Abstract Recent studies show mid-latitude western boundary currents (WBCs) substantially influence the atmosphere aloft, and an important feature is enhanced rain band over the WBCs in climatological mean field. However, how such long-term, climate phenomena are related to shorter, weather timescale phenomena are generally remained to be explored. In this paper, diurnal precipitation and cloud variations are investigated global mid-latitude oceans with emphasis on air–sea interactions over WBCs using satellite-derived precipitation and outgoing longwave radiation (OLR) datasets. Strong 24-h period components of precipitations are found over the Gulf Stream in summer and over the Kuroshio in the East China Sea in early summer (Baiu–Meiyu season), respectively. Similar diurnal precipitations are not observed in WBCs in the Southern Hemisphere year around. The diurnal precipitation cycles over the Gulf Stream and the Kuroshio exhibit peak phases in the early to late morning for the Gulf Stream and late morning to early afternoon for the Kuroshio, with southeastward phase propagations. High cloud frequency derived from OLR data exhibit consistent diurnal cycles. A substantial difference of diurnal cycles between the Gulf Stream and the Kuroshio regions are associated with the large-scale Baiu–Meiyu rain and cloud bands for the latter region. Diurnal precipitation and high cloud variability is found in the vicinity of the Kuroshio itself, embedded in the Baiu–Meiyu rain and cloud bands distributing in a wider area without a strong diurnal component. The spatial

and seasonal distributions of the diurnal variability over these WBCs strongly suggests that the diurnal precipitation and cloud cycles are essential aspects of *deep heating mode* of atmospheric response recently reported for these WBCs. These results indicate that these WBCs in the Northern Hemisphere play an important role in modulating short-term precipitation variations, and on the other hand diurnal variability can be a substantial agent for the mid-latitude air–sea interaction.

1 Introduction

How mid-latitude oceans fronts, associated with western boundary currents (WBCs) and meso-scale eddies, influence the overlying atmosphere is a rapidly developing research field. In particular, air–sea interactions over four mid-latitude WBCs, i.e., the Gulf Stream, the Kuroshio and its extension, the Agulhas Return Current, and the Brazil–Malvinas currents, have attracted much attention (see reviews by Chelton et al. 2004; Xie 2004; Small et al. 2008; Chelton and Xie 2010). Among these four regions, prominent tropospheric responses to the WBCs above the Marine Atmospheric Boundary Layer (MABL) were reported for the Gulf Stream (Minobe et al. 2008, 2010; Czaja and Blunt 2011), the Kuroshio Extension (Tokinaga et al. 2009; Czaja and Blunt 2011) and the Kuroshio in the East China Sea (Xu et al. 2011; Sasaki et al. 2012), characterized by enhanced rain accompanied by ascent. Also, cloud distribution and tropospheric temperatures are modified over the Agulhas Return Current region (Liu et al.

2007; Shimada and Minobe 2011). These studies, however, mainly investigated seasonal or annual mean climatologies. The atmospheric responses found in the time mean fields must involve time varying phenomena on shorter time-scales. This is especially true for precipitation, because its occurrence is highly intermittent and is closely related to shorter timescale phenomena such as synoptic scale disturbances and diurnal variability.

Most of the previous studies that have investigated the relation between shorter timescale phenomena and air–sea interaction over the mid-latitude WBCs have focused on synoptic scale variations. Synoptic scale disturbances strongly modify air–sea heat fluxes in WBC regions as found in observations (e.g., Alexander and Scott 1997; Zolina and Gulev 2003; Shaman et al. 2010; Rudeva and Gulev 2011) and also in modeling studies (e.g., Nonaka et al. 2009; Taguchi et al. 2009; Brayshaw et al. 2011). The sensible and latent heat fluxes are important in maintaining the surface baroclinicity (e.g., Hoskins and Valdes 1990; Nakamura et al. 2004, 2008), which is crucial for developments of extratropical cycles (Hoskins et al. 1985) and thus important in determining the nature of the storm tracks (e.g., Inatsu et al. 2003; Inatsu and Hoskins 2004; Brayshaw et al. 2008, 2011; Ogawa et al. 2012). In particular, surface storm tracks and high wind distributions are strongly affected by WBCs (Sampe and Xie 2007; Joyce et al. 2009; Booth et al. 2010), and atmospheric latent heating associated with precipitation plays an important role in cyclone development over WBC regions (e.g., Kuo et al. 1991; Kuwano-Yoshida et al. 2010; Booth et al. 2012). Furthermore, an observational study by Nakamura et al. (2012) showed that wintertime extratropical cyclone tracks are modified by the Kuroshio's large meander south of Japan, which was confirmed in the numerical experiment by Hayasaki et al. (2013).

In contrast to the large body of work on synoptic scale variability, the linkage between air–sea interaction over the WBCs and diurnal variability is much less well studied. Most studies of diurnal precipitation cycles focused their attention on diurnal variations over land (e.g., Wallace 1975; Oki and Musiak 1994) or in the tropics (e.g., Janowiak et al. 1994; Yang and Slingo 2001; Nesbitt and Zipser 2003; Kikuchi and Wang 2008), probably reflecting data availability in early studies and also the overall tendency for strong diurnal variations over land and/or the tropics. However, one can see that a relatively strong diurnal cycle of precipitation occurs over the Gulf Stream in a global analysis (Fig. 2 in Kikuchi and Wang 2008) or in a regional analysis focused on North America (Fig. 6 in Dirmeyer et al. 2012) in summer, though the possible dependency of this diurnal precipitation to the Gulf Stream was not mentioned in these papers. Diurnal cloud variations over the Gulf Stream region were also reported a decade ago by

Alliss and Raman (1995), though their analysis was limited to the western portion of the Gulf Stream (west of 71°W) using 6-hourly data, which is coarsely sampled compared with hourly or 3-hourly sampled data used in recent studies (e.g., Dai et al. 2007; Kikuchi and Wang 2008).

Given the fact that the oceanic diurnal precipitations are generally stronger in the tropics than in the mid-latitudes, it is worthwhile to note that tropical-like atmospheric responses to mid-latitude WBCs have been identified in recent studies. Minobe et al. (2010) found a stark difference in the atmospheric response over the Gulf Stream between the summer and winter seasons. In summer, maximum upward winds are found in the middle of the troposphere, just above the enhanced precipitation over the Gulf Stream, accompanied by horizontal convergence in the lower troposphere. Atmospheric heating has its maximum also in the mid-troposphere, where convective latent heating dominates. The authors referred to this type of atmospheric response as the *deep heating mode*. In winter, upward winds have their maximum in the lower troposphere (850–700 hPa), and the corresponding horizontal convergence is mostly limited to the MABL, though summer time convergence is not confined in this layer. The corresponding atmospheric heating consists of sensible heating (including vertical diffusion of heat in the MABL) and convective latent heating just above the top of the MABL, resulting in total atmospheric heating that exhibits a maximum in the lower troposphere. The authors referred to this type of atmospheric response as the *shallow heating mode*, and showed that a bimodal variation of the atmospheric heating profile exists between deep and shallow distributions.

A deep heating mode as energetic as that over the Gulf Stream is also found in the atmospheric response over the Kuroshio in the East China Sea in June, i.e., middle of early summer rain season in this region (Sasaki et al. 2012). This long-lasting precipitation phenomenon prevailing from southeast China to Japan is called Baiu in Japan and Meiyu in China. The Baiu–Meiyu rainband is caused by basin–scale interactions between the atmosphere, land and the ocean. Moisture transport by low-level jets along the western flank of the subtropical high is a key factor in generating the Baiu–Meiyu rainband (e.g., Ninomiya and Akiyama 1992), whereas horizontal temperature advection from the Tibetan Plateau also plays an important role in determining its location (Sampe and Xie 2010). Sasaki et al. (2012) found that a localized atmospheric response to the Kuroshio, with the deep heating mode, is embedded in the large-scale Baiu–Meiyu rainband. A weak deep heating mode is also observed over the Kuroshio Extension in summer (Minobe et al. 2010; Tokinaga et al. 2009), and over the East China Sea in spring (Xu et al. 2011). The presence of tropical-like atmospheric responses to the Gulf Stream may be related to the aforementioned diurnal precipitation

over the Gulf Stream. If so, is similar diurnal precipitation variability also found over the Kuroshio in the East China Sea? Can prominent diurnal precipitations be found in WBCs in the Southern Hemisphere? Minobe et al. (2010) suggested that for an energetic deep heating mode to exist, sea-surface temperature (SST) warmer than 24–26 °C may be necessary, and further suggested that the absence of the deep heating mode (i.e. as strong as over the Gulf Stream) for the WBCs in the Southern Hemisphere due to the relatively cold SSTs in those regions.

The purpose of the present paper is, therefore, to investigate diurnal variability of precipitations over mid-latitude WBCs. For this purpose, we analyze a satellite-derived precipitation dataset globally in order to investigate the overall connection of diurnal variations to the WBCs and also regionally to determine the detailed spatio-temporal structures. The rest of the present paper is organized as follows. In Sect. 2, we describe the datasets and analysis method. In Sect. 3, diurnal precipitations are analyzed globally. This global analysis indeed reveals strong diurnal precipitation variability in summer over the Gulf Stream and over the Kuroshio in the East China Sea. Thus, in the following two sections (Sects. 4, 5), we conduct closer analyses for these two regions. Discussion and conclusions are presented in Sect. 6.

2 Data and method

We analyzed a satellite-derived precipitation dataset and an outgoing longwave radiation (OLR) dataset. The precipitation dataset is GSMaP MVK version 5 (Ushio et al. 2009). The rain rates in this dataset are estimated using a Kalman filter from multiple micro-wave satellites combined with an infra-red (IR) dataset provided by National Oceanic and Atmospheric Administration–Climate Prediction Center (NOAA–CPC), and are provided on an hourly, $0.1^\circ \times 0.1^\circ$ grid from March 2000 to December 2010. The IR data are used for moving vectors of estimated precipitation and also for the estimation of the precipitation itself from brightness temperatures. It should be noted that most of the previous studies of diurnal precipitation used the TRMM 3B42 dataset, which is on a three-hourly $0.25^\circ \times 0.25^\circ$ grid (Huffman et al. 2007), whereas the GSMaP MVK has higher spatial and temporal resolutions than that.

We also analyzed a global 3-hourly, $1^\circ \times 1^\circ$ OLR dataset of NASA/GEWEX Surface Radiation Budget (SRB) project (Stackhouse et al. 2004). This dataset is available from NASA Langley Research Center's Atmospheric Science Data Center for a period from July 1982 to December 2007, and analyzed in this study from 2000 to 2007. The data was briefly analyzed by Minobe et al. (2008), who reported frequent daytime high cloud occurrence

along the Gulf Stream based on occurrence frequency of OLR levels lower than 160 W/m^2 , which roughly corresponds to a cloud-top height of about 300 hPa. Following their approach, we also examine occurrence rate of OLR smaller than 160 W/m^2 as a measure of high cloud frequency. In order to know whether the major features found in the OLR-based high cloud frequency are consistent with independent cloud data, we also examine cloud amount for high-level clouds of D2 dataset of International Satellite Cloud Climatology Project (ISCCP) for a period from 2000 to 2009 (Rossow and Schiffer 1999). Spatial resolution D2 dataset is $2.5^\circ \times 2.5^\circ$, coarser than that of OLR, with the 3-hourly sampling interval. High-level clouds in ISCCP D2 dataset are defined clouds that have cloud top pressures are smaller than 440 hPa, and thus include lower clouds than those used for OLR-based high-cloud frequency.

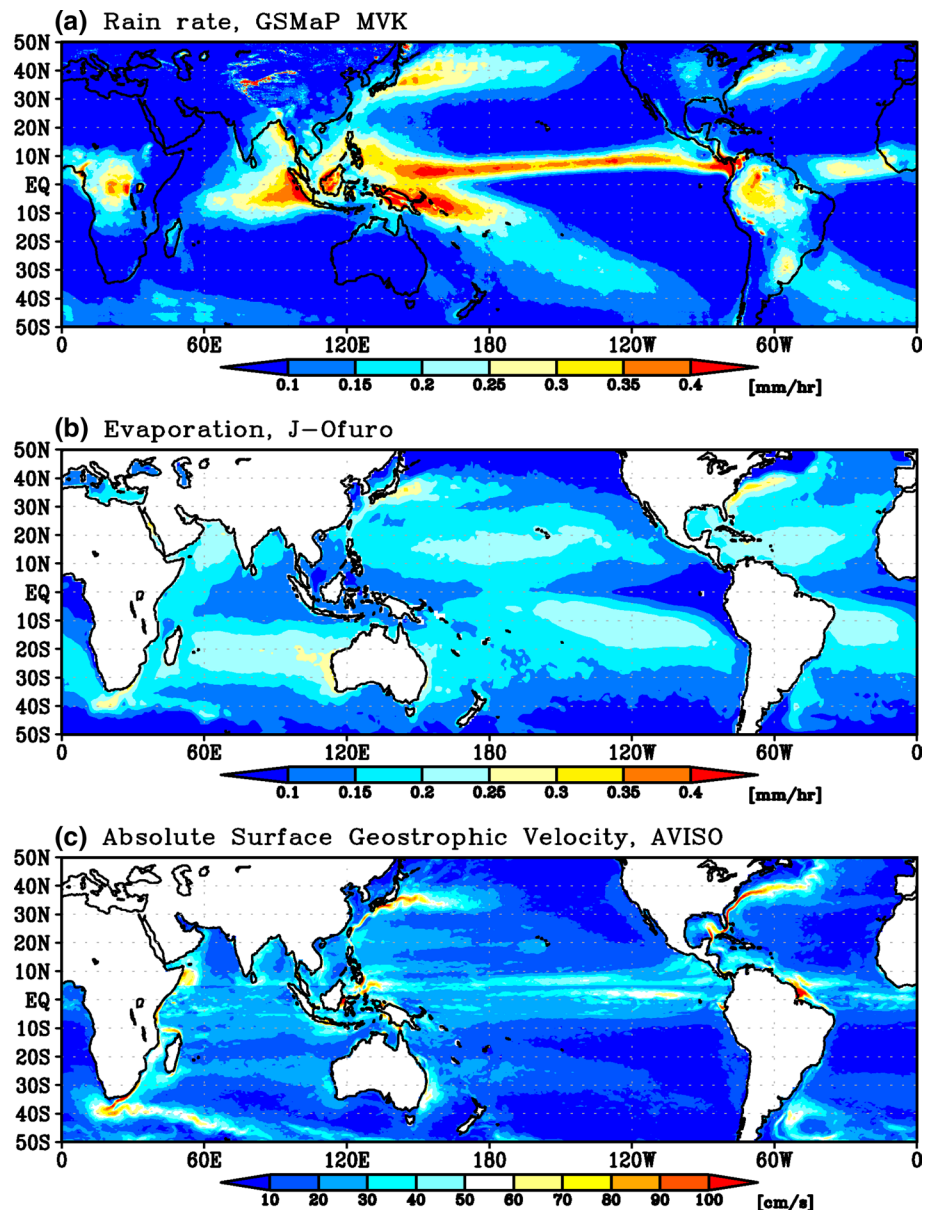

Diurnal climatologies are calculated for each month and also for each season, and from these the diurnal amplitude and phase of the 24-h Fourier component are estimated. The phase is expressed by the local solar time (LST) for the maximum of this Fourier component, where LST is calculated from coordinated universal time (UTC) with longitudinal distance between each grid point and 0° . Also, we examine relative amplitude, given by the amplitude divided by the mean value. If diurnal variability consists of pure sinusoidal wave of 24-h component, relative amplitude is in a range between 0 and 100 %. In this case, a relative amplitude of 100 % means that the daily minimum is 0 % and the maximum is 200 % of the mean value. A relative amplitude can be larger than 100 %, when precipitation occur in a narrower time range than that expected from a sinusoidal wave.

In order to show geographical relations between atmospheric and oceanic structures, we also use climatological satellite-derived SST and surface geostrophic current velocity data. SST data used for calculating climatological SSTs are optimal interpolation SST ver. 2 on a daily, $0.25^\circ \times 0.25^\circ$ grid (Reynolds et al. 2007). Weekly surface geostrophic current velocities, estimated from satellite altimeter, are provided by AVISO on a $1/3^\circ \times 1/3^\circ$ grid (<http://www.avisioceanobs.com/en/data/product-information/duacs/ssaltoduacs-products.html>).

3 Global view

Before analyzing the global diurnal cycles, in order to get some idea of precipitation and evaporation distributions associated with mid-latitude WBCs, global maps of annual mean rain rate and evaporations are shown in Fig. 1. Previous studies examined these parameters associated with WBCs over the Northern Hemisphere (Minobe et al. 2008, 2010; Tokinaga et al. 2009; Sasaki et al. 2012) but

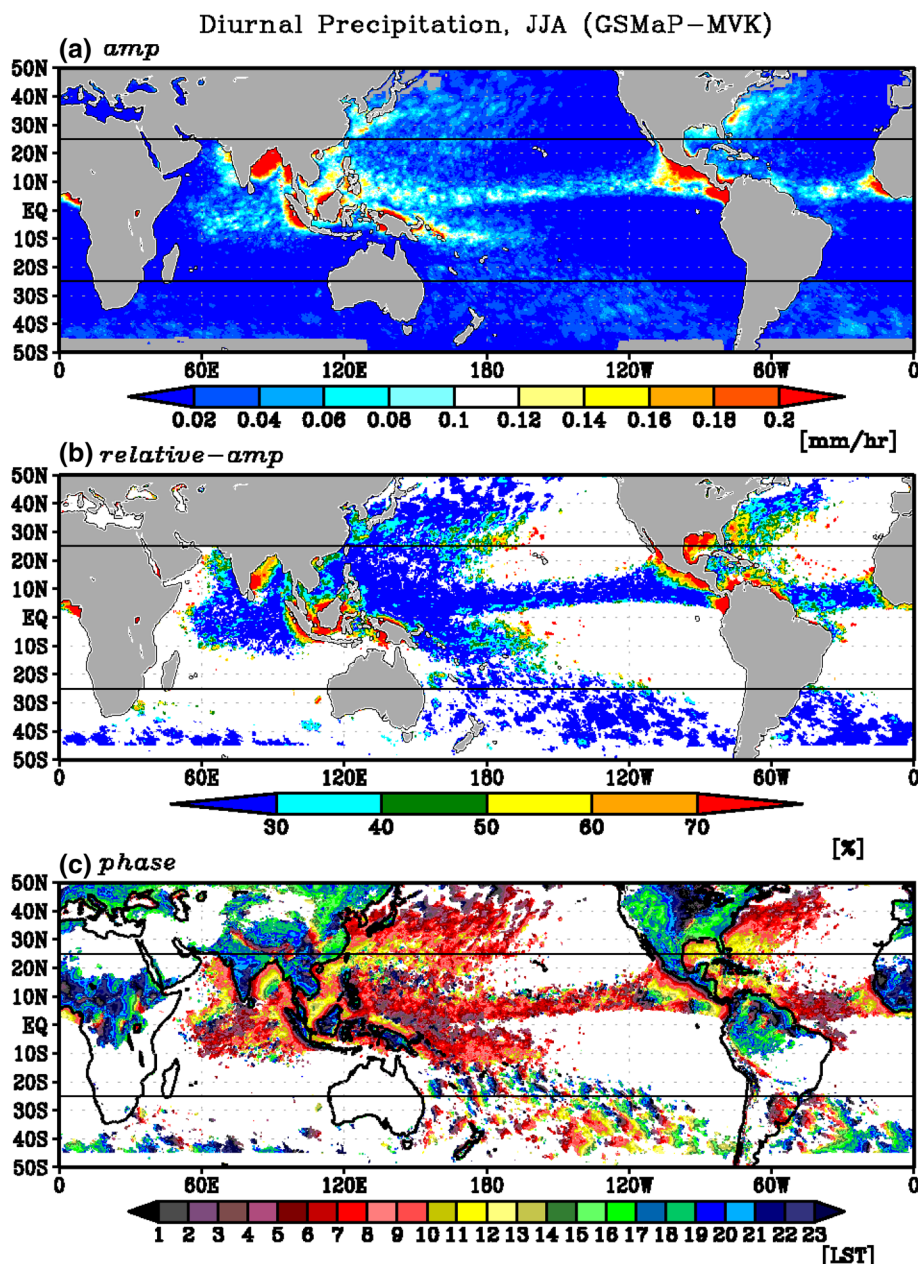

Fig. 1 Annual mean climatology of **a** rain rate from GSMaP MVK from March 2000 to November 2010, **b** evaporation from the J-Ofuro dataset from January 2000 to December 2006, **c** surface geostrophic current velocities provided by AVISO from January 2000 to December 2010

did not compare them with those in the Southern Hemisphere. Evaporation data is taken from satellite-derived data set Japanese Ocean Flux (J-Ofuro) dataset version 2.1 (Kubota and Tomita 2007) for a period from 2000 to 2006. For comparison of the precipitation and evaporation with the geographic locations of the WBCs, the absolute value of the surface geostrophic velocity is also shown in the figure. In addition to regions of strong rain rate over the tropics including the inter-tropical convergence zone (ITCZ) and the South Pacific convergence zone (SPCZ), enhanced rain also occurs over the Gulf Stream, the Kuroshio and the Kuroshio Extension, consistent with previous observational studies (Minobe et al. 2008, 2010; Tokinaga et al. 2009; Xu et al. 2011; Sasaki et al. 2012). These mid-latitude precipitation bands are accompanied by enhanced local

evaporation, in contrast to the relatively weak local evaporation in the tropical convergence zones. Over the Agulhas Return Current, slightly enhanced evaporation and precipitation is found, though the structure of the latter is somewhat noisy. The enhanced precipitation and accompanying atmospheric heating can be related to the relatively deep penetration of the oceanic influence on the troposphere in this region (Liu et al. 2007; Shimada and Minobe 2011). The magnitude of precipitation over the Agulhas Return Current, however, is much smaller than that over the WBCs in the Northern Hemisphere. In the Brazil/Malvinas confluence region in the western South Atlantic, the evaporation peaks along the poleward flowing Brazil current, but no corresponding precipitation band is observed. The strong rainbands over the Northern Hemisphere WBCs, and

The values in panels **b**, **c** are drawn for the region where the amplitudes are larger than 0.02 mm/h. *Horizontal lines indicate 25°N/S*

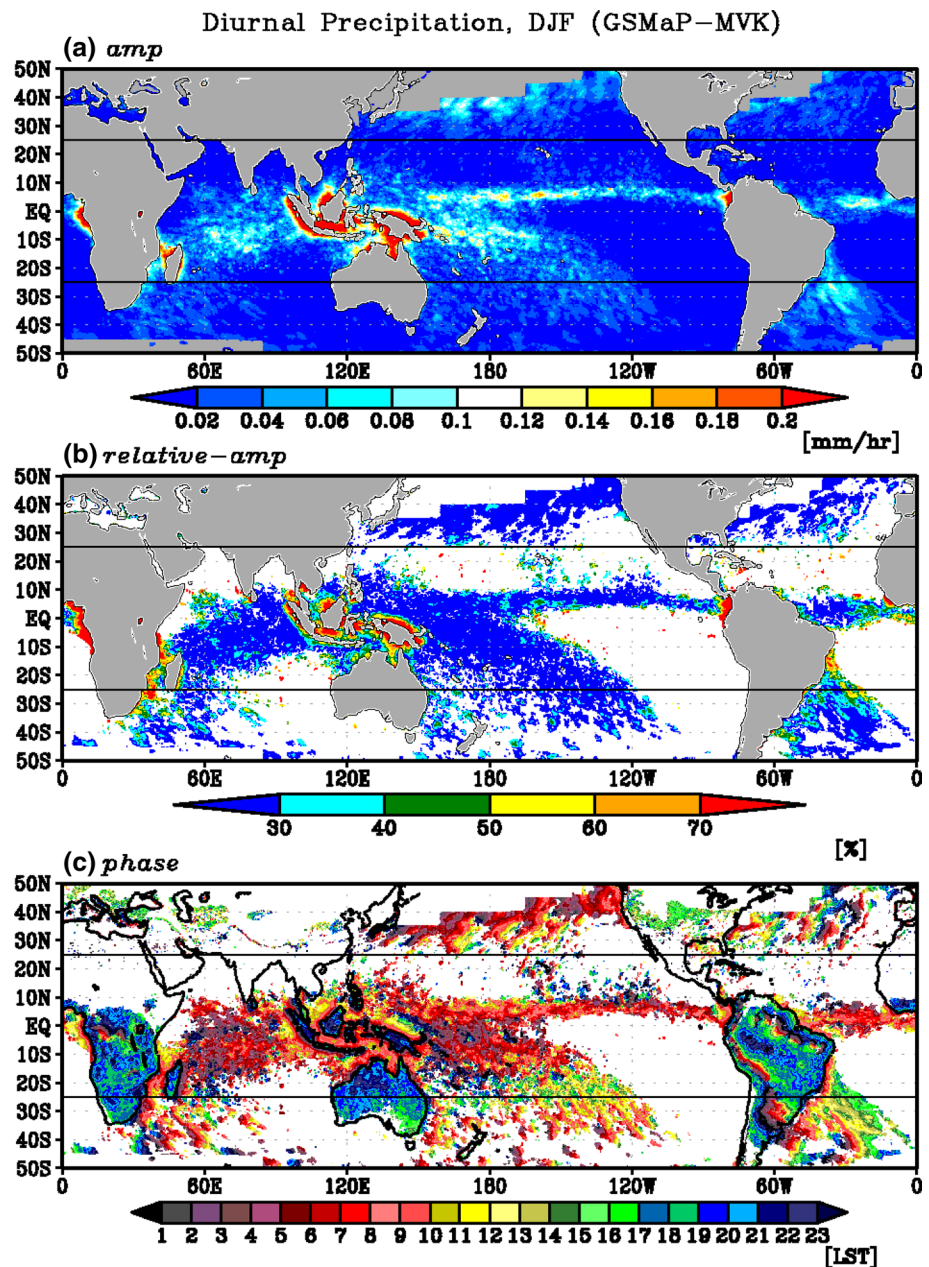

weak rainband over the Agulhas Return Current are also seen in the National Centers for Environmental Prediction (NCEP)-Climate Forecast System Reanalysis (CFSR) dataset (Saha et al. 2010).

Diurnal precipitation amplitudes derived from GSMaP MVK dataset are now examined for each season. Figure 2a shows that diurnal amplitudes of precipitation are strong over the Gulf Stream and the Kuroshio in the East China Sea and south of Japan over mid-latitude (poleward of 25°N/S) oceans in boreal summer, in addition to widely known strong diurnal precipitation in the tropics near lands and in the ITCZ and SPCZ. The maximal amplitudes reach 0.2 mm/h over both the Gulf Stream and the Kuroshio.

The relative amplitudes (see Sect. 2) of the diurnal precipitation over the Gulf Stream are about 40–70 %, and over the Kuroshio are 30–60 % (Fig. 2b). These values are much higher than general values, found to be 10–30 % over much of the ocean (Dai et al. 2007). The relative amplitudes over the Gulf Stream and the Kuroshio indicate a possibility that the diurnal cycle of precipitation in these regions provides an important contribution to the mean rain rate.

Figure 2c shows phases at which the 24-h precipitation component reaches its maximum in LST. A prominent feature is the contrasting phase over land and ocean. It is known that the diurnal cycle tends to have its maximum

Fig. 3 Same as Fig. 2, but for the boreal winter (December–February)

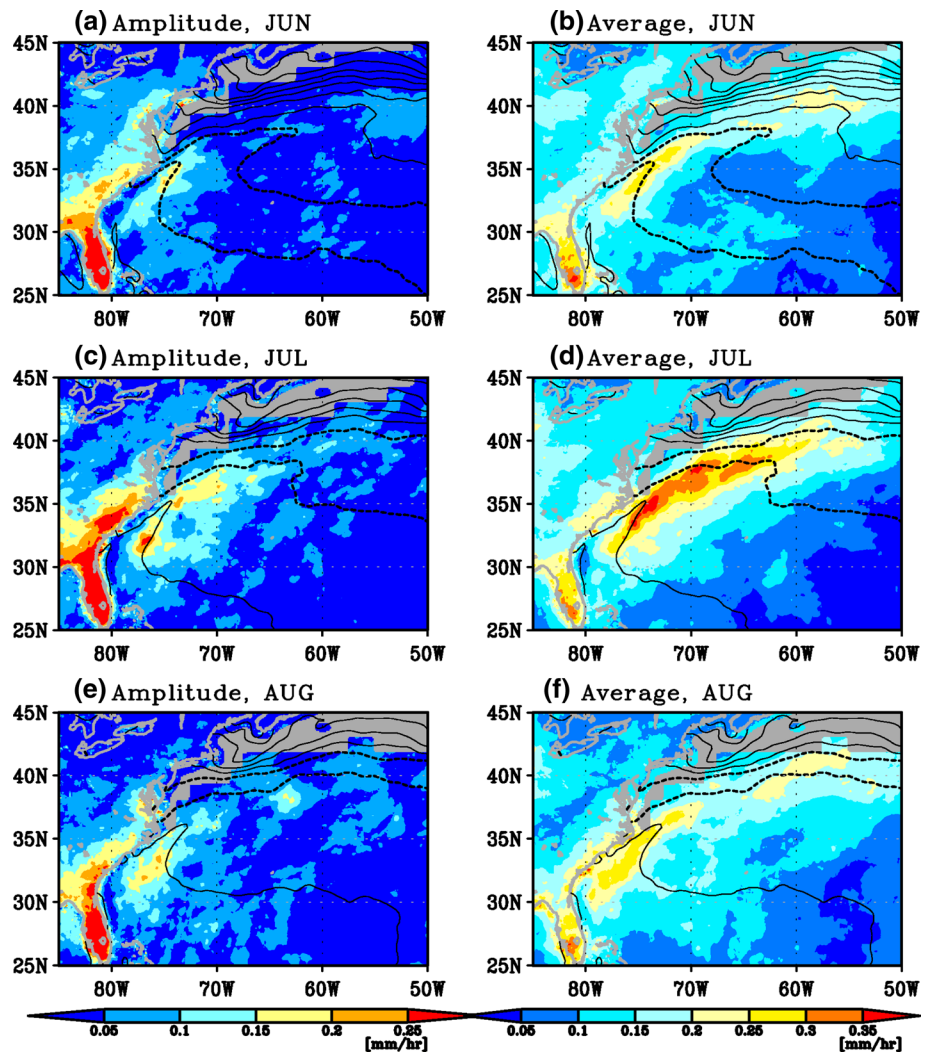

over the ocean in local morning, while over land it peaks in the local afternoon to evening (e.g., Dai et al. 2007; Kikuchi and Wang 2008). The phases over the Northern Hemisphere WBCs follow these general tendencies.

In boreal winter, diurnal precipitations in mid-latitude oceans are generally weak, especially over the mid-latitude WBCs (Fig. 3a). Moderately strong amplitudes are found over a region roughly corresponding to the North Pacific storm track (Hoskins and Hodges 2002), but corresponding relative amplitudes are generally smaller than 30 % (Fig. 3b). In the Southern Hemisphere, moderately large amplitudes ~ 0.06 mm/h are found off Brazil in the South

Atlantic, with the phases indicating a peak around noon (Fig. 3c). Although the diurnal cycles in the North Pacific and in the South Atlantic during boreal winter could be an interesting research subject in its own right, it falls beyond the scope of this paper, focusing as we do on diurnal cycles over the mid-latitude WBCs. Furthermore, amplitudes and relative amplitudes of these diurnal precipitation cycles are weaker than those found over the Northern Hemisphere WBCs in summer (Fig. 2). Therefore, we focus our attention on the diurnal variations over the Gulf Stream and the Kuroshio in boreal summer, closely examining their spatio-temporal structures in the following sections.

Fig. 4 Amplitudes of 24-h diurnal cycle (*left*) and mean rain rate (*right*) of precipitations over the Gulf Stream region in June (*top*), July (*middle*) and August (*bottom*). Gray areas in left panels are excluded from the analysis, because missing data rate due to presence of ice is larger than 20%. Contours in *each panel* indicate SSTs with a contour interval of every 2 °C and *dashed contours* for 24 and 26 °C

4 Gulf Stream analysis

Figure 4 shows climatological diurnal precipitation amplitudes, along with mean rain rate, over the Gulf Stream region in June, July and August. As reported by Minobe et al. (2010), who analyzed summer average precipitation, mean rain rate is enhanced over the Gulf Stream current axis. For convenient comparison, the spatial structure of the Gulf Stream is shown in Fig. 5. The monthly analysis indicates that the mean precipitation is especially strong in July, when the Gulf Stream rainband extends further east than in the other 2 months. The diurnal amplitudes are also strong over the Gulf Stream for all 3 months, with the maximum in July, but appear less well organized than the mean rain rate. The distribution of the strong diurnal amplitudes is also seen to be contracted westward compared with the spatial structure of the mean rain band. It is noteworthy that there are two local amplitude maxima in July; one occurs before the separation of the Gulf Stream from the coast (around 32°N, 77°W), and the other after

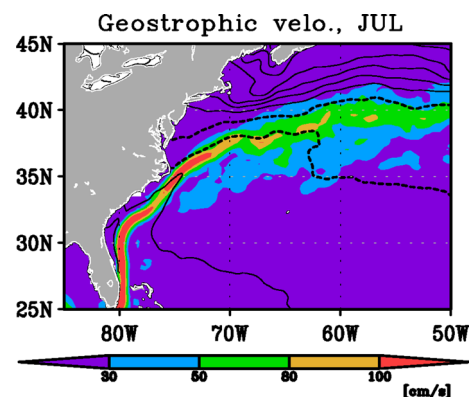

Fig. 5 Climatological absolute surface geostrophic velocity derived from satellite altimeter (*color*) and SSTs (*contours*) with a contour interval of every 2 °C and *dashed contours* for 24 and 26 °C in July

it (around 36°N, 70°W). The diurnal precipitation amplitudes over land are larger than those over the ocean, though magnitudes of mean rain rate over the ocean and land are

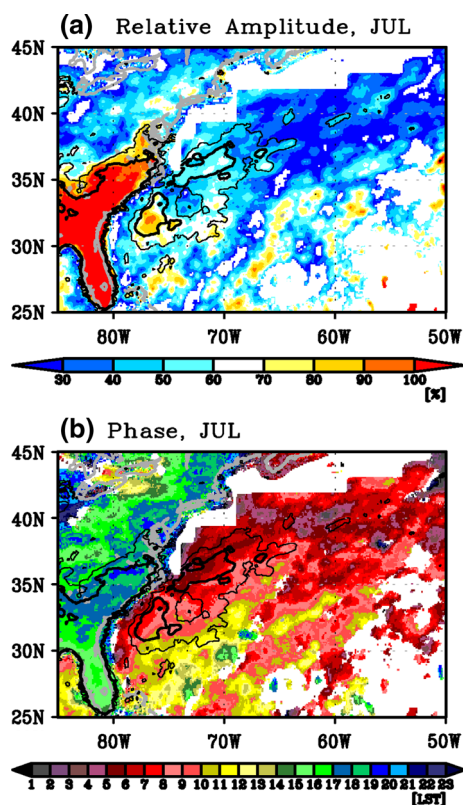

Fig. 6 **a** Relative amplitudes and **b** phases of the precipitation diurnal cycle over the Gulf Stream region in July. Phases shown by the time of maximum value of 24-h cycle in LST. Contours indicate 0.1 (*thin contour*) and 0.15 mm/h (*thick contour*) of the amplitudes shown in Fig. 4c. White regions are either missing data, due to presence of ice being larger than 20 %, or the amplitudes shown in Fig. 4c are smaller than 0.02 mm/h

comparable in June and August or are larger over the ocean in July. Although the strength of mean Gulf Stream rainband and the amplitudes of diurnal cycle are strongest in July, their spatial structures are similar during the 3 months in summer. This is in marked contrast to the Kuroshio region, where month-to-month changes of spatial patterns are quite large as will be shown later. In the rest of this section, we describe diurnal variability over the Gulf Stream in July, when the maximal diurnal precipitation amplitude is observed.

The spatial structure of relative amplitudes is not clearly associated with the Gulf Stream (Fig. 6a). Rather, large relative amplitudes (50–90 %) are found on and to the east of the Gulf Stream, over SSTs higher than about 26 °C. This means that diurnal precipitation occurs somewhat ubiquitously in this area over warm SSTs. Consequently, the large diurnal amplitudes over the Gulf Stream reflect large mean precipitation, which is an aspect of atmospheric response to the Gulf Stream (Minobe et al. 2010), combined with high relative amplitudes over warm SSTs not limited to the Gulf

Stream. The relative amplitudes over land exceed 100 % from the Florida peninsula to Cape Hatteras. The terrestrial high relative amplitudes suggest that precipitation occurs in narrower time periods than that expected from a sinusoidal wave. Indeed, this is the case, as will be shown below.

The phase of diurnal precipitation in July over the Gulf Stream (Fig. 6b) indicates that the diurnal precipitation peaks in the morning (about 5–11 LST). As mentioned previously, this early morning maximum is a common feature of diurnal precipitation cycles over the ocean (Yang and Slingo 2001; Dai et al. 2007; Kikuchi and Wang 2008). The phase generally increases seaward from the Gulf Stream, suggesting an southeastward phase propagation, with a phase speed in the range of 10–30 m/s. Seaward phase propagations of tropical diurnal precipitation cycles were reported in previous studies with speeds of 10–20 m/s, possibly due to gravity waves (Yang and Slingo 2001; Kikuchi and Wang 2008). For the aforementioned two amplitude maxima, the phase of the off-shore maximum slightly leads that of the near-shore maximum, indicating that precipitation occurs slightly earlier over the Gulf Stream after the separation than those before the separation with seaward propagation in respective regions. The phases over land indicate that the diurnal precipitation tend to peak in the late afternoon and early evening (about 15–19 LST), with phases in the Florida peninsula leading those along the coast north of 32°N.

As noted above, the diurnal precipitation cycles over the Gulf Stream and over land have roughly opposite phases. In light of this, it is natural to consider whether the diurnal precipitation cycle over the ocean is tightly related to that over land. For example, is diurnal precipitation variability over the Gulf Stream strongly influenced by the diurnal precipitation over North America? Or are these two diurnal variations are essentially independent? In order to gain some insight into these questions, we conduct a lag-correlation analysis using raw precipitation data. Here, lag-correlations at each grid point are calculated with respect to the area-averaged precipitation time series. Two reference time series are chosen; one is taken for the aforementioned near-shore diurnal amplitude maximum over the Gulf Stream (31–33°N, 78–76°W), and the other is taken from a region of strong diurnal precipitation cycle over land, along the same latitudinal band (31–33°N, 83–81°W). The observed significance of the correlations is estimated based on lag-correlations of large-lags, where data can be assumed to be uncorrelated. More specifically, we calculate lag correlations with large lags from 7 to 14 days every 6 h. In order to examine the significance at a specific grid point these large-lag correlations $\pm 5^\circ$ in latitudes and longitudes are collected. The collected correlations are then sorted in order their absolute correlations. If the observed absolute correlation is higher than top 5 % of the collected large-lag

Fig. 7 Lag correlation coefficients at each grid point along 32.05°N onto the reference area-averaged precipitation time series **a** in a region 83–81°W, 31–33°N over land and **b** in a region 78–76°W, 31–33°N over the ocean. *Positive lags* indicate reference time series leading to data at each grid point

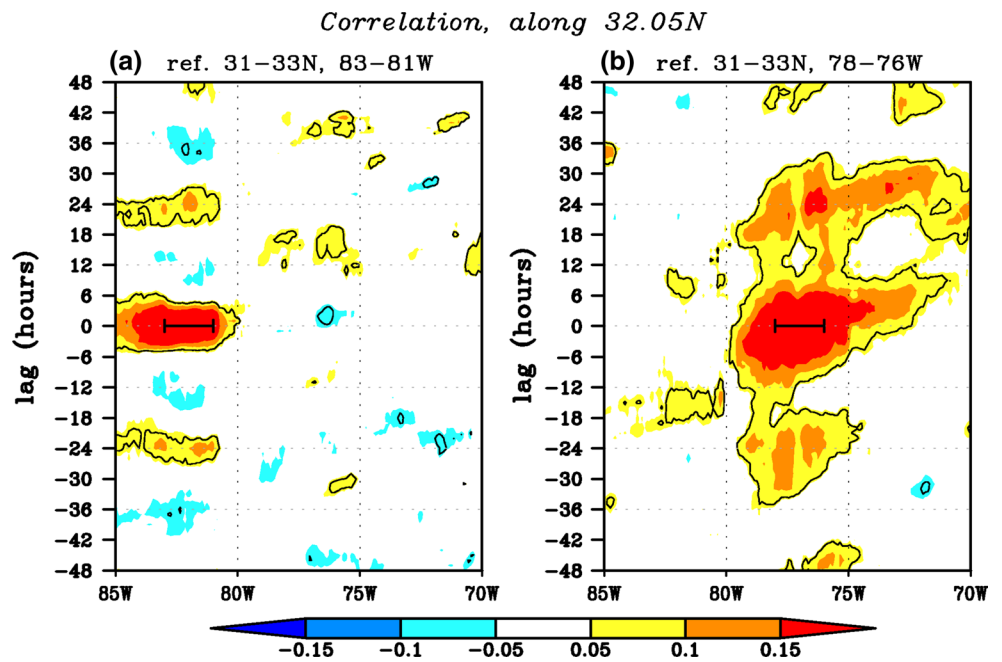

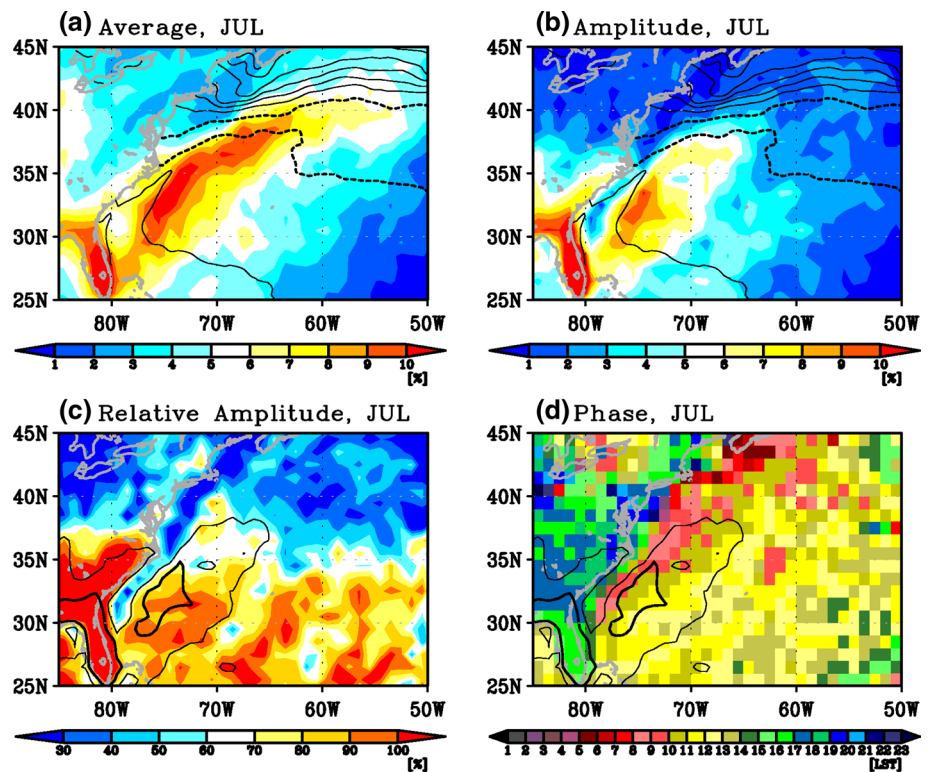

Fig. 8 **a** average, **b** amplitudes, **c** relative amplitudes and **d** phases of occurrence rate of high cloud estimated from OLR over the Gulf Stream region in July. Phases shown by the time of maximal value of 24-h cycle in LST. *Contours* in panels **a** and **b** are SSTs with a contour interval of 2 °C, where *dashed contours* indicate 24 and 26 °C, whereas *contours* in panels **b** and **c** are diurnal amplitudes of 5 and 8 %

absolute correlations, the observed correlation is considered to be significant at the 5 % significance level. This approach is better than the conventional theoretical estimation of significance, because raw hourly rain rate does not follow a Gaussian distribution, which is assumed for the theoretical estimation.

Figure 7 shows the lag-correlation at the central latitude of the reference time series (32°N). The lag-correlations do not show a significant out-of-phase relation between the ocean and land with either the land or ocean reference time series, indicating that the out-of-phase relationship between their respective diurnal climatologies in Fig. 6b

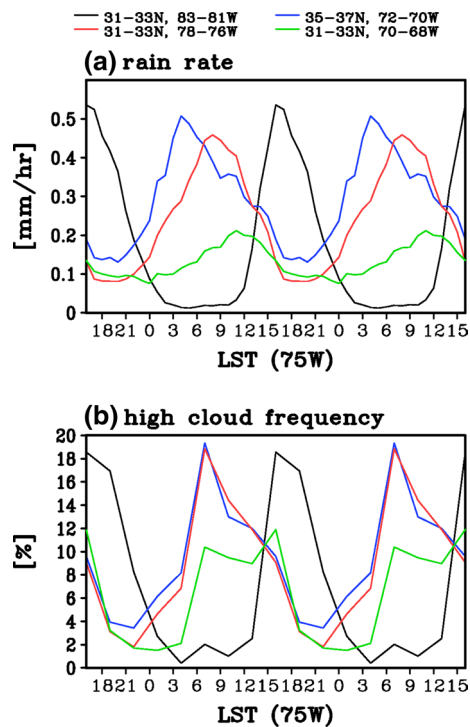

Fig. 9 Climatological time series of **a** rain rate and **b** high cloud frequency in July averaged over different box-areas. *Black line* is for a box over land (31–33°N, 83–81°W), *blue line* is for a box for the off-shore diurnal precipitation maximum (35–37°N, 72–70°W), *red line* is for a box for the near-shore diurnal precipitation maximum (31–33°N, 76–78°W), and *green line* is for a box to the east of the near-shore maximum (east of the Gulf Stream) (31–33°N, 72–78°W)

essentially arises independently. A weak land-leading relation is observed with +12 to 18 (–18 to 12) h lags Fig. 7a, b). Combined with the aforementioned afternoon and morning maxima of land and ocean diurnal precipitation, this relation means that occurrence of land-precipitation in one afternoon may slightly enhance the precipitation over the Gulf stream in next morning. Consistently, eastward propagation is seen in the lag-correlations over the ocean. The actual propagation direction is southeastward with the propagation speed about 5 m/s (not shown). This propagation speed is slower than the phase velocity estimated from the phase distribution in Fig. 6b. Alliss and Raman (1995) suggested that wind advection can cause a similar lag relation in cloud fields. Another possible mechanism may be gravity wave propagation (Yang and Slingo 2001; Mapes et al. 2003), but the clarification of the responsible mechanism is a subject of future study. Another interesting point of Fig. 7 is that positive correlations over the ocean are persistent during ± 36 h lags with the ocean reference time series (Fig. 7b) probably related to synoptic scale variability, whereas correlations over land with the land reference time series does not show such persistent tendency

but exhibit weak negative correlations around ± 12 h lags (Fig. 7a). This suggests that synoptic scale variability exhibits a stronger influence over the ocean than over land compared to diurnal cycles.

Diurnal variability is also seen in high-level clouds. Mean occurrence frequency of high-level clouds in July is enhanced along the Gulf Stream (Fig. 8a), consistent with a previous study (Minobe et al. 2008, 2010). Figure 8b shows that diurnal amplitudes of the occurrence frequency are large over the Gulf Stream west of 65°W, consistent with the diurnal precipitation amplitudes shown in Fig. 4c. The relative amplitudes of high cloud frequency (Fig. 8c) are generally larger than those of precipitations (Fig. 6a), as shown by much wider area of relative amplitudes greater than 90 % in the former. This indicates that the diurnal cycle is more apparent in high cloud frequency than in precipitation, suggesting that deep convection plays an important role in diurnal cycles. The phases for high cloud frequency (Fig. 8d) are delayed compared to those of the precipitation (Fig. 6b) by 1–2 h, but otherwise the overall spatial phase structure is quite consistent with that of the precipitation, including the southeastward phase propagation noted above. The time lag between the precipitation and high cloud occurrence may reflect the fact that the high clouds can be persistent for hours after the convection maximum (e.g., Gray and Jacobson 1977; Rickenbach et al. 2008). The pattern of amplitudes and phases of high-cloud frequency are generally consistent with those of high-cloud amount of ISCCP D2 dataset, though collocation between the amplitude maximum with the Gulf Stream current axis and southeastward phase propagations are not well resolved in the latter dataset due to coarse resolution (not shown).

Diurnal cycles may involve other components than the 24-h Fourier component, and hence it is interesting to see diurnal climatology time series at some locations. Figure 9a shows diurnal precipitation climatology time series at four locations (rectangular regions of $2^\circ \times 2^\circ$).¹ These regions are the aforementioned off-shore and near-shore diurnal amplitude maxima (blue and red curves, respectively), east of the Gulf Stream (green curve), and on land (black curve). The time series for the amplitude maxima exhibit relatively narrow peaks and wide troughs. Consistent with the large relative amplitudes described above, the difference of magnitude between the peak and the trough are remarkable. The diurnal maximum rain rate is more than four times (three times) larger than the diurnal minimum at the near-shore (off-shore) amplitude maximum. The

¹ Animation of diurnal climatology of rain rate over the Gulf Stream region in July (and also over the Kuroshio region in June examined in Sect. 5) is found at author's home page, http://www.sci.hokudai.ac.jp/~minobe/animation/diurnal_precip_WBCs/.

diurnal precipitation peak occurs at 4 LST for 75°W for the off-shore maximum and at 8 LST for the near-shore maximum, and time series in regions east of the Gulf Stream

exhibit further phase delay. These peak timings are consistent with the phase distribution of Fig. 6b, as the 4-h time lag is much larger than the about 30-min time difference in LST between these two regions. The time series over land shows a sharp, narrow peak in the afternoon, and very small rain rate in the morning (0–12 LST). The narrow peak combined with almost zero rain rate other times results in the relative amplitude larger than 100 %, as previously mentioned. These features of precipitation are generally shared by time series for high cloud occurrence rate (Fig. 9b), though phase difference over the ocean is less prominent.

5 Kuroshio

In this section, we describe diurnal cycles of precipitation and high cloud occurrence over the Kuroshio region. In particular, we focus our attention on similarities to and

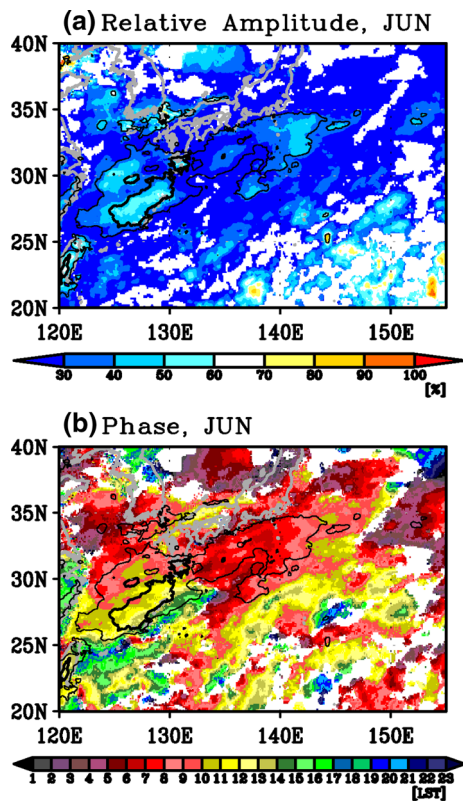

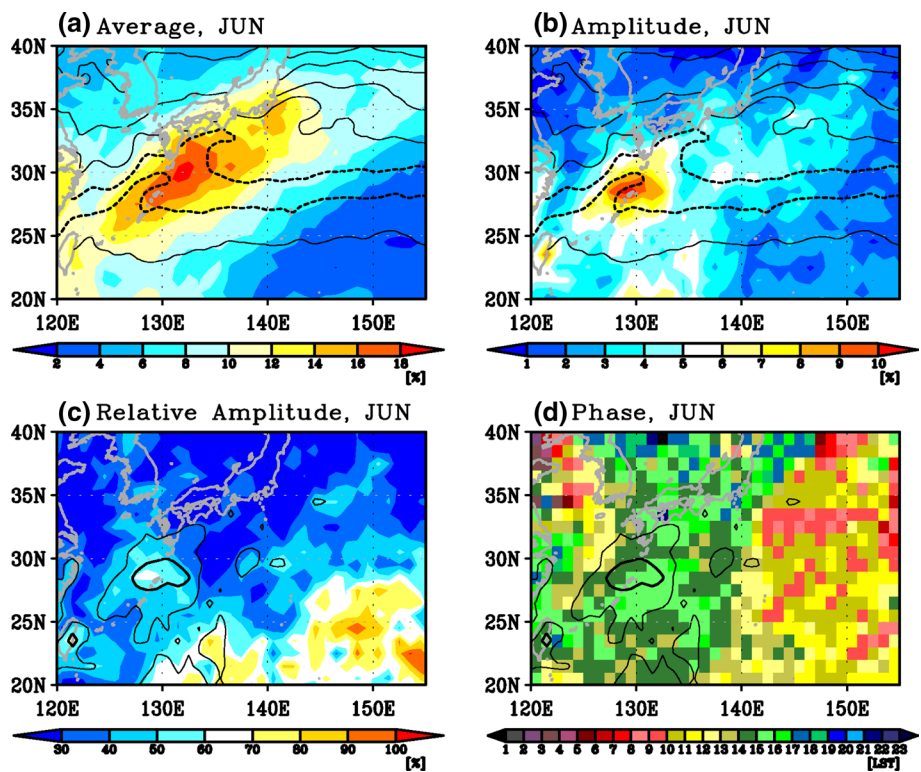

Fig. 12 Same as Fig. 6, but for the Kuroshio region in June. Contours indicate 0.1 (*thin contour*) and 0.2 mm/h (*thick contour*) of the amplitude shown in Fig. 10c

Fig. 13 Same as Fig. 8, but for the Kuroshio region. Note that the *color-scale* values for panel **a** are larger than those for Fig. 8a

differences from the diurnal cycles over the Gulf Stream described in the previous section. An important environmental factor in the Kuroshio region is the presence of the Baiu–Meiyu rain and cloud bands as introduced in Sect. 1. Baiu–Meiyu rainband typically begins in the middle of May, slowly moves northwards, and disappears in July as is somewhat reflected in the monthly mean rain rate (Fig. 10b, d, f). For example, the maximal rain rate in June to the south of the Kyushu is embedded in the large-scale Baiu–Meiyu rain/cloud band extending from southern China to the east of Japan, consistent with Fig. 3 of Sasaki et al. (2012), and relatively strong precipitation around 32–40°N in July is also associated with the Baiu–Meiyu rain band. Another important factor is that a vast land mass, similar to North America to the west of the Gulf Stream, does not exist around the Kuroshio. Therefore, a comparison of diurnal cycles between the two regions can give us some insight into the nature of the diurnal cycles over the WBCs. Again for convenient comparison, the surface geostrophic currents along with SSTs in June are shown in Fig. 11.

The strongest diurnal cycle is found in June over the Kuroshio in the East China Sea (Fig. 10c). In this month, mean rain rate is also the strongest, consistent with Sasaki et al. (2012) (Fig. 10d). The maximal diurnal amplitude is as high as 0.36 mm/h to the west of Ryukyu Islands, which is about 30 % larger than the maximum amplitude during July in the North Atlantic (0.28 mm/h), and this is

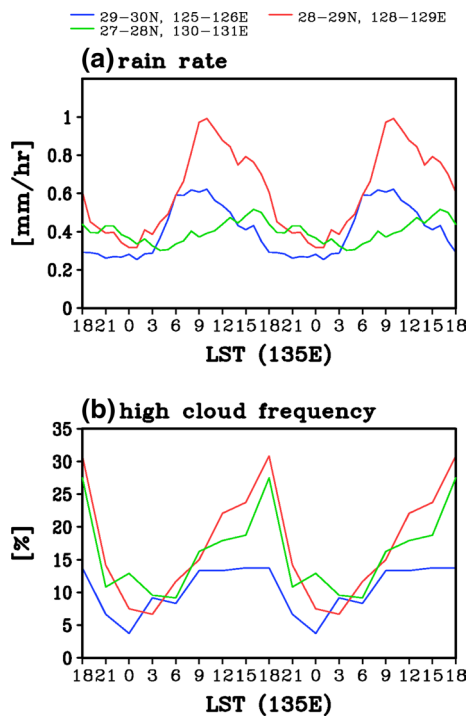

Fig. 14 Same as Fig. 9, but for the Kuroshio region in June. The *blue line* is for a box for the off-shore diurnal precipitation maximum (29–30°N, 125–126°E), *red line* is for a box for the near-shore diurnal precipitation maximum (28–29°N, 128–129°W), and *green line* is for a box to the east of the near-shore maximum (27–28°N, 130–131°W), corresponding to the west-northwest, middle, and east-southeast regions of the diurnal precipitation amplitude maximum in Fig. 10c, respectively

the largest diurnal precipitation amplitude over the mid-latitude global oceans in all calendar months. In June, the secondary amplitude maximum is seen to the south of Kyushu, and two patches of relatively high amplitude are found in the North Pacific to the south of Japan. These spatial features are not seen in the average precipitation, which is more smoothly distributed from the East China Sea to the North Pacific. The strong diurnal precipitations in the East China Sea are limited to June and not found in either May or July (Fig. 10a, c, e). This is in contrast to the diurnal cycle over the Gulf Stream, which exhibits similar spatial structures during all summer months. The rapid month to month transition of diurnal precipitations is closely related to the mean precipitation change, which is governed by the northward migration of the Baiu–Meiyu rainband (e.g., Wang and LinHo 2002). In the rest of this section, we closely examine diurnal cycles over the Kuroshio in June.

Despite the strong diurnal precipitation amplitudes over the Kuroshio in the East China Sea, the relative amplitudes in this region are slightly smaller than those over the Gulf Stream (Fig. 12a). This is because mean precipitation over the Kuroshio is much larger than that over the Gulf Stream,

and the maximum mean rain rate of the former region is about two times larger than the latter (Note that maximum value for the color scale of Fig. 10d is two times larger than that in Fig. 4d). The strong mean precipitation is associated with the large-scale Baiu–Meiyu rain band, in which enhanced precipitation due to the Kuroshio is located over the East China Sea (Sasaki et al. 2012). The Baiu–Meiyu rain band itself does not generally exhibit a strong diurnal cycle, as shown by weak relative amplitude south of Japan (Fig. 12a). These results indicate that the combination of the Kuroshio’s impact on the diurnal precipitation cycle and large-scale Baiu–Meiyu rainband with a weak diurnal cycle, is important for understanding the diurnal variations over the Kuroshio in the East China Sea.

Figure 12b shows the phase distribution of the 24-h components of precipitation over the Kuroshio region. Peak time for large diurnal amplitudes (say 0.2 mm/h or more) is 10–13 LST, few hours later than that over the Gulf Stream. Also, around the large diurnal amplitudes, phases indicate southeastward increase with the speeds of 10–20 m/s. The propagation direction is roughly the same as that in the Gulf Stream region, but the propagation speed over the Kuroshio is somewhat slower.

Diurnal variability is also found in high cloud occurrence in June over the Kuroshio. Mean high cloud occurrence (Fig. 13a) shows a similar spatial pattern to that of precipitation (Fig. 10d). The magnitude is again much larger than that over the Gulf Stream, consistent with precipitation. Diurnal amplitudes of high cloud occurrence exhibits a maximum over the Ryukyu Islands (Fig. 13b), roughly collocated with high amplitude region of diurnal precipitation variations. However, the location of the maximum high cloud amplitude is slightly shifted to the east compared to the precipitation maximum, which could be due to anvils advected by background westerlies. The maximum amplitude (11 %) is similar to the maximum value over the Gulf Stream (10 %). Relative amplitudes over the Kuroshio are, on the other hand, much smaller than those over the Gulf Stream (Figs. 8c, 13c), due to the larger mean high cloud occurrence rates. Therefore, for both the precipitation and high cloud occurrence, the diurnal component associated with the Kuroshio and the Gulf Stream have similar magnitudes, but the superimposed large-scale Baiu–Meiyu rain band without strong diurnal variability results in small relative amplitudes over the Kuroshio region.

Phases of the 24-h component of high cloud occurrence rate exhibit peaks in the early afternoon (12–16 LST) over regions of strong amplitudes, straddling the East China Sea and the western North Pacific (Fig. 13d). In this region, phases of high cloud occurrence are delayed by 2–3 h compared with those of precipitation, and this delay is slightly longer than is found over the Gulf Stream. An southeastward phase propagation is found for the large amplitude

Fig. 15 Schematics of some essential features of the diurnal precipitation and high cloud cycles over the Gulf Stream (a) and the Kuroshio in the East China Sea (b). The Gulf Stream and the Kuroshio are indicated by the *green arrows*. Diurnally modulated precipitations and high clouds are shown by *rain drops* and *cloud shapes*, respectively. *Oval in panel b* indicates large-scale Baiu–Meiyu rain/cloud band. The *wavy arrows* indicate southeastward phase propa-

gation of diurnal precipitations and clouds. In both regions, strong diurnally modulated precipitations and cloud cycles are found over the Gulf Stream and the Kuroshio, with southeastward phase propagation. Somewhat similar diurnal cycles are found to the east of the Gulf Stream with weaker amplitudes. The strong diurnal cycle over the Kuroshio is embedded in large-scale Baiu–Meiyu rainband, which does not have prominent diurnal cycles

region, consistent with precipitation. The phase and amplitude distributions of high-cloud frequency derived from OLR data are generally consistent with those of high-cloud amount of ISCCP D2 dataset (not shown).

Figure 14 shows diurnal climatology time series of precipitation and high-cloud occurrence rate at three locations around the diurnal precipitation amplitude maximum. Consistent with the aforementioned phase propagation, the time at which the diurnal precipitation peak occurs is increasingly delayed in the southeastward direction (Fig. 14a). Interestingly, the peak of high-cloud frequency in the region of the precipitation amplitude maximum occurs in evening, 18 LST, delayed by about 8 h compared to the precipitation peak (Fig. 14b). The reason why the peak time difference in the East China Sea is much larger than that over the Gulf Stream is not known to the authors, and is a potential subject of future study.

6 Discussion and conclusions

Diurnal variations over the mid-latitude oceans are analyzed using an hourly, satellite-derived precipitation dataset (GSMaP MVK ver. 5) and 3-hourly OLR data from the SRB project. Previous studies have also described diurnal precipitation cycles, including the mid-latitude oceans (e.g., Dai et al. 2007), although the link between diurnal precipitation cycles and WBCs is analyzed comprehensively in this study. It is found that over mid-latitude oceans, poleward of 25°N/S, strong diurnal cycles occur over the Northern Hemisphere WBCs, i.e., the Gulf Stream and the Kuroshio, in the boreal summer season (Fig. 2). No prominent diurnal precipitation is found over the WBCs in the Southern Hemisphere the whole year round (Figs. 2, 3).

There are some common features but also differences in the diurnal cycles between the regions over the Gulf Stream and the Kuroshio. In both regions, maximum amplitudes of diurnal precipitation occur roughly over the current axes with a pattern contracted westward compared with the rainbands, more specifically, just before and after the separation at the Cape Hatteras for the Gulf Stream (Fig. 4) and west of Ryukyu Islands in the East China Sea for the Kuroshio (Fig. 10). The maximum amplitudes are slightly larger over the Kuroshio than over the Gulf Stream. The diurnal phases commonly exhibit southeastward propagation, with peak times for the large amplitudes being from early to late morning (5–11 LST) for the Gulf Stream (Fig. 6b) and from late morning to noon (10–13 LST) over the Kuroshio in the East China Sea (Fig. 12b). Occurrence frequencies of high clouds exhibit diurnal cycles consistent with those of the precipitation. The relative amplitudes of high cloud occurrence are larger than those of precipitation, suggesting that the diurnal precipitation is mainly due to deep convection, consistent with studies of tropical diurnal precipitation over the oceans (e.g., Janowiak et al. 1994; Yang and Slingo 2001). Near the Gulf Stream, diurnal precipitation cycles over North America are roughly 180° out-of-phase of those over the ocean (Fig. 6b). The lag-correlation analysis shows that a direct link between oceanic and terrestrial diurnal cycles is not strong (Fig. 7), if it exists at all, and thus they probably originate different physical mechanisms.

Major differences between the diurnal cycles over the Gulf Stream and those over the Kuroshio are likely to be associated with the presence of large-scale Baiu–Meiyu rainband, consistent with Sasaki et al. (2012) who suggested that local atmospheric response to the Kuroshio in the East China Sea is embedded in large-scale Baiu–Meiyu rainband. The seasonal northward migration of

Baiu–Meiyu rainband, associated with development of the subtropical high, yields substantially different diurnal precipitations from a month to month. The prominent diurnal precipitation is limited to June (Fig. 10), the peak month of the Baiu–Meiyu precipitation over the East China Sea. On the other hand, the spatial patterns of the diurnal and mean precipitation over the Gulf Stream do not change much from June to August, with the maximum amplitude occurring during July (Fig. 4). The maximum mean rain rate over the Kuroshio in the East China Sea and south of Japan in June is roughly two times larger than that over the Gulf Stream in July (Figs. 4, 10). The large mean rain rate associated with the Baiu–Meiyu rainband results in smaller relative amplitudes over the Kuroshio than are found over the Gulf Stream (Figs. 6a, 12a). The large relative amplitudes of precipitation and high cloud occurrence are widely distributed over warm SSTs in the North Atlantic. Large relative amplitudes over the Kuroshio region, however, are only found in the vicinity of the Kuroshio itself. This does not necessarily mean that diurnal precipitations do not occur over a wider area, but if they occur, they may be obscured by the large-scale Baiu–Meiyu rainband in which prominent diurnal cycles are absent. Major features of the diurnal precipitation and high cloud cycles are summarized in Fig. 15.

The diurnal cycles are likely to be closely associated with the deep heating mode of the atmospheric response to the WBCs. The spatial and seasonal distributions of the strong deep heating mode found in previous studies (Minobe et al. 2010; Sasaki et al. 2012) and those of diurnal precipitation appear to be similar to one another. This is not surprising, because as discussed in Sect. 1, it is known that diurnal precipitation variability is strong in the tropics, and the deep heating mode is a tropical-like atmospheric response to ocean fronts over SSTs warmer than 24–26 °C (Minobe et al. 2010). It is noteworthy that diurnal precipitation variability over the Gulf Stream and the Kuroshio has higher relative amplitudes than those over most of the tropics. Furthermore, contributions of diurnal cycles to average rain rate are larger over the WBCs than in the ITCZ and SPCZ, and thus diurnal variability can be an important agent for producing in mean precipitations in the WBC regions. Consequently, it is strongly suggested that the diurnal precipitation and cloud cycles are intrinsic and important aspects of the deep heating mode.

A natural question is what mechanism is responsible for the diurnal cycles over the Gulf Stream and the Kuroshio? This is an open question not only for the diurnal cycles over these WBCs but also for diurnal cycles over the tropical oceans, which have been much more widely studied (e.g., Dai et al. 2007; Kikuchi and Wang 2008). Yang and Smith (2006) summarized twelve proposed mechanisms for diurnal precipitation. Among these mechanisms, a

morning maximum may be produced by two mechanisms. One mechanism is static radiation convection, in which radiative cooling from the top of clouds during the night time destabilizes the upper cloud, and thus increases convection and precipitation (e.g., Kraus 1963; Randall et al. 1991). Another mechanism is static radiation convection with enhanced moistening (Tao et al. 1996; Sui et al. 1997). In this mechanism, enhanced night time radiative cooling increases humidity, and thus amplifies condensation and precipitation. It is interesting to examine whether one of these, or other, mechanisms play a role over the WBCs in future study. The southeastward phase propagations observed over the Gulf Stream and East China Sea are somewhat reminiscent of previously reported seaward phase propagations of diurnal precipitation cycles in the tropics (Yang and Slingo 2001; Kikuchi and Wang 2008). It is suggested that the tropical seaward phase propagation is due to gravitation waves, which can be generated by topographic effects (Mapes et al. 2003) or land convection (Zuidema 2003). Another possible mechanism for the phase propagation is advection by background winds, as has been suggested for diurnal cloud developments over the Gulf Stream region (Alliss and Raman 1995).

In order to identify the mechanism, atmospheric numerical models should be useful. Indeed, Fig. 6 of Dirmeyer et al. (2012) shows that enhanced diurnal precipitation over the Gulf Stream are somewhat reproduced by several numerical models. However, in that paper, which focuses on diurnal precipitations over North America, phases over the North Atlantic are masked out due to small amplitudes for most of models, and thus it is not clear whether these models can reproduce the observed phase distribution. A model whose phase distribution over the western North Atlantic was shown in that paper is the Nonhydrostatic Icosahedral Atmospheric Model (NICAM), which exhibits reasonable phase difference between the off-shore region and near-shore region along the Gulf Stream, but the seaward phase increase is not seen (Fig. 5 in their paper). Nevertheless, a reasonable step for identifying the mechanism for the diurnal cycle in real world may be to examine these and other model outputs to assess the degree to which they can reproduce the diurnal cycles and to then identify the responsible mechanisms.

It should be worth noting that successfully capturing the diurnal cycle in numerical atmospheric models can be essential in producing mean realistic distributions of precipitation and thus atmospheric heating. Moisture used for the precipitation over the Gulf Stream and the Kuroshio is supplied by the local evaporation and moisture transport from the south along the west flank of the subtropical high (Minobe et al. 2010; Sasaki et al. 2012). The diurnal cycle can thus play an essential role in turning the moisture into precipitation in the relevant locations. If this hypothesis is correct, numerical

model tunings, which primarily focus on the diurnal cycle, can improve not only the diurnal cycle itself but also mean precipitation distributions. This hypothesis can be examined by changing parameterizations or radiation forcings in a model. According to this hypothesis, the diurnal cycle can be important not only in the context of weather, but also from a climate perspective. Consequently, the diurnal cycles over the Gulf Stream and the Kuroshio, which may be an intrinsic aspect of the deep heating mode, link the ocean and the atmosphere, and also possibly weather and climate.

Acknowledgments Many thanks for Dr. C. O'Reilly for comments on the English and also on the science, and for two anonymous reviewers for their helpful and constructive comments. This work was supported by the Japan Society for the Promotion of Science (Grant-in-Aid for Scientific Research 22106008 and 22244057).
