pseudoholes and macular holes in diabetes

A.D. Wright, N.K. Bilkhu, E.L.S. Curtis, M. Clarke;
Diabetes and Endocrinology, Birmingham Heartlands Hospital, UK.

Background and aims: Epi-retinal membrane (ERM) may be associated with diabetes and diabetic retinopathy (DR). We report how often ERM and macular holes (MH) were noted in a DR screening programme and their effects on visual acuity (VA) and grading of DR.
Materials and methods: 68,637 patients in a DR screening programme in a single year noting ERM or cellophane maculopathy or MH were reviewed and poor quality photos excluded. Screening involved two digital photographic 45º images, one macula and one disc centred, through dilated pupils. Best corrected VA (Snellen) and the English national grading standards for DR were used. 422 patients had definite ERM that was considered idiopathic with no significant ocular history or pathology in 397 eyes (94.1%). The value of two views was assessed by one senior and one primary grader in a subset of 25 patients. 93 patients had MH confirmed in hospital eye clinics.
Results: 422 patients (457 eyes) with ERM (0.61% of total screened). 213 male, 209 female; mean age 71.6 ±9.5 yrs. ERM was unilateral in 387 (91.7%) (R 181 [46.8%]; L 206 [53.2%]) and bilateral in 35 (8.3%).VA with ERM was 6/6 or better in 161 (35.2%), 6/9 in 172 (37.7%) and ≥6/12 in 124 (27.1%) eyes, with no other cause evident for VA ≥6/12 except ERM in 84 (67.8%) eyes. All eyes but one (456 eyes) had been given a DR grade (R0M0 251, R1M1 123, R2M0 5, R2M1 4, R3M0 11, R3M1 6 and ungradable 1). 251 eyes (55.1%) posed grading difficulties. Both senior and primary graders considered the two views were essential for DR grading in all but one of the subset. In contrast MH was less common (0.14% of total screened) and occurred more often in female patients (73%) than male (27%). Mean age was similar (73.8yrs) but VA more affected: 6/24 or better in 24 eyes (24%), 6/36 in 17(17%), 6/60 in 24 (24%) and worse than 6/60 in 30 (30%). DR grading posed few difficulties, apart from post-operative changes in the minority of surgically treated patients, R0/M0 79, R1/M0 9, R1/M1 5, R2/M1 2 and ungradable 5.
Conclusion: ERM and MH were relatively rare in the elderly as noted within a DR screening programme. However this study is likely to have underestimated prevalence. ERM was associated with some loss of VA and MH with severe loss. Grading of DR was difficult in 55% of ERM but two views enabled adequate assessment of the majority of patients with ERM. MH can be suspected on retinal photography but requires confirmation and assessment of staging in an eye clinic. Both lesions would be better assessed with additional ocular coherence tomography at the time of DR screening. Early detection of these lesions may become important as more effective treatments become available. DR changes were as expected.

1221

Inflammation and visceral obesity: possible link to pathogenesis of diabetic retinopathy in type 2 diabetes

M. Tomic[1], B. Novak[1], N. Car[1], S. Kastelan[2], S. Ljubic[1];
[1]University Clinic Vuk Vrhovac Clinical Hospital Merkur, [2]Clinical Hospital Dubrava, Zagreb, Croatia.

Background and aims: Diabetic retinopathy (DR), a microvascular and visually devastating diabetic complication, is the leading cause of new blindness among working-age adults in developed countries. Its pathogenesis is insufficiently understood and presumed to possibly involve chronic, low-grade inflammation. The aim of this study was to investigate the relationship between inflammation markers, other markers of endothelial dysfunction and anthropometric parameters and their association with DR in patients with type 2 diabetes.
Materials and methods: This was a cross-sectional study including 107 patients with type 2 diabetes (67 male / 40 female, mean age 66.74 ± 8.01 years, mean diabetes duration 15.05 ± 5.69 years). Markers of inflammation: C-reactive protein (CRP) and fibrinogen as well as other markers of endothelial dysfunction: glycated hemoglobin value (HbA_1c; HbA_1c_{median}), total cholesterol, HDL cholesterol, LDL cholesterol and triglycerides were determined using routine laboratory methods. HbA_1c was evaluated at the beginning of the study from a single venous blood sample, and HbA_1c_{median} was obtained by statistical analysis of data from the National Registry for Diabetes (CroDiabNet). Anthropometric parameters assessed were body mass index (BMI), waist circumference (WC), waist-to-hip ratio (WHR) and conicity index (C index). Ophthalmologic examination included best corrected visual acuity (BCVA), Goldmann applanation tonometry, slit lamp biomicroscopy of the anterior eye segment, binocular indirect slit lamp fundoscopy and color fundus photography after mydriasis of two fields (macular field, disc/nasal field) of both eyes according to the EURODIAB retinal photography methodology.
Results: According to the EURODIAB standards patients were divided into three groups: group 1 (no retinopathy; n=65), group 2 (mild / moderate nonproliferative diabetic retinopathy; n=19) and group 3 (severe NPDR / proliferative diabetic retinopathy; n=23). The groups did not differ in the levels of inflammation markers, other markers of endothelial dysfunction and anthropometric parameters. C-reactive protein was positively correlated with fibrinogen (p=0.022), HbA_1c (p=0.050), LDL cholesterol (p=0.043), BMI (p=0.038), WC (p=0.000), WHR (p=0.038) and C index (p=0.008). HbA_1c was positively correlated with cholesterol (p=0.022), LDL cholesterol (p=0.010), BMI (p=0.009) and WC (p=0.047). Logistic regression analyses showed that diabetes duration (OR=1.17, 95%CI 1.08-1.27) and prolonged poor glycemic control (HbA_1c_{median}) (OR=1.76, 95%CI 1.08-2.86) were the main predictors of DR in patients with type 2 diabetes.
Conclusion: This study showed that the association between visceral obesity, inflammation and other risk factors plays an important role in endothelial impairment involved in the pathogenesis of diabetic retinopathy. These findings point to the need for testing the effects of treatment aimed at reducing visceral obesity, decreasing inflammatory activity and improving endothelial function as a means of preventing or limiting the progression of retinopathy.

1222

Diabetic retinopathy is associated with arterial stiffness independent of albuminuric status in patients with type 2 diabetes

S. Moon, E. Kim, E. Mo, J. Han, S. Moon;
The Catholic University of Korea Incheon St. Mary's Hospital, Incheon, Republic of Korea.

Background and aims: Diabetic retinopathy and abluminuria often develop in parallel with each other and have both been linked to increased risk of cardiovascular disease. This study was conducted to investigate whether diabetic retinopathy is associated with subclinical cardiovascular disease independent of albuminuria in type 2 diabetic patients.
Materials and methods: We conducted a cross-sectional analysis among 290 subjects with type 2 diabetes. Diabetic retinopathy (DMR) was categorized into no DMR, non-proliferative DMR (NPDR), or proliferative DMR (PDR). Albuminuria is defined if urinary albumin-creatinine ratio (ACR) ≥ 30 mg/g. Subclinical atherosclerosis was assessed by measuring arterial stiffness using brachial-ankle pulse wave velocity (PWV) and carotid intima-media thickness (IMT) and plaque score using B-mode ultrasonography.
Results: DMR was diagnosed in 74 patients (25.5%). Patients with DMR had higher PWV compared to those without DMR but no difference in IMT or plaques presence in unadjusted models and in models adjusted for various confounding including cardiovascular risk factors and ACR. In multivariate logistic analysis, the odd ratios for DMR increased across PWV quartiles [1 (reference), 2.35, 7.87, 13.63; P for trend=0.006]. In the subgroup without albuminuria, the association of PWV and DMR was still remained significant [1 (reference), 1.34, 12.08, 33.15; P for trend= 0.025].
Conclusion: DMR was associated with arterial stiffness without structural changes and independent of albuminuric status and cardiovascular risk factors in patients with type 2 diabetes. Our study suggests that arterial stiffness might be an early indicator for DMR, even without combined with albuminuria.

Digital retinal imaging: community heath workers as imagers in rural areas versus an ophthamology clinic

K.M. Colleran[1], C. McAuley[1], E. Harding[1], G. Zamora[2], E. McGrew[2], D. Thomas[2], G. Axford[2], P. Soliz[2];
[1]Internal Medicine, University of New Mexico HSC, Albuquerque, [2]Visionquest Biomedical, Albuquerque, USA.

Background and aims: Currently, only 50% of U.S. citizens diagnosed with diabetes are screened for retinopathy and in underserved communities, that number is closer to 20%. Therefore, treatable causes of blindness are being missed every day. Digital retinal screening is a cost effective tool developed

to increase screening rates and is particularly beneficial in rural and underserved areas where gold standard ophthalmologic care is not readily available. In this study, we compared adequacy of digital retinal screening conducted by community health workers (CHWs) in rural clinics throughout New Mexico with that of a dedicated ophthalmology clinic.
Materials and methods: CHWs in rural and medically underserved areas of New Mexico were trained in retinal imaging. Training consisted of two days of instruction and practice. Refresher training was offered if problems were encountered. Certification was given if CHWs successfully completed ten images. A community based ophthalmology clinic for underserved patients with a dedicated retinal specialist, served as the control setting. Ophthalmology technicians performed imaging at the clinic. A standardized imaging protocol that acquires two or more images of each eye (macula centered and optic disc centered) was used for this study. A non-mydriatic (no dilation) camera was used to minimize impact on the patient. Images were forwarded via a secure internet connection to a centralized reading center where cases were read and results returned to the patient and primary care clinic within 72 hours. We evaluated number of cases requiring urgent referral, adequacy of images, and reasons for inadequate images between the two settings. Data were reported as absolute and average with standard deviations. Unpaired student's *t*-tests and ANOVA were used to analyze data sets. A $p<0.05$ was considered significant.
Results: Eight hundred and one patients from NM completed imaging studies and 1,645 patients from the clinic. Diabetic retinopathy was detected in 22% of cases in New Mexico and 26% of case at the clinic. Positive findings requiring urgent ophthalmologic intervention (5-10 days) were reported in 3.7% of cases in NM and 4.1% of cases at the clinic. Inadequate readings were reported 12.2±7% of the time in NM and 9.3±10% at the clinic, (p value >0.1, not significant). Reasons for inadequate readings included small pupils, cataracts, and blurred images but were not statistically different between the two sites.
Conclusion: A brief instructional tool for CHWs on retinal imaging with documentation of proficiency was as effective as retinal screening provided at a dedicated ophthalmology clinic with trained technicians. Digital retinal imaging using CHWs as imagers will likely be a cost effective mechanism to increase screening rates for diabetic retinopathy in rural and underserved communities.

1224

Retinopathy at diagnosis of type 2 diabetes: more or less prevalent at older ages?

I.M. Stratton[1], S.J. Aldington[1], M. Histed[2], P.J. Scanlon[1];
[1]Gloucestershire Diabetic Retinopathy Research Group, [2]Gloucestershire Diabetic Eye Screening Service, Gloucestershire Hospitals, Cheltenham, UK.

Background and aims: To compare levels of diabetic retinopathy (DR) in patients newly diagnosed with Type 2 diabetes (T2DM) in Gloucestershire in those aged 65 years or below with those 66 and above.
Materials and methods: Data were collected for patients on the screening register of the Gloucestershire Diabetic Eye Screening Service in UK. Retinopathy status as determined from ditigal retinal photographs after mydriasis were extracted from the screening service database and clinical information extracted from primary care records for those newly diagnosed with T2DM between 2005 and 2012. Clinical characteristics and diabetic retinopathy (DR) grading outcomes from the screening records were analysed and tabulated by age group and gender. Classification of DR in the Gloucestershire patients used the English NHS Diabetic Eye Screening Programme (NHS-DESP) categories.
Results: Data were available for 6247 patients within one year of diagnosis of T2DM of whom 6101 had assessable images of both eyes. Minimum age at diagnosis was 25 years, maximum 96. Men and women were of similar age in the younger group (56 (49 to 61) (mean (s.d.) vs 56 (49 to 62)) but in the older group the men were of lower age (72 (69 to 77) vs 74 (70 to 78)). In both men and women older patients were more likely to have unassessable images (0.9% and 3.7% of younger and older men respectively, 1.0% and 4.6% of younger and older women, $p<0.0001$ for both). In women, but not in men, older patients had more DR (32% vs 28% with any DR) and a significant trend to more severe DR (2.8% of older women had referable DR, 2.0% of younger women, $p=0.0076$). HbA1c was available for 5055 patients and was higher in younger than older patients (mean difference 5.2 mmol/mol, 95%Ci 4.2 to 6.2). Within each group HbA1c at diagnosis was positively associated with prevalent DR.
Conclusion: In patients newly diagnosed with T2DM DR is present across the age range. It is therefore important for all newly diagnosed patients to attend for DR screening soon after diagnosis.

Assessable images and DR level at first screen after diagnosis of diabetes

	Men 65 and below	men 66 and above	sig level for difference between older and younger men	Women 65 and below	Women 66 and above	sig level for difference between older and younger women
Number with images	2088	1443		1389	1327	
Not assessable	18 (0.9%)	53 (3.7%)		14 (1.0%)	61 (4.6%)	
Assessable	2070 (99.1%)	1390 (96.3%)	p<0.0001	1375 (99.0%)	1266 (95.4%)	p<0.0001

Obstructive sleep apnoea predicts the development of preproliferative and proliferative retinopathy in patients with type 2 diabetes: a longitudinal analysis

A. Tahrani[1], P. Dodson[2], A. Ali[3], N. Raymond[4], Q. Altaf[1], H. Wharton[5], H. Fellows[5], R. Hampshire[5], M. Shah[5], E. Curtis[5], J. Miah[5], A. Barnett[1], M.J. Stevens[1];
[1]University of Birmingham, [2]University of Aston, Birmingham, [3]University Hospital of Coventry and Warwickshire, Coventry, [4]Warwick University, Coventry, [5]Birmingham Heartlands Hospital, UK.

Background and aims: Diabetic Retinopathy (DR) is a leading cause of blindness. OSA is associated with increased oxidative and nitrosative stress and endothelial dysfunction in patients with type 2 diabetes (T2DM). Hence, it is plausible that OSA can promote the development and progression of DR.
Materials and methods: An observational longitudinal study in adults with T2DM. Patients with pre-existing OSA, end-stage renal disease and non-diabetic retinopathy were excluded. OSA (apnoea hypopnea index ≥ 5 events/hour) was assessed by a single overnight home-based cardio-respiratory monitoring (Alice PDX, etc.). DR was assesses using retinal images between 2007 and 2012. Sight threatening retinopathy (STR) was defined as pre-proliferative or proliferative DR, maculopathy or photocoagulation. Advanced DR was defined as pre-proliferative or proliferative DR.
Results: 199 patients were included (57.3% men, 47.7% White Europeans). STR and OSA prevalence were 38.7 % and 62.8% respectively. STR prevalence was higher in patients with OSA (OSA+) compared to those without (OSA-) [48.8% vs. 21.6%, p <0.001]. After adjustment for confounders, OSA remained independently associated with STR (OR 3.7, 95%CI 1.6-8.9, p=0.006, maculopathy (OR 4.5, 1.8-11.4, p=0.002) and advanced DR (OR 3.9, 1.02-15.3, p=0.047). Over 4.4±1 years, more OSA+ patients progressed from no or background DR to advanced DR (15.3% vs. 3%, p=0.01). OSA was an independent predictor of advanced DR development after adjustment (OR 6.6, 95%CI 1.2-35.1, p=0.03). OSA did not predict the development of maculopathy. Patients received continuous positive airway pressure treatment were less likely to develop advanced DR
Conclusion: OSA is independently associated with STR and predicts the development of preproliferative and proliferative DR. Interventional studies are needed to assess the impact of OSA treatment on DR.

High cystatin C level hints severe retinopathy in type 2 diabetic patients

R. He, F. Liu, J. Shen, H. Zeng, L. Li, W. Jia;
Department of Endocrinology and Metabolism, Shanghai Jiaotong University Affiliated Sixth People's Hospital, Shanghai, China.

Background and aims: In order to investigate the relationship between cystatin C and diabetic retinopathy (DR) and clarify the predictive value of cystatin C for diabetic ophthalmopathy.
Materials and methods: A total of 954 type 2 diabetes mellitus patients were recruited and divided into quartiles with respect to their cystatin C levels (≤0.8 mg/L, 0.9-1.0 mg/L, 1.1-1.2 mg/L, ≥1.3 mg/L). The severity of DR was grouped from a bilateral retinal photograph as: no diabetic retinopathy (NDR), non-sight-threatening diabetic retinopathy (NSTDR) and sight-threatening diabetic retinopathy (STDR).
Results: There were significant differences in prevalence of DR, NSTDR and STDR among cystatin C quartiles (all $P < 0.01$). After adjusted for potential confounders, elevated levels of cystatin C were associated with DR and STDR. The multivariable odds ratio (95 % confidence interval) of DR and STDR in the highest quartile was 2.96(1.48-5.91) and 18.10(5.70-57.50) respectively compared to the lowest quartile (both $P < 0.01$). There was also significant difference in cystatin C levels between three DR groups ($P < 0.01$). Multiple logistical regression analysis further revealed that cystatin C was independent risk factors for DR ($\beta = 1.253$, $P = 0.000$) and STDR ($\beta = 3.701$, $P = 0.000$). The receiver operating characteristic (ROC) curve indicated that cystatin C higher than 1.25mg/L predicts high risk of severe retinopathy [odds ratio (OR) =11.36, 95% confidence interval (CI):7.66-16.85].
Conclusion: High cystatin C level closely links the severity of DR and predicts the 11 times increasing morbidity of STDR.

GLP-1 therapy and diabetic retinopathy: temporary progression and the need to monitor

L. Varadhan[1], T. Humphreys[2], A. Walker[1], G.I. Varughese[1];
[1]Dept of Endocrinology and Diabetes, [2]Dept of Opthalmology, University Hospitals North Staffordshire NHS trust, Stoke on Trent, UK.

Background and aims: Transient worsening of diabetic retinopathy (DR) is well documented during rapid improvement of glycaemic control in instances such as pregnancy and insulin pump therapy. We had already published data on Phase 1 follow up of DR following initiation of GLP-1 therapy. 165 patients on Exenatide therapy were studied in our Phase 1 study after continuation of treatment for at about 12 months based on the lowest HbA1c achieved. 49 patients had progression of DR (New onset of DR: 16 and Worsening of pre-existent DR 33) of which 47 had reduction in HbA1c. We concluded that patients with pre-existent DR had higher risk of progression of DR during the first year of treatment, the risk being higher with greater reduction in HbA1c. The aim of this Phase 2 study was to perform an observational analysis of patients with progression of DR with sustained GLP-1 therapy.
Materials and methods: A retrospective observational interval analysis was made on the 47 patients from the previous study. Patients who discontinued GLP-1 therapy were excluded. Data on DR status was taken from Ophthalmology department records or community retinal screening database. Matched HbA1c done closer to the DR screening data was also recorded and compared against the lowest HbA1c achieved during treatment
Results: N=39 (8 patients stopped Exenatide: 3 ineffective, 2 renal function issues; 2 intolerance;1 bariatric surgery done). The average interval between DR screening between Phase 1 and Phase 2 was 439 days. The mean duration between lowest Hba1c achieved and latest HbA1c was 460 days. Overall Change in DR: 24/39 (62%) patients had improvement in DR compared to Phase 1 study; 17/24 actually had increase in HbA1c (mean increase 1.4%; range 0.2-4.8%); 7/24 had decrease in HbA1c (mean -0.6%; range -0.1 to -1.6%);7 (18%) patients had no change in DR; 6/7 had increase in HbA1c (mean 1.4%; range 0.3-5.0%); 1/7 had decrease in HbA1c; 8 (20%) patients had progression of DR: 6/8 had increase in HbA1c (mean 1.6%; range 0.1-3.1%); 2/8 had decrease in HbA1c (mean -1.5%); 3 patients developed new maculopathy (2 with increasing HbA1c); 3 required new Laser treatments (2 with increasing HbA1c). Subgroup analysis: Of the patients who developed new DR between Baseline and Phase 1 study (n=14 after attrition), DR improved in 10 (71%), no change in 3(21%) and worsened in 1 Of the patients who had progression of pre-existent DR in the previous study (n=25 after attrition), DR improved in 15(60%), no change in 41(16%) and worsened in 6
Conclusion: Progression of DR during GLP-1 therapy, with rapid reduction of HbA1c, appears to be a transient phenomenon, in keeping with other clinical instances. Majority of these changes either remain static or improve their DR with sustained treatment despite the upward trend of the glycaemic control. Worsening of DR should not deter the primary aim of intensifying diabetic control, but close observation of retinal status should be advised, especially in patients with pre-existent DR. Clear protocols based on prospective studies are required to formalize screening process for this cohort of patients with paradoxical worsening of DR.

PS 105 Autonomic neuropathy

Cardiovascular autonomic neuropathy and lower urinary tract symptoms in men with type 1 diabetes

R. Pop-Busui[1], J. Hotaling[2], H. Wessels[3], B. Braffett[4], P. Cleary[4], R. Dunn[5], C. Martin[1], A. Sarma[5];
[1]Department of Internal Medicine, University of Michigan Medical School, Ann Arbor, [2]University of Illinois, Chicago, [3]Department of Urology, University of Washington, Seattle, [4]Department of Biostatistics, George Washington University, [5]Department of Urology, University of Michigan Medical School, Ann Arbor, USA.

Background and aims: The pathophysiology of lower urinary tract symptoms (LUTS) has been reported to involve vascular, hormonal, and neural mechanisms. Data on the relationship between autonomic neuropathy and LUTS in men with type 1 diabetes (T1DM) are limited. We evaluated the association between cardiovascular autonomic neuropathy (CAN) and LUTS in subjects with T1DM participating in the Diabetes Control and Complications Trial/Epidemiology of Diabetes Intervention and Complications Study (DCCT/EDIC).
Materials and methods: Measures of CAN (R-R response to deep breathing, Valsalva maneuver, postural change in blood pressure), and LUTS were obtained in 644 DCCT/EDIC male subjects, 16/17 years after DCCT closeout. CAN was defined as:1) R-R variation<15 or 2) R-R variation between 15-19.9 plus either a Valsalva ratio≤1.5 or a supine-to-standing drop of 10 mm Hg in diastolic blood pressure. LUTS was assessed by the American Urological Association Symptom Index (AUASI), a clinically validated, standardized seven item questionnaire that quantifies the presence and frequency of the following lower urinary tract symptoms: nocturia, frequency, urgency, weak urinary stream, intermittency, straining, and the sensation of incomplete emptying. Scores range from 0 to 35. AUASI scores of 0-7 were defined as none/mild LUTS and AUASI of 8-35 as moderate/severe LUTS. Multivariable logistic regression estimated the associations between CAN and LUTS, after adjusting for DCCT cohort, DCCT/EDIC HbA1c, DCCT/EDIC systolic blood pressure, age, smoking and drinking status, and beta blocker use at EDIC year 16/17.
Results: At EDIC year 17, mean age was 52±7 years, mean diabetes duration 29±5 years, and mean DCCT/EDIC HbA1c 7.9±1.0%. Moderate/severe LUTS was reported by 158 (25%) subjects at EDIC year 17. Subjects with moderate/severe LUTS had significantly lower R-R variation at both DCCT closeout and EDIC year 16/17, and significantly lower Valsalva ratio at EDIC year 16/17 compared to men with mild/no LUTS (Table). At EDIC year 16/17, 51% of participants with LUTS also had confirmed CAN, vs. 33% of participants without LUTS (p=0.0001). In adjusted analysis, participants with CAN had 1.64 greater odds of LUTS (95% CI=1.07, 2.50).
Conclusion: The association between CAN and LUTS in the DCCT/EDIC cohort suggests that CAN may be a useful surrogate biomarker of more generalized autonomic neuropathy and may predict development of LUTS in men with long-standing type 1 DM.

CAN measures at DCCT closeout and EDIC year 16/17 by LUTS status

Outcome Measures	No LUTS N=485	LUTS N=158	p-value
At DCCT Closeout			
Confirmed CAN	29 (6)	16 (11)	0.049
R-R Variation	41.1±19.3	34.7±16.2	0.0010
Valsalva Ratio	1.96±0.4	1.91±0.4	0.418
At EDIC Year 16/17			
Confirmed CAN	158 (33)	75 (51)	0.0001
R-R Variation	25.9±17.1	21.5±16.7	0.001
Valsalva Ratio	1.72±0.3	1.66±0.4	0.028

Data are Mean±Std or N (%). P-values based the difference between those with and without FSD or UI using the Wilcoxon rank-sum test for quantitative variables or the Contingency chi-square for qualitative variables.

Prevalence and risk factors of cardiac autonomic nerve dysfunction in the elderly population with diabetes and prediabetes: the KORA S4 survey

D. Ziegler[1,2], A. Voss[3], S. Nowak[1], M. Scheer[4], W. Rathmann[4], S. Perz[5], M. Roden[1,2], A. Peters[5], C. Meisinger[5], KORA Study Group;
[1]Institute for Clinical Diabetology, German Diabetes Center, Düsseldorf, [2]Department of Metabolic Diseases, University Hospital, Düsseldorf, [3]Department of Medical Engineering and Biotechnology, University of Applied Sciences, Jena, [4]Institute for Biometrics and Epidemiology, German Diabetes Center, Düsseldorf, [5]Institute of Epidemiology II, Helmholtz Zentrum München - German Research Center for Environmental Health, Neuherberg, Germany.

Background and aims: Cardiovascular autonomic neuropathy (CAN) is associated with an increased risk of mortality, but the glycaemic threshold at which CAN develops and the associated risk factors are unclear. This study aimed to determine the prevalence and risk factors of cardiac autonomic nerve dysfunction in the elderly population with diabetes and prediabetes using a comprehensive set of parameters of heart rate variability (HRV) and QT variability index (QTVI).
Materials and methods: The population-based KORA (Cooperative Health Research in the Region of Augsburg) S4 survey included 2656 subjects aged 55-74 years, who were living in the region of Augsburg, Germany. Of these, 1636 persons participated in the present study, 304 of whom were excluded due to arrhythmias, leaving 1332 subjects aged 64.0±5.4 (mean±SD) years, 51% male, BMI: 28.7±4.3 kg/m², 1202 of whom without known diabetes had an oral glucose tolerance test (OGTT) at baseline, while 130 subjects had known diabetes (k-D). According to the ADA 2003 criteria, 565 persons had normal glucose tolerance (NGT), 336 had isolated impaired fasting glucose (i-IFG), 72 had isolated impaired glucose tolerance (i-IGT), 151 had combined IFG and IGT (IFG-IGT), and 78 had newly detected diabetes (n-D). HRV was computed by 2 linear and 9 nonlinear methods (120 indices) from resting supine 5-min ECGs. QVTI was determined as a measure of sympathetic tone. Normal ranges were defined for each of these measures at the 5th or 95th percentiles adjusted for age, sex, BMI, and medication influencing the autonomic tone.
Results: The prevalence of the most sensitive individual HRV parameters was: k-D: 12-17%, n-D: 12-14%, IFG-IGT: 9-10%, i-IGT: 2-9%, i-IFG: 7-10%, and NGT: 4-5%. Compared to NGT, reduced HRV was more prevalent in k-D, n-D, IFG-IGT, and i-IFG for Renyi entropy at α=4, total power spectrum, and Poincaré plot (all p<0.05). Moreover, abnormal HRV was more frequent in k-D, n-D, IFG-IGT than in NGT for RMSSD and low frequency power spectrum (all p<0.05). Most important risk factors for reduced HRV were heart rate, age, BMI, waist circumference, serum creatinine, hypertension, HbA1c, and medication with known adverse influence on HRV, while for increased QTVI reflecting increased sympathetic activity these were age, hypertension, low physical activity, percentage body fat, and the metabolic syndrome. A simple risk score to predict low HRV in clinical practice (AUC=0.86 for RMSSD) comprised heart rate, age, hypertension, serum creatinine, and medication suppressing HRV.
Conclusion: In the elderly general population, the prevalence of cardiac autonomic nerve dysfunction detected by linear and nonlinear measures of HRV is increased not only in known and newly detected diabetes, but also in combined IFG-IGT and, to a lesser degree, in isolated IFG. A simple risk score including cardiovascular risk factors appears useful to predict cardiac autonomic dysfunction in clinical practice.

Associations between postural hypotension and neuropathy in type 2 diabetes: the Fremantle Diabetes study phase II

T.M.E. Davis, A. Knapp, W.A. Davis;
School of Medicine and Pharmacology, The University of Western Australia, Fremantle, Australia.

Background and aims: Due to its association with mortality, it has been recommended that autonomic function be assessed at diagnosis of type 2 diabetes and then annually. The equipment and protocols for such testing are not widely available. A simple surrogate of autonomic dysfunction is orthostatic hypotension (OH) which may also be more frequent in patients with periph-

eral sensory neuropathy. The aim of this study was, therefore, to evaluate the relationship between OH and neuropathic complications of type 2 diabetes.
Materials and methods: We studied 417 unselected type 2 patients from the Fremantle Diabetes Study Phase II who underwent assessment of autonomic neuropathy between 2009 and 2012 using i) the ANS 2000 (DE Hokanson Inc, US) which measures R-R variation with deep breathing (Mean Circular Resultant and expiration/inspiration (E/I) ratio), during and after the Valsalva manoeuvre (maximal heart rate during the manoeuvre/the lowest heart rate after the manoeuvre), and on standing (the 30:15 Stand test or R-R interval at beat 30/R-R interval at beat 15), and ii) EZscan (Impeto Medical, France) which generates autonomic risk and kidney scores based on sudomotor function. OH was defined as a fall of ≥20 mm Hg systolic or ≥10 mm Hg diastolic blood pressure on standing. Peripheral sensory neuropathy was defined using the clinical portion of the Michigan Neuropathy Screening Instrument. Multiple logistic regression (forward conditional stepwise variable selection with ≥0.10 for removal) was used to determine independent associates of OH.
Results: The mean±SD age of the patients was 65.8±10.9 years, 54.2% were male, their median [inter-quartile range] diabetes duration was 10.0 [4.1-17.2] years, and 109/414 (26.3%) had OH (3 could not stand). The characteristics of those with and without OH are summarised in the Table. In logistic regression, OH was independently associated with supine systolic blood pressure (OR (95%CI): 1.28 (1.12-1.46), P<0.001 for a 10 mm Hg increase), diabetes duration (1.21 (1.04-1.40), P=0.012 for a 5-year increase), Log_e(30:15 Stand) (0.35 (0.16-0.75), P=0.007), and the EZscan autonomic risk score (0.97 (0.95-0.99), P=0.011. There was no significant bivariate correlation between the latter two measures (r=-0.002, P=0.96).
Conclusion: In our community-based patients, OH was independently associated with longer diabetes duration and a higher supine systolic blood pressure, but not peripheral sensory neuropathy. Both the 30:15 Stand test (a lower score indicates abnormal cardiovascular parasympathetic function) and the EZScan autonomic risk score (a lower score correlates with sympathetic sudomotor dysfunction) were also independent associates of OH. These data suggest that i) OH is a manifestation of complex dysfunction of parasympathetic and sympathetic systems, and ii) EZscan, a quick and simple procedure, can contribute to prediction of cardiovascular autonomic dysfunction independently of conventional heart rate-based tests.

Baseline characteristics of 414 community-dwelling people with type 2 diabetes by OH status

	OH	No OH	P-value
Age (years)	68.9±11.1	64.6±10.7	<0.001
Sex (% male)	51.4	55.1	0.58
Diabetes duration (years)	12.6 [5.0-19.7]	8.2 [4.0-16.2]	<0.006
HbA_{1c} (%)	7.1 [6.2-7.8]	6.9 [6.2-7.9]	0.75
Supine SBP/DBP (mm Hg)	150±19/81±13	140±19/79±11	<0.001/0.16
Peripheral sensory neuropathy (%)	74.3	66.9	0.19
Paced breathing: Mean circular resultant (geometric mean (SD range))	14.1 (6.8-29.4)	16.9 (7.9-36.2)	0.043
Paced breathing: E/I	1.24 (1.00-1.54)	1.23 (1.00-1.52)	0.74
30:15 Stand	1.31 (0.90-1.92)	1.43 (0.93-2.20)	0.07
Valsalva manoeuvre	1.95 (1.19-3.19)	1.99 (1.13-3.51)	0.75
EZSCAN autonomic risk score	47.5±11.8	53.1±13.0	<0.001

Gastric emptying, glycaemia, and upper GI symptoms are independent factors in diabetic gastroparesis

N. Ejskjaer[1], J. Wo[2], T. Esfandyari[3], M. Jamal[4], G. Dimcevski[5], L. Tarnow[6], R. Malik[7], P. Hellstrom[8], E. Mondou[9], E. Mondou[9], J. Quinn[9], J. Quinn[9], F. Rousseau[9], M. Richard[10];
[1]Aarhus University, Denmark, [2]Indiana University, Indianapolis, [3]University of Kansas Medical Center, Kansas City, [4]Long Beach Medical Center, USA, [5]Haukeland University Hospital, Bergen, Norway, [6]Steno Diabetes Center, Gentofte, Denmark, [7]University of Manchester, UK, [8]Uppsala University, Sweden, [9]Tranzyme Inc, Durham, [10]Texas Tech University Health Sciences Center, El Paso, USA.

Background and aims: We have previously reported symptomatic improvement in diabetic gastroparesis in a 28-day Phase 2a study of TZP-102, a novel ghrelin agonist, and we have also reported that gastric emptying dynamics show little inter-relationship with symptom severity. For patients with diabetes mellitus and delayed gastric emptying it is important to evaluate these potential inter-dependencies. The aim of this study was to assess if symptoms and glycemia have any correlation with gastric emptying overall in a subgroup of patients with severe symptomatic diabetic gastroparesis and severely delayed gastric emptying.
Materials and methods: Double-blind, randomized, placebo-controlled, parallel-group evaluation of 3 doses of TZP-102 (10 mg, 20 mg, and 40 mg), once daily for 28 days in diabetic patients with gastroparesis. After randomization (1:1:1:1) visits occurred on Days 8, 15, 28 (on-treatment). Gastric half-emptying time (T1/2) was measured pretreatment and at Day 28 and for entry T1/2 ≥150 minutes by Screening Gastric Motility Breath Test (GMBT) was required (6-hour evaluation Metabolic Solutions, Inc.) A 4-symptom PAGI-SYM5 composite score for a subset of 4 main symptoms (nausea, early satiety, bloating, and upper abdominal pain) was analyzed. Overall linear regression (all patients) was performed and the subset of patients with pretreatment T1/2≥168 minutes (healthy volunteer mean +2 standard deviation [SD]) and the subset of patients with pre-GMBT glucose <250 mg/dL were analyzed.
Results: No correlation was observed between the severity of the symptoms and the gastric emptying T1/2 overall or in the subset of patients with severely delayed gastric emptying across TZP-102 active and placebo arms at baseline or at the end of therapy (Figures 1 and 2). Linear regression analyses showed no correlation between absolute blood glucose values at the time of GMBT and gastric T1/2 (Figure 3).
Conclusion: Ghrelin agonist TZP-102, an oral once daily treatment, had a good safety profile in diabetic patients with gastroparesis. In a subset analysis based on blood glucose and gastric T1/2 thresholds the gastric emptying outcomes were similar to the overall study results. There was no correlation between change in gastric emptying during therapy and change in the severity of symptoms, suggesting that these can be independent events in diabetic gastroparesis. Gastric emptying has been correlated with glycemia in healthy subjects, but this correlation was not observed in diabetic gastroparesis patients within the context of the glucose ranges in this study.

Gastroparesis in adults with type 1 diabetes from the type 1 diabetes exchange clinic registry

G. Aleppo[1], N.C. Foster[2], K.M. Miller[2], R.W. Beck[2];
[1]Endocrinology and Metabolism, Northwestern Medical Faculty Foundation, Chicago, [2]Jaeb Center for Health Research, Tampa, USA.

Background and aims: Gastroparesis and its implications are not well characterized in adults with type 1 diabetes (T1D), in part due to small patient cohorts described to date. To better understand the prevalence and impact of gastroparesis, we investigated the clinical diagnosis of gastroparesis in the large T1D Exchange clinic registry database.
Materials and methods: The T1D Exchange clinic registry includes over 25,000 participants with T1D enrolled at 67 centers across the U.S., with data collected through medical chart review and participant questionnaires. This analysis cohort includes 7098 participants who were ≥26 years old, and had diabetes duration of ≥2 years (91% white non-Hispanic, 54% female, mean age 46.7 years, mean duration of T1D 24.7 years). Presence or absence of gastroparesis was obtained from medical records.
Results: Among the 7098 participants, 343 (5%) had the clinical diagnosis of gastroparesis. Participants with gastroparesis were more likely to be female (67% vs. 54%, P<0.001), have longer duration of T1D (mean duration 32.6 years vs. 24.3 years, P<0.001), have higher mean HbA1c (8.1% vs. 7.7%, P<0.001), and were less likely to report CGM sensor use (14% vs. 22%, P<0.001), but were not different with respect to age, race/ethnicity, or use of insulin pump. There was a higher occurrence of severe hypoglycemia characterized by seizure and/or loss of consciousness in participants with gastroparesis (25% vs. 11%, P<0.001). Among the 343 participants with gastroparesis, 87 (25%) were taking one or more of the following medications: metoclopramide, ondansetron, erythromycin, domperidone. Compared with older participants (≥50 years old), a higher proportion of younger participants (26 to <50 years old) with gastroparesis were taking medication (30% vs. 21%, P=0.04). Among the 343 participants with gastroparesis, 192 (56%) had at least one other type of neuropathy. Most of these additional types of neuropathy were diabetic peripheral neuropathy (76%); the remaining types included: erectile/sexual dysfunction (11%), charcot joint (8%), orthostatic hypotension with fixed heart rate (3%), and tachycardia with fixed heart rate (2%).

Conclusion: In adults ≥26 years of age participating in the T1D Exchange registry, 5% had a clinical diagnosis of gastroparesis. Compared with all the participants in this cohort, the subjects with gastroparesis had a longer duration of T1D, higher levels of HbA1c, and a higher frequency of severe hypoglycemic episodes.

New technologies of fertility restoration in patients with type 1 diabetes mellitus and an autonomic neuropathy
Y. Shvarts[1], D. Kurbatov[1], G. Galstian[2], A. Lepetukhin[1], S. Dubskiy[1];
[1]Andrology and Urology, [2]Diabetic Foot, Endocrinological Research Center, Moscow, Russian Federation.

Background and aims: Retrograde ejaculation (RE) in patients with Type 1 Diabetes Mellitus (DMT1) is a complication of an autonomic neuropathy, which complicated by excretory infertility. RE can be partial (excretion reduction of ejaculate) and total (absence of ejaculate) and it varies from 10% to 20% in men with Type 1 DM. The aim of the study is to assess the effectiveness of new endoscopic method of RE correction and antegrade ejaculation restoration.
Materials and methods: Inclusion criteria: spermatozoa presence in post-orgasmic urine and the disclosure of bladder neck on ultrasonography. 10 Type 1 DM patients, age of 25,7±6,1 years with total RE recruited, diabetes duration - 19±9,6 ys. Mean level of HbA1c before operation 7,1±1,3%. We used conventional irrigated urethrocystoscopy under local anesthesia. During urethroscopy the bladder neck gaping was observed in all cases. Biocompatible material was injected in three points on 14, 18, 22 hours through a special injection needle under mucous layer of a posterior urethra, reaching the closing of the opposite edges of urethra. The spermogramm was examined in 1 week after the operation.
Results: Restoration of antegrade emission of ejaculate achieved at 9 out of 10 patients. The effect of operation maintained during: 6 months at 6 patients; 9 months at 2 patients; 12 months at 1 patient. The spouses of the two men have got pregnancy after surgery. In one case pregnancy completed of spontaneous abortion on the 8th week, in other case pregnancy completed with normal childbirth.
Conclusion: The applying of new method provides highly effective restoration of a physiological passage of the ejaculate. Endoscopic operation is a low-invasive and doesn't disrupt the urination. There is the real opportunity of receiving ejaculate for the artificial insemination. Further investigation is needed.

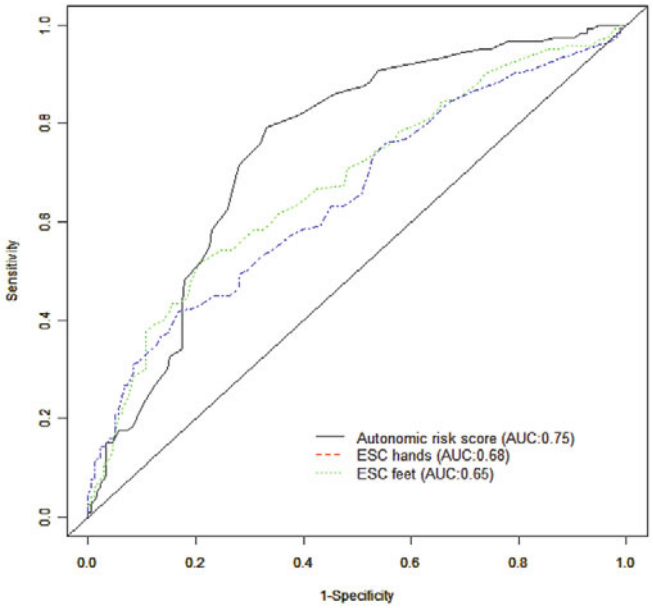
Assessment of sudomotor function as a screening tool for microvascular complications in type 2 diabetes
V. Eranki[1], J.-H. Calvet[2];
[1]Endocrinology, Appolo Hospital, Hyderabad, India, [2]Medical, Impeto Medical, Paris, France.

Background and aims: Sweat glands are innervated by small C-fibers, and sudomotor dysfunction is one of the earliest abnormalities to manifest in distal small fiber neuropathy. This study aimed to evaluate SUDOSCAN, a non invasive, quick, simple and quantitative method to measure sweat function, as a screening tool for microvascular complications in type 2 diabetes.
Materials and methods: 309 patients were evaluated for microvascular complications including peripheral neuropathy using a biothesiomether (Vibration Perception threshold > 15 V), nephropathy through measurement of creatinine clearance and calculation of Modification of Diet in Renal Disease (MDRD < 60 ml/mnx1.73 m2), and retinopathy through fundus of the eye examination. Small C-fiber status was assessed through sudomotor function by measurement of hand and foot Electrochemical Sweat Conductance (ESC) and calculation of an autonomic risk score using SUDOSCAN. Patients were required to place their palms and soles - where sweat gland density is the highest - on two large stainless-steel electrodes and then to stand still for 2 minutes. ESC, expressed in microSiemens (μS), is the ratio between current generated and the constant DC stimulus applied on the electrodes.
Results: Hand and foot ESC were lower in patients with at least one microvascular complication as compared to patients without: 49 ± 20 vs 62 ± 17 μS, p <0.001 and 59 ± 21 vs 69 ± 15 μS, p<0.001 respectively. Receiver Operating Characteristics (ROC) curve for detection of at least one microvascular complication is displayed in Figure. Sensitivity and specificity of autonomic risk score using 35% as a threshold were 82% and 61% respectively.
Conclusion: Based on this study that should be completed by a larger clinical study, SUDOSCAN could be used for the screening of microvascular complications in type 2 diabetes and may aid in adhering to follow-up guideline recommendations which are currently unfulfilled.



1235

Screening for diabetes and its microvascular complications in subjects at risk by a rapid and non-invasive measurement of sweat function
J.-H. Calvet;
Impeto Medical, Paris, France.

Background and aims: Several studies have shown a sweat dysfunction, witness of autonomic neuropathy, beginning in people with prediabetes and present in type 2 diabetes patients with microvascular complications. EZSCAN is a new quick and noninvasive technology to assess the sweat function at the palms and soles. It is based on the measurement of conductance resulting from the electrochemical reaction between the chloride ions of sweat and electrodes in contact with the skin. The purpose of this study was to compare this method with conventional tool for screening of diabetes and for screening of microvascular complications of diabetes in patients involved in the AUSDIAB program.
Materials and methods: This study was conducted in 1307 subjects at risk for diabetes. The patients underwent the questionnaire AusDrisk, a fasting plasma glucose, an oral glucose tolerance test (OGTT), an HbA_{1C}, the calculation of Modification of the Diet in Renal Disease (MDRD) index to assess nephropathy and measurement EZSCAN risk score based on measurement of electrochemical sweat conductances of hands and feet. Receiver operating characteristics curve with calculation of the area under the curve (AUC) were performed and odds ratio (OR) were calculated to evaluate screening performances of diabetes or its microvascular complications of this new method.
Results: Based on OGTT2h ≥ 11.1 mmol/l or FPG ≥ 7 mmol/l or HbA_{1C} ≥ 6.5 %, 131 of the subjects involved in the study had diabetes. When looking at screening of diabetes the AUC of the ROC curves was 0.77 for EZSCAN risk while it was 0.75 for AusDrisk score. When focusing on patients with diabetes the OR when compared to patients with no risk according to EZSCAN (4/257) was 5.9 (p<0.001) for patients defined at moderate risk (72/851) and 24.2 (p<0.001) for patients at high risk (55/199) after adjustment on age the OR were 5.4 p=0.002 and 21.1 p<0.001 respectively. When looking at screening of diabetes complications and choosing MDRD < 60 ml/min/1,73m² as reference the AUC of the ROC curve was 0.82 for EZSCAN and 0.73 for AusDrisk.
Conclusion: This study shows that EZSCAN could be used for screening of diabetes or its microvascular in population at risk. These results have to be confirmed on a larger population and with a comparison to other methods of screening.

1236

Sudomotor dysfunction is associated with increased mortality in patients with chronic kidney disease, with or without diabetes mellitus

D.S. Tesic[1], N. Papanas[2], S. Vodopivec[3], B. Malinovic[3];
[1]Clinic of Endocrinology, Diabetes and Metabolic Diseases, University of Novi Sad, Serbia, [2]Outpatient Clinic of the Diabetic Foot, Democritus University of Thrace, Alexandroupolis, Greece, [3]Department of Haemodialysis, University of Novi Sad, Serbia.

Background and aims: Little is known on the association of sudomotor dysfunction with mortality in patients with chronic kidney disease. Therefore, we carried out a prospective 1-year study to examine this issue.
Materials and methods: We included 153 patients as follows: 97 from dialysis unit [28 with diabetes (DM) and diabetic nephropathy; 37 with nephroangiosclerosis, (NA), 18 with glomerulonephritis (GN), 14 with other conditions (O)]; 32 with type 2 DM and creatinine clearance (CrCl) 30-50 ml/min; and 24 transplanted patients with CrCl>30 ml/min (of these 8 had DM). Somatic sensory neuropathy was documented using the Neuropathy Disability Score (NDS) and the vibration perception threshold (VPT). Sudomotor dysfunction was evaluated by time to colour change of the Neuropad® test. Peripheral vascular disease (PAD) was diagnosed on the basis of Ankle-Brachial Index (ABI) measurement, abnormal waveforms or history of PAD. Investigations were performed twice: 1 year ago and this year. For patients who had died, we only used the data from the first examination.
Results: Among DM patients, 13 exhibited IWGDF risk level 3 diabetic foot pathology (3 critical ischaemia, 3 Charcot foot, 2 ulcer, 2 minor and 3 major amputation). There was 1 patient with critical ischaemia in the NA group and 1 in the GN group. In the 12-month period, 14 patients on haemodialysis had died: 9 in the NA group (mean age 66.8±11 years), 4 among DM (mean age 59±11.9 years), and 1 in the O group (73 years). In univariate analysis, the presence of IWGDF risk 3 level was related to dialysis treatment [odds ratio (OR): 1.18, 95% Confidence Interval (CI): 1.09-1-29, p=0.02]), PAD (OR: 0.55, 95% CI: 0.47-0.64, p=0.01]), VPT (OR: 12.6, 95% CI: 2.7-58.1, p<0.001]), sensory loss (OR: 548, 95% CI: 52.9-5682, p<0.001]). In univariate analysis, death was related to age (OR: 1.06, 95% CI: 1-1.11, p=0.02]), dialysis treatment (OR: 1.17, 95% CI: 1.08-1.27, p=0.003]), VPT (OR: 3.1, 95% CI: 0.99-9.8, p=0.04]), loss of ankle reflexes (OR: 1.7, 95% CI: 1.1-2.8, p=0.007]), and abnormal Neuropad® response (OR: 1.1, 95% CI: 1.03-1.19, p=0.004]). In multivariate analysis, only abnormal Neuropad® test remained significant (p<0.05). Time to complete Neuropad® colour change was 26.4±8.2 minutes in patients who had died and 17.8±9.8 minutes in those remaining alive on dialysis or pre-dialysis renal failure (p=0.002). In univariate ANCOVA test, the association between complete colour change time of Neuropad (dependent variable) and PAD (fixed factor), using age and CrCl as covariates, was significant (p<0.001).
Conclusion: These findings indicate that sudomotor dysfunction is associated with increased mortality in patients with chronic kidney disease, with or without DM. Therefore, we suggest more the widespread use of Neuropad® test, including such population.

Sexual dysfunction among Sri Lankan adults: effect of diabetes

R.M. Jayawardena[1], D.A. Lamabadusuriya[2], P. Ranasinghe[3,4,]
D.H. Punyadasa[3], R. Sheriff[3], D.R. Matthews[5], P. Katulanda[3];
1Department of clinical medicine, Diabetes research unit, Colombo, Sri Lanka, 2Department of clinical medicine, Diabetes resarch unit, Colombo, Sri Lanka, 3Department of clinical medicine, Diabetes research until, Colombo, Sri Lanka, 4Department of Pharmacology, Faculty of Medicine, University of Colombo, Colombo, Sri Lanka, 5University of Oxford, Oxford Centre for Diabetes Endocrinology and Metabolism,, Oxford, UK.

Background and aims: Diabetes has become an important public health problem due to its numerous microvascular and macrovascular complications. Diabetes is recognised to be associated with all aspects of sexual dysfunction in men, including desire, erection (arousal), ejaculation (orgasm) and satisfaction. Similarly, diabetes also affects all stages of female sexual response, especially the arousal. Despite diabetes being increasingly recognised among South Asians, there is a paucity of data on sexual dysfunction, especially among the South Asian women. We aimed to determine the prevalence of sexual dysfunction and the effects of diabetes on sexual function in Sri Lankan adults.
Materials and methods: Data on sexual function, relevant socio-demographic factors and diabetic status were obtained from a nationally representative sample of 4485. Recruitment was performed using a multi-stage stratified cluster sampling technique between August 2005 and September 2006. Diabetes was diagnosed using fasting plasma glucose and 75g oral glucose tolerance test according to the World Health Organisation criteria. Anthropometric measurements were performed according to the standard methods using calibrated equipment. All aspects of sexual function were assessed using a modified questionnaire based on the International Index of Erectile Function in men and Female Sexual Function Index in women. A stepwise multiple regression analysis was performed using presence of any form of sexual dysfunction as the dependant variable to identify covariates of sexual dysfunction.
Results: Sample size was 4.485 (response rate -89.7%), 39.5% (n=1,772) were males and 17.6% (n=789) were residing in urban areas. Mean age was 46.1±15.1 years. Crude prevalence of diabetes was 12% (n=536). Overall, 2597 adults admitted to being sexually active. Among the 1109 sexually active males, 73 (6.6%) had a sexual problem whereas among the 1488 sexually active women, 117 (7.9%) complained. Men with diabetes compared to non-diabetic individuals had a higher prevalence of any form of sexual dysfunction (18.4% vs. 5.1%, p< 0.001); lack of desire (6.4% vs. 1.5%, p< 0.001), erectile dysfunction (16.8% vs. 3.7%, p<0.001) and lack or delay in orgasm (3.2% vs. 1.2%, p<0.001). The presence of any form of sexual dysfunction was significantly higher among the women with diabetes (13% vs. 7.3%, p<0.05). Similarly, women with diabetes when compared to the non-diabetic counterparts had higher prevalence of lack of desire (8.9% vs. 3.3%, p<0.01), reduced lubrication (4.1% vs. 1.5%, p<0.05) and absence of orgasm (4.1% vs. 1.1%, p<0.01). In the stepwise multiple-regression analysis, the duration of diabetes (OR: 3.8, 95% CI 2.4-6.1) significantly associated with any form of sexual dysfunction.
Conclusion: We found that sexual dysfunction is significantly common in those with diabetes compared to the non-diabetic adults in Sri Lanka. Primary prevention of diabetes and prevention of diabetic complications by good diabetes care may improve the overall sexual health of the population especially in ethnicities like South Asians with higher prevalence of diabetes.

PS 106 Neuropathy I: correlates and treatments

Association between distal arterial calcification and diabetic neuropathy in diabetes mellitus

N.A. Molitvoslovova[1], O.V. Manchenko[2], M.V. Yaroslavceva[1], G.R. Galstyan[1]; [1]Diabetic Foot Clinic, Endocrinology Research Centre, [2]Endocrinology Research Centre, Moscow, Russian Federation.

Background and aims: Medial arterial calcification is common in diabetes mellitus (DM) and is an independent risk factor for major amputation, cardiovascular and all-cause mortality. There is evidence that distal arterial calcification is associated with distal polyneuropathy (DPN) and cardiovascular autonomic neuropathy (CAN) and that the extent of coronary artery calcification (CAC) is closely associated with CAN. The aim of the study was to assess quantitatively tibial arterial calcification (TAC) and CAC in patients with DM and to correlate the extent of calcification with the presence and severity of DPN and CAN.
Materials and methods: 85 patients with DM (54 women, 31 men, type 1 -37, type 2 -48, mean age -51,9±11,9 years) were assessed. Exclusion criteria were: peripheral artery disease (ankle-brachial index<0,9), glomerular filtration rate (GFR)<30 ml/min/1,73 m², DM 1 duration<5 years. Nerve function was assessed by 10-g monofilament detection, vibration threshold, electrophysiological study of peroneal nerves and cardiovascular tests. All patients underwent multislice computed tomography. Calcium scores were determined according to the method described by Agatston et al.
Results: Patients with DM2 had significantly higher CAC scores than DM1 patients (p=0,007) with no difference in TAC scores. There was significant inverse correlation between TAC scores and peroneal amplitude (r=-0,45, p<0,0001), vibration threshold (r=-0,44, p<0,0001), and nerve conduction velocity (r=-0,5, p<0,0001). Significant correlation was found between TAC and CAC scores (r=0,4, p<0,0001). The severity of CAC also correlated with vibration threshold (r=-0,3, p<0,006). In 60% of patients with TAC scores>1000 CAN was diagnosed, but there was no significant association between the quantity of TAC and CAC scores and the presence of CAN.
Conclusion: No association between autonomic neuropathy and artery calcification was found. Medial artery calcification is strongly associated with DPN and coronary calcification. These data suggest that DPN might be an independent cardiovascular risk factor.

1238

Skin microvascular reactivity relates to advanced glycation end-products accumulation and endothelial activation in patients with diabetes

J. Skrha Jr.[1,2], J. Soupal[1], L. Landova[2], J. Kvasnicka[2], M. Prazny[1], J. Skrha[1]; [1]Third Department of Internal Medicine, [2]Institute of Medical Biochemistry and Laboratory Diagnostics, First Faculty of Medicine, Charles University and General University Hospital, Prague, Czech Republic.

Background and aims: The development of diabetic microangiopathy is associated with changes of microvascular reactivity (MVR). Moreover, the advanced glycation end-products (AGEs) accumulation is supposed to be involved in the pathogenesis of diabetic angiopathy. The aim of our study was to measure parameters of skin MVR and skin autofluorescence (AF) reflecting AGEs accumulation, and compare them with markers of endothelial activation in patients with diabetes.
Subjects and methods: Microvascular reactivity (post-occlusive reactive hyperemia /PORH/ and thermal hyperemia /TH/), assessed by laser-Doppler fluxmetry using PeriFlux 4001 (Perimed), was measured on the forearm in 47 patients with diabetes (26 Type 1 /T1DM/, 21 Type 2 /T2DM/; aged 55 ± 14 yrs; diabetes duration 17 ± 10 yrs) and 25 healthy controls (aged 45 ± 10 yrs). Skin AF, expressed in arbitrary units (AU), was measured by AGE-Reader (Diagnoptics BV) on the forearm as well. In all patients, glycated haemoglobin HbA_{1c} (expressed in IFCC units), parameters of endothelial activation (vWF, ICAM, VCAM, E-selectin, P-selectin) and markers of microangiopathy (microalbuminuria, vibration perception threshold estimated by Biothesiometer) were assessed.
Results: Diabetes control expressed by glycated heamoglobin was similar in patients with both T1DM and T2DM (73 ± 20 vs. 67 ± 18 mmol/mol, NS). Microangiopathy (positive albuminuria and/or neuropathy) was present in 41 % of patients with diabetes. Patients with diabetes were evaluated together, since the differences between T1DM and T2DM did not reach statistical significance both in skin AF and microvascular reactivity. Skin AF was significantly higher in patients with diabetes as compared to controls (2.38 ± 0.54 vs. 2.04 ± 0.47 AU, p<0.01). Patients with higher skin AF (AF>2.3 AU) had significantly lower MVR in comparison to patients with lower skin AF (AF<2.3 AU) as expressed by PORH: 353 vs. 526 %, p<0.002; and TH: 908 vs. 1494 %, p<0.02. Significant inverse relationship was found between skin AF and MVR in patients with diabetes (PORH: r=-0.42, p<0.006; TH: r=-0.45, p<0.004). Interestingly, vWF as a marker of endothelial activation was positively associated with skin AF (r=0.61, p<0.001) and inversely associated with TH (r=-0.46, p<0.02) in T1DM and T2DM together. Regarding endothelial activation (EA), if all patients with diabetes were divided according to the activity of vWF into the EA negative (EA-, vWF<110 %) and EA positive (EA+, vWF>110 %) subgroups, significantly lower MVR was observed in EA+ than in EA- patients (PORH: 397 vs. 496 %, p<0.05; TH: 1006 vs. 1776 %, p<0.04).
Conclusion: This is the first study describing significant inverse relationship of the skin microvascular reactivity and skin autofluorescence in patients with diabetes. Our results demonstrate that increased accumulation of advanced glycation end-products in the skin is associated with worsened microvascular reactivity as well as elevated endothelial activity. Causal relationship is suspected but it will be further elucidated in the follow-up study.

1239

Serum osteoprotegerin levels are associated with peripheral neuropathy in patients with type 2 diabetes

I. Eleftheriadou[1], P. Grigoropoulou[1], I. Mourouzis[2], V. Argiana[1], A. Kokkinos[1], D. Perrea[3], N. Katsilambros[1], N. Tentolouris[1]; [1]First Department of Propaedeutic and Internal Medicine, Athens University Medical School, Laiko General Hospital, [2]Department of Pharmacology, Athens University Medical School, [3]Laboratory of Experimental Surgery and Surgical Research, Athens University Medical School, Athens, Greece.

Background and aims: Recent data suggest that serum osteoprotegerin (OPG) is a useful marker of atherosclerosis and vascular dysfunction in diabetes. The purpose of this study was to determine the relationship of serum OPG levels with peripheral sensorimotor neuropathy (PN) in patients with type 2 diabetes (T2DM).
Materials and methods: A total of 71 patients with T2DM were recruited (mean age 67.7±8.9 years, mean diabetes duration 15.0±10.6 years, male/female 45/26). Diagnosis of PN was based on neuropathy symptom score (NSS), neuropathy disability score (NDS) and vibration perception threshold (VPT). Serum OPG levels were measured using Luminex Multiplex assay. Diagnosis of peripheral arterial disease (PAD) was based on the presence of either biphasic, monophasic or blunted waveforms at the pedal arteries.
Results: Patients with PN (n=39) had significantly higher serum OPG levels in comparison with those without PN (744.8±296.2 vs 555.8±165.5 pg/ml). OPG levels were significantly associated with indices of PN, such as NDS (r=0.390, p<0.001) and VPT (0.412, p<0.001). Univariate logistic regression analysis showed that age (p=0.026), diabetes duration (p<0.001), male gender (p=0.003), smoking (p=0.004), BMI (p=0.024), dyslipidemia (p<0.001), presence of PAD (p<0.001) and OPG levels (p<0.001) were significantly associated with PN. No significant associations were found with HbA1c and arterial hypertension. Multivariate logistic regression analysis, after adjustment for age, gender and BMI, demonstrated that PN was associated significantly with diabetes duration [odds ratio (OR): 1.01, 95% confidence intervals (CI): 1.01-1.11], p=0.023), smoking (OR: 8.2, 95% CI: 1.41-47.92, p=0.019), dyslipidemia (OR: 4.3, 95% CI: 1.50-12.44, p=0.007), presence of PAD (OR: 3.0, 95% CI: 1.17-7.83, p=0.023) and OPG levels (OR: 1.0, 95% CI: 1.001-1.007, p=0.007).
Conclusion: Serum OPG levels are increased in patients with PN and are associated with the presence of PN irrespective of age, diabetes duration, gender, smoking, BMI, dyslipidemia and PAD status.

Osteoprotegerin, RANKL, RANK genes polymorphisms in diabetic Charcot neuroosteoarthropathy

A. Korzon-Burakowska[1], B. Bruhn-Olszewska[2], J. Jakobkieiwcz-Banecka[2], G. Wegrzyn[2];
[1]Diabetology, Medical University, [2]Biotechnology, University of Gdansk, Poland.

Background and aims: Charcot neuroosteoarthopathy(CN) is a rare but devastating complication of diabetes. The etiology is not fully understood but it involves interaction of several factors including abnormalities in bone metabolism. Bone reapsorption is a frequent feature of Charcot foot . Inflammatory condition definitely contributes to the pathogenesis. It is however likely that the cytokines of RANK, RANKL and OPG pathway may contribute to the pathogenesis of osteolysis in Charcot foot. Recently we have suggested an association between two OPG polymorphisms (1181G>C and 245T>G) and diabetic Charcot neuroosteoarthopathy. We have now analysed the frequency of OPG gene polymorphisms in a larger cohort of patients with Charcot neuroosteoarthropathy, diabetic patients with neuropathy (N), diabetic patients without neuropathy(D) and healthy controls(C).
Material and methods: A total of 237 subjects: 64 Charcot neuroosteoarthropathy patients, 44 diabetic patients with neuropathy, 34 diabetic patients without neuropathy and 95 healthy controls were genotyped for 5 different single nucleotide polymorphisms (SNP) within the OPG gene:T245G (rs3134069) G1181C (rs2073618), T950C (rs2073617), C1217T (rs3102734) and A6890C (rs7844539), two polymorphisms in RANK gene C421T (rs35211496) and C575T (rs1805034) and three polymorphisms in RANKL gene:C290T (rs9525641), C643T(rs9533156) and C693G (rs9533155). We have used RFLP and minisequencing to analyze polymorphisms. We have also used ELISA to determine serum levels of OPG and RANKL proteins.
Results: Statistically significant differences between the group of subjects with neuropathy but no Charcot neuroarthropathy and the control group were found only for T245TG (rs3134069) polymorphism. We did not confirm our previous observation of the association of Charcot neuroosteoarthropathy with C1217T(rs3102734) polymorphism . Our analysis showed no significant correlation between studied RANKL gene polymorphisms. With respect to serum OPG concentration statistically significant differences were found only between the patients with neuropathy (N) in which OPG levels were higher and the group with diabetes and no neuropathy (D). Biochemical analysis showed increased levels of RANKL protein in blood serum in patients with neuropathy but not in patients with Charcot's arthropathy.
Conclusion: Genetic factors, particularly T245G (rs3134069) OPG gene polymorphisms, may play a role in the development of diabetic Charcot neuroarthropathy.

Long-term effect of quinapril or losartan or their combination on diabetic autonomic neuropathy and left ventricular function over a period of 4 years

T.P. Didangelos[1], G. Arsos[2], E. Moralidis[3], F. Iliadis[1], A. Zantidis[1], A. Hatzitolios[1];
[1]Diabetes Center, 1st Propedeutic Department of Internal Medicine Medical School; "AHEPA" Hospital, [2]Laboratory of Nuclear Medicine,"Papageorgiou" Hospital of Thessaloniki, [3]Laboratory of Nuclear Medicine,"AHEPA" Hospital of Thessaloniki, Aristotle University of Thessaloniki, Greece.

Background and aims: To investigate the effect of angiotensin converting enzyme inhibition or angiotensin receptors blockers or their combination on definitive Diabetic Autonomic Neuropathy (DAN) and left ventricular (LVF) systolic and diastolic function over a period of four years
Materials and methods: Sixty patients (30 women, 34 with type 1 DM, aged 51.7±15.7 y, DM duration 20.3±7.0 y) with DAN were studied for a 4 years. No patient with coronary artery disease included. Patients were randomly allocated in 3 groups A (n=24), B (n=18), C (n=18) receiving 20 mg quinapril (Q), 100 mg losartan (L) and 20 mg Q +100 mg L respectively. The presence of DAN was established if 2 or more of the 4 Cardiovascular Reflex Tests (CRT) were abnormal and analyzed with Mean Circular Resultant (MCR), Valsalva index (VALS), 30:15 ratio (POST) and postural hypotension (HYPO). LV function was investigated with radionuclide ventriculography (RNV) at rest. Ejection fraction (EF) was used to assess LV systolic function, while peak filling rate (PFR), first third filling fraction (1/3FF), and atrial contribution to ventricular filling (A/V) were used to investigate LV diastolic function. CRT and RNV performed at baseline and after 4 years. We measured Heart Rate (HR), Systolic and Diastolic Arterial Pressure (SAP,DAP) and HbA1c, also.
Results: In all groups improvement was observed after 4 years of treatment in MCR (A, 16.9± 5.6 vs 29.4± 15.6, p= 0.007, B, 17.3± 9.2 vs 27.2± 17.5 p=0.014, C, 12.9± 10.0 vs 23.0± 13.9, p<0.001). In group C a decrease in SAP and DAP observed at 4 years (142.3±23.7 vs 129.2.0±15.2, 83.2±8.8 vs 77.0±7.9, p<0.05 respectively). In group A a decrease in A/V (%SV) observed 24.4±8.7 vs 20.6±7.3, p<0.05. The rest of CRT and RNV indices were not significantly changed over base line values in 4 years. HR and HbA1c did not change significantly
Conclusion: DAN improved after four years of treatment with quinapril, losartan, or their combination. No deterioration observed in systolic and diastolic LVF except for group A, also. Improved autonomic balance and no decline of LVF may be of clinical importance in long-term prognosis of DM patients

1242

Amelioration of neuropathic changes with correction of nerve insulin resistance in diabetic Goto-Kakizaki rats treated with DPP-IV inhibitor vildagliptin

K. Tsuboi, H. Mizukami, W. Inaba, K. Kamata, S. Ogasawara, S. Yagihashi; Hirosaki University, Hirosaki, Japan.

Background: Peripheral insulin resistance is one of the main pathogenetic processes in type 2 diabetes. Recently, insulin resistance in the peripheral nerve has been proposed to contribute to the pathogenesis of diabetic neuropathy (DN) and may be a novel therapeutic target for DN. While there were several investigations that demonstrated that incretin therapy was beneficial for neuropathy in type 1 diabetic animals, the effects on type 2 diabetic models are yet to be examined. The mechanism of how incretin influences on DN was not well addressed in those studies. We therefore investigated whether the treatment with DPP-IV inhibitor, vildagliptin (VG), is beneficial for neuropathy in type 2 diabetic model, Goto-Kakizaki rats (GK) and also explored if insulin signaling in the peripheral nerve is implicated in the incretin effects on DN.
Materials and methods: Male GK 4 weeks of age were divided into 3 groups; untreated, treated with restricted diet (diet group), and treated with DPP-IV inhibitor, vildagluptin (VG) at a dose of 15 mg/kg/day orally twice a day. Age- and sex-matched Wistar rats (W) divided into similar 3 groups served controls. During observation period of 18 weeks, blood glucose, serum insulin, GLP-1 level, motor and sensory nerve conduction velocities (MNCV and SNCV) were monitored. At end, dorsal root ganglia (DRG) and sciatic nerves were extirpated for structural and molecular analyses.
Results: VG-treatment suppressed hyperglycemia, corrected serum level of insulin and GLP-1 in GK (p<0.01). Diet on GK also suppressed hyperglycemia to the extent similar to that in VG-treated GK, improved serum insulin but not GLP-1. Both MNCV and SNCV were significantly delayed in GK. VG treatment on GK improved both NCV near normal levels, but recovery of NCV was equivocal in diet-GK. RT-PCR disclosed an expression of GLP-1 receptor-mRNA in DRG, but not in sciatic nerve, and western blot revealed its protein in both DRG and sciatic nerve. The expression levels were comparable between GK and W. Western blot also demonstrated marked reduction of phospho-CREB, Akt and S6RP expressions in DRG of GK compared to W. They all recovered near 90% of normal in VG-treated GK, but not in diet GK. IRS-2 expression in DRG was similar between GK and W, but immnoprecipitation analysis demonstrated marked reduction of phospho-tyrosine residues of IRS2 in GK compared to W. VG-treatment in GK reverted the phosphotyrosine by 60%, but this was not the case in diet GK. Excessive phosphoserine residue of IRS2 as a marker of insulin resistance was demonstrated in GK, and was normalized in VG-treated GK. The recovery of phospho-serine was partial (30%) in diet GK.
Conclusion: DN in GK was ameliorated by VG-treatment which may have directly exerted GLP-1 receptor signal together with activation of insulin signals. Correction of hyperglycemia by diet alone was not sufficient to fully improve cellular signals of DRG in GK.

1243

Treatment for chronic pain syndrome of diabetic peripheral neuropathy in type 2 diabetics with thioctic acid and standardised protein-free dialysate of calf blood

L.A. Ivanova, O.N. Rostovtseva;
Endocrinology, Kuban State Medical University, Krasnodar, Russian Federation.

Background and aims: The aim of the study was to reveal the advantages of the combined treatment of pain syndrome with thioctic acid and standardized protein-free dialysate of calf blood in type 2 diabetes mellitus (DM2) patients with diffuse symmetric distal sensorimotor polyneuropathy.
Materials and methods: The study enrolled 62 DM2 patients with diffuse symmetric distal sensorimotor polyneuropathy and chronic pain syndrome (29 females and 28 males). The mean age of the patients was 68.2±5.3 years, the mean duration of DM2 was 17.6±3.3 years, the mean level of glycated hemoglobin (HbA1c) was 7.6±1.2 %. The initial mean intensity of the pain syndrome was 8.07±0.31 points. Blood glucose-lowering therapy, i.e., sulfonylureas (n=16), insulin therapy (n=23), or both (n=18), remained unchanged throughout the whole follow-up period. After signing the informed consent form, patients were randomly assigned to one of the three groups: group I (n=21) included patients who were given 15 intravenous infusions of thioctic acid at a dose of 600 mg/day and then received it orally at the same dose over 24 months; in group II (n=21), daily intramuscular injections of 212.5 mg standardized protein-free dialysate of calf blood over 15 days were added to thioctic acid (15 intravenous infusions of 600 mg/day followed by oral administration at 600 mg/day over 24 months). The control group (n=20) consisted of patients who had initially received 15 intravenous infusions of thioctic acid at 600 mg/day followed by its oral administration at the same dose (600 mg/day) over 2.5 months. HbA1c levels and pain intensity (using a 10-point visual-analogue scale) were evaluated at baseline and at 3, 6, and 24 months. The results were statistically treated using Statistica 6.0 software. The results were considered significant at $p<0.05$.
Results: At 3, 6, and 24 months, pain intensity in group I was reduced on average by 4.3±0.3 points (16.2%; p=0.67), 4.0±0.1 points (33.3%; $p<0.01$) and 4.1±0.1 points (60.0%; $p<0.001$), respectively, as compared to the control. Pain syndrome with the intensity of 4 points relapsed in one patient with an acute exacerbation of chronic bronchitis treated with 3rd generation cephalosporins; in one patient from group I, pain syndrome provoked by cooling of lower extremities persisted. Pain recurrence was relieved by intravenous infusions of thioctic acid at 600 mg in the physiological saline in combination with intramuscular injections of 212.5 mg standardized protein-free dialysate of calf blood for 15 days. In group II, pain intensity was reduced on average by 5.8±0.2 points (56%; $p<0.001$), 5.4±0.1 points (80.1%; $p<0.001$), and 5.1±0.2 points (96.2%; $p<0.001$) at 3, 6, and 24 months, respectively, as compared to the control. The relapse-free period was significantly longer in patients continuing administration of thioctic acid over 24 months (group II) as compared to both the control group and group I (85% vs. 30% and 66%, respectively).
Conclusion: Combined treatment with thioctic acid and standardized protein-free dialysate of calf blood administered through intramuscular injections at a dose of 212.5 mg was significantly more effective in reducing pain syndrome intensity and frequency of relapses in patients with DM type 2 and diabetic peripheral neuropathy as compared to thioctic acid monotherapy for 3 or 24 months.

PS 107 Neuropathy II: large fibres, small fibres, peripheral and central

The influence of diabetic neuropathy on imbalance in patients with diabetes mellitus

O.S. Fedorova[1], I.V. Gurieva[1,2], I.A. Strokov[3], L.T. Ahmedzhanova[3];
[1]Federal Bureau of Medical and Social Expertise, [2]Russian Medical Academy of PostGraduate Education, [3]I.M. Sechenov First Moscow State Medical University, Moscow, Russian Federation.

Background and aims: It is well known that presyncope and syncope due to autonomic neuropathy with orthostatic hypotension are the common cause of falls in patients with diabetes mellitus (DM). Imbalance of diabetic patients unrelated to orthostatic blood pressure reduction are studied less. The aim of this study was to assess posture stability using computerised dynamic posturography in type 1 and type 2 diabetes mellitus patients and to identify the association between diabetic neuropathy and deterioration of balance.
Materials and methods: The 102 (age between 22 and 74 years) type 1 and type 2 DM patients participated. The postural stability was evaluated using sensory organisation test (SOT), motor control test (MCT) of computerised dynamic posturography (CDP). Neurological disability score (NDS) and neuropathy impairment score of the lower limbs (NIS-LL) were used to determinate specific somatosensory loss. Trail making test was used to assess the role of frontal dysfunction in posture stability.
Results: Patients were divided into 3 groups: 1) without reduction of proprioception (kinaesthesia), vibration or tactile sensation, n=27; 2) with reduction of vibration or tactile sensation, but without reduction of proprioception, n=37; 3) with reduction of proprioception, vibration and tactile sensation (large fiber dysfunction), n=38. Equilibrium scores in sensory organisation test (SOT) 1, 2, 3 conditions and the composite muscle response latencies in MCT were significantly worse ($p\leq0.03$) in the group 3 as compared to the group 1. The composite muscle response latencies were 148.5 msec (142.0; 156.0) in the group 3 and 140.0 msec (132.0; 148.0) in the group 1 ($p<0.01$). The patients from group 3 were characterized longer duration of diabetes, more frequent events of imbalance complaints and history of falls as compared to the group 1. There were not significant differences between three groups in age, BMI, levels of HbA1c, in presence of vestibular syndrome and trail making test parameters. Large fiber dysfunction was associated with increased risk of history of falls (1.6, 95% CI 0.9 to 2.8) and with increased risk of imbalance complaints (1.4, 95% CI 1.1 to 1.9).
Conclusion: Peripheral neuropathy with large fiber dysfunction is independent risk factor of postural instability in diabetic patients. The large fiber dysfunction with the reduction of proprioception leads to instability in enviroments of low lighting, visual movement and in case of unexpected external disturbances.

1245

Function of large nerve fibres and levels of HSP27 in type 1 diabetes: a longitudinal follow-up

K. Pourhamidi[1], H. Skärstrand[2], L.B. Dahlin[3], O. Rolandsson[1];
[1]Department of Public Health and Clinical Medicine, Family Medicine, Umeå University, [2]Department of Clinical Sciences, Lund University, Skåne University Hospital, [3]Department of Clinical Sciences, Hand Surgery, Skåne University Hospital, Lund University, Malmö, Sweden.

Background and aims: Diabetes mellitus is regarded as the leading causes of peripheral neuropathy. However, there is a lack of a circulating biomarker of peripheral nerve dysfunction. Heat shock protein 27 (HSP27) is proposed as a neuroprotective factor and may even be important for axonal regeneration. Therefore, it is of interest to study whether HSP27 serves as a potential biomarker for nerve dysfunction in individuals at risk. Currently, there are no prospective studies investigating serum HSP27 concentrations and progression of peripheral nerve dysfunction among individuals with type 1 diabetes mellitus or in healthy subject. Thus, our aims were to investigate possible associations between serum HSP27 concentration and measures of peripheral nerve dysfunction, and whether HSP27 concentrations differ between individuals with and without type 1 diabetes (T1DM).
Materials and methods: This longitudinal study is based on patients with T1DM that were regularly treated in our Diabetes Clinic and received their

diagnosis between the ages of 15 and 26. The patients were asked to participate in a study of neuropathy in 1993 and were then followed-up in 2005. Nerve conduction studies, vibration and thermal threshold tests were performed on the lower extremities at baseline and follow-up. Serum HSP27 concentrations were determined at baseline and follow-up as well as for healthy non-diabetic subjects in 2004.
Results: Twenty-three T1DM subjects, including 11 women, and with baseline age of 40±8 years and diabetes disease duration of 22±8 years were included. HbA1c and blood pressure were not significantly different between baseline and follow-up. Serum HSP27 concentrations were not significantly different at follow-up (median 363 pg/ml, IQR 312-1047) than baseline (median 462 pg/ml, IQR 312-969). Healthy non-diabetic controls (n=372) had higher HSP27 concentrations (median 900 pg/ml, IQR 454-1465) than T1DM ($p = 0.014$ at baseline, $p = 0.005$ at follow up). The dynamic change of HSP27 (baseline HSP27 - follow-up HSP27; delta HSP27, median 25 pg/ml, IQR -380-190) significantly correlated to that of large nerve fiber function (delta vibration thresholds, median -11 Hz, IQR 1-51, $r = -0.47$, $p = 0.03$; delta nerve conduction, median 0.7 z-score, IQR -0.2-1.7, $r = 0.44$, $p = 0.04$), but not to small nerve fiber function (cold thresholds $r = -0.33$, $p = 0.14$ and heat thresholds $r = -0.15$, $p = 0.58$). Gender and age did not correlate with delta HSP27. Univariate linear regressions revealed that deteriorating nerve conduction and vibration thresholds from baseline to follow-up were associated with a decrease of HSP27 concentration ($B = 0.001$, SE 0.001, $\beta = 0.44$, $p = 0.038$), and $B = -0.02$, SE 0.01, $\beta = -0.47$, $p = 0.031$, respectively).
Conclusion: A novel finding is that individuals with type 1 diabetes had lower serum HSP27 concentrations than healthy non-diabetic controls. A decrease in large nerve fiber function in individuals with type 1 diabetes is associated with a decrease in serum concentration of HSP27 over time. Despite the small number of type 1 diabetes participants, our preliminary data suggests that HSP27 might potentially be used to follow the progression of peripheral neuropathy.

1246

Prevalence of chronic use of metformin-related vitamin B12 deficiency is lower in Asian population
H. Chun, Y.-B. Ahn, S. Ko, S. Moon, S.-H. Ko;
Endocrinology, St.Mary's Hospital, Seoul, Republic of Korea.

Background and aims: Metformin is widely used in patients with type 2 diabetes but may cause Vit B12 deficiency. The objective of this study was to evaluate the presence of vitamin B12 deficiency and the factors associated with serum vitamin B12 levels in Korean type 2 diabetic patients.
Materials and methods: We conducted a cross-sectional study of 381 type 2 diabetic patients at the university-affiliated diabetes center of St. Vincent's Hospital. Vitamin B12 deficiency was defined as serum B12 concentrations <300 pg/mL. Statistical analysis was performed to evaluate the relationship between metformin and vitamin B12 deficiency.
Results: Vitamin B12 deficiency was present in 14.1% (n=54) of patients using metformin. Mutivariate analysis revealed statistically significant associations between vitamin B12 deficiency and age, metformin use duration and metformin daily dosage. Compared with metformin use of less than 3years, the adjusted OR was 4.107 (95% CI, 1.799-9.375) (P =0.001) for metformin use of at least 3 years. Current dose of metformin was a strong independent predictor of vitamin B 12 deficiency (OR, 2.916 ; CI, 1.363-6.240) (P =0.006) Increased age appeared to be positively related to vitamin B 12 deficiency (adjusted OR, 1.055 ; CI 1.018-1.093) (P=0.003). Significantly increased risks were not found with concurrent use of H2 receptor antagonists, proton pump inhibitors or vitamin B12 supplements.
Conclusion: Our study indicates an increase risk of vitamin B12 deficiency associated with older age, current dosage and duration of metformin use despite adjustment for many potential confounders. The risk factors identified have implications for planning screening or prevention strategies in metformin-treated patients.

1247

Pain threshold values of small fibres are associated with the severity of diabetic complications
D. Kukidome, M. Sato, S. Shimoda, T. Nishikawa, E. Araki;
Metabolic Medicine, Faculty of Life Sciences, Kumamoto, Japan.

Background and aims: Nerve conduction study (NCS) is regarded as the "gold standard" for the evaluation of diabetic neuropathy. However, by NCS, it is difficult to evaluate the impairment of small fibers, such as Aδ and C fibers although diabetes mellitus (DM) is the most common identifiable cause of small fiber neuropathy. Previously, Inui et al. reported that intra-epidermal electrical stimulation (IES) can selectively activate Aδ and C-nociceptors. In addition, PNS-7000, which is a portable stimulator specialized for IES and can evaluate small fiber function by measuring pain threshold value of Aδ and C fibers, has been newly developed. Therefore, in this study, we have examined the degree of small fiber neuropathy by using PNS-7000 in type 2 DM (T2DM) and non-DM subjects and evaluated the association between samll fiber neuropathy and the severity of diabetic complications.
Materials and methods: 87 Japanese subjects with T2DM (mean age 58.7 years; 60 men; BMI 26.0; glycated hemoglobin A1c (HbA1c) 9.3% and 36 Japanese subjects without DM (mean age 45.7 years;16 men; BMI 23.4; HbA1c 5.3%) were recruited for the study. The subjects were examined pain threshold values of Aδ and C fibers by using PNS-7000, clinical features, several clinical neurological examinations (neuropathic symptoms, vibratory sensation in foot, and Achilles› tendon reflex (ATR)) and the severity of diabetic neuropathy, retinopathy or nephropathy. The severity of diabetic neuropathy was evaluated by the staging proposed by Diabetic Neuropathy Study Group in Japan.
Results: The pain threshold value of C fibers was 0.061 mA in non-DM subjects, while that of T2DM subjects was 0.149mA ($p < 0.001$). In addition, similarly to C fibers, the pain threshold value of Aδ fibersin T2DM subjects was significantly higher compared with that of non-DM subjects (0.143 vs 0.042 mA, $p < 0.001$). When the T2DM subjects were divided into two groups according to with or without abnormalities of each clinical neurological examinations, the pain threshold values of C fibers were significantly higher in the group with abnormality compared with the group without abnormality (0.294 vs 0.172, 0.254 vs 0.155, 0.262 vs 0.137 mA, for neuropathic symptoms, abnormality of vibratory sensation in foot and abnormality of ATR, respectively, $p < 0.01$). Respect to pain threshold of Aδ fibers revealed a statistically significant difference only between the group with and without neuropathic symptoms (0.193 vs 0.108 mA, p: 0.013). In addition, the pain threshold values of Aδ and C fibers were significantly higher in accordance with the severity of diabetic neuropathy, retinopathy or nephropathy in T2DM subjects.
Conclusion: This study showed that small fiber neuropathy was observed in T2DM subjects, and PNS-7000 was useful to detect small fiber neuropathy. In addition, small fiber neuropathy was closely associated with the abnormalities of clinical neurological examinations, and the severity of diabetic neuropathy, retinopathy or nephropathy. Because PNS-7000 takes shorter time and is less invasive compared to NCS, PNS-7000 could be useful to predict the diabetic complications.

Retinal nerve fibre layer thickness is associated with measures of small fibre neuropathy in long-term type 1 diabetes
K.A. Sveen[1], K. Ørstavik[2], D. Fosmark[3], K. Dahl-Jørgensen[4], K.F. Hanssen[1];
[1]Dept of Endocrinology,Obesity and Preventive Medicine, [2]Section of Clinical Neurophysiology, [3]Dept of Ophthalmology, [4]Dept of Pediatrics, Oslo University Hospital, Oslo, Norway.

Background and aims: Corneal confocal microscopy (CCM) can measure small nerve fibers in the cornea and has been shown to correlate with other measurements for early neuropathy in diabetes (small fiber neuropathy). Optical coherence tomography (OCT) can evaluate the retinal nerve fiber layer (RNFL). RNFL thinning is associated with peripheral neuropathy in type 2 diabetes. Little is known about this in type 1 diabetes. Our aims were to investigate the relationship between retinal nerve fiber layer thickness, peripheral neuropathy and small fiber neuropathy in long-term type 1 diabetes by using CCM. We also wanted to evaluate if the advanced glycation endproduct N-epsilon-(carboxymethyl) lysine (CML) ,which has been implicated in oxidative stress and diabetic late complications, was associated with RNFL.

Materials and methods: The level of neuropathy was assessed clinically and by nerve conduction studies (NCS) in 29 patients (53±7 years) with type 1 diabetes of 40 years duration and in 20 healthy controls. Corneal confocal microscopy (CCM)(Confoscan4, Nidek, Italy) was used as a proxy for small fibre damage. Global and sectoral retinal nerve fibre layer thicknesses were measured around the optic nerve head using OCT (Rtvue, Optovue, USA). The advanced glycation endproduct CML was measured in serum ten years prior to these examinations by immunoassay. None of the participants had unstable retinopathy at the time of examination.
Results: NCS were abnormal in 16 patients (59%) and compatible with diabetes neuropathy.Corneal nerve fibre density (CNFD) measured with CCM was significantly lower in the diabetes patients compared to controls, 8.9±2.7 vs. 10.6±2.0 no./mm², p=0.029. CNFD was negatively associated with the presence of peripheral neuropathy (r=-0.42, p=0.032). A thinner inferior retinal nerve fibre layer (RNFL) was observed in the diabetes patients compared to controls (93.5µm±12.3 vs. 102.7±10.2µm, p=0.045). Global RNFL was negatively associated with corneal nerve fibre length and CNFD, r=-0.46, p=0.0011 and r=-0.44, p=0.0017, respectively. No significant association was observed between RNFL and peripheral neuropathy evaluated by NCS. RNFL was negatively associated with the advanced glycation endproduct CML in serum. After adjusting for age, sex and duration of diabetes, CML was still independently associated with RNFL, r^2= 0.37, p=0.016.
Conclusion: RNFL of the inferior retina was thinner in diabetes patients compared to controls. Corneal nerve fiber density was signifcantly lower in diabetes patients and negatively associated with peripheral neuropathy. Measures of RNFL and CCM were positively correlated. These results may suggest that changes in the cornea and possibly in the retina (central nervous system) may parallell changes in the peripheral nervous system. RNFL thinning may be interesting as a novel marker of small fiber neuropathy. This study also indicates that CML may have a prognostic value in RNFL thinning.

Association of subclinical inflammation with polyneuropathy in the older population: KORA F4 study
C. Herder[1], B.W.C. Bongaerts[2], W. Rathmann[2], M. Heier[3], B. Kowall[2], W. Koenig[4], B. Thorand[3], M. Roden[1,5], C. Meisinger[3], D. Ziegler[1,5];
[1]Institute for Clinical Diabetology, German Diabetes Center, [2]Institute of Biometrics and Epidemiology, German Diabetes Center, Düsseldorf, [3]Institute of Epidemiology II, Helmholtz Zentrum München, Neuherberg, [4]Department of Internal Medicine II – Cardiology, University of Ulm Medical Center, [5]Departments of Endocrinology & Diabetology & Metabolic Diseases, University Hospital Düsseldorf, Germany.

Background and aims: Distal sensorimotor polyneuropathy (DSPN) contributes to significant morbidity and increased mortality among diabetic subjects, and several studies suggest that DSPN is also more prevalent in individuals with prediabetes when compared to those with normal glucose tolerance. Inflammatory processes have been implicated in the pathogenesis of DSPN, but their possible relationship has not been assessed at the population level. Therefore, the aim of our study was to investigate whether circulating concentrations of seven pro- and anti-inflammatory immune mediators are associated with clinically diagnosed DSPN and neuropathic impairments in older subjects from the general population.
Materials and methods: We determined serum concentrations of mediators of subclinical inflammation among 1047 participants aged 61-82 years from the population-based Cooperative Health Research in the Region of Augsburg (KORA) F4 study (Germany). Logistic and linear regression models were fitted to assess associations between immune mediators (log-transformed) and the presence of clinical DSPN (dichotomous variable) or Michigan Neuropathy Screening Instrument (MNSI) examination score (continuous variable), respectively.
Results: Serum concentrations of the anti-inflammatory interleukin-1 receptor antagonist (IL-1RA) were positively associated with the presence of DSPN (P=0.011) and higher MNSI scores (P<0.001) in age and sex-adjusted analyses, whereas IL-6, IL-18, and soluble intercellular adhesion molecule-1 (sICAM-1) were positively associated only with MNSI scores (all P<0.05). No associations were observed for adiponectin, C-reactive protein (CRP) or tumour necrosis factor-α (TNF-α). Associations for IL-1RA and IL-6 with the MNSI score remained statistically significant (P<0.05) after additional adjustment for waist circumference, height, hypertension, cholesterol, smoking, alcohol intake, physical activity, history of myocardial infarction and/or stroke, presence of neurological conditions and use of non-steroidal anti-inflammatory drugs.
Conclusion: We observed associations between serum IL-1RA, IL-6 and specific manifestations of DSPN and conclude that DSPN is linked to proinflammatory and anti-inflammatory, possibly compensatory, processes in the older general population. Future studies should clarify the temporal sequence and causality of these associations.

Impact of neuropathy severity on brain volume loss in diabetic peripheral neuropathy
D. Selvarajah[1], M. Maxwell[1], J. Davies[1], A. Sankar[1], E. Cachia[1], R. Gandhi[2], I. Wilkinson[3], S. Tesfaye[4];
[1]Department of Human Metabolism, University of Sheffield, [2]Diabetes Research Department, Sheffield Teaching Hospitals NHS Foundation Trust, [3]Academic Department of Radiology, University of Sheffield, [4]Academic Department of Diabetes and Endocrinology, Sheffield Teaching Hospitals NHS Foundation Trust, Sheffield, UK.

Background and aims: We have recently demonstrated significant intracranial peripheral grey matter density reduction, attributed to atrophy, in subjects with established diabetic peripheral neuropathy (DPN). This atrophy, which was localised to the sensorimotor cortex, suggests that DPN has significant impact upon the structural integrity and organisation of the brain. It is not fully understood how changes in brain volumes relates to DPN severity. Exploring this relationship is important to understand the pathophysiological significance of brain atrophy in DPN.
Materials and methods: Fifty six patients with type 1 diabetes [No-DPN, n = 22, Established-DPN, n = 34] underwent detailed clinical and neurophysiological assessments. A neuropathy composite score (NCS) was calculated from transformed percentile points for vibration detection threshold, sural (NCV, SNAP), peroneal (NCV, CMAP, DL) and tibial (DL) nerve conduction attributes. Patients with Established-DPN had at least one abnormal nerve conduction parameter in both the sural and peroneal nerves and at least one neuropathic symptom or sign. All subjects underwent T1-weighted volumetric brain MR imaging at 3T. Images were analysed using FSL (fMRIB, Oxford, UK); a library of analysis tools for brain imaging data. The relation between total and peripheral grey matter volumes (adjusted for age, height, weight and HbA1c) and individual attributes of nerve function and NCS was analysed using linear regression analysis.
Results: Both groups were matched for gender [No-DPN vs Established-DPN; males (%): 68.1 vs 67.6], age (42.3 vs 48.0 years; p=0.08) and HbA1c (71.9 vs 77.5 mmol/mol; p=0.24). No-DPN subjects had significantly greater peripheral grey matter volume compared to Established-DPN [632.1 vs 606.0ml; p=0.01). Cortical atrophy was localised to postcentral gyrus, precentral gyrus and cerebellum. Adjusting for age, height, weight and HbA1c, we found that higher peroneal nerve conduction velocity was associated with larger peripheral grey matter volume (R=0.41; p=0.02). The amplitudes in both sural and peroneal nerves were not related to peripheral grey matter volume at a statistically significant level. Peripheral grey matter volume was inversely related to DPN NCS, with each point associated with a volume reduction of 1.55ml (95% CI -2.82 to -0.29). The associations of peripheral grey matter atrophy with vibration detection threshold were not statistically significant.
Conclusions: The significant inverse linear trend and the continuous relations found with NCS are in keeping with a continuing loss of peripheral grey matter volume as the disease progresses. Significant correlations were also found between peripheral grey matter volume and neurophysiological parameters. We postulate that reduction in cortical grey matter volume localised to the primary somatosensory cortex may be induced through reduced cellular activity triggered by peripheral nerve axonopathy. Conversely, atrophy of the motor neurons is most likely indicative of retrograde degeneration due to DPN. Thus we demonstrate clinically eloquent relationships which require future assessments in longitudinal studies.

PS 108 Diabetic foot: epidemiology, risk factors and outcomes

1251

Reduced incidence of lower-extremity amputations in a Danish diabetes population from 2000 to 2012

M.E. Jørgensen, T.P. Almdal, K. Faerch
Steno Diabetes Centre, Gentofte, Denmark.

Background and aims: Diabetic foot disease and amputations severely reduce the quality of life and have major economic consequences for patients, their families, and society. Important improvements in diabetes care have occurred over the last decades, but it is not clear to which extent recent advances in diabetes care have reduced the excess mortality in patients with T1 diabetes. The aim was to estimate time trends in the incidence of lower-extremity amputations (LEA) in Danish diabetes patients.
Materials and methods: We studied major and minor LEA from 2000 to 2012 among 11,332 diabetes patients from our Diabetes Center. Amputations were identified by linkage of the electronic medical system with the National Patient Registry. Sex-specific incidence rates of amputations by age, diabetes duration, calendar time, and diabetes type were modelled by Poisson regression.
Results: From 2000-2012, 384 incident LEA (205 major, 179 minor) occurred during 100,495 years. From 2000-2012 the incidence of all LEA decreased by 90.9% among men and 81.8% among women with type 1 diabetes and by 94.7% among men and 85.1% among women with type 2 diabetes (P<0.001). Particularly there was a decline in major LEA. In 2011 the incidence rates of major LEA were 0.25 among men and 0.21 among women per 1000 p.y. at age 50 years and 0.56 among men and 0.41 among women per 1000 p.y. at age 70 years. No significant change in incidence of minor amputations was observed.
Conclusion: The incidence of major LEA reduced significantly from 2000 to 2012 in Danish diabetes patients.

1252

Pre-hospital delay in patients with diabetic foot problems: influencing factors and subsequent quality of care

B. Zhou, J. Yan;
The First Affiliated Hospital of Chongqing Medical University, Chongqing, China.

Background and aims: To investigate the proportion of delay in reporting their foot problems in diabetic foot patients, examine the possible risk factors and prognosis.
Materials and methods: In a retrospective study, 270 patients with diabetic foot problems were classified into three groups: those with diabetic foot duration ≤7 days were group 1, those with diabetic foot duration >1month were group 3, the rest were group 2. Compare their demographic and clinical characteristics, laboratory results, treatment data, sequent outcomes (hospital stays, amputation rate and mortality), and analysis the factors influencing patients pre-hospital delay.
Results: 270 patients were enrolled in our study, their mean time to hospital presentation was 46.49 days. A total of 77(28.5%) patients arrived within one week, 106 (39.3%) patients between one week and one month, and 87(32.2%) patients arrived longer than one month after symptom onset. Among numerous factors, we found nine variables were associated with long pre-hospital delay according to univariate analysis (P<0.05), they were no previous ulcer, no health insurance, bad housing conditions, low income level, low education level, seldom foot inspection, few follow up, absence of diabetic foot education and lack of the knowledge of diabetic foot problems. Multivariate logistic regression analysis indicated that never received diabetic foot education (OR 2.70 [95%CI 1.03-7.06], P=0.043) and lack of diabetic foot knowledge (OR 2.14 [95%CI 1.16-3.94], P=0.015) were independent factors for patients pre-hospital delay. Our study also showed that pre-hospital delay was an important risk factor leading to amputation (OR 2.22 [95%CI 1.36-3.64],P = 0.002) and mortality (OR 2.69 [95%CI 1.35-5.33],P = 0.005).
Conclusion: Long pre-hospital delay is most marked in those groups known to: no previous history, low socio-economic status, seldom performance of foot inspection, few follow up, never received diabetic foot education and lack of diabetic foot knowledge; and these delay is likely to be significant contributor to these poorer outcomes, lower extremity amputation and mortality. Considerations should be given to developing a community intervention program targeting at risk communities to encourage earlier assessment directed by the multidisciplinary team service, to reduce disparity and improve foot outcomes.

1253

The impact of impaired renal function on diabetic foot complications prediction: Should it be included on foot risk classifications?

M. Monteiro-Soares[1], D. Martins-Mendes[2,3], M. Dinis-Ribeiro[1], R. Guimarães[4], A. Távora[4], E. Lemos[4], J. Sobral[4], I. Duarte[4], J. Campos-Lemos[4], D. Brandão[4], M. Madureira[4], M. Ribeiro[4], M. Oliveira[4];
[1]CIDES / CINTESIS - Health Information and Decision Sciences Department (U753-FCT), Faculty of Medicine of the University of Porto, [2]Internal Medicine Department, Centro Hospitalar de Vila Nova de Gaia / Espinho EPE, Vila Nova de Gaia, [3]Dept of Biochemistry (U38-FCT), Faculty of Medicine of the University of Porto, [4]Endocrinology, Diabetes and Metabolism - Diabetic Foot Clinic, Centro Hospitalar de Vila Nova de Gaia / Espinho EPE, Vila Nova de Gaia, Portugal.

Background and aims: Impaired renal function is considered a powerful risk factor for diabetic foot complications; such as peripheral vascular disease (PVD), diabetic foot ulcer (DFU) and lower extremity amputation (LEA). Nevertheless, it was seldom assessed and never included in the diverse diabetic foot risk stratification systems (RSS). Thus, we aim to evaluate the role of impaired renal function in DFU development at 3 years.
Materials and methods: A retrospective cohort study was conducted on consecutive patients with diabetes without active DFU attending our Diabetic Foot Clinic from 01/2007 to 12/2009 [n=551, 47% male, mean age of 65 years (± 11), diabetes duration of 16 years (± 11) and HbA1c of 8% (± 2%); 98% had type 2 diabetes and 40% used insulin]. Baseline characteristics and all variables included in RSS were collected from the clinical file by one investigator. Subjects were followed for at least 3 years or until death. Clinical characteristics and outcomes' comparison was conducted between those with chronic kidney disease (CKD) stage 4 or 5 and the remaining subjects, using the 2013 American Diabetes Association (ADA) classification.
Results: Within a median follow-up of 36 months (range 1-36), 164 subjects (30%) developed a DFU, 33 (6%) required LEA and 75 (14%) died. Those with CKD stage 4 or 5 (n=26, 5%) were more frequently insulin treated, presented longer diabetes duration, physical impairment, foot deformity, diabetic peripheral neuropathy (DPN) using tuning fork and DFU or LEA history. Variables associated with DFU occurrence were older age, longer diabetes duration and higher HbA1c value; male gender; physical and visual impairment; CKD stage 4 or 5; presence of onychomycosis, foot deformity, DPN diagnosis [using Semmes-Weinstein monofilament (SWM) and tuning fork] and symptoms, PVD (diagnosed by pulses palpation), intermittent claudication, previous DFU and previous LEA. In multivariate analysis, only HbA1c value, physical impairment, foot deformity, SWM altered sensation, intermittent claudication and previous DFU maintained statistical significance. Neither considering estimated glomerular filtration rate as a continuous variable nor using different cut-offs of CKD stages [namely stage 5 (dialysis) vs remaining; stages 4 or 5 vs remaining or stage 0 or 1 vs stages 2 or 3 vs stages 4 or 5] an independent association with DFU was maintained.
Conclusion: So far, only 4 studies assessed nephropathy's impact on DFU risk without consensual results. This is the first study using the recently modified CKD's ADA classification and multivariate analysis adjusting the results for other relevant variables. We believe that nephropathy should not be included in foot RSS as it can potentially be a confounding variable. However, prospective studies in inception and larger cohorts should be conducted.

Diabetic foot and endothelial precursors cells (EPC): preliminary results of an Italian AIL (Italian Leukaemia Association section of Treviso) research project

S. Maria[1], E. Seganfreddo[1], A. Paccagnella[1], A. Furlan[2], F. Canal[3], A. Dei Tos[3], F. Gherlinzoni[2];
[1]Metabolic Unit, [2]Ematologic Unit, [3]Pathological Anatomy Unit, Santa Maria di Ca' Foncello Hospital, Treviso, Italy.

Background and aims: Reduction of peripheral mononuclear cells (PMNC) with surface cluster differentiation CD34+, CD133+ common to endothelial

precursor cells (EPC) characterize diabetic vascular complications. Myeloid calcifying cells (MCC) are involved in carotid placques in vitro but not in calcified vascular diabetic lower limb arterial lesions in vivo. Indeed ex novo KDR+ vasculogenesis and/or preexistent precursor cluster CD133+31+34- angiogenesis describe vascular homeostasis.
Materials and methods: We evaluate CD34+, CD133+, KDR+, CD31+, CD45- EPC by citofluorimetry in non coronaropatic patients with acute (timing restitutio until 6 weeks) or remote III-IV TUC diabetic foot lesions and its relationship with coexistent critical vascular calcification. Subject: 9 C controls and 54 type 2 diabetic patients with peripheral somato-sensory neuropathy (positive DNI): 15 N without foot lesions; 16 N1 and 23 NV with foot lesions without or with endovascular or by vascular surgery revascularized critical limb ischemia (CLI: oximetric value < 30 mm Hg).
Results: CD34+ were related with age (p< 0.03; R2=.45) only in C+N and were reduced in NV (239±31 mean± SE for 106 cell counts) versus N1 and C (p< 0.001). CD133+ were reduced in N, N1 and NV versus C (1857±254 mean± SE p< 0.03). In acute lesions, CD34+KDR+ and CD133+31+ were respectively significant reduced in NV and increased in N1 versus remote lesions and correlate with ABI (ankle brachial oscillometric index).
Conclusion: CD34+ peripheral precursor cells are consumed by age and this correlation is lost in diabetes with advanced complications. Neuropatic and vascular foot lesions determine different vasculogenic or angiogenic homeostasis in terms of KDR or CD31+133+ surface cluster pattern. This phenomenon has a rule in worse prognosis of medial distal arterial calcification. It remains to clarify if microvascular neuropathy precedes diabetic distal macroangiopathy.

Diabetic foot in patients on renal replacement therapy in Lleida health area (Spain)
V. Rosado[1], R. Pacheco[1], M. Doria[1], M. Hernández[1], B. Àngels[2], V. Maria[2], V. Joan[3], F. Rius[1], D. Mauricio[1];
[1]Endocrinology and Nutrition, [2]UDETMA, [3]Unit of Biostatistics, Hospital Universitari Arnau de Vilanova, Lleida, Spain.

Background and aims: To assess the prevalence of diabetic foot (DF) and associated conditions in patients with diabetes mellitus (DM) under renal replacement therapy in Lleida health care area (Spain).
Materials and methods: A cross-sectional study was performed between November 2010 and March 2011. All diabetic patients on dialysis (DL) in our health area were included. Electronic health records were reviewed and a podiatric exam was performed, including vibratory sensitivity with neurotensiometer, inspection for deformities, presence of diabetic foot ulcers (DFU) or lower extremity amputations (LEA). PEDIS classification was used for ulcer classification. Vascular assessment included ankle brachial index (ABI) and carotid ultrasound for the detection of atherosclerotic plaques and measurement of carotid intima-media thickness (IMT). Risk for DF was stratified following the international consensus on DF 2011 (IWGDF). Bivariate and multivariable analysis using logistic regression models were performed to evaluate potential risk factors associated with ulceration and amputation. The time between the start of DL and LEA was also documented.
Results: At the time of the study 92 patients (62% men) with DM (type 2 diabetes: 82%) followed DL treatment (35.8% of the total population in DL), with a mean age 70.9±12.1 years and a mean diabetes duration of 22.3±12.2 years. Mean DL duration was 4.8±4.3 years with 92.4% under hemodialysis treatment. Current or previous smoking was present in 43.5%, and 68.5% had dyslipidemia and 84% hypertension. Diabetic retinopathy (DR) was present in 62% of the patients (blindness: 12%), peripheral neuropathy in 89.1% and peripheral vascular disease in 64.8%. Prevalence of previous ischemic heart disease or stroke was 22.8% and 10.9%, respectively. Prevalence of former DFU was 19.6% and of current DFU was 17.4% (64% neuroischemic). 16.3% of patients had a previous LEA (70.4% minor amputations). Mean IMT was 0.90 ± 0.17mm and 92.5% of patients had non-stenosing carotid plaques (CP). Most patients (67.4%) had 2-3 IWGDF risk stratification. Bivariate analysis showed a relative risk (RR) of DFU of 6.84 for DR and 2.74 for stenosing CP (p < 0.001 and p = 0.05 respectively). RR of LEA was 3.94 (p=0.02) and 4.62 (p = 0.03) for DR and stenosing CP respectively. After multivariate analysis the association remained significant between DR and DFU or LEA (p = 0.004 and p = 0.013, respectively) and also between DR and LEA (p = 0.023). LEA were performed during the first year of DL in 18.8%, and after four years the percentage reached 50% of all LEA.
Conclusion: There is a very high prevalence of DFU in diabetic patients under renal replacement therapy and a high frequency of LEA after starting DL. Presence of DR and stenosing carotid plaques are the main risk factors for DF in these patients.

1256

Migratory activity of circulating endothelial progenitor cells predicts mortality in patients with diabetic foot
G. Spinetti[1], O. Fortunato[1], C. Specchia[2], E. Sangalli[1], S. Losa[1], G. Clerici[1], M. Caminiti[1], E. Faglia[1], P. Madeddu[3];
[1]IRCCS MultiMedica, Milan, [2]University of Brescia, Italy, [3]University of Bristol, UK.

Background and aims: Prediction of clinical outcome for patients with diabetic foot relies on clinical data. This prospective study investigates if the abundance and functional activity of endothelial progenitor cells (EPCs) predict adverse events, i.e. post-angioplasty restenosis, amputation, and death for cardiovascular causes.
Materials and methods: A consecutive series of 116 diabetic patients with critical limb ischemia (CLI, TASC guidelines) referring to the Diabetic Foot Centre for percutaneous angioplasty (PTA) were enrolled to the study. A blood sample (30mL) was obtained for isolation of mononuclear cells (MNCs). Cell migration was studied in a transwell system using SDF-1α (100ng/ml) as chemoattractant and vehicle as control. Freshly isolated and migrated/non-migrated EPCs were measured by flow cytometry of CD45dim/CD34pos/CXCR4pos/KDRpos cells. Time to event during the 12 months follow-up was defined as the time from patient's hospital admission to the occurrence of the adverse events. The association between basal EPC counts and migratory activity and the risk of an event was evaluated in a multivariable Cox regression analysis.
Results: Fourteen cardiovascular deaths out of 116 diabetic patients were observed during the 12 months follow up. Three occurred after restenosis and 1 after restenosis+amputation. The age and hematocrit (Ht) of patients died for cardiovascular causes were significantly higher than that of event-free subjects (age: 78±4 vs. 70±10 years, p=0.005; Ht: 39.4±2.8 vs. 36.5±5.0%, p=0.018). Percentages of EPCs did not differ in patients with event vs. no event. Surprisingly, the percentage of EPCs migrated towards vehicle (spontaneous migration) or SDF-1α (chemoactrattant-induced) were significantly higher in patients with cardiovascular death compared with event-free subjects (0.13±0.20 vs 0.04±0.06, p=0.018 and 0.08±0.11 vs 0.03±0.04, p=0.017 respectively). These results were confirmed in a multivariable regression model adjusted by age and Ht levels (HR=1.36, 95% CI 1.04 to 1.77, p=0.026 for EPC-vehicle and HR=1.49, 95% CI 1.06 to 2.08, p=0.02 for EPC-SDF). Given that EPCs have been expressed in log 2 scale, this means that for a doubling of these cell counts, the hazard of a cardiovascular death increases by 36% and 49%, respectively. Time to event analysis of restenosis (n=39) and restenosis+amputation (n=12) showed no significant association with the abundance and functional activity of EPCs.
Conclusion: Results newly indicate that unbalanced migratory activity of EPCs is significantly associated to a higher risk for cardiovascular mortality in patients with diabetic foot.

1257

Lower-limb risk factors for falls in those with and without diabetes mellitus
C. MacGilchrist[1], L. Paul[2], B.M. Ellis[3], T.E. Howe[4], B. Kennon[5], J. Godwin[4];
[1]School of Health Sciences, National University of Ireland, Galway, Ireland, [2]Faculty of Medicine, University of Glasgow, [3]The Graduate School, Glasgow Caledonian University, Glasgow, [4]Institute for Applied Health Research, Glasgow Caledonian University, [5]Centre for Diabetes and Metabolism, Southern General Hospital, Glasgow, UK.

Background and aims: Falls are more common in older people with Diabetes Mellitus (DM) than without. Particular lower-limb risk factors for falls have previously been identified in the DM population. This study aimed to identify if the specific lower-limb risk factors associated with falls in DM are different from age/gender matched controls.
Materials and methods: One-hundred and twenty participants over 55 years of age were recruited (n=60 DM; n=60 age/gender matched controls). 'Fall-

ers' were identified as individuals who self-reported at least one fall in the previous year. In addition to DM status and demographic information and the following risk factors generally associated with falls were assessed in all participants: neuropathy symptom score (NSS), neuropathy disability score (NDS) combined algorithm used to classify neuropathy, foot deformity score (FDS), Tinetti performance-oriented assessment of mobility (POMA). Ankle muscle strength: dorsiflexion (DF), plantarflexion (PF), inversion (IN) and eversion (EV), spatial and temporal gait parameters - an average of 3 passes along a 61cm x 366cm walkway [GAITRite© System]. Data from 'fallers' and 'non-fallers' across both control and DM participants were compared using t-tests and binary logistic regression analysis was performed to identify variables predictive of falls.

Results: Thirty-five percent (n = 21) of DM participants had fallen in the preceding year in comparison to 22% (n = 13) of controls. Higher levels of neuropathy existed in the DM group (67%) in comparison to controls (8%). In terms of 'fallers' 86% (n=18) of DM 'fallers' demonstrated neuropathy in comparison to 23% (n=3) of control 'fallers'. The FDS identified that 55% (n=33) of DM participants demonstrated significant foot deformity in comparison to 25% (n=15) of controls (p = 0.002). With regards to ankle muscle strength assessment, within the control group, 'fallers' displayed lower muscle strength values among control 'fallers' in comparison to control 'non-fallers' for all muscle groups assessed; p<0.001). 'Fallers' demonstrated lower muscle strength for all muscle groups assessed in DM and controls. Statistically significant differences were identified between DM and control participants in terms of velocity (p<0.001), double support left and right (p=0.006; p=0.009), step length left and right (p<0.001 bilaterally) and step time left and right (p=0.001, p<0.001). DM 'fallers' had lower walking velocity (p = 0.001), shorter step length left (p=0.002) and right (p=0.001) in comparison to control 'fallers'. Binary logistic regression analysis identified NDS, dorsiflexion strength and gait velocity to significantly contribute to the model and correctly classified 83.9% of cases overall.

Conclusion: Lower-limb risk factors for falls are similar between DM and controls. NDS, DF strength and gait velocity made a significant contribution to the model, and both these modalities were significantly compromised for 'fallers' in comparison to 'non-fallers', irrespective of DM status. These modifiable risk factors for falls should be specifically targeted in falls prevention in both DM and control populations.

Assessment of optimum transcutaneous oxygen pressure to predict diabetic foot ulcer healing and indicate angiography

J. Jirkovská[1], J. Venerová[1], J. Skibová[2], A. Jirkovská[2], L. Fialová[1], L. Vedralová[1], J. Faltová[1], S. Solař[1], M. Zavoral[1];
[1]Medical Department of the First Faculty of Medicine and Military University Hospital, Charles University, Centre of Diabetology, [2]Department of Diabetes, Institute for Clinical and Experimental Medicine, Prague, Czech Republic.

Background and aims: Peripheral arterial disease (PAD) is unquestionably one of the important factors relating to the outcome of a diabetic foot ulcer (DFU). Indication by angiography (AG) based on transcutaneous oxygen pressure measurement (TcPO2) can be useful in clinical practice. According to the international guidelines, the probability of healing based on TcPO2 is usually severely impaired when TcPO2 <30 mmHg, defined as critical limb ischaemia. However, the 40mmHg threshold can also be used for ischaemia detection. The aim of our study was to compare sensitivity of both 30 and 40mmHg TcPO2 thresholds to healing within 6 months as well as to angiographically verified stenosis.

Materials and methods: 53 consecutive patients with DFU and clinical suspicion of PAD treated at our foot clinic between February 2010 and October 2012 were included into the study. The primary outcome was the relationship between basal TcPO2 (measured in the beginning of the follow-up) and healing within 6 months according to the TcPO2 thresholds 30 and 40mmHg. In a subgroup of patients with AG, the sensitivity for TcPO2 levels ≤30 and ≤40mmHg to angiographically verified arterial stenosis were counted.

Results: 45/53 (84,9%) patients completed the 6 months follow-up. 25/45 (55,5%) patients with DFU were healed. Using multivariate stepwise logistic regression, the healed and unhealed groups differed significantly in CRP (11,915.0 vs. 41,644,4 mmol/l, p=0,012). There was significant difference in gender (64,7% healed men vs. 27,3% women, p=0,029). There was no difference in the other characteristics. Mean basal TcPO2 was higher in the healed group vs. unhealed (28,418,3 vs. 19,212,5mmHg, p=0,062). Regarding the primary endpoint, 15/32 (46,8%) patients with basal TcPO2≤30mmHg and 10/13 (76,9%) patients with basal TcPO2>30mmHg were healed (p=0,13 N.S.); 16/35 (45,7%) patients with TcPO2≤40mmHg and 9/10 (90%) patients with TcPO2>40mmHg were healed (p=0,033), respectively. Sensitivity to healing within 6 months was 85% (95%CI 62,1-96,8) for the 30mmHg TcPO2 threshold and 95% (95%CI 75,1-99,9) for the 40mmHg TcPO2 threshold, respectively. In a subgroup of 24 subjects. AG was performed with 22 percutaneous transluminal angioplasty (PTA). Subjects separated by TcPO2 30 vs. 40mmHg thresholds were comparable in number of PTA. Regarding the secondary endpoint, sensitivity of basal TcPO2 to angiographically verified stenosis was 86,7% (95%CI 65,1-97,1) for ≤30mmHg TcPO2 threshold and 90,9% (95%CI 70,8-98,9) for ≤40mmHg TcPO2 threshold.

Conclusion: Results of our study show that the basal 40mmHg TcPO2 threshold has higher sensitivity to DFU healing as well as to the indication of AG compared to the 30mmHg TcPO2 threshold. These data are in accordance with the trend of early vascular intervention in DFU with already mild signs of ischaemia.

The long-term outcomes of endovascular procedure in diabetic patients with critical limb ischaemia according to chronic kidney disease stage

G. Galstyan, O. Bondarenko, N. Ayubova, I. Sitkin;
Diabetic Foot Clinic, Endocrinology Research Center, Moscow, Russian Federation.

Background and aims: To evaluate outcomes after percutaneous transluminal angioplasty (PTA), and the relationship between calcification in tibial arteries and frequency of re-interventions and amputations in diabetic patients with critical limb ischemia(CLI) according to glomerular filtration rate (GFR).

Materials and methods: 93 diabetic patients with CLI were underwent percutaneous transluminal angioplasty of lower limb arteries. 45 patients were underwent non-contrast CT scanning of lower extremities to assess the level of tibial arteries calcification, calculated according to the modified Agatston system, which usually uses for scoring coronary calcium. Follow-up assessment included clinical examination for primary patency, limb salvage (LS) and common survival (CS). After interventional procedure duplex ultrasound (DU) surveillance was performed.

Results: The patients were divided into 2 groups, according to GFR (MDRD) (chronic kidney disease (CKD) 0-2 stage): A-with GFR>60 ml/min/1.73m^2 and B-with GFR<60 ml/min/1.73m^2 (CKD 3-5 stage). In group A were 48 patients (16 males), DM 1/2type -2/46, respectively; mean age-59,8±13,4 years, mean HbA1c -8,0±0,8%; myocardial infarction in anamnesis was in 9 patients (18%), stroke in 5(11%), retinopathy II-III stage was in 19(39%). In group B were 46 patients (22 males), DM 1/2 type - 17/29, mean age-58,9±14,2 years, mean HbA1c -7,9±1,15; myocardial infarction in 11(25%); stroke in12(22%); proliferative retinopathy in 28(61%).CKD obtained in groups A/B: stage 1(8/0), stage 2(14/0), stage 3(0/26), stage 4(0/3), stage 5(0/17).Severe neuropathy in groups A/B was diagnosed in 38(80%)/40(87%), respectively. Chronic limb ischemia according Rutherford classification in group A/B were: 8(16%)/16(35%)patients with 6 category, 28(58%)/30(65%) with 5 category, 12(26%)/4(9%) with 4 category. 21/24 patients from A/B groups were underwent non-contrast CT scanning. In patients with renal insufficiency the level of tibial arteries calcification by CT was significantly higher (8000±1450 vs. 3000±1230, p<0,05). The residual stenosis (>50% remaining diameter) was 12(25%)vs.35(76%)(p<0,05) in groups A/B. During 2-year follow-up 18(38%) in group A and 31(65%) patients in group B were obtained re-occlusions documented by DU (p<0,05). Repeat angioplasty was performed in 15(35%) vs. 22(47%) (p>0,05) patients in groups A/B. In group A vs. group B there were 1(2%)vs.6(13%)major amputations(log-rank, p<0,05); LS rate was 98%vs. 87%(log-rank, p<0,05); mortality was 0(0%)vs.7(15%),CS was 100%vs.85%(log-rank, p<0,05),respectively.

Conclusion: Extensive arterial calcification in diabetic patients with CLI due to CKD is associated with poorer outcome after PTA and high risk of amputations.

PS 109 Pregnancy: treatment, efficacy and safety

Effectiveness of metformin in gestational diabetes: systematic review and meta-analysis

M.O. Khin[1], M. Vatish[2,3], S. Gates[4], P. Saravanan[1,5];
[1]Division of Metabolic and Vascular Health, [2]Division of Reproduction, Warwick Medical School, University of Warwick, Coventry, [3]Women & Children's Unit, University Hospital Coventry & Warwickshire, Coventry, [4]Clinical Trials Unit, Warwick Medical School, University of Warwick, Coventry, [5]Department of Diabetes & Endocrinology, George Eliot Hospital, Nuneaton, UK.

Background and aims: Gestational diabetes (GDM) is a common condition and contributes to significant maternal and neonatal morbidity. The prevalence of GDM will triple, from ~5% to 16-18%, if universal screening and the new IADPSG (International Association of Diabetes and Pregnancy Study Groups) cut-off for diagnosis are adopted. Management of GDM is time and resource intensive. Because of the concerns of diluting the existing resources, these guidelines are not yet universally followed. Treatment involves dietary control, followed by insulin therapy if dietary control is ineffective. Oral hypoglycaemic agents, metformin or glibenclamide, are considered safe but used as second line to insulin and are not widely used. Glibenclamide has shown to be effective but does increase the risk of hypoglycaemia. In one large "non-inferiority", open label, randomised controlled trial (RCT) metformin was shown to be as effective as insulin but not routinely prescribed probably due to lack of superiority trials. We conducted a methodologically robust systematic review to evaluate whether metformin is superior over insulin or glibenclamide in GDM.
Materials and methods: Five databases were searched by two independent reviewers without any restriction along with hand searching of relevant references in the primary publications. All primary studies comparing metformin to insulin or glibenclamide and reporting maternal and neonatal outcomes of GDM were included. Nine studies compared with insulin (4 RCTs and 5 non-RCTs/NRCTs) and two RCTs with glibenclamide were identified. Quality assessment of the RCTs and NRCTs used separate risk of bias tools, in line with PRISMA and MOOSE guidelines.
Results: In the meta-analysis of RCTs with insulin, metformin appeared superior to insulin in preventing neonatal hypoglycaemia (odds ratio (OR): 0.67; 95% confidence interval (CI): 0.48,0.94) and minimising maternal weight gain (weighted mean difference (WMD): -1.80kg; CI:-2.57,-1.02). Similar effects were observed in the meta-analysis of NRCTs (neonatal hypoglycaemia: OR: 0.42; CI: 0.27,0.64; maternal weight gain: WMD: -1.77kg; CI: -1.91,-1.64), along with reduction in macrosomia (OR: 0.63; CI: 0.42,0.93) and neonatal intensive care admissions (OR: 0.57; CI: 0.40,0.82). Compared to glibenclamide, metformin reduces the risk of macrosomia (OR: 0.32; CI: 0.08, 1.19) and birth weight (WMD: -249.13g; CI: -355.88,-142.38). There are no differences in the risks of other outcomes.
Conclusion: Metformin in GDM appears to be superior to insulin and glibenclamide in a number of maternal and neonatal outcomes. Metformin is likely to improve the compliance and is less expensive compared to insulin. Therefore, using metformin as a first line therapy for GDM after diet and lifestyle might offer an effective strategy and less strain on the existing resources. This may also enable to manage more mothers with GDM if the new IADPSG guidelines are adopted. However, an adequately powered randomised controlled, superiority trial based on the IADPSG criteria, to demonstrate the differences in the key maternal and neonatal outcomes is urgently warranted.

Study of the safety and efficacy of the use of insulin and metformin in combination in gestational diabetes

D. ODonoghue[1], G. Adebayo[2], C.M. McHugh[2];
[1]Medicine, National University of Ireland, Galway, [2]Medicine, Sligo Regional Hospital, Sligo, Ireland.

Background and aims: Analogue insulin, NPH insulin and metformin have been shown to be safe in pregnancy. This study aims to determine the safety and efficacy of the use of insulin and metformin in combination in gestational diabetes.
Materials and methods: A retrospective observational study of all women diagnosed with gestational diabetes in a District General Hospital from 2008 to 2012. Women were screened using a 75 gm oral glucose tolerance test (OGTT) between 24 and 28 weeks gestation. A positive OGTT was defined as a fasting glucose >5.8mmol/L, 1 hour >10.0mmol/L and 2 hour >7.8mmol/L.
Results: 287 pregnancies with gestational diabetes during the study period with 3 foetal losses (27, 27, 31 weeks). There was no difference at baseline (antenatal booking) in mean body mass index (BMI, 30.54±0.43, p=0.16), systolic blood pressure(121±0.7,72±0.5mmHg, p=0.14), previous foetal losses (0.44±0.05, p=0.23), or maternal age (33.52±0.3 years, p=0.09). Diagnosis was made earlier in the metformin alone group (26.18±0.48 weeks, p=0.024) compared to the diet alone group (27.42±0.26 weeks). Diastolic blood pressure was lower at baseline in the diet alone compared to the metformin group (71.1±0.6mmHg vs 71.7±1.4mmHg p=0.001) and lower in the metformin compared to the insulin alone group (73.6±1.3 vs71.7±1.4mmHg, p<0.001). There was no difference in the mean Hba1c after 20 weeks gestation (p=0.7) in any group (insulin group was 5.61%±0.84, metformin 5.56±0.72%, insulin and metformin 5.68±0.1%, diet 5.47±0.18%. BMI at 32 weeks gestation was significantly higher in the metformin group than the diet groups (31.92±0.97, 30.64±0.58, p=0.001). There was no difference seen between any other groups. There was no difference between systolic BP at 34 weeks between the groups (p=0.054). Diastolic BP is higher in the metformin group compared to the insulin group (78.3±0.77,72.3±1.2, p<0.001) and compared to diet only (78.3±0.77, 73.83±0.75 p=0.001). There was a correlation between BMI and diastolic BP at 34 weeks (p=0.038, R^2 =0.031) in these groups on regression analyses. There was no significant difference in gestation at delivery (39.3±0.8 weeks p=0.22), birth weight (3.55±0.31kgs, p=0.64) or Apgar score at 0 or 5 minutes (8.78±0.6, 9.81±0.3, p= 0.58, p=0.14) between the groups. 47 received insulin alone ((12 received insulin glargine alone, 1 glulisine alone, 12 aspart alone, 6 glargine and glulisine, 13 glargine and aspart), 58 received metformin alone, 30 received metformin in combination with insulin and 154 were treated with diet alone). The mean total dose during pregnancy of metformin used in the metformin only group was 659.4 mgs/kg/day for 7.58 weeks and commenced at 31.29 weeks gestation. The mean total dose of metformin in the metformin and insulin group was 1123.67 mgs/kg/day for 8.22 weeks and commenced at 28.97 weeks gestation and the total dose of insulin used in this group was 4.16 units/kg/day of glargine, 4.5 units/kg/day of Aspart, 2.43 units/kg of Lispro and 0.79units/kg of Isophane for a mean of 7.41weeks and commenced at a mean of 30.91 weeks gestation. The mean total dose of insulin was 3.92 units/kg/day of glargine, 6.43 units/k/day of glulisine, 6.54 units/kg/day of aspart for 6.67 weeks, commenced at 31.94 weeks gestation.
Conclusion: This study shows the non-inferiority of insulin in combination with metformin in foetal and maternal outcomes. It also demonstrates the link between maternal BMI and diastolic blood pressure during pregnancy.

Breaking down misclassifications: not all gestational diabetes needs treatment as not all children need insulin

D. Iafusco[1], A. Napoli[2], G. Balbi[3], N. Tinto[4], L. Sacchetti[4], C. Giuliani[2], O. Bitterman[2], V. Rozzi[2], A. Zanfardino[1], F. Stoppoloni[1];
[1]Department of Pediatrics, Second University of Naples, [2]Department of Clinical and Molecular Medicine, Sant'Andrea Hospital, Sapienza University, Rome, [3]Department of Obstetrics and Gynecology, Second University of Naples, [4]CEINGE-Federico II University, Naples, Italy.

Background and aim: The new criteria suggested by the HAPO Study for the diagnosis of gestational diabetes determinated a doubling of the pregnant women diagnosed with this disease. Not all the gestational hyperglycemias have the same etiology, as demonstrated in pediatric diabetology where, before the discover of the existence of monogenic forms of not autoimmune diabetes, all patients with hyperglycaemia were classified as "type 1 diabetes" and treated with insulin. The objective of the present study was to distinguish the diseases on yet by their phenotypes but by their pathogenesis providing a "*taylored medicine*".
Materials and methods: Two hundred and sixty four women with gestational diabetes for HAPO study criteria (fasting glycemia ≥ 92 mg/dl, and/or OGTT T60 ≥ 180 mg/dl and/or T120 ≥ 153 mg/dl) were recruited. 110 were overweight or obese (BMI >25) and were excluded by the study because patients with monogenic diabetes have low levels of insulin and generally are not overweight. One hundred and fifty four women had normal weight and continued to be enrolled. Gynecologist and Diabetologist treated all the women with low amount of CHO diet and/or insulin if the glycaemic control was not

obtained. We have typed for MODY-2 and MODY-1 mothers who gave birth newborns with birthweight <2.500 Kg and their children.
Results: The women who gave birth newborns with birthweight <2.500 Kg were 5/154 (3.24%) and were all positive for mutation for monogenic, autosomic dominant, diabetes: four with heterozygous mutation of the GCK gene (MODY-2) and one for HNF4alpha gene (MODY-1). All the newborns were heterozygous for the same mutation of their mother.
Conclusions: The treatment of a mother affected by MODY2 or 1 is the same of a mother with gestational diabetes to avoid the birth of a LGA child, due to the maternal hyperglycemia. It's far different if both mother and child carry a MODY2 mutation: in this case the inborn has a poor insulin secretion that, if not increased by the exposure to maternal higher glycaemic levels, may determinate a Small for Gestational Age (SGA) baby. Intra uterine growth of the fetus has to be investigated by familial anamnesis to suspect monogenic diabetes. We are confident that wider research of monogenic diabetes in pregnancy will avoid not necessary and sometimes *dangerous* therapies. This is the real *cutting edge* perspective of the modern medicine that has to pull down the categories in order to *tailor* the therapy on the patients and not on their disease.

1263

Preliminary data on pregnancy outcome of diabetic mothers treated with basal insulin lispro-protamine in a multicentre study in northeast of Italy

M. Dalfrà[1], A. Filippi[1], A. Soldato[1], P. Moghetti[2], S. Lombardi[3], C. Vinci[4], T. Romanelli[5], A. Lapolla[1];
[1]Medicine, University of Padova, [2]Medicine, University of Verona, [3]UO Diabetologia, ULSS5, Montecchio Maggiore(VI), [4]UO Diabetologia, ULSS10, Noventa di Piave (TV), [5]UO Diabetologia, Azienda ULSS Trento, Italy.

Background and aims: The occurrence of gestational diabetes or pre-gestational diabetes worsen maternal-fetal outcomes in terms of morbidity-mortality.Insulin treatment could improve glycemic control and pregnancy outcome. Aim of the study is to evaluate pregnancy outcome in women affected by type 1, type2 or gestazional diabetes treated during pregnancy with Insulin LisproProtamine(L-P) .
Materials and methods: 606 women treated with L-P basal insulin were retrospectively evaluated and compared with a control groups(793women) treated with NPH basal insulin. The results are shown in table1.
Results:

	GDM		Type 1		Type2	
	L-P (508)	NPH (125)	L-P (37)	NPH (504)	L-P (67)	NPH (164)
Age (yrs)	36.3 (16.2)	24.9 (4.7)	35.5 (4.4)	29.9 (4.8)	33.2 (5.6)	33.2 (4.8)
Prepregnancy BMI	27.2 (6.0)	26.0 (6.7)	24 (6.0)	23.3 (3.4)	28.7 (5.7)	28.1 (6.4)
Pregnancy hypertension(%)	6.9	6.9	8.1	12.8	8.9	9.4
Cesarean section(%)	48.7	48.8	46	73	46.5	69.3
Birthweight (G)	3295 (558)	3423 (533)	3550 (743)	3300 (670)	3235 (820)	3200 (760)
Macrosomia (%)	5.3	6.9	21	13.3	8.9	11.9
Congenital malformation(%)	0	0	0	5.9	0	1.9
Ketoacidosis (%)	0	0	0	5.4	0	0
Severe hypoglycemia(%)	0	0	5.4	15	1.5	1.3

HbA1c improved in the same way in both prepregnancy diabetic groups during pregnancy from 7.46% in preconception period to 7.1% in the 1st trimester,6.5% in the 2nd trimester and 6.4% in the 3rd trimester in type 1 L-P treated diabetic mothers, from 7.5% to 7.2,7.2,6.4 in NPH group ; in type 2 women from 6.7% in preconception period to 6.4 in 1st trimester,5.8 in the 2nd trimester and 6.2 in the 3rd trimester in L-P group and from 6.6% to 6.1,6.4,5.7 in NPH group. A reduction in severe hypoglycemic events and ketoacidosis in L-P treated type 1 women was found. In GDM group maternal anf fetal outcome was not different. In type 1 and type 2 L-P groups a lower frequency of cesarean Section was observed with respect to NPH: Macrosomia was not significant higher in type 1 L-P group with respect to NPH ones but was lower in type 2 group
Conclusion: Our preliminary data suggest that the use of insulin lispro-protamine to be safe and effective in pregnancy.

Insulin treatment in women with gestational diabetes mellitus: Is there a label effect on delivery characteristics?

D. Tundidor, A. García-Patterson, M.A. María, J. Ubeda, J.M. Adelantado, A. de Leiva, R. Corcoy;
Hospital de la Santa Creu i Sant Pau, Barcelona, Spain.

Background and aims: Maternal diabetes mellitus is associated with spontaneous preterm birth and abnormal myometrial contractility. On the other hand, the "label" of gestational diabetes mellitus (GDM) has been associated with an unexplained rate of cesarean delivery (CS) in some series. We aimed to evaluate delivery characteristics in women with GDM in relation to insulin treatment.
Materials and methods: We conducted a retrospective cohort study of all singleton pregnancies of women with GDM progressing to >22 weeks and delivering in a tertiary care center between 1986 and 2008. Potential predictive variables included anthropometrics, obstetric history, GDM diagnosis characteristics (gestational age, blood glucose values) , HbA1c (after diagnosis and in the third trimester) and insulin treatment. Outcomes variables were gestational age at delivery, preterm birth (total/ spontaneous/ induced), elective delivery and cesarean section. Statistics: descriptive, bivariate and multiple logistic regression analysis (backwards method).
Results: A total of 2302 pregnancies were included. Insulin treatment was used in 48.4% pregnancies and the results of outcome variables were as follows: gestational age at delivery 39 (38, 40) weeks, 10% preterm birth, 5.3% spontaneous preterm births, 31.3% elective deliveries and 24.4% cesarean sections. In women receiving insulin treatment, baseline maternal characteristics and glycemic control were more unfavourable. As to delivery characteristics in women receiving insulin treatment vs those without were as follows: gestational age at delivery 38.6 vs 38.8 weeks, p <0.05; preterm birth 11.2 vs 8.9%, p <0.05, spontaneous preterm birth 5.5 vs 5.1%, elective delivery 34.3 vs 28.6%, p <0.05 and CS 26.7 vs 22.4%, p <0.05. After adjustment for othe potential predictors, the logistic regression analyses revealed an independent negative association between insulin treatment and preterm birth (OR 0.583 , CI95 0.373, 0.913) and spontaneous preterm birth (OR 0.411, CI95 0.228, 0.745), a positive association with elective delivery (OR 1.293, CI95 1.034, 1.618) and no significant association with iatrogenic preterm birth or CS.
Conclusion: In these women with GDM, insulin treatment did not have a consistent label effect on delivery characteristics. Contrariwise, insulin treatment was associated with a protective effect against spontaneous preterm labour, independent of other predictors.

1265

Type 1 diabetes and pregnancy: continuous subcutaneous insulin infusion systems versus multiple daily injection therapy

J. Saraiva[1], S. Paiva[1], L. Ruas[1], L. Barros[1], C. Baptista[1], M. Melo[1], M. Alves[1], S. Gouveia[1], C. Moreno[1], D. Guelho[1], E. Marta[2], L. Gomes[1], P. Moura[2], F. Carrilho[1];
[1]Serviço de Endocrinologia [2]Serviço de Ginecologia e Obstetrícia - Centro Hospitalar e Universitário de Coimbra, Portugal.

Background and aims: Intensive insulin therapy through multiple daily doses of insulin (MDI) or subcutaneous insulin infusion (CSII) contributes to obtain good metabolic control and thus decrease the risk of maternal and fetal complications during pregnancy in DM1. This study aims to evaluate and compare the CSII and MDI therapy during pregnancy.
Materials and methods: Retrospective analysis of data of pregnancies in women with type 1 diabetes followed in Endocrinology-Obstetrics Department since 2005 treated with CSII and MDI. We evaluated metabolic control (A1C), maternal and fetal outcomes. Statistical analysis program SPSS 18.0 was used.
Results: We followed 18 pregnant women (19 pregnancies) treated with CSII and 65 with MDI, mean age 30.4±4.3years and 29.3±4.6years, respectively. Mean duration of diabetes 17±6.7years, with CSII, and 11.7±6years with MDI (p=.006). The pre-conception counseling was higher in the group with CSII (84.2% versus 51.6%, p=.02). No differences were observed in diabetic chronic complications (nephropathy and retinopathy). Prepregnancy A1C was

similar in both groups (8%±1.5 in pump group and 7.9%±1.5 in MDI). The metabolic control was similar in the 2 groups, except for the 2nd trimester, when a significant improvement in the pump group was observed (7.1%±0.8 versus 7.3%±1.2, 6.2%±0.5 versus 6.7%±1, 6.7%±0.7 versus 6.6%±1). The pregnancy-induced hypertension was higher in pregnant women with pump (27.8% versus 5.3%, p=.007), the occurrence of preeclampsia was similar. Preterm delivery occurred in 52.6% of pregnant women with CSII versus 27.9% with MDI (p=.045). The percentage of caesarean sections was high in both groups and related to the longer duration of diabetes (p=.01); CSII 73.7% versus 60.7% (p=ns). Birth weight did not differ between groups (3563g±675 versus 3514g±513). Birth weight >4000g occurred in 26.3% in the pump group versus 13.1% (p=ns). These differences remained regardless of the duration of diabetes. The morbidity and neonatal malformations were similar in both groups.
Conclusion: These data show that the metabolic control and fetal prognosis did not differ significantly with these two modalities of intensive insulin therapy. Both were effective in improving maternal glycemic control. However pregnancy-induced hypertension and preterm delivery were higher in women with CSII. The use of infusion pump in pregnancy should be decided on an individual basis taking into account not only the glycemic balance as well as other factors that may determine the maternal-fetal prognosis.

1266

Real-time continuous glucose monitoring in pregnant women with type 1 diabetes at high risk of severe hypoglycaemia
E.R. Mathiesen[1,2], A.L. Secher[1,2], E. Stage[3], L. Ringholm[1], C. Barfred[3], P. Damm[3,2];
[1]Department of Endocrinology, Center for Pregnant Women with Diabetes, Rigshospitalet, [2]Faculty of Health and Medical Sciences, University of Copenhagen, [3]Department of Obstetrics, Center for Pregnant Women with Diabetes, Rigshospitalet, Copenhagen, Denmark.

Background and aims: Severe hypoglycaemia occurs in up to 45% of pregnant women with type 1 diabetes, especially before 20 gestational weeks and in women with a history of severe hypoglycaemia. Given severe hypoglycaemia the year prior to pregnancy, 70% of the women followed in our center also experience severe hypoglycaemia during pregnancy, and these women can therefore be selected as women at specifically high risk of severe hypoglycaemia during pregnancy. The aim of this study was to evaluate whether continuous use of real-time continuous glucose monitoring (CGM) prevents severe hypoglycaemia in this subpopulation of women at specifically high risk of severe hypoglycaemia in pregnancy.
Materials and methods: In the study period of February 2011-November 2012, pregnant women with type 1 diabetes at estimated high risk of severe hypoglycaemia were offered initiation of continuous real-time CGM (Guardian® Real-time Continuous Glucose Monitoring System mainly with the Enlite Sensor; Medtronic Minimed) from early pregnancy on. A questionnaire on real-time CGM alarms and satisfaction was collected median 3 (range 1-7) times during the intervention period. Episodes of severe hypoglycaemia were recorded prospectively. Pregnancy outcomes were collected from hospital records.
Results: Continuous real-time CGM was initiated in 11 (8%) of 140 referred pregnant women with type 1 diabetes, all 11 with episodes of severe hypoglycaemia either before pregnancy (n=10) or early in the current pregnancy (n=1). HbA1c at first pregnancy visit was 6.7% (5.8-11.5) (IFFC 50 (40-102) mmol/mol) and the duration of diabetes was 13 (6-21) years. Nine women were on multiple daily injections and two women were on insulin pump therapy. Real-time CGM was used from 10 (6-18) gestational weeks for 11 (3-32) weeks and was generally well-tolerated. The real-time CGM hypoglycaemic alarm was set at 3.8 (3.0-4.5) mmol/l and these alarms occurred 11 (1-38) times weekly, whereof 4 (1-12) during night time. From onset of real-time CGM to 38 (32-39) gestational weeks, two (18%) women experienced one episode of severe hypoglycaemia each. Firstly, one woman had a severe hypoglycaemic event at 18 gestational weeks during ongoing real-time CGM, but the sensor did not alarm for hypoglycaemia. Secondly, another woman experienced severe hypoglycaemia at 22 gestational weeks after termination of real-time CGM. Real-time CGM was reinitiated without any additional severe hypoglycaemic event until now (32 gestational weeks). As of April 3rd 2013, 10 women have given birth at 38 (34-39) gestational weeks to 10 infants weighting 3,548 (2,516-4,248) grams.
Conclusion: In this subset of women with type 1 diabetes at specifically high risk of severe hypoglycaemia during pregnancy, continuous use of real-time CGM seems to be an efficient tool in preventing these episodes.

1267

Serum levels of the myokine and adipokine irisin are decreased in pregnancies complicated by preeclampsia
S. Kralisch-Jäcklein[1,2], J. Richter[1], H. Stephan[3], J. Hindricks[1,2], A. Jank[3], W. Schaarschmidt[3], S. Schrey[3], U. Lössner[1,2], B. Jessnitzer[1], M. Blüher[1,2], M. Stumvoll[1,2], M. Fasshauer[1,2], T. Ebert[1,2];
[1]Department of Endocrinology and Nephrology, University Leipzig, [2]IFBAdiposityDisease, Leipzig, [3]Department of Obstetics, University Leipzig, Germany.

Background and aims: Preeclampsia (PE) is a serious cardiovascular complication in pregnancy which is associated with an increased life-time metabolic and cardiovascular risk for mother and newborn. Irisin has very recently been introduced as a novel myokine and adipokine that drives brown-fat-like conversion of white adipose tissue, reverses obesity, and improves glucose metabolism in mice. Therefore, we investigated circulating levels of irisin in women with and without preeclampsia during pregnancy and after delivery.
Material and methods: We measured serum irisin levels in patients with PE (n=51) as compared to healthy, age-matched controls (n=51) during and 6 months after pregnancy. Furthermore, association of irisin with markers of renal function, glucose and lipid metabolism, as well as inflammation, was elucidated in all individuals.
Results: Median maternal irisin serum concentrations adjusted for body mass index and gestational age at blood sampling were significantly, almost 1.4-fold decreased in PE patients (499.3 ng/l) as compared to healthy, age-matched pregnant women (668.8 ng/l) ($p < 0.001$). Furthermore, irisin concentrations were independently correlated with low density lipoprotein (LDL) cholesterol in pregnant women. Interestingly, median irisin serum concentrations adjusted for body mass index remain significantly 1.4-fold decreased in former PE patients (266.8 ng/ml) compared to healthy controls (372.6 ng/ml) 6 month after pregnancy. Furthermore, multiple regression analysis showed that PE, time between delivery, and systolic blood pressure (SBP) were independent variables influencing serum irisin levels at 6 months postpartally (p=0.001). Moreover, irisin serum levels significantly decreased more than 2-fold in former pregnant women (614.7 ng/ml) to 6 months after pregnancy (291.8 ng/ml) ($p < 0.001$) in the study population in which pre- and postpartal serum specimens were available.
Conclusion: Maternal irisin serum concentrations are significantly decreased in PE during and 6 month after pregnancy. Furthermore, LDL cholesterol is an independent predictor of circulating irisin in pregnant women, while PE, time between delivery, and SBP were independent associated with irisn serum levels 6 month after pregnancy suggesting that irisin may play a crucial role in future metabolic and cardiovascular risk after pregnancy complicated by preeclampsia.

GDm-Health: telehealth for remote monitoring and treatment of gestational diabetes
L. Loerup[1], O.J. Gibson[1], J.E. Hirst[2], A.J. Farmer[3], K. Bartlett[2], J.E. Blincowe[2], Y.M. Kenworthy[2], D.A. Kevat[2], L.H. MacKillop[2], L. Tarassenko[1], J.C. Levy[2];
[1]Institute of Biomedical Engineering, [2]Oxford University Hospital NHS Trust, [3]Department of Primary Care Health Sciences, University of Oxford, UK.

Background and aims: Widening screening criteria, lowering diagnostic thresholds and underlying demographic changes threaten to overwhelm resource-limited services for women with gestational diabetes mellitus (GDM). We have developed a mobile phone-based telehealth system (GDm-Health) with the aims of supporting treatment of GDM, reducing clinic visits, improving response time to abnormal BG readings and increasing women's satisfaction with the care they receive. This pilot study aimed to demonstrate the feasibility of the GDm-Health system in clinical practice, to assess blood glucose (BG) control and user satisfaction and to inform the design of a randomised controlled trial of the technology.
Materials and methods: Pre- and post-meal BG results are transferred wirelessly in real-time from a blood glucose meter to a smartphone app (where they can be annotated by the patient) and then to a server. The data are tabulated and presented on both the server and the smartphone in graphical formats with out-of-target colour codes. Diabetes specialist midwives and doctors review the automatically-prioritised data and recommend dose changes by text messages or phone calls. Women can request a call from their

care team to discuss their diabetes, which the diabetes midwife can schedule around her other tasks. The technology has been used by 50 women with GDM from two Oxfordshire hospitals.
Results: To date, 41 women have finished using the system, all of whom have had live births. 15,609 BG results have been transmitted. The women tagged 98% of these readings with annotations indicating whether they were taken before or after a meal. Free text comments from the women about diet and other factors were attached to 16% of the readings. The clinical care team sent 403 text messages to the women, including 110 medication adjustments. Initial prescriptions of metformin or insulin were given in clinic but dose adjustment to manage the progressively rising glucose levels were also given by phone in response to regular inspection of the automatically-prioritised results. Women made 56 requests for calls from their diabetes midwife, primarily to obtain prescriptions, lancets and strips (39% of calls) or discuss their diet and medication (18%). Of 32 women who have returned questionnaires to date, 31 (97%) agreed that the system was convenient (27 strongly agreed) and 31 women (97%) agreed that the method of monitoring fitted with their lifestyle (20 strongly agreed). All 32 women reported a good relationship with their diabetes care team.
Conclusion: The GDm-Health system allowing remote delivery of care works well in clinical practice and has been positively received by patients and healthcare professionals. A randomised controlled trial will be conducted to establish whether its use can maintain effectiveness while improving quality and efficiency of care, with fewer clinic visits and time and cost savings for both patients and the health service.

PS 110 Pregnancy outcomes in GDM

1269

Pregnancy outcome in gestational diabetes mellitus compared to the Swedish birth register
C. Nilsson[1], D. Ursing[2], H. Strevens[3], M. Landin-Olsson[4];
[1]Department of Pediatrics, Institution of Clinical Science, Helsingborg, [2]Department of Endocrinology, [3]Department of Obstetrics and Gynecology, Institution of Clinical Science, Lund, [4]Department of Endocrinology, Institution of Clinical Science, Helsingborg and Lund, Sweden.

Background and aim: Gestational diabetes mellitus (GDM), depending on the population studied, affects 1-14% of all pregnant women. In Sweden 2% of pregnancies are complicated by GDM. GDM is often more common in populations with a high frequency of type 2 diabetes, and it is well known that women with GDM have a substantial risk of developing type 2 diabetes later in life, but the risk of developing type 1 diabetes is also increased. Known risk factors for developing GDM are higher age, overweight, and heredity for diabetes. It is of general belief that an intrauterine environment complicated by maternal diabetes increases the risk for overweight and obesity in the offspring. However, overweight among women with GDM per se can also increase risk for overweight and obesity in their offspring. The aim of this study was to compare pregnancy outcome of GDM pregnancies against Swedish general population pregnancies, from the Swedish Birth Register.
Materials and methods: In our region in Sweden, all pregnant women are tested with a 2-hour oral glucose tolerance test (OGTT) consisting of 75 g glucose in solution as a general screening for GDM in the 28th gestational week. The cut off value for GDM in Sweden is ≥10.0 mmol/l in capillary plasma glucose and is based on the European Association for the Study of Diabetes (EASD) recommendations. Women who receive a GDM diagnosis are transferred to our specialised maternity unit with a team of obstetrician, diabetologist, midwife and dietician. Between 2000 and 2010 we had 704 women with at least one GDM pregnancy. The women's medical journals from their GDM pregnancy were studied retrospectively and the data was compared to all pregnancies (n=1102729) in the Swedish Birth Register from this time period.
Results: Age of the mother was 32yrs ±5.5 (n=704) in GDM pregnancies and 30yrs ±5.2 (n=1099161; p=<0.0001) in the general population. First weight of the mother during GDM pregnancy was significantly higher than the weight of the general pregnant women, 72.9 kg ±17.5 (n=688) and 68.0 kg ±13.2 (n= 990604; p=<0.0001) respectively. However, there was no significant difference in weight of the mother at delivery. For women with GDM weight at delivery was 82.63kg ±17.2 (n=602) and for the general population 81.9 ±14.1 (n=366046; p=NS). Birth weight of the child in GDM pregnancies was 3468.8g ±546.4 (n=708) and for the general population 3520.1g ±591.2 (n=1112381; p=0.02). Gestational length in GDM pregnancies was 38.8weeks ±2.4 (n=652) compared to 39.3weeks ±2.0 (n=1114513; p=<0.0001). The percent of caesarean delivery was 21% in the GDM pregnancies and 17% of the general population (p<0.005).
Conclusion: Even though women with GDM have a higher initial weight during pregnancy, there was no significant difference in weight at delivery compared to the general population. This is probably due to a combination of intense dietary advice at our clinic to achieve good metabolic control during pregnancy and shorter duration of the pregnancy. The higher frequency of caesarian section terminates the pregnancies earlier and birth weights of the newborns were similar in our patients compared to the general population in Sweden. The prevention of large infants is crucial to avoid complications during delivery.

Maternal prepregnancy body mass index but not gestational diabetes determines postnatal growth from birth to 4 years
P. Gil-Lluís, R.E. Yañez, S. Näf, G. Llauradó, M. Ballesteros, J.J. Vendrell, A. Megía;
Hospital Universitari Joan XXIIII. IISPV. Universitat Rovira i Virgili. CIBERDEM, Tarragona, Spain.

Background and aims: Maternal hyperglycaemia and obesity determine in utero environment and have been associated with postnatal overgrowth. Some controversy exists about the capacity of gestational diabetes (GDM) treatment to mitigate such. The aim of the study was to analyse the influ-

ence of GDM and prepregnancy body mass index (BMI) on birth weight and postnatal growth in a cohort of children born to GDM and normal glucose tolerant (NGT) women.
Materials and methods: This is a longitudinal study in which we analyzed postnatal growth in infants born to women with GDM and NGT and who were delivered between January 2006 and February 2009. Their mothers were recruited during pregnancy and outcome data were recorded prospectively in a database. Postnatal weight and height were also recorded. We analysed maternal age, prepregnancy body mass index, BMI gain during pregnancy, gestational week of delivery, glucose tolerance status, neonatal sex, birth weight and length. From an initial cohort of 484 children, in this study we included 243 children whose weight and height were recorded at birth and at 6, 12, 24 and 48 months. Weights and BMIs were transformed into a Z Score using gender-specific references of children's growth. Student's t-test, the chi-square, ANOVA and ANOVA of repeated measures were used to evaluate differences between groups.
Results: Ninety-two infants born to GDM and 151 born to NGT women were included in the study. No differences were observed in birth weight and in postnatal growth between infants born to GDM compared to those born to NGT women. According to maternal prepregnancy BMI, children were divided in three groups: 140 infants in the normal weight group (<25), 61 in the overweight group (25 to <30) and 42 in the obesity group (≥30). Gender distribution (p=0.727) and glucose tolerance status (p=0.284) were similar among the three groups. BMI gain at the end of pregnancy, birth weight, birth weight Z score and birth BMI Z score were significantly different among groups (p<0.01 for all). BMI gain was lower in the obesity group compared to the normal weight group (p<0.05), whereas neonates born to obese mothers were significantly heavier than those born to normal weight and overweight mothers (p<0.05). No differences among the groups were observed in weight and BMI Z Score at 6 and 12 months, but they were significantly different at 24 and 48 months' evaluation (p<0.01). Children born to obese mothers were significantly heavier than those born to normal weight women at 24 (<0.05) and at 48 months (p<0.01) months. These differences persisted after adjusting for glucose tolerance status and BMI gain during pregnancy. See figure 1.
Conclusion: The offspring of treated GDM women have similar postnatal growth compared to those born to NGT women, whereas maternal pregnancy BMI is an independent determinant of birth weight and postnatal growth.

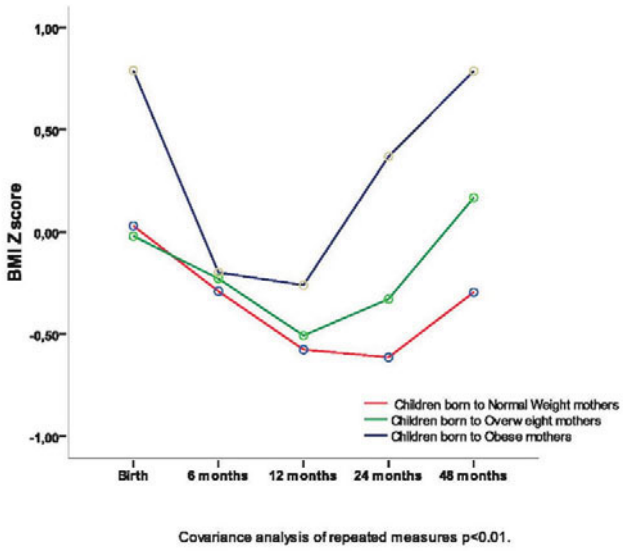

Figure 1. Postnatal BMI Z score according to prepregnancy maternal weight adjusted for glucose tolerance status and BMI gain during pregnancy.

Effects of prepregnancy weight on foetal growth in patients with well controlled gestational diabetes mellitus

G. Perez Lopez[1], A. Becerra Fernandez[2], R. Villar[3], L. Yus Lopez[1], M. Menacho Roman[4];
[1]Endocrinology Unit, Hospital Comarcal de Melilla, [2]Endocrinology, Hospital Universitario Ramón y Cajal, [3]Endocrinology, Hospital Universitario de Fuenlabrada, [4]Clinical Biochemistry, Hospital Universitario Ramón y Cajal, Madrid, Spain.

Background and aims: The relative impact of prepregnancy body mass index and maternal glycemia during pregnancy on adverse maternal and perinatal outcomes is difficult to tease apart. Moreover, excess gestational weight gain complicates a large number of pregnancies and is highly correlated with maternal overweight and obesity, as well as the development of Gestational Diabetes Mellitus. Many studies examining the effects of maternal obesity and/or glucose levels have not accounted for this important factor. The aim was to determine effect of prepregnancy weight on the risk of fetal macrosomia in women with well controlled gestational diabetes mellitus (GDM) attending in Outpatient Endocrinology Clinic
Materials and method: Retrospective cohort study of the association of prepregnancy weight in women with well controlled GDM and term (≥37 weeks) singleton live borns and macrosomia (birthweight ≥4000 g) between January and December 2012. Anthropometric and analytical variables were determined for each patient, including body mass index (BMI), HbA1c and thyroid function. Multivariate logistic regression models were used to adjust for covariates and test for interactions.
Results: Of 150 women studied, the mean HbA1c (±standard deviation) was 6.1% ± 0.3. Prepregnancy body mass index (BMI) categories were: normal (39.6%), overweight (28.5%) and obese (31.9%). The mean (±standard deviation) weight gain (kg) for these groups was: 12.5 ± 4.9, 11.0 ± 5.9 and 8.5 ± 7.1 (P<0.0001), whereas the occurrence of macrosomia was 8.3, 12.5 and 21.2%, respectively. Women with an obese BMI were twice as likely to have a macrosomic infant compared with women in the normal BMI group (odds ratio, OR 2.0; 95% CI 1.4-3.0; P<0.005). Independently, women who exceeded recommended gain weight during pregnancy were two times more likely to have a macrosomic infant (OR 2.5, 95% CI 2.2-3.1 , P<0.0001).
Conclusion: Maternal prepregnancy weight and weight gain during pregnancy appear to be significant and independent risk factors for macrosomia in women with well controlled GDM

1272

Maternal glucose levels in early pregnancy, gestational diabetes, prepregnancy BMI and the risk of childhood obesity: the mother child cohort, RHEA study in Crete, Greece

L. Chatzi[1], M. Karachaliou[1], V. Daraki[1], V. Georgiou[1], S. Koinaki[1], G. Chalkiadaki[1], A. Pappas[2], M. Kogevinas[3];
[1]Department of Social Medicine, Heraklion, [2]Diabetes Center, Venizelio Hospital, Heraklion, [3]National School of Public Health, Athens, Greece.

Background and aims: Obesity in childhood is indicated to have its origin in early life. A hypothesis is that hyperglycaemic environment in utero, apart from leading to f0etal hyperinsulinaemia and increased growth, may also programme biological regulatory mechanisms with long term effects in offspring, like increased risk of overweight and obesity. Many studies, in diverse populations, have examined the association between maternal hyperglycaemia/gestational diabetes mellitus (GDM) and childhood body size in different ages, but the results are not conclusive. The aim of this study was to assess the associations of maternal glucose and insulin levels in early pregnancy, GDM, and prepregnancy BMI with the risk of obesity in offspring at 4 years of age.
Materials and methods: The mother-child "Rhea" study in Crete is a prospective cohort examining pregnant women (Greek and immigrants) residents at the prefecture of Heraklion that became pregnant during one year starting in February 2007. Eight hundred sixty three (863) mother-child pairs, were available for the present analysis after excluding twin pregnancies and women with pre-gestational diabetes. Maternal fasting serum samples were collected at the time of the first major ultrasound (Mean: 12 weeks, SD: 1,5). Insulin sensitivity was calculated by a homeostasis model assessment approach (HOMA index). Pregnant women were screened for GDM between 24 and 28 weeks of gestation, and GDM was defined by the criteria proposed by Carpenter and Coustan. Weight, height, abdominal circumference, and thickness

of triceps, subscapular, suprailiac, and subscapular were measured at 4 years of age. Multivariable linear and log-binomial regression models were used to estimate the effect of maternal glucose and insulin levels in early pregnancy, and GDM on the risk of obesity in preschool children after adjusting for maternal age, education, parity, and pre-pregnancy BMI.
Results: The most prominent risk factor for childhood obesity was maternal pre-pregnancy BMI. Maternal obesity prior to gestation increased significantly the risk of overweight/obesity in preschool children (RR: 1.7, 95% CI: 1.2-2.5), while almost doubled the risk of abdominal obesity (waist circumference >90th percentile: RR: 2.1, 95% CI: 1.3-3.3). An elevation of 20 mU/ml in fasting insulin levels in early pregnancy was associated with elevated levels of fat mass as measured by the sum of skinfolds measurements (b coef 0.9, 95%CI 1.3-4.4), while a per unit increase in HOMA index was associated with increased fat mass (b coef 0.15, 95% CI 0.01-0.28), and waist circumference in preschool children (b coef 0.08, 95% CI 0.01-0.15). Gestational diabetes, and maternal fasting glucose levels in early pregnancy were not associated with increased risk of obesity in offspring after adjustment for potential confounders.
Conclusion: Maternal obesity and f0etal exposure to high maternal insulin concentration in early pregnancy may contribute to the development of adiposity in the offspring, while GDM was not found to be significantly associated with childhood obesity. Further follow up of this cohort will allow to determine whether maternal hyperglycaemia/diabetes in pregnancy is associated with a broader range of cardiometabolic risk factors in childhood.

Predictors of newborn and placental weight and placental ratio in women with gestational diabetes mellitus
A.E. Ramos[1], F. Caimari[1], I.M. Pujol[1], A. Garcia Petterson[1], G. Ginovart[2], J.M. Adelantado[3], R. Corcoy[1];
[1]Endocrinology, [2]Pediatrics, [3]Gynecology, Hospital Santa Creu i Sant Pau, Barcelona, Spain.

Background and aims: Excessive fetal growth is the most common complication in diabetic pregnancy. Placental is also disproportionately enlarged with an increment in the placental to birth weight ratio. We aimed to analyze, in women with gestational diabetes mellitus (GDM) and singleton pregnancies, the predictive ability for birth weight, placental weight and placental to birth weight ratio of acknowledged birth weight predictors.
Materials and methods: Retrospective cohort study. Setting: Tertiary hospital. Diagnosis of GDM: universal screening with 50 gram oral load, National Diabetes Data Group criteria. Placental to birth weight ratio (PWBW) was defined as (placental weight/ birth weight) x100. Quantitative variables: expressed as median (P25, P75) or mean ± SD according to their distribution. In the multiple regression analyses; dependent variables were: birth weight, placental weight, PWBW. Potential predictors: maternal ethnicity, anthropometrics, smoking habit, family history of DM, personal history of prior glucose intolerance, prior pregnancy, prior macrosomia, gestational age and glucose values at GDM diagnosis, insulin treatment, mean HbA1c in the third trimester, chronic and pregnancy-induced hypertension, gestational age at delivery and fetal sex. Inclusion criteria: singleton pregnancy, GDM, delivery between 1982 and 2009.
Results: We evaluated 2431 women; placental weight was available in 85.4% of deliveries. Birth weight was 3250 g (2963, 3560), placental weight 620 g (540, 720) and PWBW 19.27 (17.20, 21.47). Of the 12 significant predictors of birth weight, 13 predictors of placental weight and 11 of PWBW, most were coincident. In Table 1 we display the coefficients of significant predictors of PWBW and the corresponding ones for birth weight and placental weight. Most anthropometric and metabolic parameters had a disproportionate influence on placental weight, both when promoting growth (maternal weight or 3rd trimester HbA1c) or when restricting it (insulin treatment). However smoking habit restricted fetal growth with a disproportionate effect on the fetus.
Conclusion: In women with GDM and singleton pregnancies, predictors of birth weight, placental weight and PWBW are largely concordant. The influence of different predictors has a disproportionate influence on the fetus and the placenta.

Coefficients of significant predictors of PWBW

Predictors	Birth Weight	Placental Weight	PWBW
Maternal weight	7,973	3,174	0,043
Smoking habit	-127,841	-15,525	0,788
Prior history of GDM		1,318	0,022
Family history of DM			0,333
Prior pregnancy	74,623		-0,351
Gestational age at diagnosis	4,596		-0,031
3 hours blood glucose at diagnosis	11,548	4,729	0,130
Mean HbA1c in the 3rd trimester		17,893	0,505
Insulin Treatment		-17,921	-0.642
Gestatinal age at delivery	120,433	8,718	-0,492
Weight gain	20,991	6,176	0,055

ATLANTIC DIP: gestational weight gain and pregnancy outcomes in women with pregestational and gestational diabetes mellitus
A.M. Egan, M.C. Dennedy, W. Al-Ramli, A. Heerey, F. Dunne;
School of Medicine, National University of Ireland, Galway, Ireland.

Background and aims: The aim of this study was to assess if excessive gestational weight gain (GWG) in pregnancies complicated by diabetes mellitus results in higher adverse obstetric outcomes when compared to pregnancies with non-excessive gestational weight gain.
Materials and methods: The ATLANTIC DIP database identified 802 women with diabetes in pregnancy who had a booking and predelivery weight and height recorded. The cohort comprised 543 (68%) women with gestational diabetes mellitus (GDM) and 259 (32%) with pregestational diabetes mellitus (PGDM), Type 1 and Type 2. GWG was categorized as excessive or non-excessive according to the maternal booking BMI and using Institute of Medicine guidelines. Maternal and neonatal outcomes were assessed based on the additional effect of GWG. Adjusted odds ratios (aOR) were calculated using logistic regression.
Results: Over 50% of women had excesive GWG and this was noted more frequently in women who were overweight (BMI 25-29.9kg/m2) at first antenatal visit (p=0.0001). In women with PGDM, excessive GWG resulted in higher adjusted odds overall for large for gestational age (LGA) [aOR 3.972 (1.849, 8.530); p<0.001] and macrosomic [aOR 3.583 (1.773, 7.238); p=0.000] infants. Similar results were found in women with GDM [aOR 2.008 (1.241, 3.248); p=0.005 for LGA and aOR 2.166(1.321, 3.550) for macrosomia]. In addition, in women with GDM, treatment with insulin further increased the adjusted odds for LGA [aOR 2.802 (1.231, 6.379); p=0.014] and macrosomia [aOR 5.630 (2.158, 14.685); p<0.0001]. Excessive GWG in women with GDM also increased aOR of pregnancy induced hypertension (PIH) [aOR 1.719 (1.037, 2.852); p=0.036].
Conclusion: In a population already at high risk of LGA and macrosomic infants, excessive GWG further increases this risk. LGA and macrosomic infants are more likely to succumb to neonatal morbidities and birth trauma. Macrosomic infants are also at risk of adolescent obesity and diabetes. Thus, this study highlights the importance of intensive weight management throughout pregnancy to prevent excessive GWG in women with GDM and PGDM. Prevention of excessive GWG is likely to translate into meaningful improvements in neonatal outcomes which may translate into long term benefits for these offspring in adult life.

Serum interleukin-1-receptor antagonist levels in women with prior gestational diabetes mellitus and in control women
Z. Janicsek[1], E. Szabó[1], T. Tänczer[1], V. Ferencz[1], Á.G. Tabák[1,2];
[1]1st Departement of Medicine, Semmelweis University Faculty of Medicine, Budapest, Hungary, [2]3Department of Epidemiology and Public Health, University College London, UK.

Background and aims: Soluble interleukin-1-receptor antagonist (IL1Ra) is the natural competitive inhibitor of interlukin-1, an independent predictor of type 2 diabetes. IL1Ra levels are elevated in prediabetic individuals however its potential role in gestational diabetes (GDM - a prediabetic state) has

not yet been investigated. Thus our aims were to investigate the association (1) between current IL1Ra levels and gestational glucose tolerance status 3 years before IL1Ra measurement, (2) and between IL1Ra levels and current glucose intolerance. (3) We also determined the independent covariates of serum IL1Ra levels.
Materials and methods: We report results from a case-control study nested in a cohort: early GDM (n=46, diagnosed between 16-20 weeks of gestation), late GDM (n=43, diagnosed between 24-28 weeks of gestation), controls (n=64). Women with known diabetes were excluded. IL1Ra levels were measured by. Quantikine Human IL-1Ra Immunoassay. Glucose intolerance (GI, n=28) was defined as impaired fasting glucose or impaired glucose tolerance based on a 75g oral glucose tolerance test (WHO 1999). Other covariates were lifestyle measures, anthropometrics, blood pressure, blood lipids, and C-reactive protein (CRP). IL1Ra levels were modelled using multiple linear regression.
Results: The severity of GDM (early GDM > late GDM > control) was positively associated with age, blood pressure, 2-hour blood glucose, frequency of current GI, and negatively with height (all p for trend<0.05). Serum IL1Ra concentration was positively related to the severity of GDM (median [interquartile range]): control 329 [266] vs. late GDM 353 [338] vs. early GDM 384 [225] ng/l (p for trend=0.028). Elevated IL1Ra levels were found in women with current GI compared to controls (728 [740] vs. 518 [569], p=0.03). In a model adjusted for current GI status prior GDM remained an independent predictor of current IL1Ra levels (β-attenuation: 21%). The independent covariates of IL1Ra levels were higher BMI, higher CRP, lower HDL-cholesterol levels (all p<0.05).
Conclusion: The anti-inflammatory process observed 3 years after a GDM pregnancy (independent of current metabolic status) may be a compensatory response to the inflammatory effects associated with the earlier GDM event.

1276

Metabolic characterisation of women with prior gestational diabetes maintaining normal glucose tolerance up to five years postpartum
Y. Winhofer[1], A. Tura[2], A. Thomas[3], T. Prikoszovich[4], C. Winzer[4], G. Pacini[2], A. Luger[1], A. Kautzky-Willer[3];
[1]Department of Internal Medicine 3, Division of Endocrinology and Metabolism, Medical University of Vienna, Austria, [2]Metabolic Unit, ISIB, CNR, Padova, Italy, [3]Department of Internal Medicine 3, Division of Endocrinology and Metabolism, Unit of Gender Medicine, Medical University of Vienna, [4]Department of Internal Medicine 3, Division of Nephrology, Medical University of Vienna, Austria.

Background and aims: Women with prior gestational diabetes (priorGDM) display a high-risk population for the development of overt type 2 diabetes, and the majority of priorGDM convert to diabetes within the first five to ten years postpartum. Previous reports have shown that conversion to overt glucose intolerance is linked to declining beta-cell-capacity to compensate for increased insulin resistance (=disposition index), which is associated with weight gain, decreasing adiponectin and HDL-cholesterol and rising markers of subclinical inflammation. However, the fact that some women are able to maintain normal glucose tolerance (NGT) over the years raises the question whether metabolic disturbances in these women have only been temporary (during pregnancy) and may disappear by time. Therefore, the current study aimed to investigate the metabolic characteristics of priorGDM with maintained glucose tolerance five years after delivery by comparing them to women without a history of GDM (healthy controls).
Study population and methods: Until now, data of 43 priorGDM with NGT and 10 healthy controls (parous women without a history of GDM) five years postpartum, who participated in the Viennese Post Gestational Diabetes Project, a longitudinal follow-up study, were analysed. All women underwent oral and intravenous glucose tolerance tests three to six months after the index pregnancy (baseline) and five years thereafter (follow-up). PriorGDM and CON were matched for age (37.5±4.3 and 35.0±5.6 years, respectively, p=ns) and BMI (25.9±4.3 and 24.7±3.2kg/m2, respectively, p=ns). In addition, blood samples for the measurement of metabolic and inflammatory parameters were taken.
Results: At baseline, only waist circumference and the 1 hour-glucose concentrations during the OGTT were increased in priorGDM compared to CON. At five years postpartum, priorGDM showed significantly increased serum concentrations of CRP (0.46±0.35 vs. 0.21±0.18mg/dl, p=0.03) and decreased concentrations of HDL-cholesterol (55.2±10.1 vs. 63.1±12.8mg/dl, p=0.04) and adiponectin (7.6±2.8 vs. 12.3±6.2 μU/ml, p=0.02). In addition, in priorGDM insulin sensitivity (5.4±2.9 vs. 9.0±4.9 10-4min-1/(μU/ml), p=0.009) and the disposition index (2.46±2.39 vs. 4.43±2.67 10-2min-1, p<0.05), both derived from IVGTT, were significantly lower compared to CON. Waist circumference -despite comparable BMI- remained higher in priorGDM.
Conclusion: The metabolic disturbances, which have recently been reported to characterise priorGDM with impaired glucose metabolism, can also be found in those who were able to maintain NGT up to five years postpartum. Hence, it seems that these changes may not be solely responsible for metabolic deterioration in this population. It furthermore highlights the importance of regular screening for glucose intolerance/diabetes in priorGDM.

1277

A multiplatform metabolomics study of gestational diabetes mellitus
D. Dudzik[1,2], M. Zorawski[2], M. Skotnicki[3], W. Zarzycki[4], G. Kozlowska[4], K. Bibik-Malinowska[5], C. Barbas[1];
[1]CEMBIO (Center for Metabolomics and Bioanalysis), CEU San Pablo University, Madrid, Spain, [2]Department of Pharmacology, [3]Clinical Department of Perinatology, [4]Clinical Department of Endocrinology, Diabetology and Internal Diseases, Medical University of Bialystok, [5]Department of Gynecology, J. Sniadecki's District Hospital, Bialystok, Poland.

Background and aims: Metabolite fingerprinting has been successfully used for diagnosis of many diseases and becomes a powerful tool for biomarkers discovery. The combination of different untargeted metabolomics methods allows for simultaneously measuring as many metabolites as possible from a single biological sample that offers important advantages for global metabolome profiling. Metabolite fingerprinting approach by using multiplatform analytical techniques (LC-QTOF-MS, GC-Q-MS and CE-TOF-MS) has been applied to identification of clinically relevant changes in circulating metabolites in the plasma and urine samples of women with Gestational Diabetes Mellitus (GDM). Metabolite fingerprinting is nowadays one of the best available tools for understanding the molecular bases of the onset and progression of GDM. In addition the platform can help to understand the highly associated risk of diabetes mellitus type 2 development.
Materials and methods: Plasma and urine of 20 women with GDM and 20 pregnant women with normal glucose tolerance (after 2-h 75-g OGTT) matched according to week of gestation and age, were enrolled into the study. Liquid chromatography/mass spectrometry (LC-QTOF-MS; Agilent 6550), gas chromatography/mass spectrometry (GC-Q-MS; Agilent 7890A) for plasma and capillary electrophoresis/mass spectrometry (CE-TOF-MS; Agilent 6224) for urine analysis followed by matrix data alignment, data filtration as well as univariate and multivariate statistical analysis have been applied to the study.
Results: 309 masses in positive and 346 in negative LC-QTOF-MS ionization mode were found to have statistically significant differences according to univariate (*t* test) and multivariate (jack-knifed confidence interval) statistic. Identification of metabolites was performed by searching for possible identity of accurate masses in several databases including CEU Mass Mediator database and by final confirmation according to LC-MS/MS. By GC-Q-MS analysis we determined 12 relevant compounds and 6 out of 59 significant masses obtained by CE-TOF-MS were confirmed by available standards.
Conclusion: Most of identified compounds are related to carnitine, aminoacids, glycerophospholipids, fatty acids and sphingolipids metabolism and metabolic pathways perturbations. The importance of metabolites as alpha-hydroxybutyric acid or sphingosine-phosphate related to the biochemical mechanism of insulin resistance and impaired glucose regulation should be emphasized. Meaningful information obtained by metabolomics fingerprinting can help to detect early prognosis markers or contribute to the development of new diagnostics strategies for impaired glucose in diabetes mellitus.

Gestational diabetes mellitus after gestational diabetes mellitus

C. Giuliani[1], O. Bitterman[1], C. Festa[1], V. Rozzi[1], P. Bianchi[2], L. Mattei[1], M. Bongiovanni[1], V. Toscano[1], A. Napoli[1];
[1]Department of Clinical and Molecular Medicine, [2]Department of Gynecological, Obstetric and Urologic Sciences, Sant'Andrea Hospital, Sapienza University, Rome, Italy.

Background and aims: Gestational Diabetes Mellitus (GDM) in an index pregnancy increases the risk of recurrent GDM in subsequent pregnancies. The recurrence rate of GDM has been reported to range between 30% and 84%. Factors identified as predictive of GDM recurrence include advanced maternal age, multiparity, obesity, weight gain between pregnancies, requirement of insulin therapy and macrosomia during the initial pregnancy. Although previous studies have reported important data regarding GDM recurrence rates, there are no evidences about clinical and matabolic features of GDM arising in women with prior GDM. The aim of this study was to assess GDM recurrence rates in a cohort of pregnant women with prior GDM, who came on the occasion of a following pregnancy, and to compare clinical and metabolic features recurrent GDM with those of previous GDM (G1 vs G2).
Materials and methods: We carried out a longitudinal observational study of the main clinical and metabolic features in 30 women (age: 32,88±4,6 yy in G1 and 36,27±4,8 yy in G2) with GDM in an index pregnancy (G1), at least a subsequent pregnancy (G2) and normal glucose tolerance between the two. GDM was diagnosed, until 2010, according to Carpenter and Coustan criteria (glycaemia 0'>90, 60'>180, 120'>155, 180'>140) and, from 2010, according to IADPSG criteria (glycaemia 0'≥92, 60'≥180, 120'≥153). Insulin resistance was defined as HOMA-IR, pancreatic function was defined as HOMA-B% and insulin secretion was defined as AUC IRI/AUC BG. Statistics: χ^2, *t-test*, Mann Whitney, Multilevel mixed model multivariate analysis, $p<0,05$.
Results: GDM recurrence rate: 93,3% (*n* 28/30); pre-pregnancy BMI not significantly increased in G2 (22,26 vs 23,05 *ns*); pre-pregnancy BMI≥30 in 12,5% (G1) vs 8,3% (G2); earlier GDM diagnosis in G2 (gestational week of diagnosis: 24,8±6,3 vs 20,27±8,12, $p=0,022$), due to the early OGTT execution in a gestational age in wich the insulin resistance degree is lower (BG0': 88,47±15,86 vs 88,76±11,69 ns; BG60': 196,82±42,84 vs 160,65±37,4, $p=0,002$; BG120': 169,31±43,07 vs 123,81±33,2 mg/dl $p=0,001$); insulin resistance not significantly reduced in G2 (HOMA-IR: 2,19±1,15 vs 1,1±0,33, ns); pancreatic function reduced in G2 (HOMA-B%: 120,52±44,48 vs 102,42±40,19, $p=0,018$); increased insulin therapy use in G2 (70,4% vs 96,3%, $\chi^2=0,011$); insulin therapy started earlier in G2 (29,37±5,7 vs 21,9±7,6 weeks, $p=0,003$). Maternal and neonatal outcomes are statistically comparable between the two pregnancies: macrosomic infants number reduction in G2 (*n* 1 vs 0) and LGA number reduction in G2 (*n* 2 vs 1); maternal hypertension rate reduction in G2 (26,1% vs 4,3%, $\chi^2=0,04$).
Conclusions: High GDM recurrence rate in normal weight/overweight women; slight deterioration of pancreatic function in the second pregnancy.

Women clinical and metabolic features in G1 and G2

	G1	G2	p-value
GDM	100% (n 30)	93,3% (n 28)

PS 111 Pregnancy - GDM: risk factors and delivery outcomes

1279

Genetic background of gestational diabetes mellitus in the Czech population

D. Vejrazkova[1], P. Lukasova[1], M. Vankova[1], O. Bradnova[1], T. Halkova[1], J. Vcelak[1], V. Cirmanova[1], K. Andelova[2], H. Krejci[3], B. Bendlova[1];
[1]Department of Molecular Endocrinology, Institute of Endocrinology, [2]Department of Mother and Child Care, UPMD, [3]Department of Obstetrics and Gynecology, General University Hospital, Prague, Czech Republic.

Background and aims: As part of our extensive study mapping the genetic background of selected polygenic endocrinopathies, in this communication we have focused on gestational diabetes mellitus (GDM). GDM is defined as glucose intolerance that is first detected during pregnancy and subsides spontaneously after the childbirth. Its prevalence increases due to better screening but also owing to rise in obesity as well as on account of higher age of pregnant women. It is well known that GDM has a strong genetic component. Our aim was to provide broad genetic information regarding GDM in the Czech population.
Materials and methods: Our cohort of studied subjects consisted of 987 women, 514 of them were diagnosed with GDM (age 34,0±5,97 years; BMI 24,3±4,98 kg/m2) and 473 were control non-diabetic women without history of GDM (age 34,8±13,97 years; BMI 24,1±4,58 kg/m2). We used the ABI TaqMan SNP Genotyping Assays to genotype 128 single nucleotide polymorphisms (SNPs) in 65 genes, which have been described in association with type 2 diabetes mellitus (T2DM), insulin resistance, insulin secretion, obesity, energy metabolism, or lipid spectrum. Statistic analysis was conducted using the NCSS 2004 software (Chi-squared test).
Results: Concerning the allelic distribution between the GDM group and controls, the most significant association with GDM showed the C/G SNP rs738409 in the obesity-associated gene adiponutrin (minor allele G frequency 27.8 % in GDM group compared with 21.9 % in controls; $p<0.01$). Furthermore, strong association with GDM was found in the intergene blood lipid-associated T/C SNP rs4942296 (minor allele C frequency 32.8 % in GDM group compared with 42.8 % in controls; $p<0.01$). Also the C/T SNP rs7903146 in the TCF7L2 gene showed association with GDM: the minor T allele, which confers risk for T2DM, was represented by 33.3 % in the GDM group compared with 26.9 % in controls ($p=0,02$). In addition, statistical analysis of genotype distribution of the A/G SNP rs7498665 in the obesity-associated SH2B1 gene revealed higher proportion of gestational diabetics among the G allele carriers (72.0 %) compared with only 63.6 % of controls ($p=0.01$).
Conclusion: Of the 128 SNPs in 65 genes conferring risk for T2DM, insulin resistance, obesity, and metabolic syndrome, we confirmed the strongest association of GDM with SNPs in genes TCF7L2, adiponutrin, SH2B1, and the intergene SNP rs4942296. According to genome-wide association studies, the TCF7L2 gene was found to be significantly associated with T2DM. Our results confirm also in GDM that the risk is linked to the minor allele T of the rs7903146 in this gene. The two SNPs in adiponutrin and SH2B1 represent obesity-susceptibility loci. Considering almost identical BMI in the compared groups of gestational diabetics and controls in this study, described associations of the two SNPs with GDM suggest that obesity and diabetes share the common etiopathological roots operating prior to the obesity manifestation.

Daily arsenic contamination associated with gestational diabetes and low Apgar score

F. Jebunnesa[1], B. Banu[2], L. Ali[1];
[1]Dept of Biochemistry & Cell Biology, [2]Dept of Health Education & Health Promotion, Bangladesh Institute of Health Sciences (BIHS), Dhaka, Bangladesh.

Background and aims: Much evidence suggest that populations exposed to high level of arsenic in water, increases the risk of diabetes, but little is known about exposers during pregnancy and to Gestational Diabetes (GD) and poor pregnancy outcome, such as Low Apger Score (LAS). The study was undertaken to investigate the arsenic level of daily water usage associated with GD and low apger score babies.

Materials and methods: The study was observational case-control design. Total of 263 pregnant women (age, M±SD, 21±3.7 and BMI, 25.1±4.1 kg/m^2 were matched) were included in this study. All women were 28-38 wk of gestation. Clinical and anthropometric parameters were measured by standard techniques. Serum glucose level by glucose oxidase method. Arsenic level measured by Standard Methods. Arsenic exposer assessed by daily using (drinking, cooking, washing and bathing) water of each household. Statistical analysis was performed mean±SD and median(range), univariate and multivariate was also analyzed where as appropriate.
Results: Arsenic concentration was significantly higher in GD subjects [µg/l, median (range), 62(22-306)] compared to non-GD subjects [µg/l, 3.6(1-99)]. Significantly higher level of 2 hr 75g glucose (mg/dl, 12,2±1.7) in GD as compare to non-GD subjects (6.3±0.6). The apger score is significantly lower in GD subjects (4.7±0.8) when the compared to non-GD subjects (6.4±0.7) (p<0.001). The Pearson' correlation showed daily arsenic contamination is a significantly positive correlation with Glucose level (r=0.638, p=0.034) and lower apger score (r=0.892, p=0.041). Linear regression also showed arsenic concentration was strongly associated with higher glucose level and lower apger score in GD subjects (p<0.001).
Conclusion: The above findings imply that Arsenic contamination may play a role in glucose intolerance and may associated with an increased risk of GD; it may be contributed to lower apger score in babies.

Gestational diabetes screening: new considerations on the recent Italian recommendations

B. Arcidiacono[1], C. Capula[2], E. Chiefari[1], V. Ventura[1], S. Iiritano[1], A. Vero[2], L. Puccio[2], V. Pullano[2], D. Foti[1], A. Brunetti[1], R. Vero[2];
[1]Health Sciences, University „Magna Graecia" of Catanzaro, [2]Complex Operative Structure Endocrinology-Diabetology, Hospital Pugliese-Ciaccio, Catanzaro, Italy.

Background and aims: Recent recommendations from the Italian Ministry of Health indicate that screening for gestational diabetes mellitus (GDM) must be performed in all pregnant women ≥35 years old or in women <35 years old, in the presence of risk factors such as BMI ≥25, previous GDM, previous newborn with macrosomy, familiarity for type 2 diabetes. Our aim was to determine the effectiveness of these recommendations compared with the criteria established in 2010 by the International Association of the Diabetes and Pregnancy Study Groups, recommending GDM screening in all women not previously diagnosed with overt diabetes.
Materials and methods: This is a retrospective cohort study of 2448 pregnant women admitted to the University of Catanzaro outpatient clinics, and to the Struttura Operativa Complessa Endocrinologia-Diabetologia, Ospedale Pugliese-Ciaccio, Catanzaro, Italy, from May 1, 2010 to December 31, 2012 for GDM screening. Out of these, 893 (36.5%) pregnants were ≥35 years old and 1555 (63.5%) <35 years old. In this latter group, 34.6% (538/1555) showed no risk factors for GDM. GDM was diagnosed with 75 g oral glucose tolerance test (OGTT) at 24-28 weeks of gestation, following the IADPSG 2010 cut-offs. Different maternal and neonatal outcomes were considered. Effect of GDM was analyzed by multiple regression analysis.
Results: Overall, 674 (27.5%) women were diagnosed with GDM. In particular, GDM was diagnosed in 31.8% (171/538) of <35 years old pregnants without risk factors for GDM, who would have not been tested according to the Italian recommendations. Interestingly, diagnosis was made at baseline (55.5%), at 1 hour (39.8%), or at 2 hours (4.7%) during OGTT. Despite of the appropriate treatment, GDM represented a risk factor for primary caesarean section [adjusted odds ratio (AOR)=1.92, 95% confidence interval (CI) 1.21-3.06; P=0.006]; polyhydramnios (AOR=4.48, 95% CI 1.20-16.73; P=0.025); increased birth weight (P<0.001); admission to the neonatal intensive care unit (AOR=4.39, 95%CI 1.44-13.37; P=0.009); and large for gestational age (AOR=3.53, 95%CI 1.34-9.34; P=0.011).
Conclusion: Our findings indicate that over 30% of pregnant women <35 years old, without risk factors for GDM, would miss diagnosis of GDM by adopting the recent Italian recommendations. The fact that these women have increased risk for adverse pregnancy outcomes suggest to extent the screening to all pregnants. To limit costs for GDM screening (with a ~5% drop in sensitivity), OGTT could be restricted to two steps, basal and 1 hour.

1282

Prediction for development of gestational diabetes mellitus in the 1st trimester of gestation based on levels of HOMA-IR index

Z. Zabarovskaya[1], S. Pavlukova[2], O. Zabarovskaya[3];
[1]Endocrinology, [2]Obstetrics and Gynecology, Belorussian State Medical University, [3]Endocrinology, Belorussian Medical Academy of Postgraduate Education, Minsk, Belarus.

Background and aims: As is well know gestational diabetes mellitus (GDM) are diagnosed in the 2nd trimester of gestation (after 24 week of fetation). Prediction for development of GDM in the 1st trimester of pregnancy is a very important problem. The aim of the study was to determine a cut-off level of HOMA-IR index for prediction of development of GDM in 1st trimester of gravidity.
Materials and methods: We estimated and compared the HOMA-IR indices in 1st, 2nd and 3rd trimesters in 160 women with GDM and in 39 pregnant healthy subjects (control group). Using ROC-analysis we determined cut-off level for prediction of developing of GDM in 1st trimester of gestation.
Results: The HOMA-IR index values were significantly higher in women with GDM compared with control group in 1st (Me [P25; P75] 3,50 [1,16; 9,13] vs. 1,32 [0,59; 2,30], p<0,001), 2nd (Me [P25; P75] 4,96 [1,99; 38,88] vs. 1,99 [1,33; 3,21], p<0,001) and 3rd (Me [P25; P75] 4,92 [1,55; 34,72] vs. 2,64 [1,68; 4,38], p<0,001) trimesters. The predictive cut-off level of HOMA-IR index in the 1st trimester of pregnancy for development of GDM is above 1.89 Sensitivity of ROC-analysis is 90,0% (95%Cl 84,3-94,2), Specificity - 89,7% (95% Cl 75,8-97,1); Positive Predictive Value - 86,8%, Negative Predictive Value - 79,4%. Area under curve is 0,963± 0,01 (95% CI 0,92-0,98), p< 0,001.
Conclusion: The HOMA-IR index level above 1.89 in 1st trimester of pregnancy is a prognostic value for development of gestational diabetes mellitus that require more frequent control of blood glucose concentration and reduction for consumption of refined carbohydrates.

1283

Insulin secretion in addition to insulin resistance predicts gestational diabetes mellitus

E.-C. Krzizek[1], J.M. Brix[1], G.-H. Schernthaner[2], G. Schernthaner[1];
[1]Department of Medicine I, Rudolfstiftung Hospital, [2]Department of Medicine II, Medical University of Vienna, Austria.

Background and aims: Insulin resistance is a common implication of gestational diabetes (GDM). Although maternal glucose levels and fetal insulin have often been investigated, maternal insulin levels during the oral glucose tolerance tests (OGTT) were not studied in larger trials. The aim of this ongoing study was to evaluate insulin levels of pregnant women during OGTT for the prediction of GDM.
Materials and methods: 256 women (age 31±6 years) were screened for GDM in a prospective study at tertiary care unit during 24-32 (28±2) week of gestation. A 75g - OGTT was performed, glucose and insulin levels were measured at 1-hour, 2-hours and fasting. In addition, HOMA-IR and Matsuda Index were calculated for estimation of insulin resistance and insulin sensitivity. Non-parametric valuables were log10 transformed. Statistics included student's t-test, univariate and multivariate logistic regressions including confounding analysis and calculations of odds ratios (OR) per 1 STD (OR-STD).
Results: 38.7% (n=99) of the women were diagnosed with GDM. Women with GDM were significantly more obese (BMI: 30.0±5.4 vs 27.8±5.9 kg/m^2, p=0.014), older (32±6 vs 20±6 years, p=0.013) and had a higher HbA1c (5.3±0.4 vs 5.1±0.3%, p=0.001) than women without GDM (nonGDM). Fasting insulin levels were as followed: GDM: 11.2 (7.7,17.1), nonGDM: 10.6 (7.5,14.1), p=0.040; 1-hour insulin levels, GDM: 108.5 (68.2,151.4), nonGDM: 86.8 (58.2,129.4), p=0.145; and 2-hours insulin levels, GDM: 94.5 (65.6,131.7), nonGDM: 63.2 (46.1,100.9), p<0.001. Since the variance of the predictors of GDM was highly different, OR-STD were calculated. After elimination of confounders seven variables remained. In univariate fashion, OR-STD were as followed: 2-hour glucose: 2.15 (p<0.001), 2-hour insulin: 1.63 (p<0.001), HOMA-IR: 1.58 (p=0.004), Matsuda Index: 0.50 (p<0.001), HbA1c: 1.90 (p=0.001), BMI: 1.40 (p=0.017), triglycerides: 1.28 (p=0.025). After multiple stepwise backward regression, 2-hours glucose (OR: 1.036, p<0.001) and Matsuda-Index (OR: 0.842, p=0.011) were identified as final model. Thus a change in glucose of 1 mg/dl resulted in an increase of 3.6%, a change in Matsuda Index for 1 unit in a decrease of 15.8% for GDM risk. OR-STDs of the final model: 2-hours glucose: 2.15; Matsuda Index: 0.50. Thus the Magnitude of 2-hours glucose (2.15) was 7.5% stronger than the magnitude

of the Matsuda Index (2.0). However, as confounding analysis demonstrated, the Matsuda Index was independently significantly associated with GDM, whereas the significant association of 2-hours glucose was confounded by the Matsuda Index.
Conclusion: Women with GDM are significantly more often insulin resistant, as is often demonstrated by calculations of the OGTT. Our findings indicate, that first reduced insulin sensitivity might be more relevant for the establishment of GDM than previously anticipated (HOMA-IR is eliminated from the model). Second, 2-hours glucose and the Matsuda Index were identified as predictors of GDM. 2-hours glucose is just natural, however, the strong preventive power of the Matsuda Index is new. Third, our multivariate analysis revealed that the Matsuda Index was independently associated with GDM, whereas 2-hours glucose was confounded by the latter. Altogether our findings strongly argue for future determinations of insulin levels during the OGTT in pregnancy.

1284

Serum adiponectin levels in women with previous gestational diabetes
E. Szabó[1,2], Z. Janicsek[1], Á. Fürst[1,3], R. Magenheim[4], T. Taenczer[1,5], J. Kósa[1], G. Tamás[1,5], Á.G. Tabák[1,6];
[1]1st Department of Medicine, Semmelweis University Faculty of Medicine, Budapest, [2]Szent Imre Hospital, Budapest, [3]Fürst-Med Human Health Services Ltd., Győr, Hungary, [4]Department of Gynaecology and Obstetrics, St. Joseph Hospital, Berlin, Germany, [5]National Centre for Diabetes Care, Budapest, Hungary, [6]Department of Epidemiology and Public Health, University College London, UK.

Background and aims: Gestational diabetes (GDM) is a risk factor for cardiovascular disease and metabolic syndrome later in life. As both decreased adiponectin levels and GDM are important predictors of abnormal glucose metabolism, insulin resistance, and metabolic syndrome, we sought to investigate (1) the association between prior GDM status and current adiponectin levels and (2) the determinants of adiponectin levels 3 years after delivery.
Materials and methods: Our nested case-control study included 97 women with previous GDM and 44 with normal glucose tolerance during pregnancy (age [mean±SD]: 35.4±3.9 vs. 33.6±3.6 yrs, P=0.011; BMI: 25.7±5.6 vs. 24.0±4.3 kg/m2, P NS). Thirty-four women(24.1%) had glucose intolerance (GI - diabetes mellitus, impaired fasting glucose, or impaired glucose tolerance) at follow-up. We collected data on lifestyle measures (questionnaire), anthropometry, and blood pressure (physical examination). Blood samples were drawn in the fasting state and during a 75g OGGT for the determination of serum glucose, insulin, creatinine, HbA1c, sex hormone-binding globulin (SHBG), and blood lipids. Insulin sensitivity and insulin secretion was determined using homeostasis model assessment (HOMA) calculator. Serum adiponectin concentrations were measured by Quantikine Human Total Adiponectin Immunoassay (R&D System Minneapolis, USA; 4.5 hour solid-phase ELISA).
Results: Serum adiponectin levels were lower in prior GDM women compared to controls (9.44±4.41 vs. 12.33±6.83 μg/ml, P=0.013) however they were similar among GI and normal glucose tolerant women (9.19±4.81 vs. 10.71±5.58 μg/ml, P NS). Negative correlations were found between serum adiponectin and BMI (r=-0.298), waist circumference (r=-0.349), systolic and diastolic blood pressure (r=-0.210/-0.215), HbA1c (r=-0.184), fasting and 2-hour insulin (r=-0.248/-0.329), HOMA-2B (r=-0.283), serum triglycerides (r=-0.245), LDL-cholesterol (r=-0.319) and GDM status (r=-0.172). HOMA-2S (r=0.210), HDL-cholesterol (r=0.296) and SHBG (r=0.296) correlated positively with serum adiponectin. In multiple linear regression, waist circumference, serum triglycerides, LDL-cholesterol were positively, while hip circumference and SHBG were negatively related to serum adiponectin (all P<0.05).
Conclusion: The opposing direction of association between adiponectin and waist or hip circumference in the multivariate model raises the hypothesis that subcutaneous fat may play a protective role in the development of insulin resistance.

Estimation of the postpartum glucose intolerance risk in women with gestational diabetes mellitus using routine glycaemic indices assessed in the mid-trimester of pregnancy
K. Kankova[1], V. Bartakova[1], D. Maluskova[2], J. Muzik[2], J. Belobradkova[3];
[1]Dept. of Pathophysiology, [2]Institute of Biostatistics and Analyses, Masaryk University, Brno, [3]Dept. of Internal Medicine, University Hospital Brno, Czech Republic.

Background and aims: Incidences of T1DM and T2DM as well as gestational diabetes mellitus (GDM) are increasing worldwide. Given that women with previous GDM have increased risk of developing diabetes in the future compared with those normoglycaemic during pregnancy, however their participation in the postpartum screening is low the aims of our study were (1) to ascertain a frequency of early (up to 12 months post-delivery) postpartum conversion of GDM into permanent diabetes (DM) or impaired glucose tolerance (IGT), (2) to test whether the degree of glucose intolerance diagnosed by standard criteria at the time of GDM diagnosis correlates with the degree of early postpartum glucose (in)tolerance and (3) to find eventual significant predictive factors for early postpartum conversion of GDM to DM/IGT from glycemic indices routinely measured in the mid-trimester of gravidity.
Materials and methods: We carried out a retrospective epidemiological analysis of electronic health records data of an ethnically homogenous, central European population cohort of women with GDM diagnosis followed in a single medical centre during the period 2005 - 2011 that underwent repeated oGTT up to 1 year after the index delivery (n=1090 for the purpose of incidence analysis). A subgroup of 305 GDM subjects with compete anthropometric, clinical and biochemical data that underwent both mid-trimester and postpartum 3-point oGTT test in the central laboratory of the University Hospital Brno was chosen for more detail analysis of risks and predictive factors.
Results: DM/IGT was detected in a total of 11.7% subjects, of those 4.1% had DM (2.8% T2DM and 1.3% T1DM). Glycaemia in all three time-points of mid-trimester oGTT, area under the curve (AUC_{oGTT}) and mid-trimester HbA1c were significantly associated with the postpartum disorder (P<0.05, Mann-Whitney). A highly statistically significant trend was identified in the number of above threshold values during mid-trimester oGTT and the postpartum DM/IGT conversion ($P<1x10^{-12}$): 8% of patients with one oGTT value above cut-off, 25% with two and 65% with all three were diagnosed with DM/IGT within the 1 year postpartum. Uni- and multivariate regression models were used to identify the best predictive parameters (FPG and AUC_{oGTT}) for the construction of ROC.
Conclusion: Parameters of glucose metabolism measured between 24-28th week of pregnancy exhibit - apart from diagnostic value for GDM diagnosis - significant predictive potential for early reoccurrence or postpartum persistence of glucose intolerance. Considering generally low-compliance of GDM women in postpartum screening, risk-based stratification of GDM population could improve efficiency of the screening for diabetes after delivery.

1286

Changes of serum vaspin, adiponectin, MCP-1 and BDNF during course of pregnancy and their association with glucose metabolism
L. Bozkurt[1], C.S. Göbl[2], K. Leitner[1], J. Scholz[1], D. Bancher-Todesca[2], A. Luger[1], A. Kautzky-Willer[1];
[1]Internal Medicine III, Division of Endocrinology and Metabolism, [2]Department of Obstetrics and Gynaecology, Medical University of Vienna, Austria.

Background and aims: Pregnancy is characterized as having a diabetogenic effect on normal carbohydrate metabolism. Different factors were suggested to have additional time-dependant impacts on the manifestation of gestational diabetes (GDM). The objective of the present study is to assess longitudinal changes in Vaspin, Adiponectin, MCP-1 and BDNF during the course of pregnancy until 3 months postpartum and their association with insulin sensitivity and pregnancy outcome in women with GDM compared to healthy women.
Materials and methods: In a longitudinal study comprising five visits, 68 pregnant women (36 with GDM and 32 with normal glucose tolerance) were included before the 22th gestational week (GW, Visit 1) and underwent a 75g-2h-oral glucose tolerance test. In case of a negative result the test was

repeated in the GW 24-28 (V2) for final diagnosis according to the IADPSG criteria. An additional blood drawn was performed for determination of circulating Adiponectin, Vaspin, BDNF and MCP-1 levels in ≤ 22th GW (Visit 1 (V1)) as well as during GW 24-28 (V2), GW 30-34 (V3), GW 36-40 (V4) and 8-12 weeks after delivery (V5). The oral glucose insulin sensitivity index (OGIS) was calculated by using data of the diagnostic OGTT to accurately estimate insulin sensitivity. Neonatal data including length, weight and gestational age (GA) at delivery were used to calculate the Ponderal Index (PI) as well as the percentiles for adjusted birth weight in order to define small-for-GA (SGA) and large-for-GA (LGA) outcomes.
Results: While we found significant differences between GDM and NGT in Adiponectin (7.42±3.13 vs. 10.09±3.80 μg/ml, p=0.002), there were no differences in Vaspin (p=0.986), BDNF (p=0.931) and MCP-1 (p=0.375) at V1 between GDM and NGT women. However, a strong linear association of Adiponectin (r=0.464, p<0.001) with OGIS was observed already in early pregnancy. In the follow-up there appeared no time-dependant interactions in BDNF (pg/ml) between both groups with a significant decrease in V3 and V4 as compared to V1 (V3: mean difference 0.765, p<0.001; V4: mean difference 0.637, p=0.004 for log transformed data). However, Adiponectin levels in the GDM group remained constantly low during pregnancy and after delivery. At postpartum there was a relevant change regarding Vaspin and MCP-1 levels, as Vaspin significantly decreased and MCP-1 was ascending compared to the respective levels during pregnancy. There was no association of these parameters with adjusted birth weight or PI at any time point.
Conclusion: The strong predictive value of Adiponectin for glucose intolerance in women affected by GDM can be affirmed independently from point of measurement with constantly low serum concentrations beginning from early pregnancy to the first months postpartum. However, changes in time-depended courses of Vaspin, MCP-1 and BDNF are observable but were not associated with glucose tolerance status in pregnant women. Thus, during pregnancy time of blood sampling should be taken into account in analyses with group based comparisons.

1287

The effect of prior gestational diabetes on the shape of the glucose response curve during an oral glucose tolerance test 3 years after delivery
T. Tänczer[1,2], Z. Janicsek[1], B. Domján[1,2], E. Fazekas[1], V. Ferencz[1,2], Á.G. Tabák[1,3];
[1]I. Department of Internal Medicine, Semmelweis University, [2]National Centre for Diabetes Care, Budapest, Hungary, [3]Department of Epidemiology and Public Health, University College London, UK.

Background and aims: Monophasic glucose response during an oral glucose tolerance test (OGTT) is associated with decreased insulin sensitivity and β-cell function. Furthermore, it is an independent predictor of type 2 diabetes (T2DM). Since gestational diabetes (GDM) is also associated with an increased lifetime risk of T2DM, we aimed to investigate the association between the shape of the glucose response curve and (1) glucose tolerance status during a pregnancy 3 years before and (2) current glucose tolerance status. We also sought (3) other determinants of the shape of the glucose response.
Material and methods: We report of a case-control study nested in a cohort of women delivered at a Hospital in Budapest, Hungary in 2005-2006. Participants are women with early GDM (n=46, diagnosed between 16-20 weeks of gestation), late GDM (n=43, diagnosed between 24-28 weeks of gestation), and controls (n=64, normal glucose tolerance [NGT] during pregnancy). Women with known diabetes at follow-up were excluded. We defined monophasic glucose response curve if it followed an inverted U-shape and biphasic if there was a second rise in plasma glucose after the first rise. Glucose tolerance was defined by WHO 1999.
Results: At follow-up 3.5±0.7 (mean±SD) years after delivery participants were 35.1±4.0 years old, their fasting plasma glucose was 5.3±0.4 mmol/L, 2-hour glucose was 6.1±1.7 mmol/L, HbA1c 5.5±0.3%, BMI 25.2±4.9 kg/m^2, systolic blood pressure (SBP) 119±15 mmHg. Twenty percent had NGT, 5% impaired fasting glucose (IFG), and 15% impaired glucose tolerance (IGT). Thirty-seven percent had the early GDM, 32% had the late GDM, and 31% NGT during pregnancy. Women with a biphasic response had a lower hip circumference (100±9 vs.104±10 cm), lower levels of triglycerides (median [IQR] 0.9 [0.6] vs. 1.0 [0.9] mmol/L), higher levels of adiponectin (10.9 [7.6] vs. 8.1 [5.5] μg/ml), lower number of previous pregnancies (2 [1] vs. 3 [2]), and were less frequently diagnosed with early GDM (44.9 vs. 23.3%, all p<0.05). Women with biphasic response tended to be younger (34.3±4.0 vs. 35.7±3.9 year), to have a lower SBP (116±13 vs. 121±16 mmHg), and C-reactive protein (1.05 [1.85] vs. 1.10 [3.35] mg/l, all p<0.1). There was no difference between women with biphasic and monophasic curves in fasting and 2-hour glucose or insulin levels, or body mass index (all p>0.1). According to a multiple logistic regression model, a monophasic response was independently associated with a prior early GDM (OR 2.85 95% CI 1.05-7.73), elevated triglycerides (OR 1.74 95%CI 0.97-3.10 /mmol/l), and a higher number of previous pregnancies (OR 1.64 95%CI 1.03-2.51 /pregnancy).
Conclusion: We found that although the shape of the glucose response curve is independent of current glucose and insulin levels, it is strongly associated with 'severe' (early onset) glucose intolerance during pregnancy 3 years before the OGTT test. These results may suggest that the shape of the OGTT curve captures abnormal glucose regulation independent of plasma glucose and may be an earlier indicator of an elevated diabetes risk than fasting or post-load glucose however further studies are required to confirm this hypothesis.

The role of HbA_{1c} as a risk predictor for overt diabetes after pregnancy with gestational diabetes mellitus
C.S. Göbl[1], L. Bozkurt[2], T. Prikoszovich[2], A. Tura[3], G. Pacini[3], A. Kautzky-Willer[2];
[1]Department of Obstetrics and Gynecology, Division of Obstetrics and Feto-Maternal Medicine, [2]Department of Internal Medicine III, Division of Endocrinology and Metabolism, Gender Medicine Unit, Medical University of Vienna, Austria, [3]Institute of Biomedical Engineering, Metabolic Unit, Padova, Italy.

Background and aims: Risk stratification after pregnancy with gestational diabetes mellitus (GDM) is actually based on screening with the 2h-OGTT performed in the first months after delivery. However, the main limitation of this examination is the necessity of a certain time expenditure, which is possibly contributing to the non-adherence of many affected women. The assessment of HbA1c was proposed as an alternative with the advantages of independent performance at any time without requiring a fasting state and the little biological variability. Thus, this report aimed to compare the predictive accuracy of both examinations to detect pathologies in carbohydrate metabolism early after GDM pregnancy.
Materials and methods: 75 women with previous gestational diabetes (pGDM) and 41 controls participating in the "Vienna Post-Gestational Diabetes Project" were included 3-6 months after delivery and underwent a detailed metabolic characterization: frequently sampled 3h-OGTT with measurements of glucose, insulin, C-peptide and proinsulin, as well as a frequently sampled intravenous glucose tolerance test (FSIGT) to estimate insulin sensitivity and insulin secretion. pGDMs were annually invited for routine diabetes screening to a maximum of 10 years.
Results: Although, pGDM women showed higher HbA1c levels as compared to females with uncomplicated pregnancy (5.50±0.42 vs. 5.17±0.27, p<0.001), univariate analysis revealed only moderate associations of HbA1c with area under the curve (AUC) of glucose measurements during the OGTT (r=0.30, p=0.001). Moreover, no associations were found between HbA1c and OGTT dynamics of insulin, proinsulin and C-peptide. Also with regard to glucose disposition, HbA1c showed only modest correlation with FSIGT insulin sensitivity index (r=-0.26, p=0.008) and disposition index (sensitivity x secretion: r=-0.25, p=0.010), while no association was reported with first phase of insulin secretion. A multivariate linear model including fasting as well as 1h and 2h post load glucose levels showed a good predictability for the FSIGT disposition index explaining 21% of the variance. The additional inclusion of HbA1c had no further impact to improve the predictive ability of this model. Graphical tests of interactions indicated comparable effects between women after GDM and controls. During follow-up, 16 cases of overt diabetes were reported in the pGDM subgroup. Of those only 9 females (56%) were sufficiently detected by HbA1c≥5.7% at baseline, while 44% of subjects under highest risk were not detected.
Conclusion: It is clearly suggested that the predictive ability of HbA1c for the detection of subclinical alterations in glucose metabolism is inferior to that of the OGTT. As a surrogate marker of the mean plasma glucose of up to 3 months, HbA1c fails to predict latent alterations of insulin sensitivity and β-cell function before manifestation of overt diabetes. These alterations could be unmasked only by performing a standardized dynamic test as the OGTT.

Fertility in affected and non-affected siblings in families with type 1 diabetes: results from the type 1 diabetes genetics consortium (T1DGC)

J.C. Wiebe[1], Á. Santana[2], N. Medina Rodríguez[2,3], M. Hernández[4], J. Nóvoa[1,5], D. Mauricio[6], A.M. Wägner on behalf of the T1DGC[1,5];
[1]Endocrinology Dept, Complejo Hospitalario Universitario Insular-Materno Infantil de Gran Canaria, [2]Dept of Mathematics and Statistics, Universidad de Las Palmas de Gran Canaria, [3]Iuma, ULPGC, Las Palmas de Gran Canaria, [4]Endocrinology Dept., Hospital Universitary Arnau de Vilanova, Lleida, [5]Dept of Medical and Surgical Science, ULPGC, Las Palmas de Gran Canaria, [6]Hospital Germans Trias i Pujol, Badalona, Spain.

Background and aims: A recent Finnish study described reduced fertility in patients with childhood-onset type 1 diabetes (T1D). The T1DGC is an international effort aimed at the study of the genetics and pathogenesis of T1D where families with at least 2 affected siblings have been included from all over the world. The aim of our study was to assess fertility and its distribution in the T1DGC dataset available on 1st October 2009.
Materials and methods: Clinical information, including family history, was obtained using questionnaires at each of the participating centres. Only subjects aged 18 or more at the time of examination were included in the present analysis. Affected and unaffected siblings were compared regarding the number of offspring (chi squared and Wilcoxon's test) and stratified by gender. Non-parametric adjustments were performed for age of birth and age of onset. Additional analyses were performed in those families comprising both affected and unaffected siblings, and the number of offspring was compared within each family. Statistical analysis was performed using "R".
Results: A total of 2929 affected and 759 unaffected adult siblings were assessed, belonging to 1748 families. Mean age was 32.3 (11.0) years and 51% were women. Offspring were distributed as shown in the table: chi-squared= 64.33, p-value = 3.563*10-13.This distribution was skewed at the expense of women, whereas men did not show a difference. Birth year did not significantly affect the differences seen between groups. However, there was a positive correlation between the age of onset and the number of offspring: 0.28 (0.25-0.31), p<2.2 10-16. When only families with at least one unaffected sibling were included (N=1153), the difference between the affected and unaffected sibling ranged between 0.14-0.15 children (p=7.6*10-5).
Conclusion: Women with T1D have fewer children than their unaffected siblings, but such an effect is not seen in men with the disease. Birth cohort does not seem to affect this observation. Later age of onset of diabetes is associated with a higher number of offspring.

Nº of offspring	0	1	2	3	≥4
Affected (%)	60.61	16.52	16.56	4.97	1.34
Non- Affected (%)	54.35	12.01	19.79	9.50	4.35

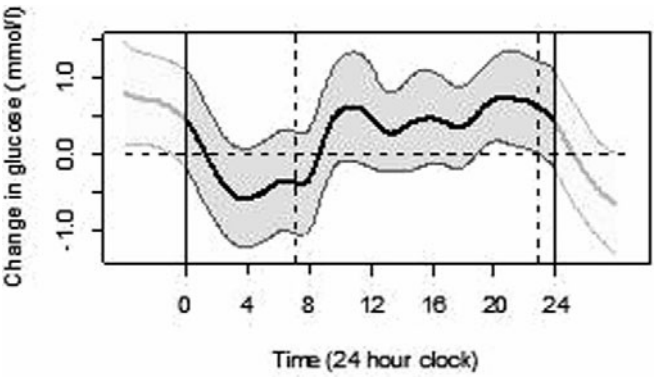
Circadian variation in glucose during diabetic pregnancy is associated with macrosomia in the newborn

E.M. Scott[1], G.T.H. Ellison[2], R. Temple[3], H. Murphy[4], G.R. Law[2];
[1]Division of Cardiovascular and Diabetes Research, [2]Division of Biostatistics, University of Leeds, [3]Norfolk and Norwich NHS Trust, Norwich, [4]Institute of Metabolic Sciences, University of Cambridge, UK.

Background and aims: Macrosomia is the commonest complication of diabetic pregnancy, often occurring despite achieving good glucose control as measured by HbA1c and home blood glucose monitoring. Although it is commonly attributed to hyperglycemia, the actual continuous glucose profile across the 24 hour day/night cycle that is associated with its development has not been described. The purpose of this study was to determine the circadian glucose profile associated with macrosomia in well controlled diabetic pregnancy, utilising functional data analysis of glucose obtained by CGMS (Continuous Glucose Monitoring System) from a previous observational study.
Materials and methods: We developed functional data analysis to analyse the numerous and complex data obtained by CGMS in 35 Type 1 and 14 Type 2 diabetic pregnancies. 256640 glucose measurements were made over 171 measurement sessions. Knot placement was fixed at equally-spaced points every 30 minutes over the 24 hour time period, with extensions by 4 hours either side of midnight to remove edge effects. Mean functions were calculated for subgroups of mothers, divided by Type of diabetes, or by those with or without macrosomia. A functional regression model was fit with the outcome glucose as a function and trimester, Type of diabetes and macrosomia as scalar variables. Pointwise 95% confidence intervals were calculated. Macrosomia was defined as above the 90th centile for gestation-adjusted birth-weight.
Results: Of the 49 live births, 23 (47%) pregnancies resulted in a baby with macrosomia, and 26 (53%) babies did not have macrosomia. Mothers who developed macrosomic babies had a greater circadian variation in glucose with significantly higher levels of glucose during the daytime and evening (by 0.8 mmol/l), but lower levels from 1am until 9am (by 0.6 mmol/l), compared to mothers who did not develop macrosomia (see figure).
Conclusions: This study is the first to demonstrate, using functional data analysis, the circadian variation in glucose that is associated with the development of macrosomia in diabetic pregnancy. It confirms established evidence that postprandial hyperglycemia during the day is associated with macrosomia, but gives novel information about the contribution of nocturnal glucose control and suggests that relative hypoglycemia has an important role to play. This information is important to enable development of more accurate diagnostic and prognostic assessments, and optimize the application of new therapeutic technologies in insulin administration. Glucose levels associated with macrosomia with 95% pointwise confidence intervals derived from a functional regression model.



1291

In pregnancy maternal active ghrelin levels predict positively neonatal birth waist and negatively cord blood insulin levels

G. Valsamakis[1], D.C. Papatheodorou[1], A. Naoum[1], A. Margeli[2], I. Papassotiriou[2], E. Kapantais[3], G. Creatsas[4], G. Mastorakos[1];
[1]Endocrine Unit, Aretaieion University Hospital, [2]Department of Clinical Biochemistry, "Aghia Sophia" Children's Hospital, [3]Diabetes and Obesity, Metropolitan Hospital, [4]2nd Department Obs&Gynae, Aretaieion University Hospital, Athens, Greece.

Background and aims: During pregnancy maternal appetite-dependent mechanisms contribute to energy intake for mother and fetus. Neonatal waist is associated to its future growth and metabolic health while it reflects adipose tissue and hence, energy deposits. We aimed to investigate, during pregnancy, the association of fasting maternal appetite-related hormones levels [the gut-derived ghrelin (active), GLP1(active) and total PYY and the adipocytokine leptin] with neonatal waist, percent total body fat and insulin levels at birth.
Materials and methods: 80 non-obese non-diabetic primigravidae women (mean±SD; age: 26.9±2.5 years; pre-pregnancy BMI 23.5±2.2 kg/m^2) were seen at each of the three trimesters. At each visit they had blood sampling for hormones measurements and a 2hr 75gr oral glucose tolerance test. At birth, neonates were submitted to anthropometry and cord blood sampling for c-peptide, glucose, insulin, adiponectin and leptin measurements.
Results: Second trimester maternal active ghrelin levels correlated positively with neonatal waist (p=0.04, r=0.75) while the former, by using stepwise multiple regression, were the best positive predictor of the latter (p=0.03, beta=0.84)among all fasting maternal appetite related hormones studied. Third trimester maternal active ghrelin levels correlated negatively with percent total neonatal body fat (p=0.04, r=-0.94), fetal HOMAR (p=0.021, r=-0.829) and cord blood insulin levels (p=0.04, r=-0.829) while maternal active ghrelin levels were by multiple regression analysis, the best

negative predictor of cord blood insulin levels (p=0.02, beta=-0.99)among all fasting maternal appetite related hormones. Third trimester maternal leptin levels correlated negatively with neonatal waist (p=0.027, r=-0.81). **Conclusion:** During a non-diabetic non-obese pregnancy circulating maternal active ghrelin, a pro-appetite hormone, is associated with neonatal visceral energy storage (as expressed by neonatal waist).By inhibiting glucose-driven maternal insulin secretion, ghrelin ensures adequate fasting glucose and nutrient supplies to the fetus while limiting overall fetal adipose tissue deposition.

Risk factors of macrosomia in type 1 diabetes pregnancy: one centre analysis between 1999 and 2012

K. Cyganek[1], B. Katra[1,2], J. Skupien[2], A. Hebda-Szydło[1], I. Janas[1], I. Trznadel-Morawska[1,2], M. Szopa[2], P. Witek[1,2], E. Kozek[1,2], M.T. Malecki[1,2]; [1]Department of Metabolic Diseases, University Hospital, [2]Department of Metabolic Diseases, Jagiellonian University, Medical College, Krakow, Poland.

Background and aims: Type 1 diabetes mellitus (T1DM) in pregnancy is associated with increased risk of maternal and fetal complications. Macrosomia is one of the most frequent complications of pregnancy in T1DM women. Its risk remains high in spite of recent advances in diabetes care during pregnancy and improvement in glycemic control observed in many European countries. We aimed to examine the impact of maternal glycemic control on birth weight and to identify risk factors of macrosomia in T1DM women.
Materials and methods: We accessed records of 502 T1DM pregnancies, treated at the Department of Metabolic Diseases between 1999 and 2012. We excluded women who experienced miscarriages (n=40), preterm deliveries (n=71) or with missing outcome variables (n=16). In 375 women, linear regression models were used to examine the impact of glycemia assessed by HbA1c and mean of measurements in daily glucometric profiles in each trimester on birth weight. We also evaluated maternal age, BMI, weight gain and pregnancy planning. Logistic regression was used to model risk of macrosomia (> 4 kg). The models were adjusted for gestational age.
Results: The mean age (±SD) of the women was 28.2±4.7 years, diabetes duration - 11.9±7.6 years. Their pregestational BMI was 24.0±4.4 kg/m2. The mean birth weight was 3.57±0.58 kg at 39.3±1.5 gestation week. There were 85 (22.7%) macrosomic newborns. HbA1c in the 1st, 2nd and 3rd trimester was 6.8±1.3, 5.8±0.9 and 5.7±0.8 %, respectively, while mean glucose in daily profiles was 6.1±1.3, 5.8±0.9 and 5.8±0.9 mmol/l. There was no association between 1st trimester HbA1c or glucose and birth weight. Birth weight was higher by 74 g per 1% increase in 2nd trimester HbA1c (p=0.024) and by 157 g per 1 mmol/l increase in mean glucose (p<0.001). The corresponding effects in the 3rd trimester were 219 g per 1% and 155 g per 1 mmol/l (p<0.001 each). Third trimester HbA1c and glucose were independent predictors of birth weight and macrosomia, as was maternal age. The analysis restricted to women who reached the recommended criterion of HbA1c<6.0% in the 3rd trimester (n=210) revealed similar risk factors.
Conclusion: Macrosomia in children of T1DM mothers was prevalent (> 20%) in this one-center cohort despite excellent metabolic control. Hyperglycemia during the 3rd trimester was predominantly responsible for this condition, other risk factors were 2nd trimester glycemia and maternal age.

1293

1, 5-Anhydroglucitol (1, 5 AG) and neonatal complications in pregnancy complicated by diabetes

L.A. Wright[1], I.B. Hirsch[1], T. Gooley[2], Z. Brown[3]; [1]Endocrinology, [2]Biostatistics, [3]Maternal Fetal Medicine, University of Washington, Seattle, USA.

Background and aims: Macrosomia is characterized by disparate rates of fetal growth and abdominal obesity. Large for gestational age (LGA) babies are at risk of neonatal hypoglycemia (NH) despite excess abdominal fat, attributed to poor maternal glycemic control; mainly postprandial hyperglycemia (PH). Low levels of 1,5 AG are associated with PH in non-pregnant diabetic patients. We investigated associations of 1,5 AG on neonatal birth weight (NBW) and parameters of fetal growth (FG) by ultrasound (US) that may help predict LGA and NH and compared to HbA_{1c}.
Materials and methods: Retrospective cohort of 102 consecutive pregnancies: 17 with gestational diabetes (GD), 48 with Type 1 and 37 with Type 2 diabetes seen at the University of Washington Medical Center. To determine the association of 1,5 AG with parameters of FG and NBW, we extracted monthly simultaneous 1,5 AG and HbA_{1c} values throughout pregnancy until delivery. From the infants' records, NBWs were evaluated by standardized z-scores, controlling for gestational age at delivery and gender. Generalized Estimating Equations were used to examine the association of 1,5 AG with FG measurements: length, abdominal (AC) and head circumference (HC), after adjusting for gestational week. Linear regression was used to assess the association of 1,5 AG and HbA_{1c} with NBW z-scores. NH was defined by a note in the infant record, capillary glucose in mmol/l of <1.7 in the first 24 h or <2.5 in the first 48 h after birth. A t-test or Welch's approximate t-test was used to compare the mean 1,5 AG of mothers with babies with NH vs those without. Data were analyzed by type of diabetes and trimester.
Results: A negative association was found between 1,5 AG and NBW z-scores; and 1,5 AG and AC. With 1,5 AG modeled as a linear function, increasing values were associated with decreased z-scores, R=-.28, p=.008. There was also evidence that the association was non-linear, with a larger negative association for lower 1,5 AG values relative to larger values. In contrast the association between HbA_{1c} and z-scores was NS. Results were similar across type of diabetes and trimester, independent of BMI. Similarly as 1,5 AG increased, AC decreased, p=.0002. 1,5 AG's association with length or HC was NS. The mean 1,5 AG (μg/ml) in all women was lower in the NH group vs the non-NH: 4.68 (*n 54*) vs 6.13 (*n 47*) respectively, but NS, p=.08. In women with GD and NH, the mean 1,5 AG vs the no-NH GD group was significant: 6.08 (*n 7*) vs 10.86 (*n 10*), p=.01; more so in the 3rd trimester: 5.62 (*n 7*) vs 12.54 (*n 7*), p=.006; but not for other types of diabetes.
Conclusion: AC is the most reliable prenatal parameter to assess the risk of LGA. Our preliminary analysis demonstrates an association of 1,5 AG with AC by US and NBW. 1,5 AG's lack of association with length and HC is in agreement with previous observations on the disproportionate size of the abdomen girth described in diabetic fetopathy but normal HC and length. The mean 1,5 AG was lower in the NH group but statistically significant only for GD. Further examination of this is called for, as the *n* in this cohort provides limited statistical power. 1,5 AG's association with known complications related to PH, superior to HbA_{1c}, support the notion of its utility in all types of diabetes during pregnancy and across trimesters. 1,5 AG can help predict risk of LGA early in pregnancy and alert aggressive glycemic interventions to reduce its occurrence.

1294

Pregnancy outcomes in diabetic type 1 patients of an academic centre combining endocrine and obstetric care from before conception to delivery; still not good enough

L.B.E. Hoeks[1], H.W. de Valk[1], A.C. de Kat[2], G.H.A. Visser[3]; [1]Internal Medicine, University Medical Center, [2]Internal Medicine, University Utrecht, [3]Obstetrical Gynaecology, University Medical Center, Utrecht, Netherlands.

Background and aims: Numerous studies in the last decades have shown that pregnancies in women with type 1 diabetes remained associated with an increased incidence of adverse outcomes, such as congenital malformations, perinatal mortality and fetal macrosomia. Not only optimal glycaemic control, from preconception period until and including delivery, is of paramount importance but also careful planning of pregnancy, preconceptional counselling and adequate timed obstetrical interventions at the end of pregnancy are very important issues. Therefore, close collaboration between the endocrinologist and the obstetrician is of prime importance in the management of the diabetic pregnancy. We report the pregnancy outcomes during the past 18 years of working with a structured clinical collaborative scheme extending from the preconceptional to the post-delivery period in an attempt to optimise treatment with special emphasis on the patients who were treated from preconceptional period until and including delivery.
Material and methods: This is an observational, cohort study. All women with type 1 diabetes mellitus with a singleton pregnancy progressing beyond 16 weeks of gestational age who delivered at our center from January 1993 until January 1, 2011 were included. Baseline characteristics: maternal data and diabetes-related parameters. Outcome measurements: HbA1c**,** perinatal mortality (PNM), congenital malformations, Large for Gestational Age(LGA) infants ,preeclampsia, preterm delivery, low Apgar score, obstetric interventions.
Results: 243 pregnancies in 156 women fulfilled inclusion criteria. Pregnancy outcomes were still unfavourable with 9.2% of congenital malformations and 40.9% of LGA children. Overall PNM was 2.1%, but only 0.6% in women

treated from before conception till delivery. Median HbA1c before pregnancy in the latter group was 7.0% and 1st, 2nd, 3rd trimester values were 6.8, 6.1 and 6.3, respectively. Preterm delivery in this group occurred in one-third of the pregnancies, almost exclusively between 35 and 37 weeks. More than half of the pregnancies in group 1 ended in a Caesarean section (56.9%).
Conclusion: Despite our multidisciplinary efforts in a combined and specialised outpatient clinic the aims of the St Vincent declaration were still not met. Although perinatal mortality was reduced, at the cost of high intervention rates, the incidence of malformations and LGA infants remained unchanged. Apparently at this moment we are not able to meet the specific demands of a diabetic pregnancy. Further improvements may prove difficult. A radical rethinking is maybe needed with more emphasis on the periconceptive period as well as innovative steps to meet social as well as medical social requirements. We must pose the important question how much patients themselves as well as the general society are willing to invest in overcoming the final gap to the goal of the St Vincent declaration.

1295

Obesity and gestational weight gain both contribute to the risk of large for gestational age babies in women without gestational diabetes mellitus
E. Cosson, P. Valensi, I. Pharisien, M. Nguyen, L. Carbillon;
AP-HP, Jean Verdier Hospital, Bondy, France.

Background and aims: The aim was to retrospectively evaluate, in a highly-selected cohort of pregnant women universally screened and treated for gestational diabetes mellitus (GDM), the association between prepregnancy overweight (OW) or obesity (OB) and pregnancy complications.
Materials and methods: We selected 15.551 women without prepregnancy diabetes or hypertensive disorders, neither from Asia India Pakistan Sri Lanka origins nor underweighted, who delivered between 2002 and 2010 of singleton babies. Women were classified according to BMI (normal (N: BMI 18.5-24.9) n=9.317; OW n=4.075; OB (BMI≥30 kg/m^2) n=2.159), GDM and gestational weight gain (GWG <7: 32%; 7-11.5: 37%; 11.6-16: 23%, >16kg: 8%).
Results: GDM (12.8, 14.4, 14.9%, p<0.01), GWG (9.1±5.6, 8.8±5.6, 8.5±5.8 kg, p<0.001), small for gestational age babies (14.3, 12.7, 12.3%, p<0.01), preeclampsia (2.0, 2.2, 2.9%, p<0.05) but neither large for gestational age babies (LGA: 8.4, 8.9, 9.4%, p=0.27) nor caesarian section (20.9, 21.2, 21.2%, p=0.97) were associated with N, OW and OB status, respectively. The higher the BMI (N, OW, OB) and GWG classes, the more frequent LGA in the women with GDM (overall effect p<0.001, BMI effect NS, GWG effect NS, interaction NS) or without GDM (overall p<0.001, BMI effect p<0.05, GWG effect p<0.05, interaction p=0.051). For example, in women without GDM, the prevalence of LGA babies was 5.5% in women with normal BMI and GWG <7 kg, and 20.3% in those with OB and GWG >16 kg. The respective prevalences in the women with GDM were 14.3 and 29.2%.
Conclusion: OW/OB is associated with more GDM and preeclampsia. The risk of LGA babies associated with OW/OB is amplified by GWG particularly in women without GDM. This suggests that dietary advice should be given to OW/OB women to control GWG.

1296

Outcome of pregnancies in women with type 1 diabetes
M. Landin-Olsson[1], D. Ursing[2], H. Strevens[3];
[1]Department of Clinical Sciences/Endocrinology, [2]Department of Endocrinology, [3]Department of Obstetrics and Gynaecology, Lund University, Lund, Sweden.

Introduction and aims: The outcome of pregnancies in women with type 1 diabetes has improved significantly during the last decades. The previous high frequencies of miscarriages, malformations, premature births, and other complications have declined due to better glycaemia control. In this study we have compared outcome of pregnancies among type 1 diabetic women in our Hospital to the outcome for all pregnancies in the general population in Sweden. Our model for taking care of pregnant women with type 1 includes the following: optimising glucose control prior to pregnancy, a specialised unit for gestational care including obstetrician, diabetologist, midwife and dietician, intensified self monitored glucose measurements with daily seven point curve of p-glucose, weekly phone communication with diabetologist to adjust insulin dose after sending glucose values by Diasend, possibility to direct contact with diabetologist 24 h a day for both pregnant women, midwifes and obstetricians, extra ultrasound late in pregnancy to estimate growth of foetus, liberality to start labour if rapid growth and continuous contact with diabetologist during labour.
Materials and methods: During the years 2000-2010, the pregnancies of 202 consecutive women with type 1 diabetes have been studied. A team of obstetrician, diabetologist, midwife and dietician took care of these women at a specialist unit. The goal was to normalise the glucose levels by tight control with frequent self monitored glucose measurements and weekly contact with diabetologist to adjust the insulin dose.
Results: These women had have diabetes for 15.5±8.0 yrs, their initial daily dose of insulin increased from 50.0±17.5 E to 86.3±35.4 E, weight increased from 70.1±10.3 kg to 85.0±11.1 kg. HbA_{1c} decreased from 55.2±10.5 to 39.2±4.7 mmol/mol at the end of the pregnancy. The mean weight of the newborns was 3566±721 g. The frequency of preeclampsia was 25/201 (12.3%), instrumental delivery 26/200 (12.7%) and prematurity 40/201 (19.6%). The frequencies of newborns having Apgar ≥7 after 5 min was 98%, neonatal hypoglycaemia 44/200 (22%), any type of malformation 16/202 (7.9%), and neonatal death was 3/202 (1.5%).
Conclusion: The outcome of pregnancy in women with type 1 diabetes is comparable with normal pregnancies due to an extreme good metabolic control, which requires a multidisciplinary team and high compliance of the patients.

Deliveries - mother with T1D compared to background population

Maternal high fat diet alters weight regulation and blood glucose prior to mating but not during gestation, and reduces offspring weight at weaning
K. Rooney[1], K. Fredericks[1], P. Ruell[1], Y. Mavros[1], C. Thompson[2], S. Ozanne[3];
[1]University of Sydney, Lidcombe, [2]University of Adelaide, Australia, [3]University of Cambridge, UK.

Background and aims: We have previously reported elevated abdominal adiposity together with reduced hepatic insulin signalling proteins in 15 week old offspring of dams fed a high fat (HF) diet during gestation. We have also reported that physical activity during pregnancy reduces birth weight of offspring born to HF mothers. What is currently unknown is the specific maternal characteristics that may be driving disturbed metabolic development in the offspring and if these disturbances are present in offspring from birth or develop in the post-weaning environment. These are important questions to answer in aid of informing targeted interventions at the developmental origins of disease. We therefore aimed to characterise our high fat fed maternal model in both sedentary and exercise trained mothers as well as investigating offspring outcomes at weaning.
Materials and methods: 24 females (150g) were fed either a HF diet (34% omega-6 PUFA, 26% Protein, 22.3 kJ/g n = 12) or a standard chow (C) diet (11% fat, 23% Protein, 13.9 kJ/g n = 12) for 28 days. On day 24 fasting blood was collected and analysed for glucose, insulin and leptin. On day 28, mating pairs were established. Following conception, six females from each dietary group were randomly allocated to a training intervention. Training consisted of 30min of treadmill running at a moderate intensity for 10 days of the 16 between mating and spontaneous delivery. A fasting blood sample was collected from all females on the 19th day of gestation. Following delivery, all pups were weighed and litter sizes standardised to 8 (4m, 4f) per dam. During lactation all mothers were fed standard laboratory chow. Body weight was recorded throughout lactation and a fasting blood sample was collected from offspring and mothers at weaning (day 25 post-partum).

Results: Maternal body weight prior to mating was similar between all groups as was plasma insulin and leptin. However, maternal blood glucose was significantly elevated in HF mothers prior to mating ($p = 0.002$). During pregnancy, blood glucose normalised between groups. Plasma insulin was similar between all groups, however insulin was significantly elevated compared to pre-mating values ($p < 0.004$) for all groups. While exercise training did not significantly affect weight gain during pregnancy, HF did result in lower weight gain in the HF sedentary group compared to sedentary controls ($p = 0.02$). Offspring of HF mothers displayed lower body weight ($p = 0.03$) compared to controls throughout lactation. No significant effect of maternal diet or activity was observed for offspring glucose, insulin or leptin. Interestingly, fasting induced weight loss was greatest in C mothers prior to mating and during gestation.
Conclusion: HF feeding resulted in maternal hyperglycaemia prior to mating and disturbances in weight regulation during fasting. Metabolic outcomes were normalised however during gestation. Furthermore, offspring of HF mothers were smaller than controls despite comparable metabolic outcomes. Our data suggest that the developmental origins of disease in our model are more likely related to an interaction between maternal diets *per se* and offspring post-weaning environment.

Excretion of amino nitrogen and ammonia with the urine in patients with type 1 diabetes, according to the gestational age and the severity of nephropathy

Z.R. Alimetova, F.V. Valeeva;
Hospital Therapy, Kazan State Medical University, Kazan, Russian Federation.

Background and aims: To study excretion of amino nitrogen and ammonia with a daily urine for the early detection of tubular dysfunction in women with diabetes mellitus type 1, depending on gestational age and stage of diabetic nephropathy.
Materials and methods: We monitored 100 pregnant women with type 1 diabetes: 58 women - in the first trimester up to 12 weeks, 58 pregnant women - in the 2nd trimester, 22-24 weeks, 53 patients - in the 3rd trimester, 32-34 weeks. Age of women was from 19 to 37 years [26 (23, 29) years], diabetes duration of 1 month to 20 years [9 (2.75, 12.5) years]. Stage of diabetic nephropathy was defined by the level of albumin in the urine. The function of the proximal tubules was assessed by daily excretion of amino nitrogen (nitrogen of amino acids that are in the test substrate), of the distal tubules - the ability to maintain the acid-base status - daily ammonia excretion (indicator of reabsorbed amino acids metabolism). The control group consisted of 18 healthy women in different trimesters of pregnancy at the age of 20 to 32 years, an average of 27 (23, 32) years. Statistical analysis was performed with nonparametric methods of statistics.
Results: The study showed an increase of excretion of ammonia and amino nitrogen in the urine of pregnant women with type 1 diabetes in all trimesters of pregnancy compared to healthy pregnant women. In the study of excretion of ammonia and amino nitrogen with the daily urine in patients with normoalbuminuria showed its increase in 2 and 3 trimesters of pregnancy, which is more pronounced in the 2nd trimester. In patients with microalbuminuria showed a reduction in excretion of ammonia and amino nitrogen with increasing of gestational age. In patients with macroproteinuria we found increased excretion of ammonia and amino nitrogen in the 2 trimester with a reduction of these values in 3rd trimester which are even lower than in 1 trimester. Regardless of the trimester, with the progression of nephropathy showed a reduction in ammonia excretion in the urine and increased excretion of amino nitrogen. We revealed high correlation between ammonia and amino nitrogen during all trimesters of pregnancy in all groups of patients, with complete direct link in the group of macroproteinuria in 1 trimester (r=1) and the complete reverse link of the same group in the 3rd trimester of pregnancy (r=-1). A strong correlation was also found between the level of ammonia and glomerular filtration rate in the group of microalbuminuria in the 3rd trimester of pregnancy (r=0,9), and in all three trimesters in macroalbuminuria group (r=1, r=0,77 and r=1, trimesters, respectively). A strong correlation was also observed between the excretion of ammonia and ethanolamine in the urine in the normoalbuminuria group in 1 trimester (r=0,75), microalbuminuria group 1 (r=0,75) and 2 (r=0,75) trimesters of pregnancy, macroproteinuric group 1 (r=-1), 2 (r=0,77) and 3 (r=1) trimesters.
Conclusion: In patients with type 1 diabetes with increasing of gestational changes ammonia and urinary amino nitrogen excretion with a daily urine indicate involvement of the both distal and proximal tubules. Differences in rates depending on the stage of nephropathy and pregnancy can point to different compensatory potentials of kidneys.

Endothelial dysfunction induced by dipeptidyl peptidase-4 in isolated mice mesenteric microvessels

C.F. Sanchez-Ferrer[1], T. Romacho[2], S. Vallejo[1], L.A. Villalobos[1], N. Wronkowitz[2], H. Sell[2], J. Eckel[2], C. Peiro[1];
[1]Farmacologia, Universidad Autonoma de Madrid, Spain, [2]Paul-Langerhans-Group, German Diabetes Center, Düsseldorf, Germany.

Background and aims: Cardiovascular diseases are the main cause of morbidity and mortality in obese and diabetic patients. Dipeptidyl peptidase-4 (DPP-4) is a multifunctional glycoprotein playing a major role in the regulation of glucose homeostasis. At present, DPP-4 inhibitors are used to prolong the insulinotrophic effects of incretins. Recently, DPP-4 has been identified as a novel adipokine over-secreted in obesity where it promotes insulin resistance and may represent a link between adipose tissue and the metabolic syndrome (Lamers et al. Diabetes 60: 1917-25, 2011). The aim of this study was to analyse the ability of DPP-4 to directly impact on endothelial function with special focus on endothelium-derived relaxation.
Material and methods: Mesenteric microvascular segments isolated from 3 month-old female B57BL/6 mice were mounted on a small vessel wire myograph to determine vascular reactivity.
Results: In the mice mesenteric microvessels pre-incubated with DPP-4 (20 to 500 ng/mL), the contractility to noradrenaline (1 nmol/L to 1 μmol/L) was not altered. However, DPP-4 impaired the endothelium-dependent relaxation to acetylcholine (1 nmol/L to 1 μmol/L) in a concentration-dependent manner by a 75%, without modifying endothelium-independent relaxations to sodium nitroprusside (1 nmol/L to 10 μmol/L). Moreover, the co-incubation of DPP-4 (200 ng/mL) with its enzymatic inhibitor K579 (100 nmol/L) prevented the impaired endothelium-dependent relaxation by DPP-4. Similarly, the cyclooxygenase inhibitor indomethacin (10 μmol/L) and the thromboxane A2 receptor antagonist SQ29548 (10 μmol/L) did abrogate the impairing action of DPP-4. The NADPH-oxidase inhibitor apocynin (10 μmol/L) did not restore the relaxation impaired by DPP-4.
Conclusion: DPP-4 directly impairs endothelium-dependent relaxation, through a mechanism that involves cyclooxygenase activation and likely the release of a vasoconstrictor prostanoid. Over-production of DPP-4 in obesity and diabetes might therefore contribute to endothelial dysfunction associated with both metabolic diseases.

Hyperglycaemia-induced resistance to GLP-1 in the endothelium: the possible involvement of NRF2 and PKC pathway

G. Pujadas[1], L. La Sala[1], A. Ceriello[1,2];
[1]Diabetes and CVD Research Group. Institut d'Investigacions biomèdiques August Pi i Sunyer (IDIBAPS), [2]CIBER de Diabetes y Enfermedades Metabólicas Asociadas (CIBERDEM), Barcelona, Spain.

Background and aims: Hyperglycaemia induces endothelial dysfunction, which contributes to the development of cardiovascular disease (CVD) in diabetes. Activation of transcription nuclear factor (erythroid-derived 2)-like 2 (NRF2) is associated with its translocation into the nucleus stimulating the expression of a great number of genes responsible for the synthesis of antioxidant proteins, including heme oxygenase-1 (HMOX-1) and NAD(P)H dehydrogenase quinone-1 (NQO-1). Recently, GPL-1 has been proposed as an antioxidant agent, because it increases intracellular antioxidant gene expression. Furthermore, we have recently reported, in vivo, that hyperglycaemia induces endothelial resistance to the action of GLP-1, in terms of reducing GLP-1 effects on endothelial function, inflammation and oxidative stress. It has been also reported that PKCβ overexpression, induced by hyperglycaemia, is able to reduce GLP-1 receptor expression. The aim of this study is to asses if hyperglycaemia induced PKCβ activation is involved in the appearance of GLP-1 resistance and test if other molecular mechanisms are involved.
Materials and methods: HuVEC cells were cultured for 21 days in normal (5mmol/L, NG) or high glucose (25mmol/L, HG), and treated with GPL-1 at 50nmol/L for 1h before being harvested. Differences on gene and protein expression of the antioxidant enzymes HMOX-1 and NQO-1, of the ER stress/UPR genes (CHOP and PERK) and of the proliferation/apoptosis-related genes (BCL-2 and CDKN1A) were evaluated by quantitative real time PCR and immunobloting. In parallel, GLP-1 receptor and PKCβ protein levels were also tested, as well as NRF2 cytoplasm-nucleus translocation.
Results: High glucose, as well as GLP-1 added in normoglycaemia, induced the expression of antioxidant genes HMOX-1 and NQO-1, (NG vs HG or vs NG+GLP-1, HMOX-1 $p<0.01$ and $p<0.05$; NQO-1 $p<0.05$ and $p<0.05$, respectively). GLP-1 induces NRF2 translocation into the nucleus in normoglycaemia, allowing antioxidant response, but this was not happening when GLP-1 was added after sustained high glucose exposure. The same effect was observed with UPR markers CHOP and PERK (NG vs HG or vs NG+GLP-1, CHOP $p<0.05$ and $p<0.05$; PERK $p<0.01$ and $p<0.05$, respectively). Moreover, proliferation related genes, CDKN1A and BCL-2 were induced and repressed by hyperglycaemia, respectively (NG vs HG $p<0.05$ CDKN1A and $p<0.01$ BCL-2), as well as GLP-1 increases its expression in normoglycaemia in both cases (NG vs NG+GLP-1, $p<0.01$ and $p<0.05$, CDKN1A and BCL-2 respectively). Interestingly, a complete loss of GLP-1 capacity was observed after HuVECs were exposed to high glucose (NG vs HG p=NS in all cases). All these effects were accompanied by a reduction of GLP-1 receptor protein levels (NG vs HG $p<0.05$) and by an increase in PKC isoform βI expression (NG vs HG $p<0.05$).
Conclusion: These findings suggest that endothelial cells, after the exposure to high glucose, lose their ability to normally respond to the GLP-1 action, in terms of activating their antioxidant capacity, in a possible NRF2-responsive dependent manner. HuVECs also lose GLP-1 capacity in regulating ER function and UPR response to GLP-1 under hyperglycaemia. This resistance to GLP-1 during chronic high glucose exposure could be due to an increase in PKCβ activity that reduces GLP-1 receptor pathway.

The phosphodiesterase-5 inhibitor tadalafil decreases ET-1 expression in HUVECs and suppresses circulating ET-1 levels type 2 diabetes mellitus patients

J. Olausson, L. Sjögren, L. Mattsson Hultén, P.A. Jansson;
Molecular and Clinical Medicine, Göteborg, Sweden.

Background and aims: Impaired insulin action reduces synthesis of nitric oxide (NO) and elevates expression of endothelin-1 (ET-1) in vascular endothelial cells, i.e. promotes endothelial dysfunction and vascular inflammation. Tadalafil is a selective phosphodiesterase-5 (PDE-5) inhibitor that enhances NO signaling pathway by augmenting formation of cyclic guanosine monophosphate (cGMP) through reduction of its hydrolysis by cGMP-degrading PDEs. Thus, PDE-5 inhibitors may induce anti-inflammatory effects through an enhanced NO signaling in endothelial cells. However, it is unknown whether acute administration of tadalafil may decrease circulating ET-1 levels in type 2 diabetes (T2DM). Therefore, the aim of this study was to evaluate whether tadalafil attenuates ET-1 expression in HUVECs in vitro and if tadalafil 20 mg compared with placebo decreases ET-1 levels after a mixed meal in T2DM patients.
Materials and methods: TNF-α was used to mimic inflammatory activation in HUVECs. Cells were treated with 1 μM tadalafil and after 12 hours medium from cell culture was collected and RNA was extracted and analysed with quantitative PCR. Twenty-six T2DM patients who met the following criteria: (1) Age 40-70 (men) and 50-70 years (postmenopausal women); (2) BMI 27-40 kg/m2; (3) HbA1c <60 mmol/mol, were recruited to a study with parallel groups, and after a double blind randomisation they received either 20 mg tadalafil or placebo 30 min prior to a mixed meal consisting of 74 g carbohydrates, 25 g protein and 42 g fat. Arterial blood sampling was conducted at baseline, three and five hours after intake of the meal. Differences in vitro were analysed using paired t-test, while in vivo we used Mann-Whitney U-test, p-value < 0.05 was considered significant.
Results: After TNF-α stimuli tadalafil was able to significantly attenuate mRNA expression of ET-1 by 48 % in HUVECs compared to cells stimulated by TNF-α alone. Similarly, when measuring ET-1 in conditioned medium, ET-1 levels were decreased by 17 %, a moderate but significant reduction. Three hours after a mixed meal circulating ET-1 levels were significantly decreased in patients treated with tadalafil compared with placebo treated patients (Fig 1, $p<0.05$). No significant differences appeared in Gender (F/M): 5/9 vs 4/8; Age (years): 60±2.3 vs 62±1.7 BMI (kg/m2): 29.8±1.0 vs 30.9±1.2; HbA1c (mmol/mol): 45±1.8 vs 45±2.3; Glucose AUC300: 2465 vs 2525; Insulin AUC300: 9158 vs 10689, between the tadalafil- and placebo treated groups, respectively.

Conclusion: In summary, our data show that tadalafil decreases ET-1 expression in human vascular endothelial cells in vitro and suppresses circulating ET-1 levels in vivo after a mixed meal. We propose that tadalafil may act as a potent drug against endothelial dysfunction induced by ET-1 in T2DM patients.

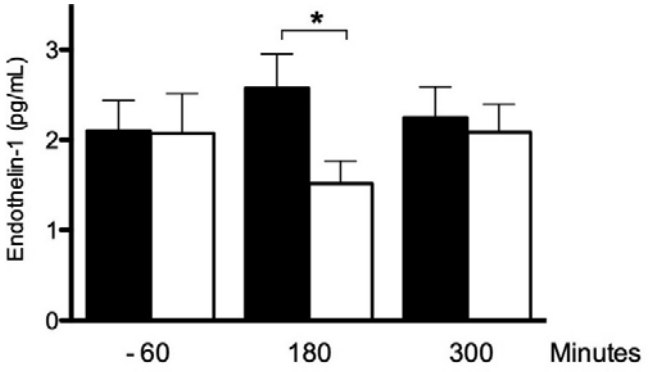

Fig 1. Arterial concentrations of Endothelin-1 before and after a mixed meal in T2DM patients randomised to tadalafil 20 mg or placebo. Black bars placebo n = 12; white bars tadalafil n = 14. *, $p < 0.05$, data presented as mean ± SEM.

The new role of PDK4 in vascular calcification

I.-K. Lee[1], S.-J. Lee[1], J. Jeong[1], K.-U. Lee[2];
[1]Internal Medicine, Kyungpook National University, Daegu, [2]Internal Medicine, University of Ulsan College of Medicine, Seoul, Republic of Korea.

Background and aims: Vascular calcification is a well-established risk factor of cardiovascular events associated with aging, diabetes, renal failure, vitamin D intoxication, and hyperphosphatemia. Osteogenic switch of vascular smooth muscle cells (VSMCs) triggered by procalcific stimuli such as ROS and excess inorganic phosphous (Pi) was recognized as a key step in mechanism of vascular calcification. We observed that pyruvate dehydrogenase kinase 4 (PDK4), a mitochondrial protein to regulate of glucose oxidation, increased its expression in human VSMCs cultured mineralization medium. We assessed whether inhibition of PDK4 could decrease vascular calcification and further investigated the molecular mechanism in details.
Materials and methods: We evaluated the mineralization induced by Pi in vitro using von Kossa staining and quantitative analysis of calcium in VSMCs and isolated aorta. Vitamin D was injected to PDK4 deficient mice for inducing vascular calcification in vivo.
Results: PDK4 overexpression by using PDK4 containing adenoviral vector, even without BMP2 pre-treatment, increased vascular calcification. PDK4 deficient mice showed profound attenuation of aortic calcification induced by Vitamin D in vivo. The VSMCs cultured from PDK4 deficient mice also presented a decrease of mineralization and mRNA expression of osteogenic markers. Furthermore, DCA, known PDK inhibitor, attenuated the mineralization of VMSCs and aorta cultured in Pi-treated medium. We found that PDK4 directly bound R-smad and further enhanced phosphorylation of R-Smad confirmed by GST-pull down assay and in vitro kinase assay. In consistent with these results, vascular calcification induced by Vitamin D in vivo was also decreased in DCA-treated mice by gavage (20mg/kg/day for 3weeks).
Conclusion: In this study, we showed that PDK4 augmented osteogenic switch of VSMCs and vascular calcification through the direct phosphorylation of R-Smad. This study suggests that PDK4 might be a novel target to inhibit vascular calcification.

FoxO1 compartmentalisation results in different metabolomic profiles in human endothelial cells

R. Menghini[1], V. Casagrande[1], M. Cardellini[1], M. Fabrizi[1], E. Martelli[1], F. Davato[1], M. Morelli[1], M. Mavilio[1], R. Stoehr[1], A. Ippoliti[1], D. Accili[2], M. Federici[1];
[1]University of Tor Vergata, Rome, Italy, [2]Dept. of Medicine, Columbia University, New York, USA.

Background and aims: FoxO1 is a pivotal element in the regulation of endothelial activation. Compartmentalization and activity of FoxO1 is regulated by post translational modifications, but the implication in endothelial dysfunction and atherosclerosis remain controversial. Our aim was to identify FoxO1 post translational modifications and related metabolic signatures associated to improved endothelial function.
Materials and methods: RT-PCR and western blot were performed on mRNA and protein extracted from human atherosclerotic plaques (n=70). Human umbilical endothelial cells (HUVECs) were infected with adenoviral vector expressing the wild type FoxO1 (WT), the acetylation defective mutant (KR), the unphosphorylated nuclear localized mutant (ADA) and the GFP control vector. Cell lysates and supernatants as well as mRNA and proteins were collected for GC/MS and LC/MS/MS metabolomics, RT-PCR and western blot.
Results: Preliminary data in human atherosclerotic plaques indicated that the acetylated form of FoxO1 is associated with increased markers of inflammation and cellular activation (VCAM-1, ICAM-1, TLR4, MMP9), whereas the phosphorylated form of FoxO1 acts inversely. In HUVECs overexpressing different FoxO1 mutants we confirmed the upregulation of VCAM-1 and ICAM-1 in ADA cells. Next, in HUVECs we analyzed metabolite markers associated to distinct FoxO1 activated proteins. In ADA cells, consistently with reduced NO production, we identified increased levels of dymethilarginine (SDMA+ADMA), the endogenous inhibitors of endothelial nitric oxide synthase (eNOS). ADA expression is also associated to higher levels of lysophosphatidic acid (LPA), suggesting that constitutive dephosphorylation of FOXO1 may lead to activation of angiogenic, inflammation or cell death programs in endothelial cells. The levels of 7-alpha and 7-beta-hydroxycholesterol, lipid peroxidation products from cholesterol increased in in response to all three alleles of FOXO1 over-expression compared to the GFP control which would be consistent with FoxO1 dependent increased lipid peroxidation Next, we analyzed by RT-PCR, the three major enzymes involved in ADMA generation, protein arginine methyltransferase 1 and 2 (PRMT1, PRMT2) and dimethylarginine dimethylaminohydrolase (DDAH1), founding that DDAH1 was significanlty downregulated in ADA cells. Moreover ADA expression resulted in an inhibition of Srebp2 mRNA that, in turn, is involved in the regulation of DDAH1 expression, suggesting a mechanism linking FoxO1 and Srebp2.
Conclusion: Our data suggest that FoxO1 affects endothelial cell function through several metabolic pathways potentially implied in endothelial activation and dysfunction, two processes that are associated to increased incidence of atherosclerosis.

1304

Monoamine oxidase activity promotes type 1 diabetes-induced mitochondrial dysfunction and cardiac damage

N. Kaludercic[1], N. Paolocci[2], F. Di Lisa[1,3];
[1]Neuroscience Institute, National Research Council of Italy, Padova, Italy, [2]Division of Cardiology, Johns Hopkins Medical Institutions, Baltimore, USA, [3]Department of Biomedical Sciences, University of Padova, Italy.

Background and aims: Oxidative stress is well known to contribute to the development of diabetic cardiomyopathy. Mitochondrial respiratory chain and NADPH oxidase are described as major sources of reactive oxygen species (ROS) in this setting. However, this accepted concept overlooks the potential contribution of other ROS sources. Monoamine oxidases (MAOs) are mitochondrial enzymes that catabolize neurotransmitters such as norepinephrine, generating hydrogen peroxide in this process. These mitochondrial flavoenzymes are responsible for oxidative stress and cell death in failing and ischemic/reperfused hearts. Here we assessed whether MAO contributes to the onset and progression of cardiac alterations occurring in type 1 diabetes (T1D).
Materials and methods: Mitochondrial ROS production (Mitotracker Red CM-H_2XRos) and membrane potential (TMRM) were measured in neonatal

rat cardiomyocytes cultured in normal glucose (NG, 5 mM), high glucose (HG, 30 mM) or high mannitol (HM, 30 mM) containing media in the absence or presence of MAO inhibitor pargyline. T1D was induced by single streptozotocin injection (STZ, 150 mg/kg) and mice were randomized into vehicle- or pargyline-treated groups. After 4 weeks, cardiac tissue was analyzed for oxidative stress (malondialdehyde levels), protein oxidation and apoptosis (TUNEL assay).
Results: Mitochondrial ROS production was significantly higher in HG myocytes (+30%, p<0.005) as compared to other groups. Pargyline completely prevented this increase. When myocytes were co-incubated with ATP synthase inhibitor oligomycin, HG-treated cells started depolarizing immediately whereas NG- or HM-treated cells were able to maintain their membrane potential longer (>50 minutes). Pargyline prevented this suggesting that MAO activation triggered by HG induces a latent mitochondrial dysfunction causing mitochondria to hydrolyze ATP. In in vivo model of T1D, hearts of STZ-treated mice displayed high oxidative stress (+70%, p<0.05) accompanied by oxidation of contractile proteins such as tropomyosin (p<0.005) and a 3-fold increase in apoptosis (p<0.05). Pargyline administration to STZ-treated mice completely prevented these changes, suggesting that MAO activation provides a major contribution to cardiac dysfunction in diabetes.
Conclusion: These data provide the novel evidence of a pivotal role of MAO in diabetes-induced oxidative stress and mitochondrial abnormalities that are responsible for contractile derangements and loss of cardiomyocyte viability. Based upon the present findings MAO inhibition should be exploited as a novel therapeutic approach to counteract diabetic cardiomyopathy.

Repetitive selective breeding for susceptibility to glucose intolerance accelerates atherosclerotic lesion formation in mice
A. Asai, M. Nagao, Y. Shuto, M. Kawahara, H. Sugihara, S. Oikawa;
Division of Endocrinology, Diabetes and Metabolism, Graduate School of Medicine, Nippon Medical School, Tokyo, Japan.

Background and aims: Epidemiological evidence demonstrates that postprandial hyperglycemia in people with impaired glucose tolerance (IGT) is an independent risk factor for atherosclerotic cardiovascular disease. However, there are few suitable animal models for understanding the involvement of IGT in the pathogenesis of atherosclerosis in vivo. We recently established two lines of mice with different susceptibilities (prone and resistant) to high fat diet (HFD)-induced glucose intolerance by selective breeding (designated SDG-P and SDG-R, respectively). Here, we examined intergenerational changes in atherosclerotic lesion formation in SDG-P and SDG-R during the selective breeding for different glucose tolerance.
Materials and methods: The selective breeding of SDG-P and SDG-R was performed with C57BL/6J, C3H/HeJ and AKR/N mice as background strains. After 5-week HFD feeding (32% energy as fat; 5-10 weeks of age), mice showing high and low 120-min blood glucose levels ($BG_{120\ min}$) in OGTT (2.0 g/kg body weight) were selected and bred repetitively over 20 generations to produce SDG-P and SDG-R, respectively. During the selective breeding, we evaluated atherosclerotic lesion formation in female SDG-P and SDG-R. After 20-week atherogenic diet feeding (1.25% w/w cholesterol, 0.5% w/w sodium cholate, 36% energy as fat; 8-28 weeks of age), serial frozen sections (10 μm thickness, spanned 450 μm) of aortic sinus were prepared and the lesion size was quantitated from oil red O-stained area (mean of 9 sections, each separated by 50 μm). Data are expressed as mean±SEM. Intergenerational changes in glucose tolerance and atherosclerotic lesion size were examined by Pearson's correlation analysis. Differences between SDG-P and SDG-R were assessed by Student's *t* test.
Results: As the breeding generations proceeded, female SDG-P mice became more susceptible to HFD-induced glucose intolerance (p=0.0004; $BG_{120\ min}$ during 5th-20th generations (G5-G20)); meanwhile, female SDG-R mice maintained normal glucose tolerance during the generations. At G20, $BG_{120\ min}$ in SDG-P was more than 2-fold higher than that in SDG-R (9.6±0.5 vs 4.3±0.2 mmol/l, n=15-17, p<0.0001). Male SDG-P and SDG-R showed similar intergenerational trends in glucose tolerance. After the atherogenic diet feeding in female mice, atherosclerotic lesion size of SDG-P was greater than that of SDG-R in all paired experiments (p<0.05; 4 paired experiments during G12-G19). At G18-G19, the lesion size in SDG-P was 4-fold greater than that in SDG-R (37.6±5.5 vs 9.4±3.0 ×10^3 μm^2, n=4-6, p=0.0020). In addition, the differences in lesion size tended to increase as the generations proceeded (p=0.0519).
Conclusion: Glucose intolerance-prone mice (SDG-P) are more susceptible to atherosclerotic lesion formation relative to glucose intolerance-resistant mice (SDG-R). Furthermore, as the breeding generations proceeded, the lesion formation in SDG-P was accelerated concomitantly with worsening glucose intolerance. Thus, the differences in atherosclerotic lesion formation may reflect different glucose tolerance status. The newly established two lines of mice with different glucose tolerance may therefore serve as suitable animal models for investigating pathogenesis, prevention, and treatment of atherosclerotic complications in IGT.

Histone methyltransferase EZH2 regulates glucose induced VEGF production through H3K27 methylation in retinal endothelial cells
M.A. Ruiz, S. Chakrabarti;
Pathology, Western University, London, Canada.

Background and aims: Glucose induced augmented vascular endothelial growth factor (VEGF) production is a key event in diabetic retinopathy. We have previously demonstrated that downregulation of miR-200b causes overexpression of VEGF, mediating structural and functional changes in the retina in diabetes. However, regulation of miR-200b is not known. Histone methyltransferase, enhancer of the zeste homolog (EZH2), has been demonstrated to repress miRNAs in neoplastic process. We hypothesized that, in diabetes, EZH2 represses miR-200b through its H3K27 methylation mark.
Materials and methods: Human retinal microvascular endothelial cells and endothelial cells of dermal origin, isolated from both type 1 and type 2 diabetic and non-diabetic individuals, were treated in high glucose (25mM) or normal glucose (5mM) for 24 hours. Expression of EZH2, VEGF and various miRNA were measured by qPCR. Loss-of-function experiments were also performed using a chemical inhibitor for EZH2, 3-Deazaneplanocin A (DZNep).
Results: When treated with high glucose, all cell types showed significantly increased VEGF expression (p<0.05). Retinal endothelial cells showed increased expression of EZH2 with decreased expression of miR-200b. Dermal endothelial cells isolated from diabetic patients showed increased EZH2 and decreased miR-200b expression as well. Furthermore, inhibition of EZH2 in retinal endothelial cells produced increased miR-200b expression with parallel decreased VEGF, demonstrating a causal link.
Conclusion: This research has demonstrated a repressive relationship between EZH2 and miR-200b. These data further provide evidence of a novel mechanism of miRNA regulation through another epigenetic pathway, i.e, histone methylation. Understanding such pathways will potentially yield new treatment strategies.

Impaired glucose tolerance in rats is associated with a reduced expression of hepatocyte growth factor
J. Klimas[1], L. Pivackova[1], L. Mesarosova[1], B. Gajdacova[1], L. Mensikova[1], J. Srankova[1], E. Malikova[1], K. Galkova[1], P. Ochodnicky[2], P. Krenek[1];
[1]Dpt. of Pharmacology and Toxicology, Faculty of Pharmacy, Comenius University, Bratislava, Slovakia, [2]Dept. Pathology, Academic Medical Center, University of Amsterdam, Netherlands.

Background and aims: Hepatocyte growth factor (HGF) contributes to organ protection and repair and its alterations were suggested to play a role in the development of diabetic end-organ damage. However, little is known about its function in the state of impaired glucose tolerance.
Materials and methods: In male Wistar rats, impaired glucose tolerance was induced by administration of low doses of streptozotocin (25mg/kg/d i.p.) for 3 consecutive days (STZ). Controls (CON) received vehicle. After 8 weeks, oral glucose tolerance test (OGTT) was performed. Additionally, we tested endothelial function of isolated aorta by relaxation to acetylcholine. Expressions of HGF were analyzed in aortas and kidneys by qRT-PCR. In addition, endothelial NO-synthase (eNOS) as a key factor regulating vascular relaxation was analyzed in aortas by Western blotting.
Results: Both groups of rats showed a normal fasting glucose (CON: 6.2 ± 0.3 mmol/l vs. STZ: 6.2 ± 0.9 mmol/l) but STZ rats exhibited significantly elevated plasma glucose concentration in OGTT (Glc levels after 1 h - CON: 8.1 ± 0.4 mmol/l vs. STZ: 15.2 ± 2.2 mmol/l, p<0.01; total AUC - CON: 1835 ± 55 vs. STZ: 3079 ± 415, p<0.01). Additionally, STZ rats showed a blunted endothelium-dependent relaxation to acetylcholine (pD2 - CON: 6.71 ± 0.16

vs. STZ: 6.27 ± 0.08, p<0.001; Emax CON: 37.1±3.1 % vs. STZ: 23.6±1.4 %, P<0.01). Endothelium-independent relaxation to sodium nitroprusside was not altered. Accordingly, we observed a significant downregulation of eNOS protein in STZ aortas (CON: 1.00 ± 0.13 vs. STZ: 0.39 ± 0.07, p<0.001). STZ rats had a significantly lower expression of aortic HGF mRNA in comparison to controls (CON: 1.00 ± 0.10 vs. STZ: 0.71 ± 0.07, p<0.05) and a trend of lowered HGF expression in kidney (CON: 1.00 ± 0.28 vs. STZ: 0.77 ± 0.19, NS).
Conclusion: In summary, we observed a significant decrease of HGF expression in aortas and a tendency to decrease in kidneys of rats with glucose intolerance. Our data suggest that HGF downregulation could contribute to the early development of renal injury and endothelial dysfunction in impaired glucose tolerance.

PS 114 Sleep apnoea, cognitive function and musculoskeletal complications

1308

Obstructive sleep apnoea is independently associated with arterial stiffness and in-hospital early clinical outcome after first-ever ischaemic stroke in type 2 diabetes

C. Voulgari[1,2], T. Loukopoulos[3], K. Fotopoulou[1], S. Chorepsima[4], P. Tsiodra[1], C. Stefanadis[2], K. Tsioufis[2];
[1]3rd Department of Internal Medicine, Athens General Regional Hospital "G. Gennimatas", [2]1st Department of Cardiology, Athens University Medical School, "Hippokration" General Hospital, [3]Health Center of Vyronas, "Hippokration" General Hospital, [4]3rd Department of Internal Medicine, Athens University Medical School, "Sotiria" Regional Chest Disease Hospital, Athens, Greece.

Background and aims: Obstructive sleep apnaea (OSA) syndrome significantly increases the risk of stroke independently of other risk factors. Pulse wave velocity analysis (PWV), a marker of aortic stiffness, has independent predictive value for cardiovascular morbidity and mortality, especially fatal stroke, and for long-term functional stroke prognosis. We determined the early (7 days) prognostic significance of OSA in relation to arterial stiffness in patients with type 2 diabetes (T2DM) and functional disability after acute first-ever ischemic stroke.
Materials and methods: In a 90 days after the stroke, prospective study, we enrolled 270 patients with T2DM and acute first-ever ischemic stroke (122 women/148 men), aged 58.0 ± 11.2 years, mean ± SD. National Institutes of Health stroke scale (NIHSS) scored 7.1 ± 5.5 at admission. Patients enrolled were defined a priori as having an apnoea-hypopnea index ≥5 (≥five events per hour of sleep) during 2-hours of attended sleep monitoring. Patients with an apnoea-hypopnea index ≤5 constituted the comparison group. Carotid-femoral (CF) PWV and central augmentation index (cAIx) were measured by applanation tonometry (SphygmoCor, Atcor, Australia) 7 days after stroke onset. At hospital discharge, favourable outcome was defined as a ≥4-point improvement from baseline NIHSS or NIHSS of 0-1. Data were analyzed with logistic regression.
Results: The mean apnoea-hypopnea index among the OSA patients was 35±29 compared to 3.0±1.5 in the comparison group. Baseline characteristics of patients included in the two groups were similar. CF-PWV and cAlx were significantly different between patients with and without OSA (11.6±3.1m/s vs. 9.5±1.4m/s, and 34.6±21.6% vs. 12.4±15.6%, respectively, p<0.001). In multivariate analysis, after adjustment for age, gender, body-mass index, NIHSS score, blood glucose, lipids on admission, as well as heart-rate, systolic and mean blood pressure, high sensitivity C-reactive protein and homocysteine values measured at day 7±2, both low CF-PWV (p<0.001), and cAIx (p=0.002), were significantly associated with early favourable outcome. Moreover, a 40% decrease of both CF-PWV and cAlx values on admission and at day 7 was significantly correlated with baseline NIHSS score and favourable outcome. Adjusting for age, gender, smoking and alcohol-consumption status, body-mass index, and presence/absence of hyperlipidemia, atrial fibrillation, and hypertension resulted in a significant association between OSA and clinical outcome, including death as end-point (1.92; 95%CI, 1.80 to 3.16; p<0.001). The risk of death in patients in the most severe quartile of OSA was three times that in the comparison group.
Conclusion: In patients with T2DM and acute first-ever ischemic stroke, aortic stiffness predicts early stroke functional outcome, independent of other known prognostic factors. Presence of OSA is significantly associated with increased arterial stiffness and functional disability, as well as death, in these patients.

Characterising sleep apnoea syndrome in type 2 diabetes (Sweet Sleep study)

A. Lecube[1,2], A. Ciudin[3], C. Hernández[3], G. Sampol[4], O. Romero[4], J. Mesa[3], R. Simó[3];
[1]Diabetes Research Unit, Vall d'Hebron Institut de Recerca, Barcelona, [2]Endocrinology Department, Hospital Universitari Arnau de Vilanova, Lleida, [3]Endocrinology Department, Diabetes Research Unit. Vall d'Hebron Institut de Recerca, Barcelona, [4]Sleep Unit. Pneumology Department, Hospital Universitari Vall d'Hebron, Barcelona, Spain.

Background and aims: Sleep apnoea is highly prevalent in patients with type 2 diabetes mellitus (T2DM). However, it is unknown whether or not diabetic patients share the same sleep breathing pattern than non-diabetic patients.
Materials and methods: Case-control study between 119 T2DM patients and 238 non-diabetic subjects closely matched by age, gender, BMI, waist and neck circumferences, and smoking status. The exclusion criteria included chronic respiratory disease, neuromuscular and cerebrovascular disease, alcohol abuse, use of sedatives, and pregnancy. Examination included a respiratory polysomnography, oxygen saturation measures as the cumulative percentage of time spent with oxygen saturations below 90% (CT90), and the degree of sleepiness using the Epworth Sleepiness Scale (ESS). Studies with less than 5 hours of correct signal recording were ruled out. An apnoea was defined as cessation of airflow with duration of at least 10 seconds, and differentiation between obstructive and central apnoeas was made. The apnoea-hypopnea index (AHI) was defined as the sum of apnoeas plus hypopneas divided by time in bed.
Results: A higher AIH was observed in T2DM patients (34.0±3.4 vs. 26.0±2.8 events/hour; p=0.017). When sleep events were evaluated separately, a similar incidence of hypopnea events was present in diabetic and non-diabetic patients (18.3±1.1 vs. 16.7±3.9 e/h; p=0.951). However, in T2DM patients, a significantly increase in the number of apnoea events (15.2±8.2 vs. 10.3±3.2 e/h; p=0.048) and in the CT90 (18.0±33.5 vs. 10.7±10.4 %; p=0.042) were detected. No differences between obstructive and central apneas were observed. In addition, diabetic patients also showed higher daily sleepiness (7.5±3.6 vs 6.0±3.2, p=0.012) than non-diabetic subjects.
Conclusion: T2DM adversely affects breathing during sleep, becoming an independent risk factor for higher rates of sleep apnoeas, as well as severe nocturnal hypoxemia and daily sleepiness.

Association between glycaemic control and impaired lung function in Japanese adults

Y. Kabeya, K. Kato, M. Okisugi, M. Kawasaki, M. Tomita, T. Katsuki, Y. Oikawa, A. Shimada;
Tokyo Saiseikai Central Hospital, Tokyo, Japan.

Background and aims: Several studies have reported that diabetes is associated with impaired lung function. However, evidence on the dose-response relationship between measures of glycaemic control and impaired lung function is still scarce. In the present study, we hypothesized that there could be a continuous and inverse association between glycaemic control and lung function and examined the hypothesis in a large health checkup population which included both diabetic and non-diabetic individuals.
Materials and methods: This was a cross-sectional study performed in the medical checkup unit of one general hospital in Japan. All participants(n=3,611) who were apparently healthy and underwent a medical checkup focusing on metabolic syndrome from May 2008 to December 2011 were invited to the study. Information on lifestyle was obtained by a questionnaire. Blood samples and anthropometric data were obtained under a fasting condition. Lung function tests were performed by trained personnel. A total of 361 participants were excluded because of missing anthropometric, laboratory or lifestyle data. Finally, 3,250 participants (mean age, 56±12 years; 69% men; 15% diabetic individuals) were included in the analysis. The differences in forced vital capacity (FVC) and forced expiratory volume in 1 second (FEV1) were estimated across HbA1c categories (<5.5%, 5.5-5.9%, 6.0-6.4%, 6.5-6.9% and 7.0-%). Multiple linear regression was used to adjust the differences for age, sex, body mass index, waist to hip ratio, smoking status, hypertension, dyslipidaemia and white blood cell count.
Results: FVC decreased steadily as HbA1c increased. Compared with individuals with HbA1c <5.5%, the adjusted differences in mean FVC among those with HbA1c of 5.5-5.9%, 6.0-6.4%, 6.5-6.9% and 7.0-% were -14.6ml, -118.6ml, -195.4ml and -239.9ml, respectively. HbA1c was also analysed as a continuous variable, yielding a significant decrease in FVC of -77.3ml for a 1% increase in HbA1c levels. Similarly, FEV1 was inversely associated with HbA1c levels. Compared with those with HbA1c of <5.5%, the adjusted differences in mean FEV1 among those with HbA1c of 5.5-5.9%, 6.0-6.4%, 6.5-6.9% and 7.0-% were 1.1ml, -57.4ml, -122.8ml and -140.8ml, respectively. A 1% increase in HbA1c was significantly associated with a 40.9ml reduction in FEV1.
Conclusion: The present study found that there was an inverse and continuous relationship between glycaemic control and lung function in Japanese adults. The association was observed in a wide range of HbA1c levels which included both diabetic and non-diabetic individuals. The result suggests that the lung could be another organ to be affected by hyperglycaemia.

Association of HbA1c levels with lung function (FVC and FEV1)

	Adjusted difference in FVC (ml) (95%CI)	Adjusted difference in FEV1 (ml) (95% CI)
HbA1c (%)(categorical)

Type 2 diabetes is an independent risk factor for dementia conversion in mild cognitive impairment patients

A. Ciudin[1,2], A. Espinosa[3], A. Ruiz[3], M. Alegret[3], C. Hernández[1,2], M. Boada[1,3], R. Simó[1,2];
[1]Institut de Recerca Vall d´Hebron, Universitat Autònoma de Barcelona (VHIR-UAB), [2]CIBER de Diabetes y Enfermedades Metabólicas Asociadas, Instituto de Salud Carlos III, [3]Fundació ACE. Barcelona Alzheimer Treatment & Research Center, Barcelona, Spain.

Background and aims: Mild cognitive impairment (MCI) is a clinically heterogeneous syndrome associated with an elevated dementia conversion rate, in particular the Alzheimer´s disease. It has been reported that diabetes is a risk factor for MCI. However, there is no information whether the rate of dementia conversion in MCI patients is higher in type 2 diabetic patients. In order to shed light on this issue a case-control study aimed at exploring whether type 2 diabetes is a risk factor for dementia conversion in MCI patients was designed.
Materials and methods: Design: longitudinal nested case-control study. Cases: 101 type 2 diabetic patients older than 60 years with MCI. Controls: 101 non-diabetic patients with MCI matched by age and gender. All patients were functionally literate, without severe auditory and visual abnormalities. A neuropsychological, neurological and psychiatric evaluation, as well APOE genotyping was performed. The mean of follow-up was 28 months (SD± 18) without any significant difference between cases and controls. Statistical analysis: Chi-square, Student's t test. In order to evaluate the risk factors independently associated to dementia conversion from MCI a logistic regression analysis was performed taking into account as independent variables the following: age, presence of diabetes, hypertension and hypercholesterolemia, APOE genotype and time of follow-up. Data were analyzed using SPSS for Windows v.18.
Results: The dementia conversion rate was 57, 4% in type2 diabetic patient vs. 42, 6% in non-diabetic patient (p= 0, 02). We did not found any difference in either the type of dementia (Alzheimer´s disease, vascular dementia, mixed dementia [Alzheimer´s disease and vascular], frontotemporal dementia and dementia with Lewy´s bodies) or *APOE* genotype between cases and control subjects. The logistic regression analysis shown that type 2 diabetes (OR: 2.09; CI 95%: 1.15-3.79) and APOE ε4 allele (OR: 2.56; CI: 1.32-4.96) were independent risk factors for developing dementia in MCI subjects.
Conclusion: Type 2 diabetes is an independent risk factor for dementia conversion in MCI patients. Further studies addressed to explore the underlying mechanisms are warranted.

1312

Selective cognitive decline is related to focal brain volume loss in type 1 diabetes patients with microangiopathy: a 4 year follow-up

E. van Duinkerken[1], F. Barkhof[2], M. Klein[3], F.J. Snoek[3], R.G. IJzerman[4], M. Diamant[4];
[1]Medical Psychology and Diabetes Centre/Internal Medicine, [2]Radiology and Nuclear Medicine, [3]Medical Psychology, [4]Diabetes Centre/Internal Medicine, VU University Medical Centre, Amsterdam, Netherlands.

Background and aims: Cross-sectional studies showed cognitive and structural brain changes in type 1 diabetes (T1DM) patients, predominantly in those with peripheral microangiopathy. Whether these brain changes progress over time is not well known.
Materials and methods: In 25 T1DM patients with microangiopathy (baseline age: 46.1±7.8yrs and HbA1c: 7.9±1.0%; 40% male; baseline estimated IQ: 112±12.7) and 25 matched controls (baseline age: 44.3±8.5yrs and HbA1c: 5.4±0.3%; 52% male; baseline estimated IQ: 109.4±11.0) we assessed general cognitive ability, memory, information processing speed, executive functions, attention, motor and psychomotor speed at baseline and follow-up. A 3D-T1 structural MRI-scan at both time points was used to determine whole-brain volume loss, analysed with FSL-SIENA. Group differences and associations over time were analysed with regression analyses corrected for mean follow-up time, baseline age, sex and baseline cognitive performance when assessing change in cognition, baseline total brain volume when determining brain change or both when determining associations between change in cognition and brain volume.
Results: After 4 years, patients versus controls showed significantly greater decline in executive functions (patients: δz=-0.402±0.63sd vs. controls: δz=-0.007±0.39sd; β=-0.397; P=0.006). Furthermore, patients versus controls had a larger percentual whole-brain volume loss (patients: -1.34±1.0% vs. controls: -0.68±0.63%; β=-0.314; P=0.022), most marked in the right frontal and central areas. In all participants, larger loss of right frontal and central brain volume was related to accelerated executive functions decline (β=-0.330; P=0.025). In patients, higher baseline HbA1c was associated with larger executive performance decline (β=-0.407; P=0.043) and higher baseline systolic blood pressure was correlated to frontal brain volume loss at follow-up (β=-0.501; P=0.011).
Conclusion: At 4-years follow-up, loss of executive performance and brain volume was significantly greater in T1DM patients with microangiopathy compared with healthy controls. Poorer glycaemic control and higher systolic blood pressure at baseline predicted both cognitive and brain alterations over time.

Hypoglycaemia related events due to falls in elderly diabetics (H.E.A.L.E.D) study using a US commercial database

J. Mukherjee[1], S. Kachroo[2], H. Kawabata[3], S.A. Colilla[3], L. Shi[4], Y. Zhao[4], V.A. Fonseca[4], U. Iloeje[1];
[1]Bristol-Myers Squibb, Wallingford, [2]Bristol-Myers Squibb, Nassau Park, [3]Bristol-Myers Squibb, Hopewell, [4]Tulane University, New Orleans, USA.

Background and aims: Falls are a major cause of concern in the elderly population resulting in increased morbidity and mortality. The goal of this project was to examine the association of hypoglycemia with falls and fall-related events in elderly patients with type 2 diabetes mellitus (T2DM).
Materials and methods: A retrospective cohort study was conducted in patients with T2DM. Records were obtained from Truven Health MarketScan® Commercial Database for patients (N= 1,147,937) with at least 2 records of T2DM diagnosis from 1/1/2008 to 12/31/2011. The first date of a recorded hypoglycemia diagnosis (ICD-9-CM codes: 250.8, 251.0, 251.1 and 251.2) was defined as the index date for a case, ensuring that there is a one-year baseline and one-year follow-up. The control cohort (no hypoglycemia record) was 1:1 randomly matched by age and gender. Patients were required to be ≥ 65 years at cohort entry with a continuous enrolment and pharmacy benefits throughout one year prior to cohort entry. Fall-related outcomes of fractures and head injuries were defined as ICD-9-CM codes between 800.x -995.x, with a fall being the external cause defined as ICD-9-CM E-codes between E880 - E888; which were recorded within ±2 days of each other in any order. Unadjusted chi-square tests were done. Conditional logistic regression models were used to compare the post-index fall-related events within 30 days, 90 days, 180 days and 365 days between the two cohorts. Adjusted odds ratios (aOR) and corresponding 95% confidence intervals (95% CI), controlling for baseline characteristics and co-morbidities, were estimated from logistic regression models. Two subgroup analyses (age categories <75 years and >=75 years) were also conducted.
Results: A total of 21,613 cases were matched with 21,613 controls. Patients with hypoglycemia consistently had higher fall-related events: 235 events (1.09%) among the cases and 37 events (0.17%) among the controls within 30 days; 373 events (1.73%) and 118 events (0.55%) within 90 days; 520 events (2.41%) and 204 events (0.94%) within 180 days; and, 720 events (3.33%) and 351 events (1.62%) within 1 year. All frequency differences between cases and controls were statistically significant; p-values <0.0001. Conditional logistic regression analyses showed an elevated risk of fall-related events over 365 days (aOR=2.10, 95% CI=1.85-2.39). The sub-group analyses showed elevated risk for both groups: <75 years group (aOR=2.53, 95% CI=2.06-3.09) and >=75 years group (aOR=1.83, 95% CI=1.54-2.17).
Conclusion: The risk of fall-related events increased by 2-fold among elderly diabetic patients who experienced hypoglycemia. Physicians treating elderly diabetes patients need to make treatment decisions that minimize the risk of hypoglycemia and thereby avoiding the ensuing complications of falls. In addition, patients with hypoglycemia may need additional education and other preventive measures to reduce the risk and clinical impact of falls.

1314

Incidence and predictors of hip fracture in type 2 diabetes: the Fremantle Diabetes study

W.A. Davis, E.J. Hamilton, M. Zakaria, T.M.E. Davis;
School of Medicine and Pharmacology, The University of Western Australia, Fremantle, Australia.

Background and aims: Most studies that have examined the relationship between diabetes and hip fractures have utilized administrative databases and/or have had limited/incomplete data including recognized hip fracture risk factors. The aim of this study was to determine the incidence and predictors of hip fracture in well-characterized community-based patients with type 2 diabetes.
Materials and methods: We studied a cohort of 1,296 type 2 diabetic participants (mean±SD age 64.0±11.3 years, 49% male, median diabetes duration 4.0 years) in the longitudinal observational Fremantle Diabetes Study Phase I (FDS1) together with 5,159 age-, gender- and postcode-code-matched non-diabetic residents. All deaths and hospitalisations in the state of Western Australia (WA) are recorded in the WA Data Linkage System which was used to provide outcomes from 1982 until end-December 2010. The main outcome measure was incident hospitalization for/with hip fracture between FDS1 study entry in 1993-6 and end-2010. In the diabetic cohort only, mobility was assessed by self-administered questionnaire and peripheral sensory neuropathy was defined using the clinical portion of the Michigan Neuropathy Screening Instrument. Cox proportional hazards modelling was used to identify independent predictors of first hospitalization for/with hip fracture during follow-up.
Results: During 12.0±5.4 years of follow-up, 86 (6.6%) patients were hospitalized on 135 separate occasions for a fractured hip (8.7/1,000 patient-years). This compared with 285 matched non-diabetic residents fracturing their hip on 471 occasions during 13.3±5.0 years' follow-up (6.8/1,000 patient-years). The incidence of hip fracture amongst those with type 2 diabetes was thus 28% higher than in matched non-diabetic residents (incident rate ratio (IRR) (95% CI): 1.28 (1.05-1.55), P=0.011). Amongst the diabetic patients, older age, female sex, lower BMI, peripheral sensory neuropathy (hazard ratio [95% CI]: 2.10 [1.31-3.36]), and any reduction in mobility (1.98 [1.18-3.32]) were independently associated with risk of first hospitalization for/with hip fracture (P≤0.010).
Conclusion: The risk of hip fracture is moderately increased among community-dwelling type 2 diabetic patients compared with matched non-diabetic residents. Peripheral sensory neuropathy and reduced mobility both double the risk of hip fracture in patients with type 2 diabetes. Further research is required to determine if hip fractures can be prevented in diabetic patients, especially older females, through interventions aimed at optimal detection and management of mobility and peripheral neuropathy.

Diabetes is not a risk factor for the carpal tunnel syndrome: a case-control study

S.H. Hendriks[1], P.R. van Dijk[1], K.H. Groenier[1,2], P. Houpt[3], H.J.G. Bilo[1,4], N. Kleefstra[1,4];
[1]Diabetes Centre, Isala Clinics, Zwolle, [2]Dept. of General Practice, University Medical Center Groningen, [3]Dept. of Plastic Surgery, Isala Clinics, Zwolle, [4]Dept. of Internal Medicine, University Medical Center Groningen, Netherlands.

Background and aims: The Carpal Tunnel Syndrome (CTS) seems to occur more frequently in patients with Diabetes Mellitus (DM) and might be associated with specific diabetic related factors. Previous studies described a relationship between duration of diabetes, microvascular complications, glycaemic control and CTS but many of these studies were in small cohorts. Moreover, many studies investigated diabetes as a risk factor for musculoskeletal disorders of the hand and shoulder in general, but not for CTS in particular. The aim of the present study was to determine if DM can be identified as a risk factor for CTS. Furthermore we investigated the influence of duration of DM, microvascular complications and glycaemic control on the development of CTS.
Materials and methods: Retrospective case-control study using data from electronic patient charts from a Dutch clinic complemented by data of a diabetes specific database of the Diabetes Centre of that clinic. All patients who were diagnosed with CTS in the period from January 2011 to July 2012 were included. These patients were compared with a control group of herniated nucleus pulposus patients who went for surgery. Primary outcome was the prevalence of DM in both groups. Secondary outcomes were duration of DM, known microvascular complications and glycaemic control in both groups. The sample size required for the control group to detect a difference in DM prevalence of 5%, with an estimated CTS group size of 900 patients, a power of 0.8 and an alpha of 0.05 was 459. Statistical analysis was carried out using logistic regression, adjusting for confounding variables using three different models. Multiple imputation was used for missing data.
Results: A total of 1014 patients with CTS and 594 controls were included. In 92.2% of the cases the diagnosis CTS was confirmed by nerve conduction tests. Prevalence of DM was 12.3% in the CTS group versus 7.2% in the control group (Odds Ratio (OR) 1.80 (95% confidence interval (CI) 1.25-2.59)). Mean (±SD) age (55.7 ± 15.2 year vs. 49.3 ± 13.0 year), BMI (28.4 ± 5.4 kg/m^2 vs. 26.7 ± 4.6 kg/m^2) and percentage of female patients (71.1% vs. 49.3%) were higher in the CTS group compared to the control group (all p <0.001). In multivariate analyses with correction for gender, age and BMI, DM was not significantly associated with CTS (OR 1.12 (95% CI 0.75-1.66)). There were no differences in duration of diabetes, microvascular complications or glycaemic control between groups.
Conclusion: Although DM was more frequently diagnosed among patients with CTS, it could not be identified as a separate risk factor. Furthermore, no associations were found between the duration of diabetes, complications of diabetes or glycaemic control and the development of CTS.

Urologic complications and health-related quality of life in type 1 diabetes: long-term follow-up in the DCCT/EDIC study

A.M. Jacobson[1], B.H. Braffett[2], P.A. Cleary[2], R.L. Dunn[3], M.E. Larkin[4], H. Wessels[5], A.V. Sarma[3], DCCT/EDIC Research Group;
[1]Diabetes, Obesity and Cardiometabolic Research Center, Winthrop-University Hospital, Mineola, [2]Biostatistics Center, George Washington University, Rockville, [3]Epidemiology, University of Michigan, Ann Arbor, [4]Medicine, Massachusetts General Hospital, Boston, [5]Urology, University of Washington, Seattle, USA.

Background and aims: Limited data exist on the influence of urologic complications on health-related quality of life (HRQOL) in patients with type 1 diabetes (T1DM). We used biomedical information gathered during the Diabetes Control and Complications Trial and its Epidemiology of Diabetes Interventions and Complications follow-up (DCCT/EDIC) to examine the relationship between urologic complications and HRQOL.
Materials and methods: We studied 664 men and 580 women, mean (SD) ages 51.6±6.9 and 50.6±7.2; BMI 28.9±4.8, 28.6±5.9; duration of T1DM 29.5±4.8, 29.8±5.1; mean time-weighted HbA_{1c} 7.9%±1.0, 8.0%±0.9, respectively. Assessments made at EDIC year 17 (an average of 23.5 years after DCCT baseline) included patient reports of sexual dysfunction (International Index of Erectile Function and abbreviated Female Sexual Function Index), lower urinary tract symptoms (LUTS) in men using the American Urological Association Symptom Index and urinary incontinence (UI) in women with the Sandvik Scale. General HRQOL was assessed using the Medical Outcome Survey Short Form 36 (SF-36), which generates 9 sub-scales from 0-100 and perceived value of health with the EuroQol5 (EQ5D) utility index (scale 0-1). Diabetes-related quality of life was assessed using the Diabetes Quality of Life Scale (DQOL) (scale 0-100). Analyses were adjusted for age and education level.
Results: Among men, 31% reported very low to low confidence in maintaining an erection and 25% reported moderate to severe LUTS. Among women, 26% reported sexual dysfunction; 30% reported moderate to severe UI. Each urologic complication was consistently associated with lower general and diabetes-specific HRQOL in both men and women. For example, in women moderate to severe UI compared to minimal symptoms, was associated with lower mean EQ5D health utility scores (0.78 vs. 0.88, p<0.0001), SF-36 social functioning scores (67.9 vs. 76.4, p<0.0001) and total DQOL score (69.7 vs. 74.8, p<0.0001). In men, ED led to lower mean EQ5D utility score (0.82 vs. 0.90, p<0.0001), SF-36 social functioning (73.1 vs. 80.8, p<0.0001), and DQOL score (70.2 vs. 78.3, p<0.0001). In both men and women there was a cumulative negative effect of having both sexual dysfunction and urinary symptoms after adjusting for age, education and HbA_{1c}. For example, in men the odds (95% CI) of a low total DQOL (≤25th%tile, or score ≤70.00) were 3.18 (1.88-5.36) times greater in men with ED and 2.58 (1.43-4.65) times greater in men with LUTS. For those men with both symptoms the odds were 7.20 (3.96-13.11) times greater. In women the odds of a low DQOL (score ≤67.26) was 2.77 (1.53-5.01) and 2.88 (1.68-4.97) times greater among those with sexual dysfunction and UI, respectively. For those women with both symptoms, the odds were 4.20 (2.18-8.08) times greater. Similar effects were observed for the SF-36 and EQ5D measures.
Conclusion: Sexual and urinary complications in men and women with T1DM are associated with lower HRQOL. Since these complications may be embarrassing to discuss, their impact may not be fully appreciated by clinicians. HRQOL inquiries can guide such discussions.

Prevalence of urinary tract infection among type 2 diabetes mellitus patients vs non-diabetic patients in Germany

S. Yu, C. Zhao, K. Joshi, Y. Qiu;
Merck Sharp & Dohme Co., Whitehouse Station, USA.

Background and aims: Urinary tract infections (UTI) commonly occur in patients with type 2 diabetes mellitus (T2DM). However, its prevalence has not yet been reported in a European patient population other than UK. Thus,

this study aims to evaluate the prevalence of UTI in a T2DM patient population compared to non-diabetic patients in Germany.
Materials and methods: This was a retrospective cohort study using the IMS Disease Analyzer database. Patients age 18 years or older with a T2DM diagnosis between 1/1/10 and 12/31/11 (index period) were identified. Patients were excluded if they had type 1 diabetes mellitus (T1DM), gestational diabetes mellitus, or other forms of secondary diabetes. Eligible patients had an existing medical record 1 year before (baseline) and after (follow-up) the index date (first observed T2DM diagnosis during the index period). Patients with no diagnosis of diabetes during the study period were individually matched 1:1 to the T2DM patients based on age, gender, and location. UTI events were identified using ICD-10 codes for UTI, cystitis, pyelonephritis, and trigonitis during baseline and follow-up periods. Charlson comorbidity index (CCI) score was calculated based on the patient information from the baseline period, and used as the indicator for patient health status.
Results: After matching, a total of 40,337 pairs of T2DM patients and non-diabetic subjects (49.17% male, mean age = 65.35 years), were identified as the study cohort. Compared to the non-diabetic cohort, the T2DM cohort had significantly higher prevalence of all comorbidities included in the CCI calculation, except for acquired immunodeficiency syndrome (AIDS) and metastatic solid tumor. Among the T2DM cohort, 12.25% were diagnosed with diabetes related chronic complications. The 1-year prevalence of UTI was 7.80% in T2DM cohort vs. 5.65% in non-diabetic cohort (p<0.0001). The age and gender specific prevalence was reported for those <65, 65-74, and ≥75 (Figure 1). The overall risk of UTI was higher for those with a history of UTI during the baseline period than those without (crude relative risk [RR] = 5.84, [95% CI: 5.54, 6.14]). After adjusting for age and gender, the adjusted RR of UTI was 4.68 [4.44, 4.92], which suggested potential confounding effect. After controlling for comorbidities, T2DM (odds ratio [OR] = 1.13, [1.06, 1.20]), age ≥75 vs. age <65 (OR = 1.50, [1.32, 1.71]), female gender (OR = 2.66, [2.41, 2.95]), and UTI during baseline period (OR = 6.09, [5.68, 6.52]) were significantly associated with UTI in the follow-up period. However, female gender showed a moderate but yet significant protective effect in patients aged ≥75 (OR = 0.81, p=0.0059).
Conclusion: In Germany, T2DM patients have a higher prevalence of UTI as compared to non-diabetic patients. The increased infection risk was greater for T2DM, female, elderly patients, and those with previous history of UTI.

Figure 1 UTI 1-year prevalence by age and gender (T2DM vs. non-T2DM)

	<65	65-74	>74
Male - T2DM	3.62%	3.60%	5.84%
Male - Non-diabetic	2.32%	2.63%	3.89%
Female - T2DM	10.34%	10.61%	13.10%
Female - Non-diabetic	6.93%	8.84%	9.94%

1318

Disease burden of urinary tract infections among type 2 diabetes mellitus patients: a US database study
A.Z. Fu[1], S. Yu[2], Y. Qiu[2], S.S. Engel[2], R. Shankar[2], S. Rajpathak[2], K.G. Brodovicz[2], L. Radican[2];
[1]Georgetown University Medical Center, Washington, [2]Merck Sharp & Dohme Co., Whitehouse Station, USA.

Background and aims: While the association between type 2 diabetes mellitus (T2DM) and urinary tract infection (UTI) is known, the associated economic burden has not been adequately quantified. Healthcare resource utilization and costs for T2DM patients with (prevalent cohort [PC]) and without (incident cohort [IC]) a history of UTI were assessed in this study.
Materials and methods: This was a retrospective cohort study using a US commercial health insurance claims database (MarketScan). T2DM patients aged ≥18 years with continuous enrollment for ≥1 year prior to, and after, the first observed T2DM diagnosis (between 1/1/2009-9/30/2010) were included. Patients with type 1 diabetes or gestational or other forms of secondary diabetes were excluded. Cases of UTI, cystitis, and pyelonephritis were identified using ICD-9 codes, which were further used to identify UTI-related inpatient and outpatient visits. Antibiotic prescription claims for treating UTI within 7 days after inpatient and outpatient visits were used to calculate the pharmacy cost.
Results: The final study cohort comprised 93,919 T2DM patients. UTI prevalence was 7.6% (n=7,143) and 8.3% (n=7,835) at baseline and follow-up year, respectively. The age and gender specific 1-year prevalence is reported in Figure 1. During the follow-up period, 33.9% of the PC had ≥1 UTI while 6.2% of the IC had ≥1 UTI (p<0.0001). After controlling for patient characteristics and baseline comorbidities, age 75+ (odds ratio [OR]=1.36 vs. age 55-64, [95% CI: 1.26, 1.47]), female gender (OR=2.9, [2.75, 3.06]), and history of UTI (OR=5.81, [5.48, 6.15]) were the strongest predictors of UTI. Compared to the IC, the PC was more likely to have UTI related outpatient visits (96.9% vs. 95.2%, p=0.0005), more outpatient visits per patient (2.60 vs. 1.62, p<0.0001), UTI-related antibiotics use (65.8% vs. 60.9%, p<0.0001), and a greater number of UTI-related prescriptions per patient (4.97 vs. 3.30, p<0.0001). The associated outpatient cost per patient per year was also higher for the PC than IC ($630.8 vs. $415.9, p=0.001 for payers, $62.92 vs. $48.54, p=0.0006 for patients). The PC also had higher pharmacy cost as compared to IC ($36.51 vs. $23.82, p<0.0001). However, the PC had lower UTI-related inpatient cost for patients ($319.0 vs. $481.6, p=0.036). No significant difference in inpatient cost was observed for payers ($16,425 vs. $16,866, p=0.87) or in total inpatient cost ($16,744 vs. $17,347, p=0.82).
Conclusion: Among T2DM patients, UTI was associated with increased healthcare utilization and higher costs, especially for those with previous UTI.

Figure 1 UTI prevalence during 1-year follow up

	18-24	25-34	35-44	45-54	55-64	65-74	75+
Male	1.2%	3.0%	2.6%	2.9%	3.8%	4.5%	7.2%
Female	15.9%	15.6%	13.0%	12.2%	12.3%	11.6%	16.2%

Statin therapy is associated with development of new onset diabetes after transplantation (NODAT) in liver recipients
Y. Cho[1], E. Choe[1], Y. Choi[1], D. Joo[2], B.-W. Lee[1], M. Kim[2], B. Cha[1,3], H. Lee[1,3], E. Kang[1,3];
[1]Division of Endocrinology and Metabolism, Department of Internal Medicine, [2]Department of Transplantation, [3]Institute of Endocrine Research, Yonsei University College of Medicine, Seoul, Republic of Korea.

Background and aims: The metabolic complications including new onset diabetes after transplantation (NODAT) and dyslipidemia become important in organ transplantation recipients, since it is associated with graft survival as well as patient survival. The statins are most widely used for dyslipidemia treatment in general population, but it is associated with increased risk of diabetes. The aim of this study is to investigate whether statin therapy is associated with NODAT development in liver transplant (LT) recipients.
Materials and methods: A total of 154 liver transplanted recipients, who underwent surgery in the age of 20-75 without previous history of diabetes were included. We evaluated the incidence of NODAT according to the statin use and associated risk factors. The fasting blood glucose and lipid profiles were examined at baseline (before transplantation) and 6, 12, 24, 36 months after transplantation.
Results: The incidence of NODAT was significantly higher in stain group (9/29, 31.0%) compared to control group (14/125, 11.2%) (p=0.007). There were no significant differences in age, body mass index, corticosteroid cumulative dose, prevalence of hypertension and impaired fasting glucose be-

fore LT, fasting serum glucose and total cholesterol levels between the groups at baseline. The mean follow up duration was 34.46±23.56 months in statin group and 33.34±22.23 months in control group (p=0.972). Statin use over 6 months was the principal factor related to the development of NODAT after LT (OR, 4.49; 95% CI, 1.49-13.54, p=0.008)
Conclusion: Statin treatment over 6 months could contribute to the development of NODAT in liver transplantation recipients.

Table. Independent Predictors of NODAT development in LT patients

	OR (95% CI)	p-value
Sex	1.08 (0.39 to 3.02)	0.883
BMI	1.16 (0.97 to 1.39)	0.103
Age	0.99 (0.93 to 1.05)	0.696
Duration of f/u	1.00 (0.97 to 1.02)	0.721
Cummulative dose of steroid for 6months	1.00 (0.99 to 1.00)	0.253
Statin use	4.49 (1.49 to 13.54)	0.008
IFG before LT	2.82 (1.03 to 7.75)	0.044
Hypertension	0.72 (0.25 to 2.13)	0.561

Multivariate analysis was performed using multiple logistic regression.

Sex hormone-binding globulin: a new marker of non-alcoholic fatty liver disease in patients with type 2 diabetes mellitus
Y. Hu, X. Hua, G. Tong, Y. Zhong, W. Wang, L. Li, Y. Sun;
Endocrinology, Nanjing Drum Tower Hospital, Nanjing, China.

Background and aims: Recent data suggested that increased serum SHBG levels, an independent predictor of type 2 diabetes mellitus (T2DM) and metabolic syndrome, resulted from decreased liver fat. Thus we aimed to investigate the association of serum sex hormone-binding globulin (SHBG) with metabolic variables and to evaluate whether it could be a biomarker of non-alcoholic fatty liver disease (NAFLD) in T2DM patients.
Materials and methods: 438 type 2 diabetic patients who visited our university hospital were enrolled in the study. Subjects were assigned to the NAFLD group (n=181) and non-NAFLD group (n=257) according to liver ultrasound. Fasting serum SHBG, fasting plasma glucose (FPG), liver enzymes, lipids, insulin and C-peptide were measured. The correlations between serum SHBG levels and metabolic parameters as well as the presence of NAFLD were analyzed.
Results: Serum SHBG levels were significantly lower in patients with NAFLD than that in patients without NAFLD (23.86 ± 10.98 vs. 42.06 ± 17.69 nmol/L, $P < 0.001$). In the multiple linear regression model with SHBG as the dependent variable, age (β = 0.316, $P < 0.001$), waist (β= -0.175, $P = 0.033$), triglycerides (TG) (β = -0.243, $P = 0.005$), HDL cholesterol (β = 0.200, $P = 0.021$), and homeostasis model assessment of insulin resistance (HOMA-IR) (β= -0.163, $P = 0.036$) were independent contributors that influenced the levels of SHBG. With the increased quartiles of serum SHBG, age and HDL cholesterol were significantly increased (P for trend < 0.001), and levels of BMI, waist, alanine aminotransferase (ALT), gamma-glutamyl transpeptidase (γ-GT), TG, insulin and c-peptide, and also HOMA-IR were significantly decreased (all P for trend < 0.05). However, levels of aspartate aminotransferase (AST), total cholesterol, LDL cholesterol, FPG, and HbA_{1c} showed no any tendency of change. Besides, Elevated levels of SHBG were obviously and consistently associated with reduced presence of NAFLD. After adjustment for age and sex, the odds ratio (ORs) and 95% confidence interval (CI) for NAFLD from the first to the fourth quartile of serum SHBG were 1.00 (reference), 0.26 (95% CI, 0.14 - 0.47), 0.14 (95% CI, 0.07 - 0.26), and 0.03 (95% CI, 0.01 - 0.07), respectively (P for trend < 0.001). When further adjusted for potential coviables such as smoking status, alcohol use, duration of diabetes, BMI, waist, γ-GT, TG, FPG, and HOMA-IR, the inverse association between SHBG and NAFLD was slightly attenuated but still significantly existed (P for trend < 0.001).
Conclusion: Serum SHBG levels were significantly associated with age, waist, TG, HDL cholesterol, and HOMA-IR. Low serum SHBG may be a good marker in helping predict presence of NAFLD in type 2 diabetic patients.

1321

Low relative skeletal muscle mass is independently associated with NAFLD in Korean women with type 2 diabetes
Y.J. Choi[1], J.S. Lim[2], S.-H. Jee[3], E.-J. Lee[3], S.H. Lee[1], B.W. Huh[1], K.B. Huh[1];
[1]Huh's Diabetes Center, Seoul, [2]Yonsei University, Wonju, [3]Yonsei University, Seoul, Republic of Korea.

Background and aims: Diabetic patients tend to have age-related skeletal muscle loss (sarcopenia), which is associated with an increased risk of adverse health outcomes. Non alcoholic fatty liver disease(NAFLD) is highly prevalent in patient with diabetes and metabolic syndrome and the poor prognosis is associated with female sex. In this study, we investigated whether skeletal muscle mass was associated with NAFLD in women with type 2 diabetes.
Materials and methods: We enrolled 1926 women (mean age 58±12 yr) with type 2 diabetes, who visited our Diabetes Center from 2006 to 2010, who gave complete information on all covariates; who had no history of viral or other liver diseases; whose alcohol consumption was < 140 g/week; and who had undergone both bioimpedance body composition analysis and liver ultrasound. NAFLD was defined as the presence of hepatic steatosis. The skeletal muscle mass was expressed as skeletal muscle mass index (SMI = skeletal muscle mass/total body mass x 100).
Results: In the subjects, 984 (51.5%) patients had NAFLD. HbA1c, waist, triglyceride, systolic and diastolic blood pressure were higher in those with NAFLD. HDL-cholesterol and SMI were lower in those with NAFLD (SMI : 40.1±9.7 vs 41.3±9.1, p<0.01). The frequency of NAFLD was significantly decreased in higher SMI quartile(15.8%, 13.5%, 11.9%, 9.9%, p<0.01). The odds ratio for NAFLD was 2.25 (95% CI: 1.66, 3.04) in women with lowest quartile of the SMI compared with women with highest quartile of the SMI after adjusting for age, HbA1C, waist, triglyceride, systolic blood pressure and HDL-cholesterol.
Conclusion: The low relative skeletal muscle mass indicative of sarcopenia is associated with NAFLD in women with type 2 diabetes. Interventions leading to skeletal muscle build-up such as resistance training and/or amino acid supplementation may need to be investigated in diabetic women with NAFLD.

Insulin resistance and hepatic steatosis relate to increased cardiac oxidative stress in mice
J. Szendroedi[1], T. Jelenik[1], U. Floegel[2], E. Phielix[1], K. Kaul[1], P. Nowotny[1], H. Partke[1], J. Schrader[2], M. Roden[1];
[1]German Diabetes Center, [2]Department of Molecular Cardiology, University Clinics, Heinrich Heine University, Duesseldorf, Germany.

Background and aims: Diabetic cardiomyopathy has been related to lower oxidative capacity and increased oxidative stress in cardiomyocytes. Non-alcoholic fatty liver (NAFL) and insulin resistance are associated with increased cardiovascular morbidity and mortality. Here, we examined how NAFL and insulin resistance relate to cardiac oxidative stress and mitochondrial oxidative capacity.
Materials and methods: Female mice, aged 18 and 36 weeks (w), with adipose tissue-specific overexpression of the sterol regulatory-element binding protein-1c (aP2-SREBP-1c: AP2), a model of NAFL, and wild-type controls (CON) underwent hyperinsulinemic-euglycemic clamps to assess insulin sensitivity (n=5-7). Cardiac mitochondrial respiration and reactive oxygen species production from isolated mitochondria were assessed by high-resolution respirometry and Amplex Red, respectively. Cardiac morphology and function were measured in vivo by NMR imaging in 36-weeks old mice (n=8).
Results: Whole body insulin sensitivity was 71% and 70% lower in both 18- and 36-weeks old AP2 mice than in aged-matched CON (p<0.05). Ex vivo cardiac mitochondrial oxidative capacity on tricarboxylic acid cycle-derived substrates was unchanged in 18 w old, but almost doubeld in 36 w old AP2 mice (state u respiration: 2.9±0.1, CON: 1.5±0.4 nmol/mg protein/s; p<0.05). Oxidative capacity on β-oxidation-derived substrates was 60% and 125% greater in 18 w old (2.2±0.2, CON: 1.4±0.2; p<0.05) and 36 w old (2.5±0.7, CON: 1.1±0.2 nmol/mg protein/s; p<0.05) AP2 mice, respectively. H2O2 production by mitochondrial complex III was 51% higher (p<0.05) only in 36 w old mice than in age-matched CON. AP2 mice also featured 34% increase in left ventricular mass and 21% increase in wall thickness (p<0.001) suggesting myocardial hypertrophy. Finally, older AP2 mice had 24% greater stroke volume and 29% higher cardiac output (for both p<0.05 vs. CON).
Conclusion: Insulin resistance in a mouse model of hepatic steatosis associates with increased cardiac mitochondrial respiration and oxidative stress,

which develop progressively with rising age. These changes relate to left ventricle hypertrophy and increased cardiac output, which could reflect adaptation to either higher blood pressure or to increased substrate flux. Insulin resistance and steatosis may therefore lead to higher myocardial energy turnover and oxidative stress rendering the hearts vulnerable for ischemic intolerance and impaired myocardial function.

1323

Increased accumulation of skin advanced glycation end products is associated with microvascular complications and insulin resistance in type 1 diabetes

A. Araszkiewicz, J. Schlaffke, P. Niedzwiecki, D. Zozulinska-Ziolkiewicz, D. Naskret, B. Wierusz-Wysocka;
Department of Internal Medicine and Diabetology, Poznan University of Medical Sciences, Poland.

Background and aims: Advanced glycation end products (AGEs) are involved in the pathogenesis of atherosclerosis and reflect the risk of cardiovascular disease. Skin autofluorescence (AF) measured with Autofluorescence Reader (AR) device is a noninvasive tool to measure the tissue accumulation of advanced glycation end products. The aim of the study was to assess the association between AF and microvascular complications and insulin resistance in type 1 diabetes (DM1).
Materials and methods: Study population consisted of 416 type 1 diabetic patients, aged 32 years (IQR: 25-42), 227 women, with disease duration 14 years (IQR: 10-22). We evaluated the presence of late diabetic complications and indirect parameters of insulin resistance (waist circumference, estimated glucose disposal rate - eGDR, visceral adiposity index - VAI). We used AGE Reader (DiagnOptics, Groningen, the Netherlands) to measure skin autofluorescence phenomenon, which occurs because of fluorescent properties of AGEs.
Results: The median AF was 2.1 (IQR: 1.8-2.5). We found retinopathy in 188 patients (45%), diabetic kidney disease in 62 (15%) and neuropathy in 83 (20%). We found positive correlation between skin AF and diabetes duration (R=0.46, p<0.001), waist circumference (R=0.20, p<0.001), systolic blood pressure (R=0.16, p<0.001), LDL cholesterol level (R=0.13, p=0.005) and VAI in women (R=0.10, p=0.03) and negative correlation with eGDR (R=-0.14, p=0.006). There was no correlation between the AF and current measurement of HbA1c. In the univariate logistic regression AF was significantly associated with retinopathy (OR 3.4; 95%CI: 2.2-5.1, p<0.001), diabetic kidney disease (OR 2.5; 95%CI: 1.6-3.9, p<0.001), neuropathy (OR 4.4; 95%CI: 2.8-6.9, p<0.001) and with any microvascular complication (OR 4.1; 95%CI: 2.7-6.4, p<0.001). Multivariate logistic regression showed that skin AF was associated with diabetic neuropathy (OR 2.4; 95%CI: 1.3-4.3, p=0.002) and diabetic kidney disease (OR 2.2; 95%CI: 1.2-4.2, p=0.01) in connection with diabetes duration, smoking, history of hypertension and HbA1c level.
Conclusion: The tissue accumulation of AGEs is significantly associated with microvascular complications and insulin resistance in DM1. The assessment of skin AF might provide important clinical information for the risk of microangiopathy in diabetic patients.

Activated Notch1 signalling has repressive effects on wound healing in diabetes

S.-B. Catrina[1], V. Sunkari[1], I. Botusan[1], J. Grünler[1], A. Catrina[2], F. Radtke[3], X. Zheng[1], K. Brismar[1];
[1]Molecular Medicine and Surgery, [2]Rheumatology, Karolinska Institute, Stockholm, Sweden, [3]4Ecole Polytechnique Fédérale de Lausanne, Swiss Institute for Experimental Cancer Research, Lausanne, Switzerland.

Background: Diabetic wounds are characterized by impaired coordination of several cellular processes such as angiogenesis and cell differentiation. Notch signaling is a major player in cell differentiation and angiogenesis being a cell-cell system activated upon the interaction between the membrane-bound Notch receptors (Notch1-4) and their ligands (Jagged 1-2, delta 1, 3, 4). Binding of the ligands is followed by proteolytic cleavage of the receptor by γ-secretase complex which results in activation of the signaling with specific outcome depending on the members of the Notch system involved. We decided to study the potential role of Notch signaling in diabetic wound healing.
Materials and methods: The modulation of Notch system by hyperglycemia was studied *in vitro* in human dermal fibroblasts (HDF), human endothelial cells and *in vivo* in several animal models (db/db mice and Goto-Kakizaki (*GK*) *rat*) using the corresponding technique (western blot, transitory transfections with reporter gene assay or evaluation of target genes by quantitative RT-PCR). The functional consequence of the notch system modulation was studied *in vitro* by assessment of the migration of HDF and by angiogenesis assay. Notch pathway inhibition was induced either nonspecific by γ-secretase inhibitors (DAPT, L-685,458) or by specific siRNA silencing of the Notch receptors (1-4). Using cre-lox system we have generated mice that lack Notch 1 in the skin. Wound healing rate was evaluated both in db/db mice and in skin specific Notch1 knock-out mice in which diabetes was induced by streptozocin (STZ).
Results: Notch signaling is activated in the skin of several animal models of diabetes. Hyperglycemia activates Notch pathway at multiple levels and has repressive effect on fibroblasts migration and angiogenesis. Blocking Notch signaling with γ-secretase inhibitors improves wound healing rate just in diabetic (db/db mice) but not in control non-diabetic animals. Using loss-of-function genetic approaches we demonstrate both at the cellular level (fibroblasts, endothelial cells) as well as in an animal model that the Notch1 activation is the key player of the repressive effects of Notch on wound healing in diabetes, which is confirmed in the biopsies from patients with diabetic foot ulcers.
Conclusion: We propose specific targeting of Notch1 signaling as potential therapy for diabetic wounds.

Impact of established and undiagnosed type 2 diabetes mellitus on acute ischaemic stroke severity and outcome

K. Tziomalos, S. Bouziana, M. Spanou, A. Pavlidis, V. Giampatzis, M. Papadopoulou, C. Boutari, D. Magkou, F. Iliadis, C. Savopoulos, A. Hatzitolios;
First Propedeutic Department of Internal Medicine, Medical School, Thessaloniki, Greece.

Background and aims: It is unclear whether undiagnosed type 2 diabetes mellitus (T2DM) has the same prognostic significance as established T2DM in patients with acute ischemic stroke. We aimed to assess the impact of established and undiagnosed T2DM on acute ischemic stroke severity and outcome.
Materials and methods: We prospectively studied 342 consecutive patients (37.4% males, age 78.8±6.4 years) who were admitted for acute ischemic stroke. Undiagnosed T2DM was defined as fasting serum glucose levels at the second day of hospitalization ≥ 126 mg/dl in the absence of history of T2DM. Stroke severity was evaluated with the National Institute of Health stroke scale (NIHSS) at admission and the outcome was assessed with the modified Rankin scale (mRS) at discharge.
Results: Undiagnosed and established T2DM were present in 7.4 and 35.1% of the patients, respectively. At admission, the NIHSS was 8.0±9.9, 16.0±11.8 and 9.6±9.4 in non-diabetic patients and in patients with undiagnosed and established T2DM, respectively (p=0.006). In post-hoc tests, the NIHSS was higher in patients with undiagnosed T2DM than in non-diabetic patients and patients with established T2DM (p=0.005 and p<0.05, respectively) but did not differ between non-diabetic patients and patients with established T2DM. At discharge, the mRS was 2.2±2.1, 3.3±2.4 and 2.8±2.2 in non-diabetic patients and in patients with undiagnosed and established T2DM, respectively (p<0.05). In post-hoc tests, the difference in mRS approached significance only in the comparison of non-diabetic patients and patients with undiagnosed T2DM (p=0.089). Patients with established T2DM had lower serum low-density lipoprotein cholesterol levels but higher serum triglyceride and lower high-density lipoprotein cholesterol levels than non-diabetic patients. Other cardiovascular risk factors did not differ between non-diabetic patients, patients with undiagnosed T2DM and patients with established T2DM.
Conclusion: In patients admitted for acute ischemic stroke, undiagnosed T2DM is associated with more severe stroke and worse outcome than established T2DM. It is possible that the aggressive management of cardiovascular risk factors in patients with established T2DM prior to stroke negates their increased risk whereas patients with undiagnosed T2DM remain at risk.

1326

Falling or static national rates of diabetes-related vascular and renal outcomes from 2006 to 2011 despite a 50% increase in diabetes prevalence

P.L. Drury[1], P.W. Giles[2], E. Jo[3];
[1]Auckland Diabetes Centre, [2]Department of Diabetes and Endocrinology, Palmerston North, [3]Ministry of Health, Wellington, New Zealand.

Background and aims: Despite rapid and substantial increases in the national prevalence of diabetes (DM) in New Zealand (NZ) over more than 20 years, we have not seen the anticipated rise in adverse outcomes for renal and vascular morbidities.
Materials and methods: We therefore assessed the number of lower-limb amputations, renal replacement therapy access procedures, cardiovascular (CV) events and strokes occurring throughout NZ over the 6 year period 2006-2011 inclusive. All such events, identified by ICD-9 or ICD-10 codes using standard data collection and coding methods. can be linked by a unique national patient identifier available for >98% of people. We use a detailed algorithm, the NZ Virtual Diabetes Register (VDR), to define the population with DM; this defines individuals as having DM based on their specific healthcare facility and therapy usage and has ≥ 90-95% sensitivity and specificity.
Results: Diabetes prevalence using the VDR rose from 138,200 (end-2005) to 208,076 (end-2011), an increase of 50.6% over 6 years - 7.0% compound per annum (p.a.); while total national population rose only 7.3% (4.12 to 4.42 million). Lower limb amputations in people with DM remained roughly static between 648 and 782 events annually; as a rate per 1000 people with DM this fell from 0.47% to 0.39% p.a. (-17%; $p<0.05$). Renal access procedures similarly remained static (between 422 & 458 events annually, 0.24-0.33% p.a.; p=NS) with no clear trend. The absolute number and the rate of CV events fell from over 13,000 to below 11,000 (9.48 to 5.74% p.a.), -39% ; r=-0.97; $p<0.005$). Stroke events rose in absolute numbers from 2600 to 3300 but fell as a rate from 1.90 to 1.73% p.a., -9%; r=-0.90, $p<0.02$).
Conclusion: We conclude that, despite a continuing long-term increase in diabetes prevalence, national major end-point rates are either static or falling, particularly so for CV events.

1327

Diabetes mellitus and chronic kidney disease amplify accumulation of tissue advanced glycation end products in patients with peripheral artery disease

J.D. Lefrandt[1], L.C. de Vos[1], D.J. Mulder[1], R.P.F. Dullaart[2], H.L. Lutgers[2], H.J. Lambers Heerspink[3], A.J. Smit[1], P.W. Kamphuisen[1], C.J. Zeebregts[4];
[1]Vascular Medicine, [2]Endocrinology, [3]Clinical Pharmacology, [4]Vascular Surgery, UMCG, Groningen, Netherlands.

Backgrounds and aims: Diabetes mellitus (DM) and chronic kidney disease (CKD) are important risk factors for peripheral artery disease (PAD) and associated with a severely increased cardiovascular (CV) risk in these patients. DM increases production of AGEs and CKD decreases their clearance, while chronic low grade oxidative stress induces AGEs formation in both. However, human data on the role of tissue AGEs in PAD are scarce. We aimed to study the effects of DM and CKD on accumulation of tissue AGEs in patients with PAD.
Materials and methods: We performed a cross-sectional study of 486 PAD patients at the outpatient clinic of Vascular Surgery. PAD was confirmed by angiography or duplex ultrasonography. CV risk factors and CV comorbidity (coronary artery disease [CAD], cerebrovascular disease [CVD], abdominal aortic aneurysm [AAA]) were assessed. Hypertension and hypercholesterolemia were defined as the use of blood pressure and lipid lowering drugs, respectively. Patients were divided into four groups based on the presence of DM and severity of CKD (> or < 60 ml/min per 1.73 m^2). Tissue AGEs were noninvasively assessed by skin autofluorescence (SAF) with the AGE Reader™. Data are shown as mean ± standard deviation, number (%), geometric mean (95% confidence interval), or as median (Q1-Q3). ANOVA and logistic regression analysis were performed.

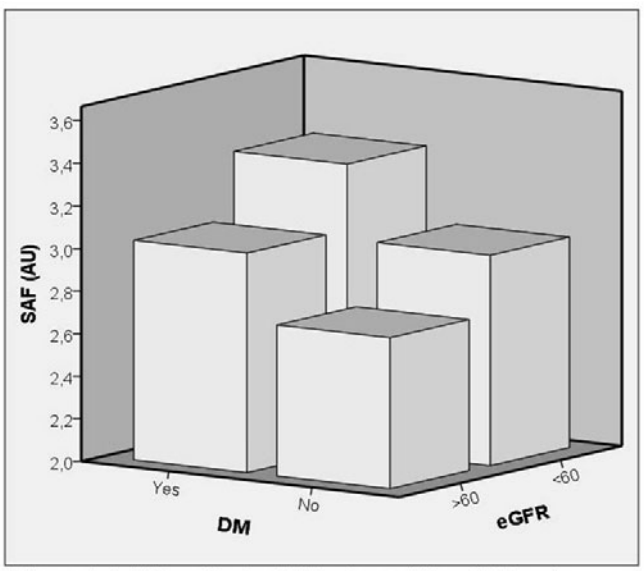

Figure 1. Additive effects of diabetes mellitus (DM) and chronic kidney disease on skin autofluorescence (SAF) in peripheral artery disease.
eGFR: estimated glomerular filtrating rate, AU: arbitrary units.

Results: Mean age of the 339 men and 147 women was 66 ± 11 years. DM was present in 123 (25%) patients who had a median HbA1c of 6.0 (5.7-6.5) % (42 [38-47] mmol/mol). Mean eGFR was 79 ± 28 in DM and 82 ± 26 ml/min per

1.73 m^2 in non-DM patients. 30 (24%) DM patients and 65 (18%) non-DM patients had eGFR< 60 ml/min per 1.73m^2. Figure 1 shows the additive effect of DM and CKD on accumulation of tissue AGEs: SAF was significantly different among the groups: DM and eGFR<60: 3.27 (95% CI: 3.02-3.52); DM and eGFR>60: 2.96 (2.81-3.10); non-DM and eGFR<60: 2.90 (2.73-3.08); non-DM and eGFR>60 ml/min per 1.73 m^2: 2.64 (2.56-2.71) arbitrary units, *P*<0.0001. SAF was associated with the presence of CV comorbidity, independent of age, gender, DM and eGFR; odds ratio 1.71 (95% CI: 1.26-2.33) per unit increase of SAF. The presence of CV comorbidity was: 70% in DM and eGFR<60, 66% in non-DM and eGFR<60, 54% in DM and GFR>60 and 41% in non-DM and eGFR>60 ml/min per 1.73 m^2, *P*=0.0001.

Conclusion: DM and CKD have additive effects on accumulation of tissue AGEs in PAD and are associated with the presence of CV comorbidity. Moreover, SAF predicts presence of CV comorbidity, independent of age, gender, DM and eGFR. Accelerated accumulation of AGEs may promote atherosclerosis and contribute to the severely increased CV risk in PAD patients with DM and CKD.

1328

Skin autofluorescence as a measure of tissue advanced glycation end products deposition is elevated in diabetic patients with peripheral artery disease

L.C. de Vos[1], D.J. Mulder[1], R.P.F. Dullaart[2], H.L. Lutgers[2], A.J. Smit[1], P.W. Kamphuisen[1], J. Westra[3], C.J. Zeebregts[4], J.D. Lefrandt[1];
[1]Internal Medicine Division Vascular Medicine, [2]Internal Medicine Division Endocrinology, [3]Rheumatology and Clinical Immunology, [4]Surgery division Vascular Surgery, University Medical Center, Groningen, Netherlands.

Backgrounds and aims: Diabetes mellitus (DM) is an important risk factor for peripheral artery disease (PAD) and associated with a particularly poor prognosis in these patients. Increased glycemic and oxidative stress in DM enhance the accumulation of advanced glycation end products (AGEs), which play an important role in the development of atherosclerosis and cardiovascular (CV) disease. Skin autofluorescence (SAF) is a validated noninvasive method to measure tissue AGEs. Earlier, we showed that SAF is increased in DM, associated with vascular complications and predictive for mortality. However, accumulation of tissue AGEs in DM patients with PAD has not been studied. We aimed to study whether tissue AGEs are increased in DM patients with PAD and to establish the determinants of tissue AGEs deposition.

Materials and methods: We performed a case control study. PAD was confirmed by angiography or duplex ultrasonography. CV risk factors and CV comorbidity (coronary artery disease [CAD], cerebrovascular disease [CVD], abdominal aortic aneurysm [AAA]) were assessed. Hypertension and hypercholesterolemia were defined as the use of blood pressure and lipid lowering drugs, respectively. SAF was measured with the AGE Reader™. Independent sample t-tests, Mann-Whitney-U tests, Chi-square tests, backward linear and logistic regression analysis were performed. Data are shown as mean ± standard deviation, median (Q1-Q3), or as number (%).

Results: A total of 127 DM patients with PAD were compared with 127 DM patients without PAD, matched for age. Characteristics are shown in table 1. Patients with PAD had more CV risk factors, but a higher estimated glomerular filtration rate (eGFR). SAF was higher in diabetic patients with PAD compared to diabetic patients without PAD: 3.11 ± 0.69 versus 2.71 ± 0.68 arbitrary units, *P*<0.0001. In the complete group (DM patients with and without PAD), the odds-ratio for presence of PAD was 2.55 (95% CI: 1.43-4.54) per 1 unit increase of SAF, adjusted for CV risk factors and CV comorbidity. In the group of DM patients with PAD; sex, age, smoking and a history of AAA were the independent determinants of SAF while hypertension, hypercholesterolemia, HbA1c, eGFR, type 1 or 2 DM and a history of CAD or CVD did not contribute to the model.

Conclusion: Skin autofluorescence is elevated in DM patients with PAD, independent of glycemic control, CV risk factors and CV comorbidity. Therefore, increased accumulation of tissue AGEs may promote atherosclerosis and contribute to the poor prognosis of DM patients with PAD.

Table 1. Baseline characteristics of DM patients with and without PAD.

Characteristics	DM with PAD	DM without PAD	*P* value
N	127	127	
Age (years)	69 ± 10	68 ± 10	0.973
Male gender	91 (72%)	62 (49%)	0.0002
Diabetes mellitus Type 1 Type 2	8 (6%) 119 (94%)	- 127 (100%)	0.004
HbA1c* (%) (mmol/mol)	7.1 (6.4-7.9) 57 (46-62)	6.6 (6.0-7.6) 48 (42-59)	0.027
eGFR (ml/min per 1.73m^2)†	76 (60-100)	65 (57-74)	<0.001
Ankle-brachial index‡	0.57 (0.49-0.63)	-	N/A
Current smoker	47 (37%)	20 (16%)	0.0001
Hypertension Hypercholesteremia	119 (94%) 103 (81%)	73 (58%) 33 (26%)	<0.0001 <0.0001
CAD CVD AAA	51 (50%) 26 (21%) 10 (8%)	22 (17%) 4 (3%) -	<0.0001 <0.0001 N/A

Data as mean ± standard deviation, number (%), median (Q1-Q3). PAD = peripheral artery disease; DM = diabetes mellitus; eGFR = estimated glomerular filtrating rate; CAD = coronary artery disease; CVD = cerebrovascular disease; AAA = abdominal aortic aneurysm; N/A = not applicable.
* Data missing for 13 DM patients with PAD.
† Data missing for 4 DM patients with PAD.
‡ Data missing in 34 patients; 13 patients had non-compressible arteries and in 21 patients angiography was directly performed for diagnosis.

Relationship between peripheral vascular calcification and accuracy of ankle brachial index and pulse palpation to screen peripheral arterial occlusive disease

A. Hartemann[1,2], C.E. Aubert[1,3], P. Cluzel[4,2], S. Kemel[4], P.-L. Michel[5], F. Lajat-Kiss[6], M. Dadon[6], O. Bourron[1,2];
[1]Diabetes and Metabolic Diseases, AP-HP, Pitié-Salpêtrière Hospital, [2]Faculty of Medicine, University Pierre and Marie Curie, Paris, France, [3]Internal Medicine, Fribourg Cantonal Hospital, Switzerland, [4]Radiology, [5]Cardiology, [6]Vascular Surgery, AP-HP, Pitié-Salpêtrière Hospital, Paris, France.

Background and aims: Accuracy of ankle brachial index and pulse palpation is discussed for screening peripheral arterial occlusive disease in patients with diabetes. Vascular calcification may indeed be associated with false negative tests. The main aim of this study was to objectively assess the association between peripheral vascular calcification and false negative screening tests for peripheral arterial occlusive disease in patients with diabetes. We also compared improvement of screening by combining pulse palpation and ankle brachial index, and assessed variables associated with peripheral vascular calcification.

Materials and methods: This was a cross-sectional study. The main exclusion criterion was severe renal disease. Peripheral arterial occlusive disease was diagnosed by color duplex ultrasonography. Vascular calcification was assessed by below-knee arteries calcification score measured by computer tomography scan. Linear regression analysis was used to study the variables associated with calcification. Lower limbs with false negative and true negative tests for pulse palpation and ankle brachial index were compared.

Results: We included 200 patients with diabetes (400 lower limbs). Accuracy of ankle brachial index and pulse palpation was low (69.5-72.5%) and not improved by combining both. Calcification score was positively associated with age, diabetes duration, male gender, neuropathy disability score, abnormal monofilament test, peripheral arterial occlusive disease, abnormal pulse palpation and ankle brachial index ≥1.30 or ≤0.90 (p<0.01 for all). Below-knee arteries calcification score was significantly higher in patients with false negative tests, than in those with true negative tests, for both pulse palpation and ankle brachial index (p<0.0001 for all) (see table).

Conclusion: False negative results of ankle brachial index and pulse palpation for screening peripheral arterial occlusive disease is associated with below-knee vascular calcification in patients with diabetes. Combination of both tests does not improve screening accuracy.

	Normal ankle brachial index, n=323 (80.5)			Normal pulse palpation, n=234 (58.5)		
	False negative, n=84 (21.0)	True negative, n=239 (59.8)	p-value	False negative, n=40 (10.0)	True negative, n=194 (48.5)	p-value
Calcification score	725 (0-6326)	102 (0-7205)	< 0.0001	625 (0-6326)	71 (0-6452)	<0.0001

Limbs with normal ankle brachial index and limbs with normal pulse palpation. Comparison of calcification scores in patients with false negative and true negative results for ankle brachial index and pulse palpation respectively.
Data are median (minimum-maximum) or n (%).

Statin therapy successfully maintains low LDL-C in type 2 diabetes mellitus and prevents the age-related LDL-C increase

H.L. Lutgers, M.M. van der Klauw, J.V. van Vliet-Ostaptchouk, S.N. Slagter, A.P. van Beek, B.H.R. Wolffenbuttel;
Endocrinology, University of Groningen, University Medical Center Groningen, Netherlands.

Background and aims: Lowering LDL cholesterol (LDL-C) level has been shown to reduce cardiovascular morbidity and mortality in type 2 diabetes patients (DM2). Several international guidelines therefore recommend to aim for an LDL-C of at least below 2.5 mmol/l in all DM2 patients. Statins are the drugs of choice to reach this goal. In the present study, we evaluated LDL-C levels per age category (decades) in DM2 patients with and without statin therapy, and compared this to non-statin users from the general population.
Materials and methods: Study participants were derived from 60,320 subjects in the LifeLines Cohort Study, a large population-based study on the role of gene-environment interaction in the development of frequently occurring diseases. 56,233 of the 58,712 (96%) non-DM participants did not use statins (group 1). All 967 DM2 participants were included in this analysis. DM2 was defined as diagnosed by a medical professional or treatment with oral blood glucose lowering agents. Among DM2 participants, there were 376 not on statin therapy (group 2) and 591 participants taking statins (group 3).
Results: Mean age in group 1,2 and 3 were: 44, 56 and 59 years, mean BMI: 26, 31 and 31 kg/m2, mean cholesterol: 5.1, 5.0 and 4.1 mmol/l, mean LDL-C: 3.2, 3.2 and 2.3 mmol/l, mean HDL: 1.48, 1.27 and 1.24 mmol/l, median triglycerides: 0.97, 1,46 and 1.44 mmol/l, mean HbA1c: 5.5, 6.8 and 7.0%, mean systolic BP: 125, 134 and 135 mmHg, respectively. In both group 1 and 2, there was a clear age-related rise in LDL-C (Figure 1). LDL-C in DM2 on statins (group 3) was similar in all age categories and was significantly lower compared to the other 2 groups (p<0.001).
Conclusion: Statin therapy adequately reduced the LDL-C level in DM2 participants below 2.5 mmol/l and prevented the age-related rise in LDL-C. The successful reduction of LDL-C in DM2 patients may be an explanation for the trend to a decrease in excess mortality in DM2 compared to the general population.

The effect of HMG-CoA reductase inhibitor of ischaemic heart disease and cerebrovascular attack in elderly diabetic individuals: difference in risk by age

T. Hayashi[1], H. Nomura[1], A. Araki[2], K. Yokote[3], M. Takemoto[3], M. Noda[4], H. Noto[4], H. Sone[5], Japan CDM group;
[1]Department of Geriatrics, Nagoya University Graduate School of Medicine, Nagoya City, [2]Division of Diabetes, Metabolism and Endocrinology, Tokyo Metropolitan Geriatric Hospital, [3]Division of Diabetes, Metabolism and Endocrinology, Chiba University Hospital, Chiba City, [4]Department of Diabetes and Metabolic Medicine, National Center for Global Health and Medicine, Tokyo, [5]Department of Internal Medicine, Endocrinology and Metabolism, Niigata University, Niigata City, Japan.

Background and aims: LDL-cholesterol (LDL-C) is a risk factor for ischemic heart disease(IHD) and agents for dyslipidemia like HMG-CoA reductase inhibitors (statins) can reduce that risk in middle-aged diabetic individuals. We reported the importance of HDL-C levels for IHD and cerebrovascular attack(CVA) in the very elderly diabetic individuals (older than 75y.o.). However, the effect of statins on IHD or cerebrovascular attack(CVA) are not known at all in very elderly. The aim is to identify factors and the effect of agents for IHD and CVA in the elderly and to investigate their differences by age.
Materials and methods: We performed a prospective cohort study (Japan Cholesterol and Diabetes Mellitus Study) with 5.5 years of follow-up. 4,014 patients with type 2 diabetes and without previous IHD or CVA (1,936 women; age 67.4±9.5 years, median 70 years; <65 years old, n=1,261; 65 to 74 years old, n=1,731; and ≥ 75 years old, n=1,016) were recruited on a consecutive outpatient basis from 40 hospitals throughout Japan. Lipids, glucose, and other factors related to IHD or CVA risk were investigated. We also registered 405 sub-cohort patients among 4014 patients in the beginning of the study. The detailed information of medicine and the laboratory data on the change of medication on sub-cohort patients as well as patients suffered from IHD or CVA have been recorded. Statin users are divided into prevalent users, new users, and non-users.
Results: One hundred fifty-three cases of IHD and 104 CVAs (7.8 and 5.7/1,000 people per year, respectively) occurred over 5.5 years. Lower HDL-cholesterol (HDL-C) were correlated with IHD in patients ≥75 years old. In contrast, systolic BP(SBP), HbA1C, LDL-C and non-HDL-C were correlated with IHD in subjects <65 years old, and the LDL-C/HDL-C ratio was correlated with IHD in all subjects. HDL-C was correlated with CVA in patients ≥75 years old. In sub-cohort study, among patients prescribed no agents for dislipidemia, prevalence of both IHD and CVA increased by age dependent manner. In IHD, the rate of incidence was higher in prevalent and new users of statins than that in non users (Hazard ratio,HR 1.558,1.782 respectively), especially in non-elderly(HR:2.25, 2.05), but not in very elderly (HR:0.58,1.35) However, in CVA, the rate of incidence was lower in prevalent and new users of statins than that in non users (HR:0.460,0.523), especially in very elderly(HR:0.51,0.21). These data are same after adjustment various factors such as glucose and blood pressure which was different by age.
Conclusion: IHD and CVA in late elderly diabetic patients were predicted by HDL-C. Statin treatment may prevent IHD and CVA, however the effect may change by age. These age-dependent differences in risk are important for developing individualized strategies to prevent atherosclerotic disease.

Vitamin D and carotid intima media thickness in 416 Danish patients with type 2 diabetes mellitus at entry into the CIMT trial

K. Winckler[1], T. Boesgaard[1], L. Tarnow[1], H. Vestergaard[2], T. Almdal[1], L. Lundby-Christensen[1], A. Vaag[3], S. Madsbad[4], C. Gluud[5], The CIMT Trial Group;
[1]Steno Diabetes Center, Gentofte, [2]Faculty of Health Science, University of Copenhagen, [3]Department of Endocrinology, Rigshospitalet, Copenhagen, [4]Department of Clinical Medicine, Hvidovre Hospital, [5]Centre for Clinical Intervention Research, Rigshospitalet, Copenhagen, Denmark.

Background and aims: A number of studies indicate a high prevalence of vitamin D insufficiency in the general population, and several epidemiologi-

cal studies have reported an association between vitamin D insufficiency and risk of cardiovascular disease (CVD). Low vitamin D status may have an impact on the degree of osteopenia, osteoporosis and cardiovascular risk factors, including thickness of carotid intima media. The aim of the present study was to investigate the association between vitamin D, risk factors for osteopenia and osteoporosis, and carotid intima media thickness (carotid IMT) in the Copenhagen Insulin Metformin Treatment Trial (CIMT).

Materials and methods: We investigated 416 patients with T2D, recruited from 8 diabetes outpatient clinics in the greater Copenhagen area. Inclusion criteria were age>30 years, HbA_{1C}>7.5 % (>58 mmol/mol), eGFR>60 ml/min and duration of T2D >1 year. Vitamin D, carotid IMT, bone mineral density (BMD), trabecular bone structure (TBS) and anthropometric measures were determined at baseline. Vitamin D was measured by immunoassay ECLIA and insufficiency was defined as 25(OH)D <50nmol/l and deficiency as 25(OH)D <25nmol/l. An ultrasound scan was performed to determine carotid IMT. BMD and TBS were measured by Dual Energy X-ray Absorptiometry (DXA) (Hologic, Discovery A). Osteopenia was defined by any T score (spine, neck and hip-neck) between -1 to -2.5 and osteoporosis as any T score<-2.5. BMD was measured in (g/cm^2).

Results: A total of 416 patients (68% men), age 60 ± 9 years [mean ± SD], BMI (kg/m^2) 32 ± 4 [mean ± SD], and HbA_{1c} 8.5 ± 1.0% [mean ± SD] were included. The prevalence of vitamin D insufficiency was 51% and 17% were deficient. Patients had a carotid IMT of 0.8 mm ± 1.7 [mean ± SD] and 70 % have plaques. Vitamin D levels correlated positively with carotid IMT (R = 0.1, P = 0.02, unadjusted and adjusted for gender and BMI) (in men R = 0.04, P = 0.02). We found no correlation in relation to carotid IMT and TBS or BMD, and similar no correlation between vitamin D and TBS or BMD.

Conclusion: A high prevalence of vitamin D insufficiency and deficiency as well as increased thickness of carotid intima media, plaques and osteopenia was found in 416 Danish patients with T2D.We found a paradoxical positive correlation between vitamin D and carotid IMT, and no correlation between vitamin D status and measures of bone mineral contents.

Improved cardiovascular function after prolonged caloric restriction in obese patients with type 2 diabetes mellitus and cardiac complications

L.D. van Schinkel[1], J.J.M. Westenberg[2], J.T. Jonker[1], A. de Roos[2], H.J. Lamb[2], J.W.A. Smit[3];
[1]Endocrinology, [2]Radiology, LUMC, Leiden, [3]Endocrinology, The Radboud University Nijmegen Medical Centre, Nijmegen, Netherlands.

Background and aims: Obese patients with type 2 diabetes mellitus (T2DM) have a higher incidence of cardiovascular disease. These patients have increased ectopic fat accumulation, which is associated with cardiovascular disease. In addition, myocardial triglyceride (TG) content is increased in patients with T2DM, leading to altered myocardial function. In obese T2DM patients without cardiac complications prolonged caloric restriction decreases myocardial TG content and improves diastolic heart function. We hypothesize that dietary interventions decrease ectopic fat accumulation, including myocardial TG, and improve cardiovascular function in patients with T2DM with cardiac complications.

Materials and methods: 27 obese T2DM patients with cardiac complications, i.e. myocardial infarction in medical history and/or coronary artery occlusion ≥ 50%, were studied before and after a 16 week low calorie diet (LCD) (450-1000 kcal/day) to achieve substantial weight loss. Cardiovascular function, ectopic fat accumulation and pulse wave velocity (PWV), a marker for aortic stiffness, were assessed with magnetic resonance (MR) imaging and myocardial TG content with MR spectroscopy. In addition, plasma hemoglobin A1c (HbA1c), and body mass index (BMI) were measured.

Results: BMI decreased from 32.2 ± 0.9 (mean ± SEM) to 26.8 ± 0.8 kg/m^2, p < 0.001, and HbA1c from 6.9 ± 0.2 to 5.8 ± 0.1 % , p<0.001. Systolic cardiac function (Left ventricular ejection fraction) increased from 54.8 ± 1.7 to 56.2 ± 1.5 %, p=0.016. PWV decreased from 7.9 ± 0.4 to 7.2 ± 0.2 m/s, p 0.016, reflecting a more compliant aorta. Myocardial TG content decreased from 1.21 ± 0.13 to 0.81 ± 0.08 %, p<0.001. In addition epicardial and paracardial fat volumes decreased from 5.5 ± 0.3 tot 4.7 ± 0.3 ml, p<0.001, and from 8.0 ± 0.7 to 5.7 ± 0.6 ml, p<0.001, respectively.

Conclusion: 16 weeks caloric restriction in obese T2DM patients with cardiac complications decreases BMI and improves glucoregulation associated with decreased ectopic fat depots and improved cardiovascular function. Therefore, therapeutic intervention by caloric restriction is an efficient and attractive intervention for improving cardiovascular function in patients with T2DM with cardiac complications.

Diabetes duration rather than the level of metabolic control is a determinant of endothelial damage in type 1 diabetes

E. Szymanska-Garbacz[1], L. Czupryniak[1], P. Grzelak[2], M. Podgorski[3], M. Saryusz-Wolska[1], M. Pawlowski[1], J. Loba[1], L. Stefanczyk[2];
[1]Internal Medicine and Diabetology Department, [2]Radiology Department, [3]Medical University of Lodz, Poland.

Background and aims: Besides clear susceptibility to developing microvascular complications, type 1 diabetes subjects are also at increased risk of cardiovascular and macrovascular complications. Recently, in a group of type 1 diabetes subjects without any vascular complications, we have documented the positive relationship between insulin resistance and QT interval. In this study we aimed at assessing arterial elasticity with the use of newly developed non-invasive two-dimensional strain imaging for estimation of vascular tissue motion and deformation (strain) during the cardiac cycle using speckle tracking. This technique enables angle-independent calculations of deformation arterial variables.
Materials and methods: Two-dimensional long- and short-axis grey-scale cine loops of the left and right common carotid arteries (CCA) were acquired in the group of 50 type 1 diabetes subjects (mean [±SD] 7.1±14.1 years, diabetes duration 13.0±12.0 years, BMI 23.8±1.6 kg/m^2, HbA_{1c} 9.1±2.2%) and 30 healthy age-, gender- and BMI-matched controls (38.6±10.8 years, BMI 24.9±2.1 kg/m^2). Circumferential strain (CS, %) and strain rate (CSr, strain per time unit, 1/s) as well as intima media thickness (IMT, mm) in CCAs were measured.
Results: Type 1 diabetes subjects presented with similar values of elasticity to the controls in left and right CCA (CS 6.04±2.50 vs 5.22±1.84; 6.01±2.60 vs 5.16±1.77%; CSr 0.97±0.55 vs 0.80±0.26; 0.90±0.32 vs 0.77±0.25 1/s, respectively). However, there was a significant positive relationship between age and IMT in left and right CCAs, and this relationship was stronger in diabetes type 1 subjects than in the controls (Pearson's correlation coefficient r=0.68 and 0.57 vs 0.59 and 0.55, all p<0.05, respectively) and negative one between age and CS or CSr (r values ranged from -0.35 to -0.64, all p<0.05), weaker in diabetes type 1 subjects than in the controls, where r values ranged from -0.58 to -0.70, p<0.05. We have also noted (figure) a positive correlation between diabetes duration and both IMT (r=0.45 and 0.34, p<0.05), but not arterial wall elasticity indices. Also, smokers with type 1 diabetes had thicker both IMT than non-smokers (0.58 vs 0.50 in left, and 0.53 vs 0.45 mm in right CCA, p<0.05). Interestingly, no relationship between HbA1c or blood lipid profile parameters were found in patients with diabetes.
Conclusion: Type 1 diabetes seems to affect intima media complex i.e. endothelium to a much greater degree than arterial wall elasticity, and diabetes duration is a more significant contributor to endothelium damage than the level of blood glucose or lipid profile control. Moreover, arterial wall strain assessment does not seem to be of high diagnostic value in vascular studies conducted in subjects with type 1 diabetes.

Prognostic impact of haemoglobin A_{1c} in high-risk type 2 diabetic patients: the Rio de Janeiro type 2 diabetes cohort study

C.R.L. Cardoso, N.C. Leite, G.F. Salles;
Internal Medicine, Universidade Federal do Rio de Janeiro, Brazil.

Background and aims: The prognostic importance of glycated hemoglobin (HbA_{1c}) in type 2 diabetes for cardiovascular outcomes after full adjustment for potential confounders remains debatable. The aim was to evaluate the prognostic impact of HbA_{1c} for cardiovascular morbidity and all-cause mortality in a cohort of 569 high-risk type 2 diabetic patients.
Materials and methods: Clinical, laboratory, and ambulatory blood pressure (BP) monitoring data were obtained at baseline. The primary endpoints were a composite of fatal and non-fatal major cardiovascular events and all-cause mortality. Multiple Cox survival analysis assessed the associations between HbA_{1c}, as a continuous variable and categorized at 3 stages (<7%, between 7 and 8%, >8%) and the endpoints. HbA_{1c} values were analyzed as the baseline value, as the mean value obtained during the first year of follow-up, and updated as time-varying covariate during the entire follow-up. In a sub-analysis, patients with pre-existent cardiovascular complications were excluded.
Results: After a median follow-up of 6.25 years, 96 total cardiovascular events and 92 all-cause deaths occurred. After adjustments for potential cardiovascular risk factors (age, sex, BMI, diabetes duration, smoking status, physical activity, number of anti-hypertensive drugs in use, presence of macrovascular and microvascular complications at baseline, 24-hour ambulatory BPs, HDL- and LDL-cholesterol, statins and aspirin use), HbA_{1c} was predictive of the composite endpoint and of all-cause mortality. First-year mean HbA_{1c} was a predictor of the composite endpoint as a continuous variable (HR: 1.20; 95% CI: 1.03-1.38; p=0.017, for increments of 1%). For all-cause mortality, both categorized baseline (HR: 1.98; 95% CI: 1.16-3.40; p=0.013; for HbA_{1c} between 7-8%; and HR: 1.83; 95% CI: 1.04-3.23; p=0.037, for HbA_{1c} >8%) and first-year mean values (HR: 1.93; 95% CI: 1.12-3.30; p=0.017, for HbA_{1c} between 7-8%; and HR: 1.85; 95% CI: 1.04-3.32; p=0.038, for HbA_{1c} >8%) were predictors in relation to the reference group with HbA_{1c} <7%. In the analysis excluding patients with cardiovascular complications at baseline, first-year mean values and time-varying HbA_{1c}, as continuous variables, were independent predictors of the composite endpoint. As a categorized variable,

only the subgroup with mean first year HbA_{1c} values > 8% showed an increased risk for the composite cardiovascular endpoint (HR: 2.82; 95% CI: 1.22-6.53; p=0.015).
Conclusion: HbA_{1c} provides cardiovascular risk prediction independent of standard risk factors, degenerative complications and ambulatory blood pressures, and improves cardiovascular risk stratification in high-risk type 2 diabetes. Achieved HbA_{1c} values during follow-up were particularly important risk predictors in patients without macrovascular complications at baseline.

Glycaemic variability is related to duration of diabetes rather than cardiovascular risk factors
G. Koh[1], S.-Y. Yoo[1], S. Lee[1], D.-H. Lee[2], H.-J. Chin[3];
[1]Department of Internal Medicine, Jeju National University Hospital, Jeju, [2]Department of Internal Medicine, Wonkwang University Hospital, Iksan, [3]Department of Internal Medicine, Hankook General Hospital, Jeju, Korea, Republic of Korea.

Background and aims: The role of glycemic variability in the development of cardiovascular diseases remains controversial. We investigated the relationship between indices of glycemic variability and cardiovascular (CV) risk factors in diabetic patients.
Materials and methods: Two hundred sixty three diabetic patients performed a seven-point self-monitoring of blood glucose during each month for 3 consecutive months. From these records, glycemic variability indices (standard deviation (SD) and M-value) were calculated. HbA1c was measured on the last day of the third month. Body mass index (BMI), waist circumference (WC), blood pressures, duration of diabetes, hsCRP, fibrinogen, alanine aminotransferase (ALT), γ-glutamyltransferase (GGT), creatinine, uric acid, total cholesterol, triglyceride (TG), HDL, LDL, Apo B and Apo AI levels, urine albumin: creatinine ratio (UACR) and ankle-brachial pressure index (ABI) were assessed.
Results: The SD was significantly correlated with duration of diabetes (r=0.281; p<0.001) and UACR (r=0.131, p<0.05), but not with BMI, WC, blood pressures, hsCRP, fibrinogen, ALT, GGT, creatinine, uric acid, lipid profile and ABI. The M-value was correlated with duration of diabetes (r=0.288; p<0.001), UACR (r=0.198; p<0.01), TG (r=0.132; p<0.05) and ABI (r=-0.212; p<0.001), but not with other parameters. Using multiple linear regression to adjust for HbA1c and other covariates, only diabetes duration (β=0.184; p<0.01 and β=0.134; p<0.01, respectively) remained independent correlate of the SD and M-value. CV risk factors failed to maintain its independent association.
Conclusion: In this study, duration of diabetes rather than CV risk factors was an independent variable of indices of glycemic variability. These findings suggest that glycemic variability is largely determined by β-cell function which deteriorates with increasing duration of diabetes, but not cardiovascular complication.

1337

Restenosis after percutaneous transluminal coronary angioplasty in individuals with different categories of glucose tolerance: a 1-year follow-up study
L. Zhang[1,2], Y. Gu[3], Y. Dong[1,2], X. Zhang[3], D. Shang[3];
[1]Qingdao Endocrine & Diabetes Hospital, Qingdao, [2]Weifang Medical University, Weifang, [3]Shandong Provincial Hospital, Jinan, China.

Background and aims: Patients with diabetes (DM) are at high risk for restenosis after coronary stenting. Data on the outcome of percutaneous transluminal coronary angioplasty (PTCA) in individuals with prediabetes is, however, limited. The study objective was to investigate the relationship between rate of restenosis after coronary stenting and baseline glucose status.
Materials and methods: We retrospectively analyzed data of 1003 patients (mean age 58.5±4.2 yrs, 61.5% of men, mean history of coronary heart disease 9.5±1.1 yrs) who undertook coronary stenting through PTCA at Emergency Department between Jan 2008 and Dec 2011. Baseline measurements included blood pressure (BP), fasting plasma glucose, lipid profile, HbA1c, C-reactive protein (C-RP), and 2-hour capillary glucose. All patients had follow-up coronary angiography 1 year after PTCA. Restenosis was defined as ≧ 50% stenosis in stent or within 5 mm adjacent to stent. The rate of restenosis was compared among patients with normal glucose tolerance (NGT, n=436), impaired glucose regulation (IGR, n=275), and DM (n=292) according to their baseline glucose levels. The diagnosis of NGT, IGR and DM was made according to 1999 WHO criteria.
Results: Patients with DM had highest levels of body mass index (BMI), BP, triglycerides (TG), and C-RP, followed by those with IGR and NGT (P<0.01). At baseline, the number of lesion was 1.6, 1.8, and 2.5 in patients with NGT, IGR, and DM, respectively (p<0.05). At the end of year 1, the rate of restenosis were 4.2%, 5.3%, and 12.0% in individuals with NGT, IGR, and DM, respectively (P<0.05). In the DM subgroup, compared with patients with HbA1c<8%, those with HbA1c>8% had increased rate of restenosis (14.6% vs. 11.2%, P<0.05). In the logistic regression model, the odd ratio (OR) of having restenosis was 1.46 (95%CI: 1.05-1.87) for DM and 1.10 (95% CI: 1.01-1.25) for IGR, after adjusting for age, history of CHD, BMI, BP, LDL-C, TG, and C-RP.
Conclusion: Restenosis occurs more frequently in patients with compared those without DM. Prediabetes is associated with increased risk of restenosis after PTCA during a follow-up period of 1 year. The data indicates that intervention of hyperglycaemia should be addressed in patients receiving PTCA.

1338

Delay in treatment intensification increases the risks of cardiovascular events in patients with type 2 diabetes
S. Paul[1], B.L. Thorsted[2], M. Wolden[2], K. Klein[1], K. Khunti[3];
[1]School of Population Health, Queensland Clinical Trials & Biostatistics Centre, University of Queensland, Brisbane, Australia, [2]Novo Nordisk A/S, Vandtårnsvej, Denmark, [3]University of Leicester, UK.

Background and aims: The results from the large clinical trials evaluating the benefits of intensified glucose lowering treatment on cardiovascular risks in patients with T2DM have been inconclusive. Also, the effects of the delay in treatment intensification in newly diagnosed patients with T2DM have not been explored at population level. Using large longitudinal data on newly diagnosed patients with T2DM from the UK Clinical Practice Research Datalink, the aims of this study were to explore the effects of delay in treatment intensification, and of remaining under poor glycaemic control on long term risk of cardiovascular events (CVEs).
Materials and methods: A cohort of 110,543 patients with diagnosis of T2DM between May 1990 and January 2010 were selected for this study under the conditions: complete measures of age, sex, smoking status and HbA_{1c} at the time of diagnosis, minimum two years of follow-up before death or censoring, and completeness of dates for prescriptions. The longitudinal data on HbA_{1c} were organised on a 6-monthly window. Treatment intensification was defined under two conditions: (i) taking at least 2 OADs simultaneously (OAD2), and (ii) taking at least 1 OAD plus insulin simultaneously (OAD+INS). Time to initiation of OAD2 and OAD+INS was calculated from the date of diagnosis. The effects of the delay in treatment intensification in interaction with glycaemic control (HbA_{1c} below or above 7%) on the risks of myocardial infraction (MI), stroke, heart failure (HF) and composite of these CVEs were evaluated using Stratified Cox Regression Models, adjusted for age, sex, smoking status, and history of CV disease.
Results: Patients were 56% male and 19% smokers; mean(SD) of age, BMI and HbA_{1c} at diagnosis were 61 (13) yr, 32 (7) kg/m2, and 8.1 (2.2)% respectively; 12% had a history of CVE before diagnosis. During median (Q1, Q3) 5.3 (3.5, 7.7) years of follow-up, 2.3% had MI, 2.2% had stroke, 3.3% had HF, and 7% experienced at least one of these CVEs, 44% took OAD2, and 11% took OAD+INS. In patients with HbA_{1c} > 7% during 1 year post diagnosis (29%), at least 31% did not receive any intensified treatment within 1 year. In patients with HbA_{1c} above 7% during 1 year post diagnosis, a 6-month delay in treatment intensification by OAD2 / OAD+INS regimen would significantly increase the risks of MI, stroke, HF and composite CV events by 26% / 26%, 15% / 15%, 24% / 25% and 20% / 21% respectively (Table). Patients with HbA_{1c} > 7% during 1 year post diagnosis had 25% increased risk of CVEs (Hazard Ratio: 1.25, 95% CI: 1.19-1.31, p<0.001). Potential limitations of this analysis include lack of information on medication adherence and residual confounding.
Conclusion: This primary care data based retrospective cohort study with more than 5 years of follow up clearly suggests the cardiovascular benefits of early treatment intensification in patients with poor glycaemic control.

CVE HR (CI) associated with delay in treatment intensification in patients with poor glucose control

	MI HR(95% CI)	Stroke HR(95% CI)	Heart Failure HR(95% CI)	Any CVD HR(95% CI)
6-month delay in Intensification to OAD2	1.26 (1.13, 1.40)	1.15 (1.03, 1.29)	1.24 (1.12, 1.36)	1.20 (1.13, 1.28)
6-month delay in Intensification to OAD+INS	1.26 (1.13, 1.40)	1.15 (1.03, 1.28)	1.25 (1.14, 1.37)	1.21 (1.13, 1.29)

Secondary prevention in patients with type 2 diabetes and previous myocardial infarction in Dutch primary care

G.E.H. Rutten, A. Wezendonk, M.J. Kasteleyn, H. Jansen;
Julius Center for Health Sciences and Primary Care, University Medical Center Utrecht, Netherlands.

Background and aims: Patients with type 2 diabetes and a previous myocardial infarction are at risk for future cardiovascular events; secondary prevention is of high importance. The aim of this study is to evaluate secondary prevention therapy in patients with T2DM and previous MI.
Materials and methods: Retrospective record study including anonymous data of 11,267 patients with T2DM from 56 general practices in the Netherlands. In 743 patients with T2DM and previous myocardial infarction, the proportion of patients with a prescription for an anti-thrombotic agent (acetylsalicylic acid, carbasalate calcium, clopidogrel or vitamin K antagonists), a beta-blocker and/or a statin was calculated. Furthermore the association between patient characteristics (i.e. age, gender, socio-economic status, duration of T2DM and time since MI) and prescription were determined by logistic regression analysis.
Results: Of all 743 patients, 78% had a prescription for an anti-thrombotic agent, 61% had a prescription for a beta blocker, 70% had a prescription for a statin and 46% had a prescription for all three types of drugs. Men were more likely to receive an anti-thrombotic agent (OR 1.57, 95% CI 1.11-2.23; p=0.01), a beta blocker (OR 1.37, 95% CI 1.01-1.84; p=0.04) and the combination of all three (OR 1.50, 95% CI 1.10-2.04; p=0.01). Older people were less likely to receive a statin (OR 0.98, 95% CI 0.97-1.00; p=0.03) and the combination of all three (OR 0.99, 95% CI 0.97-1.00; p=0.05). We found no significant independent association between socio-economic status, duration of T2DM and time since MI and the prescription of an anti-thrombotic agent, a beta blocker, a statin and all three types of drugs.
Conclusion: A substantial proportion of patients with T2DM and previous MI were insufficiently treated for secondary prevention. Our findings confirm the need for a different approach to increase the proportion of prescription in patients with T2DM and previous MI, with special attention to women.

1340

Significant impact of gender on the association of HbA_{1c} with angiographically diagnosed coronary atherosclerosis

C. Malin[1], A. Vonbank[2,3], P. Rein[2], D. Zanolin[1], C.H. Saely[2,3], H. Drexel[2,4];
[1]Vorarlberg Institute for Vascular Investigation and Treatment, Feldkirch, [2]Academic Teaching Hospital Feldkirch, Austria, [3]Private University of the Principality of Liechtenstein, Triesen, Liechtenstein, [4]Drexel University College of Medicine, Philadelphia, USA.

Background and aims: The association of HbA1c with angiographically determined coronary atherosclerosis is unclear. In particular, it has not been investigated so far whether gender modulates the association of HbA1c with angiographically diagnosed coronary atherosclerosis. We therefore aimed at clarifying this issue.
Materials and methods: We enrolled a large consecutive series of 1449 patients, 484 women and 965 men, who did not have previously known diabetes and who underwent coronary angiography for the evaluation of stable coronary artery disease. Significant coronary atherosclerosis was diagnosed in the presence of significant coronary stenoses with lumen narrowing ≥ 50%.
Results: HbA1c values of <5.7% (normal according to ADA criteria), 5.7-6.4% (at risk of diabetes according to ADA criteria), and ≥ 6.5% (diabetes according to ADA criteria) were found in 36.4%, 56.2%, and 7.4% of women and in 44.2%, 46.6%, and 9.1% of men, respectively. The prevalence of angiographically diagnosed coronary atherosclerosis in these HbA1c categories was 31.2%, 38.2%, and 47.2% among women (ptrend=0.041) and 63.2%, 65.3% and 64.8% among men (ptrend=0.589). In logistic regression models, HbA1c as a continuous variable was a strong predictor of coronary atherosclerosis among women (adjusted OR for a 1% increase in HbA1c 1.61 [95% CI 1.07-2.43]; p=0.024) but not among men (OR 0.92 [0.74-1.13]; p = 0.416). The interaction HbA1c by gender was significant (p=0.022), indicating that HbA1c was a significantly stronger predictor of coronary atherosclerosis among women than among men.
Conclusion: We conclude that gender has a significant impact on the association of HbA1c with angiographically diagnosed coronary atherosclerosis among subjects without previously known diabetes.

1341

Gender differences in cardiovascular events, cardiovascular and all-cause mortality in type 2 diabetes: lesson from the San Luigi Gonzaga Diabetes study

F.L. Cavalot, A. Pagliarino, M. Valle, L. Di Martino, F. Mazzaglia, K. Bonomo, M. Trovati;
Internal Medicine and Metabolic Diseases Unit, Dept of Clinical and Biological Sciences, University of Turin, Orbassano, Italy.

Background and aims: Whether type 2 diabetes attenuates or abrogates the cardiovascular (CV) protection conferred by female gender in the general population is a matter of debate. Therefore, we aimed to evaluate the gender differences in CV events, CV and all-cause mortality in an Italian cohort of type 2 diabetic patients.
Materials and methods: We investigated 786 type 2 diabetic patients (362 women and 424 men), belonging to the prospective study "San Luigi Gonzaga Diabetes Study", which in 1995 consecutively enrolled 786 type 2 diabetic patients followed-up at our clinic. At the enrolment, gender, age, known diabetes duration, body mass index (BMI), smoking habit, systolic and diastolic blood pressure (SBP and DBP), serum creatinine, albumin excretion rate (AER), total and HDL cholesterol, triglycerides and HbA_{1c} were assessed. Outcomes were all-cause mortality, CV mortality and the first CV event occurring during the 14-year follow-up. Univariate statistical analysis was carried out with Student's t-test for unpaired data and multivariate statistical analysis with the Cox proportional hazard model (backward method).
Results: At baseline women and men differed for age (64.03±10.04 vs 60.85±9.22 years, p=0.0001), known diabetes duration (11.22±8.77 vs 8.9±7.47 years, p=0.0001), BMI (29.54±5.01 vs 28.74±4.88 Kg/m2, p=0.025), smoking habit (previous/present) (18% vs 71%, p=0.0001), SBP (148.09±18.7 vs 145.32±17.92 mmHg, p=0.034), serum creatinine (0.79±0.24 vs 0.97±0.30 mg/dl, p=0.0001), total cholesterol (226.0±42.0 vs 212±42 mg/dl, p=0.0001), HDL cholesterol (54.0±16.0 vs 46.0±14.0 mg/dl, p=0.0001), HbA_{1c} (7.96±1.54 vs 7.62±1.26%, p=0.001). During the 14 year follow-up: a) 273 patients (W/M: 124/149) died; b) 88 (W/M: 35/53) died as a direct consequence of a CV event (defined "CV mortality"); b) 313 (W/M: 121/192) presented a first CV event (acute myocardial infarction, unstable angina, stroke, transient ischemic attack, ischemia-related lower limb amputation, sudden death and revascularization at any site). HRs for outcomes were evaluated by building three models: Model A, including gender, age and known diabetes duration; Model B, as model A + BMI, SBP, serum creatinine, total cholesterol, HDL cholesterol, HbA_{1c}; Model C: as model B + smoking habit. The HRs conferred by female gender were: a) for all cause mortality, in Model A: 0.691 (CI 0.540-0.884, p=0.003), in Model B: 0.707 (CI 0.548-0.912, p=0.008), in Model C: 0.851 (CI 0.620-1.168, p=0.318); b) for CV mortality, in Model A: 0.570 (CI 0.366-0.885, p=0.012), in Model B: 0.614 (CI 0.389-0.970, p=0.036), in Model C: 0.614 (CI 0.389-0.970, p=0.036); c) for the first CV event, in Model A: 0.589 (CI 0.466-0.744, p=0.0001), in Model B: 0.537 (CI 0.423-0.681, p=0.0001); in Model C: 0.672 (CI 0.508-0.890, p=0.005). Beside gender and age, significant predictors in Model C were: a) for all-cause mortality, AER (p=0.0001), HbA_{1c} (p=0.0001) and smoking habit (p=0.051); b) for CV mortality: AER (p=0.0001) and HbA_{1c} (p=0.002); c) for CV events: HbA_{1c} (p=0.0001), smoking habit (p=0.003), total cholesterol (p= 0.013) and SBP (p=0.037).
Conclusion: Even in the presence of type 2 diabetes, female gender confers a protection against CV events and CV mortality.

1342

Evidence for sex-specific effect of serum total adiponectin on cardiovascular death in patients with type 2 diabetes mellitus

C. Menzaghi[1], M. Xu[2], L. Salvemini[1], C. De Bonis[1], G. Fini[1], G. Palladino[1], S. Bacci[3], L. Qi[2], V. Trischitta[1,4];
[1]Research Unit of Diabetes and Endocrine Diseases, IRCCS, San Giovanni Rotondo, Italy, [2]Harvard School of Public Health, Boston, USA, [3]Unit of Endocrinology, IRCCS, San Giovanni Rotondo, [4]Sapienza University, Rome, Italy.

Background and aims: Cardiovascular disease is the first cause of death in patients with type 2 diabetes mellitus (T2DM). Unraveling new pathogenic factors involved in cardiovascular (CV)-death in diabetic patients is, therefore, urgently needed. Adiponectin has insulin-sensitizing, anti-inflammatory, and antiatherogenic effects. No data are available, so far, on the relationship between serum adiponectin and CV-death in T2DM. Our aim was to address this issue in several cohorts of diabetic patients of European ancestry.
Materials and methods: Three prospective studies of patients with T2DM, were investigated. 1) The Gargano Heart Study (GHS-prospective design; 359 patients; 7 year follow-up). 2) The Nurses' Health Study (NHS; 722 female patients, 20 year follow-up). 3) The Health Professional Follow-up Study (HPFS; 751 male patients, 16 year follow-up). In all studies the end point was CV-death.
Results: In the GHS-prospective design total serum adiponectin predicted CV-death in a model comprising age, sex, smoking habit, BMI, HbA1c, insulin therapy, hypertension, total cholesterol, HDL-cholesterol and triglycerides: HR per SD increment = 1.44, 95% CI: 1.14-1.82. This association was evident and significant among males (n = 242, HR = 1.58, 95% CI: 1.21-2.05), but not females (n = 117, HR = 0.84 , 95%CI 0.43-1.66), thus pointing to a sex-specific effect of adiponectin on CV-death. Total adiponectin levels were significantly associated with CV-death in HPFS males (HR = 1.43, 95%CI 1.20-1.71), but not NHS females (HR = 1.00, 95%CI 0.80-1.25). In a pooled analysis of all studies, a clear sex-specific association was observed: cumulative adjusted HRs being 1.50 (95%CI 1.27-1.71) in 993 males and 0.98 (95%CI 0.79-1.22) in 839 females (p for HRs heterogeneity=0.009).
Conclusion: To the best of our knowledge, this is the first report of a sex-specific counterintuitive deleterious effect of high serum adiponectin on increased CV-death in patients with T2DM of European ancestry.

Risk stratification with plasma-NT-proBNP and coronary calcium score predicts all-cause mortality in type 2 diabetic patients

B.J. von Scholten[1], H. Reinhard[1], P.G. Jørgensen[2], S. Theilade[1], P.R. Hansen[2], N. Wiinberg[3], A. Kjær[4], C.L. Petersen[3], K. Winther[3], H.-H. Parving[4], J.S. Jensen[2], P.K. Jacobsen[4,5], P. Rossing[1,5];
[1]Steno Diabetes Center, Gentofte, [2]Gentofte Hospital, Gentofte, [3]Frederiksberg Hospital, Frederiksberg, [4]Rigshospitalet, Copenhagen, [5]University of Copenhagen, Denmark.

Background: The burden of coronary artery disease (CAD) is significantly increased in type 2 diabetic patients and is associated with mortality. An effective screening tool for subclinical CAD is needed to predict and prevent cardiovascular mortality in these patients.
Methods: Plasma-NT-proBNP, Agatston coronary calcium score (CCS) and echocardiography were performed in 200 asymptomatic type 2 diabetic patients with elevated urinary albumin excretion rate (>30mg/24 h) and without prior history of CAD. Patients with P-NT-proBNP >45.2 ng/L and/or CCS ≥400 at baseline were stratified as high risk patients for CAD and were further examined for significant CAD by myocardial perfusion imaging and/or CT-angiography and/or coronary angiography. Following these investigations, patients were stratified into 3 groups, low risk (n=67), high risk without CAD (n=63) and high risk with CAD (n=70) and were followed prospectively. After 5.3 years of follow-up, vital status was assessed in all subjects, and echocardiography was re-performed in available patients (n=130) (65%).
Results: At baseline, patients were 59±9 years, 152(76%) male, with eGFR: 96±26 ml/min/1.73m^2 and diabetes duration of 13±7 years. Of 130 patients with follow-up echo-data available, 117 had normal (≥50%) left ventricular ejection fraction (LVEF) at baseline. Of these, 2(5%) and 9(12%) patients with low *vs.* high risk had reduced LVEF (<50%) at follow-up (p=0.324). During follow-up, 22(11%) patients died from all-causes, of which 1(1%) low risk, 9(14%) high risk without CAD and 12(17%) high risk with CAD (log rank p=0.012). In Cox regression analysis comparing low risk *vs.* high risk no CAD patients, the latter had significantly higher mortality (p=0.041), as was the case for low risk *vs.* high risk CAD patients (p=0.017). In Cox regression analysis comparing low risk *vs.* all high risk, the latter had significantly higher mortality (HR: 8.7, p=0.047, adjusted for gender, age, HbA1c, cholesterol, systolic blood pressure, smoking and creatinine). However, comparing the two high risk groups, mortality was similar (p=0.5).
Conclusion: Risk stratification with P-NT-proBNP and CCS predicts all-cause mortality in asymptomatic type 2 diabetes patients with microalbuminuria and normal kidney function. Additional cardiovascular evaluation did not improve risk prediction. Deterioration from normal to impaired LVEF was not significantly different between groups although this may be a power issue.

Stress cardiac magnetic resonance imaging reveals hypoperfusion in asymptomatic type 1 diabetes patients, missed by the routine non-invasive evaluation

A. Melidonis[1], K. Bratis[2], E. Fousteris[1], P. Gavra[1], V. Markoussis[2], G. Kolovou[2], K. Van Wijk[3], D. Hautemann[3], J.H.C. Reiber[3], S. Mavrogeni[2];
[1]Diabetes Center, Tzanio General Hospital, Piraeus, [2]Onassis Cardiac Surgery Center, Athens, Greece, [3]Leiden University Medical Center, Netherlands.

Background and aims: Stress myocardial perfusion cardiac magnetic resonance (stress CMR), by measuring myocardial perfusion rate index provides a reliable index to assess myocardial hypoperfusion. We tested the hypothesis that stress CMR can detect silent ischemia in asymptomatic type 1 diabetes (T1DM) patients with normal routine non-invasive cardiac profile and secondly we tried to clarify correlations of CMR indexes with other clinical and laboratory findings.
Materials and methods: A cohort of 20 (10F/10M) asymptomatic T1DM aged 33±15 yrs without history of coronary artery disease or heart failure and

with normal routine nonivasive cardiac assessment - including 12-lead ECG, echo study and exercise testing - were studied. CMR data were correlated with clinical and laboratory profile of T1DM and were compared with those of age and sex-matched controls. Stress CMR was performed in 1.5T using 140 mg/kg/min adenosine for 4 minutes based on international established protocols. All measurements were expressed as mean±SD. Statistical significance of the differences was investigated using unpaired Student's T-test. Correlation between variables was sought with Pearson's correlation coefficient. Statistical significance was considered for $p<0.05$.

Results: No difference in left ventricular (LV) volumes and ejection fraction was identified between T1DM and controls. However, MPRI was significantly lower in T1DM compared to controls (0.82±0.3 vs 3,00±0.2, $p<0.001$). A negative correlation was identified between MPRI and patients' age ($p<0.05$). Reversely, no correlation was found between MPRI and disease duration, HbA1c or other metabolic parameters. Left ventricular diastolic dysfunction, albuminuria and diabetic retinopathy were present at the 10%, 35% and 20% of study population respectively. MPRI was severely impaired in all of them, representing the earliest abnormal cardiac finding in T1DM patients. The quantitative analysis revealed regional impairment of myocardial blood flow in all T1DM patients, although late gadolinium enhanced images were normal. X-Ray coronary angiography, available in the majority of subjects, was normal; therefore, abnormal MPRI was attributed to microcirculation disease.

Conclusion: MPRI detects perfusion impairment in asymptomatic T1DM, missed by the usual non-invasive evaluation, irrespectively of disease duration and represents the earliest abnormal parameter in asymptomatic T1DM, before the development of diastolic dysfunction, albuminuria and/or retinopathy. However, the clinical implications of these findings need further evaluation in larger patients' cohorts.

1345

Impaired left ventricular diastolic function and increased systolic contractions in type 2 diabetes compared to healthy controls: a case-control study

A.P. Ofstad[1], H. Dalen[2,3], K.I. Birkeland[4], L. Gullestad[5], S. Urheim[5], O.E. Johansen[1], S. Aakhus[5];
[1]Medical Research Dep., Baerum hospital, Vestre Viken Hospital Trust, Bærum, [2]MI Lab and Department of Circulation and Medical Imaging, Norwegian University of Science and Technology, Trondheim, [3]Department of Medicine, Levanger Hospital, Nord-Trøndelag Health Trust, Levanger, [4]Department of Endocrinology, Oslo University Hospital Aker, [5]Department of Cardiology, Oslo University Hospital Rikshospitalet, Oslo, Norway.

Background and aims: Left ventricular (LV) myocardial dysfunction is prevalent in type 2 diabetes (T2D). We used advanced echocardiographic imaging techniques to compare myocardial systolic and diastolic function in T2D with matched healthy controls (CTRs).

Materials and methods: This case-control study involved a clinical examination and a detailed echocardiographic assessment, incl. tissue doppler imaging (TDI) in patients with T2D. CTRs matched for age, gender, weight and systolic blood pressure were obtained from a population based health survey (HUNT). Myocardial tissue velocity and deformation were obtained off-line from stored loops of colour tissue Doppler. Diastolic function was evaluated from the conventional Doppler variables E/A-ratio, deceleration time (DT) and mitral doppler early (MVE) and late (MVA) diastolic velocities, in addition to the longitudinal myocardial velocities in early (e') and late (a') diastole. Systolic function was assessed from biplane ejection fraction (EF) and peak systolic longitudinal strain and strainrate utilizing data from 2 apical LV imaging views.

Results: One hundred patients with T2D (29% females, age/diabetes duration (mean±SD) 58±10/6±6 yrs, BMI 30.1±5.5 kg/m², hypertension 68 %, coronary artery disease 12%, self-reported dyspnoe 53%, HbA1c 7.6±1.6%, LDL 2.9±0.9 mmol/L, blood pressure 141±18/83±9 mmHg), and 100 matched healthy CTRs were included. Patients with T2D had higher resting heart rate (72±12 vs 67±10 bpm; $p=0.001$) and diastolic blood pressure (83±9 vs 79±8 mmHg; $p=0.005$). LV cavity diameters were similar between the groups while interventricular septum was thicker in T2D (1.1±0.2 vs 1.0±0.2 cm, $p<0.001$). Diastolic function differed adversely in T2D with significantly lower E/A-ratio, deceleration time and MVA, as well as reduced e' and a' (Table). E/e', a marker of LV end diastolic filling pressure, was also higher in T2D (12.1±4.5 vs. 10.4±3.3, $p=0.001$). Patients with T2D had evidence for increased contractions with higher EF, longitudinal strain, and strain rate.

Conclusion: We observed that T2D was characterized by *impaired* LV diastolic function combined with *augmented LV myocardial contractions*. This finding supports that the acknowledged subclinical LV diastolic dysfunction in T2D is in part compensated by a raised contractile state.

Echocardiographic findings in T2D and CTRs. Data given as mean±SD, p obtained by T-tests.

Diabetes and the spectrum of hyperglycaemia adversely affects left ventricular diastolic function and is particularly toxic to South Asians

C.M. Park, K. March, S. Jones, C. Tuson, T. Tillin, N. Chaturvedi, A.D. Hughes;
International Centre for Circulatory Health, Imperial College London, UK.

Background and aims: Diabetes increases heart failure risk, via mechanisms that are currently unclear. Study of risk factor associations with subclinical disease can be informative. Diastolic dysfunction precedes the development of heart failure (HF) and predicts increased mortality. South Asians (SA) and African Caribbeans (AC) may be at particular risk due to increased prevalence of diabetes. We compared LV diastolic function in a community-based cohort of older SA, AC and White Europeans (EU) and investigated the role of established cardiovascular risk factors in ethnic differences.

Materials and methods: A population based sample of 1295 individuals (609 EU, 477 SA and 209 AC), age 69.6±6yrs (mean±SD) underwent conventional and Tissue Doppler echocardiography. Peak velocity of early diastolic relaxation (e') was used as a relatively, load-independent indicator of LV diastolic function. Subjects underwent CT to image coronary calcium (CAC), had detailed fasting blood tests, a spot urine test and blood pressure (BP) measurements. Hypertension was physician diagnosed or participant reported accompanied by BP lowering medication. Diabetes was defined according to the WHO 1999 guidelines. BP and echocardiography measurements were used to calculate total arterial compliance (TAC) and total peripheral resistance (TPR).

Results: e' was consistently poorer with advancing glucose intolerance in all ethnic groups. People with diabetes had lower e' than normoglycaemic individuals by 0.43 cm/s in EU ($p=0.04$), 0.73 cm/s in SA ($p<0.0001$) and 0.24 cm/s in AC ($p=0.3$). This adverse glycaemic effect extended into the normal range. e' was significantly lower for a unit increase in HbA_{1c} in SA and AC (Table, model 1). The association between HbA_{1c} and e' was significantly different between EU and SA (p ethnicity x HbA_{1c} interaction = 0.008). After adjustment for key cardiovascular risk factors (model 2) this ethnicity/HbA_{1c} interaction persisted ($p=0.001$) and a significant ethnicity x HbA_{1c} interaction was found between EU and AC ($p=0.04$). Additional adjustment for haemodynamic variables (Model 3) did not explain these interactions (EU and SA ($p=0.001$),EU and AC ($p=0.03$)).

Conclusion: LV diastolic function is poorer in people with diabetes, but is also adversely affected across the hyperglycaemic spectrum. This adverse association could not be accounted for by associated cardiovascular/haemodynamic risk factors, or prevalent co-morbidity. Moreover the adverse effects of

hyperglycaemia on diastolic function are more prominent in SA and AC than EU. Explanations for the effect of hyperglycaemia on LV function, and the greater susceptibility of SA and AC to this effect, need to be sought if we are to combat the increasing burden of heart failure in association with diabetes.

Change in Diastolic function (e') for a unit change in HbA_{1c}

Comparison of left ventricular filling pressures in male patients with type 2 diabetes with normal and low testosterone levels

M. Tinetti[1], M. Koury[2], A. Baranchuk[3], J.M. Farias[4];
[1]Endocrinology, Hospital Universitario Sanatorio Guemes, Ciudad Autonoma de Buenos Aires, [2]Research Department, Hospital Universitario Sanatorio Guemes, Ciudad Autonoma de Buenos Aires, Argentina, [3]Queen´s University, Ontario, Canada, [4]Sanatorio Guemes, Ciudad Autonoma de Buenos Aires, Argentina.

Background and aims: Heart failure is a complication of patients with type 2 diabetes frequently left ventricular filling pressures are increased before symptoms appear. Male patients with type 2 diabetes have low total testosterone in 30% of cases. The relationship between low testosterone levels in male diabetic patients and ventricular filling pressures is still unknown. Aims: to compare in male patients with type 2 diabetes the left ventricular filling pressures in those with normal and low total testosterone levels.
Materials and methods: We assessed diabetic patients with tissue Doppler imaging for evaluation of left ventricular filling pressures by passive transmitral left ventricular inflow velocity to tissue Doppler imaging velocity of the lateral mitral annulus during passive filling (E/e' ratio). Patients with history of heart failure, myocardiopathies, left ventricular hypertrophy, diastolic dysfunction (E/e´>15) and arrhytmias were excluded. We compared them depending on low (< 3,5 ng/ml) or normal (> 3,5 ng/ml) total testosterone levels. All patients were asymptomatic and without history of cardiovascular disease. We report preliminary analysis. Data were analyzed using Spearman correlation coefficient, Mann Whitney U test and test. Odds ratio [OR] and 95% confidence intervals (CI) were calculated using simple and multiple logistic regression
Results: 148 male diabetic patients were included. Mean age was 58±5,8 years, mean time of diabetes duration 7±3,1 years, 47(32 %) patients have low Testosterone (Group A). There was no difference between groups regarding age, time of diabetes evolution, hypertension, weight, heart rate, BMI or echocardiographic parameters .The E/e' ratio in group A was 8,05±1,9 vs. group B 6,1±1,7 p < 0,0001. Group A compared with group B, had six fold increased risk of E/e' ratio >5 (91.67% vs. 64.56%; OR=6.04 CI=1.69-21.47; p=0.005). Differences remained significant after adjust for age, time of diabetes evolution, BMI, lipids, HbA1c and drug treatment.
Conclusion: Patients with type 2 diabetes and low total testosterone levels have higher E/e' ratio, showing pre clinic increased left ventricular filling pressures compared with diabetic patients with normal testosterone levels. This finding is independent of time of diabetes evolution, hypertension, or other echocardiographic parameters.

Advanced glycation endproducts are associated with higher pulse wave velocity and 24-hour pulse pressure: preliminary results from the Maastricht study

M.G.A. van Eupen[1,2], M.T. Schram[1,2], T.T. van Sloten[1,2], R.M.A. Henry[1,2], A.A. Kroon[1,2], A.J. Smit[3], C.D.A. Stehouwer[1,2], C.G. Schalkwijk[1,2];
[1]Department of Internal Medicine, Maastricht University Medical Centre (MUMC), [2]Cardiovascular Research Institute Maastricht (CARIM), [3]Department of Internal Medicine, Division of Vascular Medicine, University Medical Centre Groningen, Netherlands.

Background and aims: Advanced glycation endproducts (AGEs) are thought to play a role in the development of cardiovascular disease (CVD). Certain AGEs, like pentosidine, form cross-links between proteins within the arterial wall, which may lead to arterial stiffness, and subsequently, an increased CVD risk. Therefore, we evaluated the association of skin autofluorescence (SAF), as a possible reflection of tissue AGEs, and plasma AGEs with arterial stiffness (AS) in individuals with normal (NGM) or impaired (IGM) glucose metabolism or type 2 diabetes mellitus (T2DM).
Materials and methods: We studied a cohort of 740 individuals from The Maastricht Study (413 NGM, 124 IGM and 203 T2DM) with mean age of 60y, 45% female. SAF was measured with the AGE reader (DiagnOptics, Groningen). Plasma levels of protein-bound pentosidine, Nε-(carboxymethyl)lysine (CML) and Nε-(carboxyethyl)lysine (CEL) were measured with HPLC or UPLC and fluorescence detection or MS/MS, respectively. Carotid to femoral pulse wave velocity (cfPWV) and 24-hour pulse pressure (aPP), as measures of AS, were measured with applanation tonometry (SphygmoCor, Atcor Medical, Australia) and ambulatory 24-hour BP monitoring (WatchBP O3, Microlife AG, Switzerland), respectively. aPP was calculated by subtracting 24-hour diastolic from systolic BP. All associations of AGEs with AS were analysed with linear regression analysis, and adjusted for age, sex, glucose metabolism status, waist, smoking, use of anti-hypertensive medication, MAP, eGFR, total-to-HDL-cholesterol ratio and triglycerides. The associations of SAF and AGEs with PWV were additionally adjusted for heart rate.
Results: Our preliminary results show that with deteriorating levels of glucose metabolism, mean SAF (AU) (2.56 vs. 2.70 vs. 2.94), CEL levels (nmol/mmol LYS) (32.9 vs. 34.1 vs. 35.9), PWV (m/s) (8.4 vs. 9.3 vs. 9.9) and aPP (mmHg) (42 vs. 47 vs. 50) were higher, and plasma CML levels (nmol/mmol LYS) (77.6 vs. 72.0 vs. 69.3) were lower (p<0.01). Higher SAF and plasma pentosidine levels were associated with higher cfPWV (table); these associations were different in individuals with T2DM (sβ 0.11 for SAF and 0.12 for pentosidine) compared to NGM (sβ 0.04 and 0.05, respectively) (p for interaction 0.02 and 0.01, respectively). In addition, SAF (borderline), plasma pentosidine and CML levels were associated with higher aPP (table).
Conclusion: These preliminary results support the hypothesis that AGEs, in particular the cross-linking AGE pentosidine, are involved in the development of AS.

	cfPWV			aPP		
	sβ	95%-CI	p	sβ	95%-CI	p

Postprandial haemodynamic responses are altered in uncomplicated type 2 diabetes

M.M. Smits, M.H.A. Muskiet, M.E. Tushuizen, K.A.A. Kwa, D.H. van Raalte, M. Diamant;
Diabetes Center / Internal Medicine, VU University Medical Center, Amsterdam, Netherlands.

Background and aims: While postprandial changes in haemodynamic variables have been well described in healthy subjects, the effects in subjects with type 2 diabetes (T2DM) or those with metabolic syndrome (MetS) remain

largely unknown. The aim of this study was to identify the effects of a standardised mixed meal on haemodynamics in a cohort of controls and subjects with MetS or T2DM without autonomic neuropathy (defined by normal Ewing-tests). In addition, the role of autonomic nervous system (ANS) balance was investigated.
Materials and methods: After an overnight fast, a standardised high-fat mixed meal (900 kcal; 75g carbohydrates, 50g fat (60% saturated), 35g protein) was given to 44 age-matched males (15 controls; 12 MetS; 17 T2DM, total mean age 55.4 yrs). Blood pressure was continuously monitored using digital finger photoplethysmography (Portapres). From the pulse wave recordings, systolic (SBP) and diastolic (DBP) blood pressure, heart rate (HR), stroke volume (SV), cardiac index (CI) and total peripheral resistance (TPR) were derived using dedicated software (Beatscope). The beat-to-beat intervals were analysed using spectral analysis to calculate ANS or sympathovagal balance (LF/HF-ratio) from low frequency (LF, sympathetic) and high frequency (HF, parasympathetic) domains. Glucose and insulin levels were measured prior to and 2 hours after the meal.
Results: Subjects with T2DM and MetS had higher BMI, baseline SBP/DBP and fasting insulin levels compared to controls, whereas subjects with T2DM had higher fasting plasma glucose and HbA1c compared to controls and MetS ($p \leq 0.001$). At baseline, 30% of T2DM and 50% of MetS had BP >140/90 mmHg, compatible with hypertension, but no individuals received antihypertensive drugs. As expected, T2DM vs controls was associated with elevated postprandial levels of glucose and insulin, whereas no differences were seen between T2DM and MetS. All groups showed a comparable significant increase in HR following the meal compared to baseline ($p \leq 0.05$). T2DM patients demonstrated significant postprandial decreases in DBP (from baseline $p=0.039$), which was accompanied by a significant decrease in TPR ($p=0.01$) and increase in SV and CI ($p=0.03$ and $p=0.011$, respectively). In MetS subjects only CI increased after the meal ($p=0.041$), while TPR and SBP/DBP remained unaltered. Controls showed no changes in postprandial BP or other haemodynamic markers compared to baseline. T2DM showed a postprandial decrease in LF/HF-ratio ($p=0.022$), whereas MetS demonstrated a decrease in HF ($p=0.038$). No changes from baseline in postprandial ANS balance were seen in controls. No correlations were found between the AUCs (baseline to 2-hours postprandial) of any of the haemodynamic or ANS parameters, glucose and insulin.
Conclusion: Postprandial haemodynamic variables show more marked changes with deteriorating states of metabolic control. While all subjects experienced a meal-related increase in HR, only patients with uncomplicated T2DM, who had no clinical signs of autonomic dysfunction, demonstrated a fall in DBP and TPR, with concomitant increase in SV and CI. Additionally, our findings suggest that meal-induced changes in haemodynamic variables in uncomplicated T2DM are independent of postprandial metabolic and ANS responses.

The co-existence of endothelial dysfunction and deteriorating glucose metabolism or insulin resistance synergistically increases incident CV event risk: the Hoorn study

R.M.A. Henry[1,2], T.T. van Sloten[1,2], G. Nijpels[3], J.M. Dekker[3,4], M.T. Schram[1,2], C.D.A. Stehouwer[1,2];
[1]Dept. of Internal Medicine, [2]Cardiovascular Research Institute Maastricht, Maastricht University Medical Center, [3]EMGO Institute for Health and Care Research, VU University Medical Center, [4]Dept. of Epidemiology and Biostatistics, VU University Medical Center, Amsterdam, Netherlands.

Background and aims: It has been suggested that endothelial dysfunction (ED) on the one hand and deteriorating glucose metabolism status and insulin resistance (IR) on the other act synergistically in the development of cardiovascular disease (CVD). Epidemiological evidence for this hypothesis, however, is scarce. We therefore investigated the interaction between ED and deteriorating glucose metabolism and IR on incident (non-)fatal cardiovascular (CV) events.
Materials and methods: In a population-based cohort (n=445, 69 years/51% women; 23% type 2 diabetes (DM2) and 28% impaired glucose metabolism (IGM) (by design)), IR was determined by the homeostasis model assessment (HOMA2-IR), and ED by flow-mediated dilatation (FMD). In addition, a morbidity and mortality registry was kept.
Results: After a follow-up of 7.6 (range 0.2; 8.9) years, 107 participants had had a CV event. After adjustment for age, sex and CVD risk factors, the results showed that FMD was associated with CV events in DM2 and IGM (HRs, per one SD smaller FMD, 1.65 [95%CI 1.10; 2.46]) and 1.42 [0.92; 2.19], respectively), but not in normal glucose metabolism (NGM) (HR 0.84 [0.62; 1.14]). Similarly, FMD was associated with incident CV events among those with IR (highest HOMA2-IR tertile; HR 1.86 [1.36; 2.53]), but not among those with normal insulin sensitivity (lower HOMA2-IR tertiles; HR 0.87 [0.62; 1.23] and 0.82 [0.57; 1.21], respectively). The interaction between FMD and DM2, IGM or IR was present on both a multiplicative (P-interaction <.05) as well as an additive scale (relative excess risk due to interaction >0). These results did not materially change when we mutually adjusted glucose metabolism status and IR for each other.
Conclusion: FMD was associated with incident CV events in individuals with DM2, IGM or IR, but not among individuals with NGM or normal insulin sensitivity. The present results support the hypothesis that ED on the one hand and deteriorating glucose metabolism and IR on the other act synergistically in the pathogenesis of CVD.

Metabolic predictors of CVD in type 2 diabetes

M. Colombo[1], F.V. Agakov[1], I. Brady[2], H.C. Looker[2], L. Groop[3], B. Thorand[4], A. Hamsten[5], U. de Faire[5], C.N.A. Palmer[2], E. Nogoceke[6], L.-M. Gan[7], V. Salomaa[8], P.M. McKeigue[1], H.M. Colhoun[2], on behalf of the SUMMIT Investigators;
[1]The University of Edinburgh, [2]University of Dundee, UK, [3]Lund University, Malmö, Sweden, [4]Helmholtz Zentrum München (GmbH), Neuherberg, Germany, [5]Karolinska Institutet, Solna, Sweden, [6]Hoffman-La Roche, Basle, Switzerland, [7]AstraZeneca, Södertälje, Sweden, [8]National Institute for Health and Welfare, Helsinki, Finland.

Background and aims: Our aim was to use a high-dimensional metabolomics platform to identify novel metabolites associated with and predictive of cardiovascular disease (CVD) in type 2 diabetes (T2D). Our aim was also to develop and apply new analyses methods appropriate for such high dimensional data.
Materials and methods: The study included baseline samples from T2D patients from Go-DARTS (n=1200), Scania Diabetes Registry (n=655), IMPROVE (n=44) and 60-year Old Stockholm Study (n=20) with incident MI or stroke (n=953 cases) or free of CVD at end of follow up (n=966 controls), matched for age and diabetes duration. Using the Metabolon mass spectrometry analysis platform UPLC-MS/MS and GC-MS, 612 metabolites were measured. Clinical factors included in the analysis were age, sex, diabetes duration, BMI, height, blood pressure, smoking, LDL, HDL, Triglycerides, HbA1c, eGFR, study centre, and medication (including anti-hypertensives, aspirin, lipid-lowering agents and insulin use). Forward selection using logistic regression, and sparse classification using L1-regularized approaches were applied and evaluated by using 50/10 nested cross-validation to select non-redundant sets of predictive biomarkers. We report those metabolites that were consistently selected by these models as being predictive of CVD. Descriptive statistics were produced by logistic regression using the identified biomarker panel.
Results: When used for predictions of CVD, the best metabolomics panel resulted in the moderate increment in the area under the ROC curve on test data from 0.67 for the clinical model to 0.70. Of 612 metabolites, 9 metabolites were consistently selected by all the models as independent predictors. The most strongly and consistently associated metabolites were L-histidine ($p<1e-5$, OR=0.77 [0.69, 0.86]) and Tryptophyl-Asparagine ($p<1e-4$, OR=1.33 [1.17, 1.52]). We also identified several metabolite CVD associations where further structural characterization of the metabolite signal is required.
Conclusion: Overall the addition of this metabolite panel to clinical factors produces a modest improvement in the prediction of CVD. However we identified several associations, some novel, of metabolites with CVD, though further validation of this work is needed. Whilst the overall improvement in prediction due to the metabolite panel is limited understanding the mechanism of these associations may lead to new insights into the pathogenesis of CVD in T2D and thereby target discovery.

DKA at diagnosis of type 1 diabetes predicts poor long-term glycaemic control

A. Rewers[1], G. Klingensmith[2], M. Rewers[2];
[1]Pediatrics, [2]Barbara Davis Center, University of Colorado, Aurora, USA.

Background and aims: The diagnosis of type 1 diabetes in children is often associated with diabetic ketoacidosis (DKA). We tested the hypothesis that DKA at diagnosis is an independent predictor of poor glycemic control later in the course of the disease.
Materials and methods: A cohort of 631 Colorado residents diagnosed with type 1 diabetes before the age of 18 yrs, in 1998-2001, was followed for up to 14 years. Of those, 224 (35%) had DKA (venous pH<7.3 or bicarbonate<15mEq/l) at diagnosis. HbA1c was measured using the DCA 2000 Analyzer at each visit (3.4 visits/yr, on average; median 24 visits/patient). Individual average HbA1c was calculated annually, starting 60 days after the diagnosis. Medians were compared using Wilcoxon rank sum test (Figure). Multiple linear regression was used to evaluate DKA at diagnosis as an independent predictor of long-term HbA1c levels.
Results: Longitudinal HbA1c levels tracked significantly higher in children diagnosed in DKA, compared to those with a less severe presentation (Figure). DKA at diagnosis was a significant (p<0.01) predictor of long-term higher HbA1c levels, independent of the age at diagnosis, sex, ethnicity and insurance status (none, Medicaid, or private) and controlling for the duration of follow-up. The difference in HbA1c between the DKA vs. no-DKA groups appeared to increase over time, from initially 0.3% to 0.7% at 10 years of follow-up.
Conclusion: DKA at diagnosis of type 1 diabetes in children predicts chronic worse glycemic control, independent of demographic factors and access to diabetes care. Lower residual insulin secretion in children presenting with DKA may be at fault and could be preventable with earlier diagnosis.

Figure. Presence of DKA at diagnosis (Dx) of T1D in children predicts worse long-term glycemic control.

The effect of treat-to-target insulin regimen on glycaemic control in overweight/obese type 1 diabetes patients

B.U. Nwosu[1], K. Cullen[1], L. Maranda[2], L. Greenman[1], J. Fleshman[1], N. McShea[1], M.M. Lee[1];
[1]Pediatrics, [2]Quantitative Health Sciences, University of Massachusetts Medical School, Worcester, USA.

Background and aims: The rising prevalence of childhood obesity has led to a parallel increase in the prevalence of overweight and obesity in patients with type 1 diabetes (T1D). The prevailing obesity-related insulin resistance leads to increased insulin requirements but poor glycemic control. There is no consensus on the best therapeutic regimen for the management of overweight or obese patients with T1D.
Objective: To determine the effect of treat-to-target insulin protocol on glycemic control, body mass index (BMI), waist circumference (WC), total daily dose (TDD) of insulin and hypoglycemia in overweight/obese T1D patients.
Materials and methods: A 3-month prospective trial of self directed treat-to-target insulin regimen in 21 overweight/obese subjects (10 males) with T1D of ages 10-20 years (mean age 15.25 ± 2.5). Inclusion criteria were T1D > 12 mo, hemoglobin A1c (HbA1c) >8% but <14%, and BMI >85%. Exclusion criteria were pregnancy, systemic illnesses, medications that alter blood glucose levels and recent history of blood transfusions. All patients were on multiple daily injections as follows: once daily injection of insulin detemir at bedtime, and multiple injections of aspart insulin before meals. Participants were asked to maintain their fasting blood glucose level between 90-120 mg/dL (5.0-6.7 mmol/L) using a titration algorithm of 2-0-2 units of insulin to adjust their detemir dose every 4th day to maintain glycemia as shown in Table 1, as follows: increase detemir dose by 2 units if the average of the 3 preceding days' pre-breakfast fasting plasma glucose (FPG) is >120 mg/dL (>6.7 mmol/L); reduce detemir dose by 2 units if the average of 3 preceding days' FPG is <90 mg/dL (5 mmol/L), and make no changes to the detemir dose if the above 3-day average is between 90-120 mg/dL (5.0-6.7 mmol/L). Insulin to carbohydrate ratios and correction factors were adjusted as in routine care. Anthropometric data were collected at enrollment and at 3 months, while TDD of insulin and hypoglycemia records were collected daily.
Results: There was no difference in mean HbA1c levels between the preceding 3mo and at baseline (9.21±1.71 vs. 9.82 ± 1.96, p=0.1). However, there was a significant reduction in HbA1c at the end of the study (9.82 ± 1.96 vs. 8.84 ± 1.15, p=0.005), and a significant increase in the TDD of insulin (71.52 ± 28.89 vs. 99.95 ± 44.49 IU/day, p<0.001), but no change in the mean BMI SDS (1.74 ± 0.43 vs. 1.66 ± 0.49, p = 0.19), weight SDS (1.66 ± 0.73 vs. 1.61. ± 0.77), and WC (93.44 ± 14.48 vs. 92.74 ± 15.0, p=0.38). No severe hypoglycemic events were reported.
Conclusion: Treat-to-target insulin regimen effectively reduced HbA1c level in overweight/obese patients with T1D. There was a significant increase in the TDD of insulin, but no change in BMI and WC. Optimal glycemic control in overweight/obese patients with T1D may require frequent structured insulin dose titrations.

Titration algorithm for long-acting insulin analog - detemir	
Average fasting plasma glucose of 3 consecutive days	Recommended long-acting insulin dose adjustments
<90 mg/dL (5.0 mmol/L)	subtract 2 units from the total dose of detemir
90-120 mg/dl (5.0-6.7 mmol/L)	no adjustments
> 120 mg/dL (>6.7 mmol/L)	add 2 units to the total dose of detemir

Clinical Trial Registration Number: NCT01334124

Study of circulating microRNAs in prepubertal obesity

F.J. Ortega Delgado[1], A. Prats Puig[1], J.M. Mercader[2], J. Moreno-Navarrete[1], M. Moreno[1], N. Bonet[3], W. Ricart[1], A. López-Bermejo[1], J. Fernández-Real[1];
[1]Hospital of Girona, [2]Joint IRB-BSC program on Computational Biology, Barcelona Supercomputing Center, [3]Genome Facility Core Service, Universitat Pompeu Fabra (UPF), Barcelona, Spain.

Background and aims: Since the presence of risk factors for metabolic disease in prepubertal children predicts the development in adulthood, it has been postulated that the prevention of obesity in children may reduce obesity-related diseases such as insulin resistance and type 2 diabetes (T2D). Thus, it is likely that the efforts thus far invested in the context of biomarker discovery for the diagnosis and clinical monitoring of obesity in children will experience major acceleration in the upcoming years, leading to a completely novel paradigm in the screening of chronic metabolic diseases. Circulating microRNAs (miRNAs) are valuable biomarkers of metabolic diseases and potential therapeutic targets in this field. In this study, we sought to define the circulating pattern of miRNAs in prepubertal obesity, identifying the miRNAs with the highest prediction power of overweight and the risk of T2D.
Materials and methods: The genome wide circulating miRNA profile was assessed in 10 boys (5 lean and 5 obese children). The most relevant miRNAs were cross-sectionally validated in 85 lean *versus* 40 obese children (63 boys and 62 girls), and prospectively validated in 45 children (23 boys and 22 girls, between age ~6 and ~10).
Results: The cross-sectional validation study disclosed that 15 specific circulating miRNAs were significantly deregulated in prepubertal obesity, includ-

ing the decreased miR-221 and miR-28-3p, and increased concentrations in plasma of miR-486-5p, miR-486-3p, miR-142-3p, miR-130b, and miR-423-5p (all p<0.0001). Indeed, the circulating concentration of these miRNAs was significantly associated with body mass index and other measures of obesity such as percent fat mass, waist circumference, regional fat distribution, and with laboratory parameters such as HOMA-IR, high molecular weight adiponectin, C-reactive protein, and circulating lipids in concordance with anthropometrical associations. Plasma concentrations of 10 of these circulating miRNAs changed significantly and differently during the 3-year follow-up in children who increased or decreased their normalized weight.
Conclusion: This study provides the first evidence that circulating miRNAs are deregulated in prepubertal obese children. Thus, the very early detection of metabolic abnormalities in obese children, as inferred by their circulating miRNA profile, may be a promising strategy in predicting metabolic disturbances such as T2D.

OGTT-modelled beta cell function and incretins in obese youth from normal to pre diabetes to overt type 2 diabetes

S.F. Michaliszyn[1], S. Lee[1], F. Bacha[2], H. Tfayli[3], L. Farchoukh[1], A. Mari[4], E. Ferrannini[5], S. Arslanian[1];
[1]University of Pittsburgh, [2]Baylor College, Houston, USA, [3]American University of Beirut Medical Center, Beirut, Lebanon, [4]Institute of Biomedical Engineering, Padova, [5]University of Pisa, Italy.

Background and aims: We previously demonstrated, using the hyperglycemic clamp together with the hyperinsulinemic-euglycemic clamp, diminished β-cell function (BCF) in obese youth with impaired glucose tolerance (IGT) and type 2 diabetes (T2DM) with ~40% and 80% impairment respectively, compared with their normally glucose tolerant (NGT) peers. The aim of the present study was a) to examine whether parameters of βCF, modeled from a simple 2-hr glucose tolerance test (OGTT), reflect similar impairments of BCF in obese adolescents across the spectrum of glucose tolerance; and b) to examine incretin hormones and their relationship to BCF.
Materials and methods: In 255 obese adolescents with NGT (173), IGT (48) and T2DM (34) we employed mathematical modeling of C-peptide during a 75g 2-hr OGTT to assess β-cell glucose sensitivity (βCGS), rate sensitivity and oral glucose insulin sensitivity (OGIS). Body composition was assessed by DEXA, subcutaneous (SAT) and visceral adiposity (VAT) by computed tomography or magnetic resonance imaging at L_{4-5} intervertebral space. Incretin hormones [total glucagon-like peptide-1 (GLP-1), gastric inhibitory polypeptide (GIP)] and glucagon concentrations were measured during the OGTT.
Results: Data are presented in the Table. Compared with NGT, βCGS was ~ 30% and 65% lower in IGT and T2DM respectively. Rate sensitivity was not different in IGT but was lower (~ 40%) in T2DM. OGIS was lower in IGT and T2DM and the significance remained after adjusting for BMI $\%^{tile}$ or VAT. Total insulin secretion was higher in IGT compared with NGT and T2DM. GLP-1 area under the curve (AUC) was higher in IGT compared with NGT with no differences in GIP AUC. Among the BCF parameters, βCGS correlated with GLP-1 AUC (r=-0.14, p=0.02) but not with GIP AUC. Glucagon AUC relative to glucose AUC increased significantly across the groups from NGT to IGT to T2DM. In a multiple regression analysis, age, race, sex, VAT, OGIS, βCGS and rate sensitivity explained 40% of the variance (R^2=0.40, p<0.001) in 2-hr glucose with βCGS (R^2=0.17, p<0.001), OGIS (R^2=0.15, p<0.001), rate sensitivity (R^2=0.07, p<0.001) and VAT (R^2=0.01, p<0.001) being significant independent contributors.
Conclusion: OGTT-modeled βCGS is a key determinant of glucose tolerance in obese youth and declines progressively across the spectrum of glucose tolerance from NGT to IGT to T2DM accompanied with escalating hyperglucagonemia. Obese youth with IGT who have normal rate sensitivity demonstrate an increase in total insulin output together with higher incretin response; however, against the backdrop of impaired βCGS, insulin secretion remains insufficient to compensate for their IGT. The inverse relationship between βCGS and GLP-1 may suggest an incretin-driven compensatory mechanism to improve insulin secretion.

The AGE methylglyoxal-derived hydroimidazolone and early signs of atherosclerosis in childhood diabetes

M. Heier[1,2], H. Margeirsdottir[3,2], P.A. Torjesen[4,2], I. Seljeflot[5,2], K. Stensæth[6,2], M. Gaarder[6], C. Brunborg[7], K.F. Hanssen[8,2], K. Dahl-Jørgensen[1,2];
[1]Pediatric Department, Oslo University Hospital, [2]University of Oslo, [3]Pediatric Department, Akershus University Hospital, Lørenskog, [4]Hormone Laboratory, [5]Center for Clinical Heart Research and Department of Cardiology, [6]Department of Radiology and Nuclear Medicine, [7]Department of Biostatistics and Epidemiology, [8]Department of Endocrinology, Oslo University Hospital, Oslo, Norway.

Background and aims: Advanced protein glycation is an important mechanism for the development of late diabetic complications and atherosclerosis. Hydroimidazolones are the most abundant advanced glycation end products (AGEs) in human plasma, and methylglyoxal-derived hydroimidazolone (MG-H1) is a major contributor. Our aim was to investigate the relationship between MG-H1 and early signs of atherosclerosis in children and adolescents with type 1 diabetes compared to healthy controls.
Materials and methods: 314 diabetic patients aged 8-18 years, were compared to 118 healthy controls of similar age and gender. Serum MG-H1 was measured by immunoassay. The development of atherosclerosis was evaluated by measuring carotid intima-media thickness by ultrasound (cIMT), arterial stiffness using Young's modulus and inflammation assessed by C-reactive protein (CRP).
Results: Mean age of the diabetic patients was 13.8 (SD = 2.8) years, diabetes duration 5.5 (SD = 3.4) years and HbA1c 8.4 (SD = 1.2) %. MG-H1 was significantly increased in the diabetic group compared to controls, 155.3 (SD = 41.0) vs. 142.7 (SD = 35.1) U/ml, p = .002. The CRP levels were also significantly higher in the diabetic group 2.0 (SD = 3.9) vs. 0.9 (SD = 2.3) mg/l, p < .001. Diabetic patients had more frequently elevated cIMT than healthy control subjects, as 19.5% were above the 90th percentile of healthy control subjects, and 13.1% were above the 95th percentile (P < 0.001). Mean cIMT was significantly higher in diabetic boys compared to controls 0.46 (SD = 0.06) vs. 0.44 (SD = 0.05) mm, p = .04, but not in girls. There was no significant difference between the groups regarding Young's modulus. However, by multiple regression analysis we found a significant positive association between MG-H1 and both Young's modulus and CRP in the diabetes group.
Conclusion: Serum levels of methylglyoxal-derived hydroimidazolone are increased, and despite short duration of disease, MG-H1 is an independent risk factor for both arterial stiffness and low grade inflammation indicative of an accelerated early atherosclerotic process in diabetic children and adolescents.

Microstructural abnormalities in white and gray matter in obese adolescents with and without type 2 diabetes

A. Nouwen[1], A. Chambers[1], H.A. Allen[2], M. Chechlacz[1,3], S. Higgs[1], J. Blissett[1], T.G. Barrett[4];
[1]School of Psychology, University of Birmingham, [2]School of Psychology, University of Nottingham, [3]Department of Experimental Psychology, University of Oxford, [4]School of Medicine, University of Birmingham, UK.

Background and aims: Compared to the general population, people with type 2 diabetes (T2DM) are at increased risk of cognitive decline. Recent studies have shown brain atrophy in T2DM in both white and gray matter of the brain, even in the absence of dementia or macro-vascular complications. Gray matter abnormalities have been associated with obesity but changes in white matter were associated with duration of diabetes. Worryingly, these brain abnormalities may already occur in adolescents with T2DM. To date, reports have focused on specific anatomical regions and have not considered more diffuse cortical losses. Given the association of T2DM and obesity, we compared white and grey matter properties in adolescents with T2DM, obesity and normal weight.
Materials and methods: 15 adolescents with T2DM (> 6 months), 21 obese (age-specific BMI > 30) and 22 normal weight adolescents underwent MRI scanning on a 3T Philips Achieva MRI system with 8-channel phased array SENSE head coil. A sagittal T1-weighted sequence and diffusion MRI sequence employing echo planar imaging (64 slices with isotropic 2x2x2 mm3 voxel) were acquired in 61 gradient directions with a b value of 1500s/mm2. Structural T1 images were processed using SPM8 with VBM8 (Statistical Parametric Mapping, Welcome Department of Cognitive Neurology, London UK). Age and gender specific templates were generated using The Template-O-Matic toolbox. DTI images were analysed using FSL DTIFIT (FMRIB, Oxford UK) to create Fractional Ansiotrophy (FA) maps. Blood glucose was measured prior to scanning. Participants also completed the Child version of the Dutch Eating Behaviour Questionnaire (DEBQ-C).
Results: Normal weight adolescents showed greater gray matter volume in the caudate and putamen bilaterally compared to those with T2DM and greater gray matter volume in the right hippocampus, left putamen, left caudate and amygdala bilaterally than obese participants ($p<0.001$, extent>200voxels; FEW cluster level corrected). Scores on DEBQ-C emotional subscale were negatively associated with gray matter density in the left hippocampus (r=-0.33), left caudate (r=-0.32), left amygdala (r=-0.34) and right putamen (r=-0.34). There was also decreased FA between controls and T2DM participants ($p<0.05$, FSL Randomise non-parametric statistical tool). Adolescents with T2DM showed reduced FA in left corticospinal tract, left thalamic radiation, body and genu of corpus callosum, left fornix, left retrolenticular internal capsule, right anterior corona radiata, left uncinate, left IFOF and left anterior external capsule.
Conclusion: T2DM is linked to significant loss in both gray matter volume and integrity of several white matter tracts. Gray matter losses were in areas previously found to be involved in emotion and memory. Participant's structural losses were also linked to higher emotional eating, possibly reflecting early loss of function linked to these areas. Widespread white matter changes could indicate vulnerability to hastening cognitive decline in adolescent with T2DM.

Brain responses to food cues in adolescents with and without type 2 diabetes

A. Chambers[1], A. Nouwen[1], H.A. Allen[2], M. Chechlacz[1,3], S. Higgs[1], J. Blissett[1], T. Barrett[4];
[1]School of Psychology, University of Birmingham, [2]School of Psychology, University of Nottingham, [3]Department of Experimental Psychology, University of Oxford, [4]School of Medicine, University of Birmingham, UK.

Background and aims: Good diet management is integral to the successful management of type 2 diabetes (T2DM). Yet, adolescents with type 2 diabetes (T2DM) have difficulty following dietary recommendations and succumb to frequent overeating. Restrictive feeding practices, often imposed by concerned parents, may have a deleterious effect on children's abilities to self regulate their own food intake. In adults with T2DM, a restrictive diet may alter brain responses to food stimuli and this is related to dietary self-care. However, little is known about the psychological effects of diets imposed for medical reasons in young people. Using combined behavioural, questionnaire and fMRI methods, we investigated i) differences in reactivity to food cues between adolescents with T2DM, obese and normal weight adolescents and ii) the effect of restrictive diets and parental feeding practices on adolescent's food responsiveness and fMRI response.
Materials and methods: Food images and visually matched non-food images were presented to 15 adolescents with T2DM, 20 with obesity and 20 normal weight adolescents. We recorded brain activity (fMRI) whilst participants imagined eating the presented food items. Questionnaire data regarding their feeding/eating behaviours were collected from both the parent and adolescent. We also measured the macro-nutrients of food consumed by both the parent and adolescent during a prepared lunch offered during the study visit.
Results: All fMRI activation was significant at $p<0.05$, $z>2.3$, cluster corrected for multiple comparisons. All groups showed higher activation for food than non-food images but activation was significantly higher in the T2DM group, illustrating the increased salience for food in this group. Participants with T2DM also had greater activation to food in brain regions associated with attention and control (medial frontal gyrus, cingulate, precuneus), if they experienced high parental restriction (as measured by the questionnaire data). This was not shown in the Obesity or Control groups. Restriction by parents however did not predict lower food consumption (if anything consumption was higher with more restriction).
Conclusion: For young people with T2DM their brain activation to food suggests parental restriction may be aiding ability to learn to control their responses to food. However the failure of cognitive control to predict a reduction in food consumption suggests at this stage it is not sufficient for effective behavioural change. As adolescents mature into adults it is not known how these increases in activation of control areas to food will interact with the known losses of cognitive function found in older adults with T2DM. It is possible that increased cognitive load may lead to erosion of the cognitive resources and a subsequent decline in control related activation. On the other hand, parental restriction encouraging the practice of cognitive control at a time of increased cognitive flexibility could improve the likelihood of better behavioural outcomes in the future.

Corneal confocal microscopy detects neuropathy before retinopathy and nephropathy in children with type 1 diabetes: a preliminary study

M. Tavakoli, R.A. Malik;
University of Manchester, UK.

Background and aims: Early detection and prevention of long-term complications by maintaining good metabolic control is the key goal of paediatric diabetes management. Whilst we have readily available diagnostic techniques for retinopathy (fundus photography) and nephropathy (UAER), there is no equally sensitive measure for diabetic neuropathy. The aim of the present study was to assess the utility of in vivo corneal confocal microscopy (IVCCM) in identifying early nerve damage in children with T1DM.
Materials and methods: 25 children with type 1 diabetes mellitus (average age: 13±1 yrs; average duration of diabetes 8 years) with no evidence of retinopathy or microalbuminuria and 10 aged matched control subjects underwent assessment with IVCCM (HRT III) to quantify corneal nerve fibre density (NFD), branch density (NBD) and length (NFL). Each examination took ~ 6 minutes and no child reported that CCM was uncomfortable.
Results: There was a significant reduction in NFD (no/mm^2) (32.5 ± 1.9 v 41.1±1.8, P=0.007), NBD (no/mm^2) (50.6 ± 4.5 v 72.5 ± 6.5, P=0.008) and NFL (mm/mm^2) (20.6 ± 0.9 v 29.4 ±1.3, P<0.0001) in children with T1DM versus control subjects. Patients were stratified into better (HbA1c <8%, n=15) and poorer (HbA1c >8%, n= 10) glycaemic control. Even in patients with better (HbA1c-7.9±0.14) glycaemic control, NFD (34.2 ± 2.4, P=0.07), NBD (51.9 ± 4.4, P=0.04), and NFL (21.3 ± 1.2, P<0.0001) were reduced compared to controls. Those with poorer (HbA1c=10.08±0.04) glycaemic control had a further non-significant reduction in NFD (27.3 ± 1.5, P=0.2), NBD (46.7 ± 13.0, P=0.8), and NFL (18.2 ± 1.4, P=0.3) compared to those with better glycaemic control.
Conclusion: Corneal confocal microscopy detects early corneal nerve damage in children with Type 1 diabetes, which worsens with poorer glycaemic control. CCM provides a fast, non-invasive and well tolerated technique to detect early nerve damage which precedes retinopathy and microalbuminuria. Longitudinal studies are required to predict those who develop overt neuropathy.

Prevalence of asthma in children and adolescents with type 1 diabetes in Germany and Austria: Is there an impact on metabolic control?

T. Hörtenhuber[1], E. Schober[1], E. Fröhlich-Reiterer[2], K. Raile[3], S. Wudy[4], R. Stachow[5], E. Molz[6], R. Holl[6];
[1]Pediatrics and Adolescent Medicine, Medical University of Vienna, [2]Pediatrics and Adolescent Medicine, Medical University of Graz, Austria, [3]Clinic of Pediatrics, Charite, Berlin, [4]Pediatrics, Medical University of Giessen, [5]Pediatrics, Fachklinik Sylt, [6]Institute of Epidemiology and Medical Biochemistry, Medical University of Ulm, Germany.

Background and aims: Recent data suggest an increased prevalence of asthma in diabetic youth in contrast to previous reports, and the concomitant diagnosis was associated with poor metabolic control. The aim of the study was to estimate the prevalence of asthma in a large cohort of children and adolescents with Type 1 diabetes mellitus (DMT1) in Germany and Austria and to analyse a possible impact on metabolic control.
Materials and methods: Observational cohort study based on the DPV-database (German/Austrian DPV initiative) data from 51926 patients with DMT1 (<20 years (Tab 1). All clinical data were documented prospectively in the DPV-data base. The data base was searched for the concomitant diagnosis asthma and for asthma medication (inhaled corticosteroids, leukotriene modifiers, sympathomimetic drugs and others). Data were analysed using the SAS software. For group comparisons, non-parametric statistical tests and a linear regression model were used, with adjustment for multiple comparisons.
Results: 1755 (3.4 %) of the whole cohort had the diagnosis asthma or received medical treatment for asthma. Patients with asthma were more often males, used higher insulin doses, had decreased height SDS, an increased BMI-SDS and experienced more often severe hypoglycaemias. No significant difference was found for HbA_{1c} between patients with and without asthma. 495 (28%) patients with asthma were treated with inhaled corticosteroids, 425 (24%) with sympathomimetic drugs, 104 (6 %) used leukotriene receptor antagonists, 72 (4%) various other medications, while 659 (37%) were without pharmacotherapy. No relevant influence of the type of asthma medication on metabolic control or BMI -SDS could be found.
Conclusion: Prevalence of asthma in children and adolescents with DMT1 in Germany and Austria seems not to be elevated compared to the background population. The diagnosis asthma and pharmacological treatment have no relevant influence on metabolic control in our cohort.
