Abstract The Epstein-Barr virus (EBV)-positive subtype of gastric adenocarcinoma is conventionally identified by in situ hybridization (ISH) for viral nucleic acids, but nextgeneration sequencing represents a potential alternative. We therefore determined normalized EBV read counts by whole-genome, whole-exome, mRNA and miRNA sequencing for 295 fresh-frozen gastric tumor samples. Formalin-fixed, paraffin-embedded tissue sections were retrieved for ISH confirmation of 13 high-EBV and 11 low-EBV cases. In pairwise comparisons, individual samples were either concordantly high or concordantly low by all genomic methods for which data were available. Empiric cutoffs of sequencing counts identified 26 (9 %) tumors as EBV positive. EBV positivity or negativity by molecular testing was confirmed by EBER-ISH in all but one tumor evaluated by both approaches (kappa = 0.91). EBV-positive gastric tumors can be accurately identified by

Introduction

Epstein-Barr virus (EBV) is a recognized carcinogenic agent for several malignancies, accounting for about 200,000 new cancer cases annually worldwide [1]. Approximately 9 % of gastric adenocarcinomas have latent EBV infection in every tumor cell [2]. In viral-positive tumors, the nucleic acids typically present as monoclonal episomes with uniform terminal repeats, indicating infection was present at the time of transformation in the clonal progenitor cell [3]. EBV-positive adenocarcinoma cases differ from other gastric cancers, exhibiting distinct epidemiological (e.g., male predominance, post-gastrectomy), pathological (e.g., preferentially non-antral anatomic subsites) and clinical (e.g., better survival) features [2, 4, 5]. Based on a comprehensive molecular analysis of 295 gastric adenocarcinomas performed by The Cancer Genome Atlas (TCGA), EBV positivity was identified to mark one of four molecularly distinct subtypes of this disease. EBV-positive tumors were characterized by extreme DNA CpG island hypermethylation phenotype (CIMP), frequent PIK3CA mutation, absence of TP53 mutation and recurrent amplifications of the chromosome 9 locus containing JAK2, CD274/PD-L1 and PDCD1LG2/PD-L2 [6].

EBV is almost ubiquitous in the human population, primarily maintained as a latent infection in a subset of

B-lymphocytes comprising roughly 10^{-5} peripheral blood mononuclear cells. Detection of EBV in tumor tissue is therefore needed to implicate the infection in gastric carcinogenesis. However, the tissue inflammation often present in gastric cancer may lead to infiltration of EBVinfected leukocytes as a nonspecific source of viral sequences. Conventionally, EBV is localized to particular cells within tumor tissue by in situ hybridization (ISH) for EBV-encoded small RNA (EBER) types 1 and 2, abundant untranslated transcription products of unknown function [7]. This assay is considered to be the "gold standard" for assigning EBV status based on its high sensitivity and specificity, as long as an adequate quantity and integrity of lesional tissue are available [8]. Importantly, in situ analvses can determine whether virions are localized within tumor cells or a different tissue compartment.

Massive parallel sequencing methodologies offer an alternative approach for detecting nucleic acids originating from infectious agents. In the current study, we determine assay cutoffs for distinguishing EBV-positive gastric cancer from other molecular subtypes in sequencing data from TCGA and evaluate agreement among four genomic technologies as well as with conventional EBER-ISH.

Methods

EBV sequences in nucleic acid extracts of 295 fresh-frozen gastric adenocarcinoma samples from TCGA were determined by whole-genome (n = 77),whole-exome (n = 263), mRNA (n = 237) and miRNA (n = 293)sequencing and normalized to corresponding human sequence counts, as previously reported [6]. Briefly, DNA or RNA sequence reads matching EBV were identified by the PathSeq [9] or BioBloom [10] algorithms, respectively. Viral DNA abundance was normalized to human sequences by dividing #reads mapped to the microbe by #reads mapped to human in the sample/average #reads mapped to human in the sample cohort/4.857, the latter constant representing the ratio of the genome size of EBV to the average of all viruses. RNA counts were normalized by millions of total reads sequenced as the #reads mapped to the microbe $\times 10^6$ /#chastity passed reads. Tumor EBV status was provisionally classified based on detection of high or low normalized viral read counts by at least two sequencing platforms. All patients provided informed consent, and local Institutional Review Boards approved tissue collection.

For comparison to conventional determination of EBV status, we retrieved formalin-fixed, paraffin-embedded (FFPE) tissue sections from a matched tumor block for 13 high-EBV cases and 11 low-EBV cases selected at random from the same tissue source. EBER-ISH was performed at

the University of North Carolina. Briefly, three adjacent sections were stained by hematoxylin and eosin and by ISH for EBER and for oligodT control RNA to confirm RNA integrity, with inclusion of known EBER-positive and -negative tumors as external controls. Hybridization was performed using the Leica Bond system with 5 min of protease digestion and 2 h of probe hybridization. A tumor was interpreted as EBV negative if EBER staining was undetected or only localized to benign-appearing lymphoid cells and EBV positive if EBER staining was localized to the nucleus of malignant epithelial cells, as previously described [11]. Cases with unsatisfactory or indeterminate results were re-tested using additional sections from the same block. Histopathologic examinations and ISH were performed under code such that laboratory personnel did not have access to the results of molecular testing.

Relative frequencies of log-transformed EBV read counts were graphed as probability density functions using *z*-scores normalized by subtracting mean counts and dividing by standard deviations. Scatterplots were used to compare sample measurements and cutoffs selected empirically to optimize concordance across assay platforms. Spearman rank correlations between read counts on different platforms were calculated for EBV-positive and -negative tumors separately and for all tumors combined, with p values less than 0.05 considered statistically significant. Sensitivity, specificity and kappa statistics were calculated for conventional EBER-ISH as compared to genomic-assigned EBV status. All statistical analyses were performed using StataSE v13 (College Station, TX).

Results

By each of the four methods of whole-genome, wholeexome, mRNA or miRNA massive parallel sequencing, numbers of normalized EBV reads across individual samples were bimodally distributed, with distinct separation of a minority of tumors having substantially higher counts. For each platform, the two modes of log-transformed values were separated by approximately three standard deviations (Fig. 1).

Pairwise comparisons of the four sequencing platforms indicated that individual samples were either consistently high or consistently low by all genomic methods for which data were available. Log-log scatterplots of the 295 TCGA samples were confined to upper right and lower left quadrants only (Fig. 2).

Overall quantitative counts were moderately correlated (all p values <0.001), with Spearman rank correlation coefficients (Rho) ranging from 0.2 to 0.8 (Table 1). Stratified by EBV status, counts were less correlated. Among EBV-positive tumors, the only significant

correlation among the four genomic platforms was between miRNA and mRNA (Rho = 0.6). Among EBV-negative tumors, four of the six pairwise correlations were significant, with higher correlation between mRNA and whole-genome (Rho = 0.6) and lower correlations for the other three comparisons (Rho <0.3).

By comparing distributions of the genomic data, empiric cutoffs were defined as 1000 normalized EBV reads for whole-genome sequencing, 100 for exome, 4 for mRNA and 5000 for miRNA for perfect concordance in identifying 26 (9 %) EBV-positive samples among the 295 TCGA tumors analyzed (Table 2).

Fig. 1 Probability density plots of normalized EBV read counts in gastric cancer tissues by whole-genome (WGS; n = 77), exome (n = 263), mRNA (n = 237) and miRNA (n = 293) sequencing

Fig. 2 Pairwise comparisons of normalized EBV read counts in gastric cancer tissues by wholegenome (WGS), exome, mRNA and miRNA sequencing. Solid circles represent EBER-positive tumors (n = 14), open circles represent EBER-negative tumors (n = 9), and dots indicate TCGA tumors not tested by in situ hybridization (n = 272) In blinded evaluations of 24 gastric cancer tissues, 13 cases exhibited distinct EBER localization to tumor cells (Fig. 3); initial assay results were equivocal for a 14th case that on re-testing was classified as EBER positive with some background staining. Nine tumors were clearly EBER-ISH negative. One case was unclassifiable because sampled fixed tissue did not contain any tumor cells in two separately evaluated sections.

For the 23 tumors with EBV status determined by both genomic and conventional approaches, agreement was observed in all but one case (Fig. 2). The sole exception was the tumor with initially equivocal EBER-ISH results, reclassified as positive; this case was EBV negative by both mRNA and miRNA sequencing and was classified as microsatellite instability-type gastric cancer by DNA methylation and other genomic data. Assuming greater accuracy of the molecular assignments, EBER-ISH was 100 % sensitive and 90 % specific with a kappa statistic of 0.91, representing 96 % observed agreement between conventional and molecular assignment of EBV status.

Discussion

The current study capitalizes on TCGA data on a large set of gastric cancer specimens collected under standardized conditions with detailed annotation and subjected to multiple analytical platforms. Four different next-generation sequencing methods had perfect concordance classifying the EBV status for gastric cancer tissues. The accepted

standard technique of EBER-ISH had excellent agreement with the genomic classification, with one presumed false positive in the presence of background hybridization.

Our data suggest that next generation sequencing platforms may provide an accurate replacement for conventional ISH. However, there are several potential hurdles to practical implementation for routine use. Quantitation of viral sequences may vary because of differences in specimen processing, assay protocols and inherent batch-tobatch fluctuation [12]. The specific cutoffs generated for this sample set may not be applicable to other cases, and testing laboratories need to determine their own criteria for establishing EBV positivity. Furthermore, these excellent genomic results were obtained on frozen tissues of optimal nucleic acid quality; replication is needed on a wider variety of sample types, including fixed tissues.

The robust detectability of EBV by whole-exome sequencing was unexpected. Our target enrichment platform (Agilent SureSelect Human All Exon) utilized 120-nucleotide RNA baits designed to capture all human exons with relative exclusion of other DNA sequences. Nevertheless, there were sufficient off-target reads to detect at least some portion of the viral genome in every EBV-positive gastric tumor. An alternative strategy pursued for TCGA analysis of esophageal cancer is to supplement the exome capture library with 120 mer probes specifically designed to cover cancer-related viruses, based on spacing, GC content, repeat content and lack of similarity to human sequences (Michael McLellan, personal communication).

EBV-positive gastric cancer tissues have much higher levels of viral miRNA compared to EBV-negative tumors [13]. Viral-derived miRNAs may also be detected in various body fluids [14], and levels in blood plasma have been evaluated as diagnostic and prognostic markers for nasopharyngeal carcinoma, the second most frequent EBV-associated malignancy [15, 16]. Circulating blood levels of EBV miRNA warrant investigation as a potential noninvasive test for EBV-positive gastric cancer when tumor tissue is inadequate or unavailable for direct assessment.

EBV-positive gastric cancers exhibit a restricted transcription pattern of viral genes, with most of the highly expressed sequences encoded in the *BamH1A* gene region of the genome [6, 17]. These transcripts and their protein products are candidate targets for functional studies to explore mechanisms of viral carcinogenesis. Elucidating the viral contribution to gastric cancer pathophysiology could lead to novel strategies for prevention and treatment, with possible extension to other EBV-related malignancies.

The recognition of EBV-positive gastric cancer as a distinct entity has informed scientific understanding of gastric carcinogenesis. Increasing availability of massive

parallel sequencing will facilitate routine identification of these tumors for clinical translation of important research findings.
