Model predictive cooperative localization control of multiple UAVs using potential function sensor constraints

A workflow to create sensor constraint based potential functions for the control of cooperative localization scenarios with mobile robots

Abstract

The global localization of multiple mobile robots can be achieved cost efficiently by localizing one robot globally and the others in relation to it using local sensor data. However, the drawback of this cooperative localization is the requirement of continuous sensor information. Due to a limited sensor perception space, the tracking task to continuously maintain this sensor information is challenging. To address this problem, this contribution is presenting a model predictive control (*MPC*) approach for such cooperative localization scenarios. In particular, the present work shows a novel workflow to describe sensor limitations with the help of potential functions. In addition, a compact motion model for multi-rotor drones is introduced to achieve *MPC* real-time capability. The effectiveness of the presented approach is demonstrated in a numerical simulation, an experimental indoor scenario with two quadrotors as well as multiple indoor scenarios of a quadrotor obstacle evasion maneuver.

1 Introduction

During the last years, there has been a dramatic increase in the use of Unmanned Aerial Vehicles (*UAVs*) for all kind of applications such as surveillance, aerial photography, transport, etc. However, the fast dynamics of these systems and the extended operational space makes their autonomous piloting a challenging task. The recent development (Wingfield 2016) of applications for such systems targets not only autonomous flying of single *UAVs*, but also the coordinated interaction of multiple *UAVs* or of *UAVs* and ground robots. One essential task herein is the precise localization of these *UAVs* and robots in their environment.

The precise global navigation of *UAVs* though typically requires expensive specialized equipment such as differen-

Fig. 1 Cooperative localization scenario

tial *GPS* in outdoor applications or laser-/RF-based global positioning systems in indoor applications. For cooperative mobile robot scenarios, one idea is therefore to deploy a reduced number of mobile robots which are equipped with the costly global localization system. The broadcasting of their global position allows all other *UAVs* to determine their own global position based on the relative position to these *UAVs*. The determination of the relative position can be achieved by less expensive onboard sensors such as optical sensors as shown in Fig. 1 in a *UAV* scenario. The major problem of this approach is the necessity to continuously detect and track the globally localized robots with sufficient accuracy. This is further exacerbated by very dynamical *UAV* scenarios and the onboard sensor limitations. Accordingly, the *UAV* motion has to be controlled in order to keep the globally localized *UAVs* within the perception space of the onboard sensors. The major focus of this work is therefore to provide a central control strategy for such cooperative localization scenarios. To limit the scope of this paper, the estimation and localization itself are not addressed and a stable communication channel is assumed. Yet, it should be mentioned that all robot systems considered here do have internal controllers. A communication failure would thus only lead to missing localization data, but not to a complete system failure.

One method to handle such complex control scenarios is model predictive control. *MPC* allows defining the control objective by means of an optimization problem. This so-called optimal control problem (*OCP*) is minimizing a given objective function subject to constraints. In general, the computational burden to solve an *OCP* is high. Hence, the efficiency of the applied solver is limiting the complexity of the controlled real-time scenarios. Nevertheless, a central *MPC* is well suited to control a small amount of robots. Such a central control simplifies the implementation of safety features and allows the computation of a global *OCP* solution without considering additional consensus techniques. However, the presented methods here are also applicable for distributed controllers which will be addressed in future work.

One essential factor for fast *MPC* is a compact description of the system's behavior. To tackle this problem, the first contribution of this work is a novel compact motion model for multi-rotor systems which is described in Sect. 4. This simplistic motion model is based on a semi-nonlinear model for multi-rotor *UAVs* from previous work (Dentler et al. 2016a). Due to its angle discontinuity problem, as shown experimentally in Sect. 4.1, this previous model is not suitable for sensor tracking as considered within this work. To address this issue, Sect. 4.2 is presenting a model, where the typical orientation description with a single yaw ψ angle is replaced by a direction vector description. For validation, Sect. 4.3 is showing the *MPC* of a real *AR.Drone 2.0* quadrotor based on the derived direction vector model. The same modeling approach can also be adapted to other velocity controlled mobile robot systems.

Another difficulty of *MPC* is the translation of the considered control scenario into an *OCP*. For this purpose, the second major contribution of this paper is a workflow that allows to represent sensor limitations in the form of potential functions, as presented in Sect. 5. The considered use case is a sensor tracking scenario which is introduced in Sect. 5.1. In this scenario, a quadrotor is controlled to keep an object within the cone-shaped perception space of the attached sensor. In this context, the sensor limitations are described as inequality constraints. These are subsequently transformed into weakened constraints that just appear in the *OCP* cost function, as shown in Sect. 5.2. This transformation is executed with unit steps and is recommended to maintain a low complexity which facilitates the mathematical and graphical validation of the resulting potential function. To improve the properties of the potential function for gradient and Newton based *OCP*-solvers, Sect. 5.3 is dedicated to the introduction of artificial gradients in undesired regions of the potential function. As last step, Sect. 5.4 is showing how the potential function is finally transformed into an analytical function by approximating all unit step functions by sigmoids.

For the experimental validation in the laboratory, additional safety constraints are introduced in Sect. 6, based on the described workflow. This includes further potential functions to avoid collision in Sect. 6.1 and to limit the operational space in Sect. 6.2. Section 7 is finally presenting the validation of the deduced potential functions in the use case scenario and the chosen control parameters. The numerical validation is described in Sect. 7.1, using the simulation environment *V-REP*. Section 7.2 is subsequently showing the results of the proposed control approach on real *AR.Drone 2.0* quadrotors. In the following Sect. 7.3, the influence of obstacles, utilized constraints and different initial conditions is discussed on the basis of a set of collision avoidance scenarios in which a *UAV* is evading an obstacle while tracking a target.

Finally, conclusion and future perspective are given in Sect. 8.

2 Related work

In order to solve a cooperative sensor based robot localization, the problem can be divided into a self-localization and a position tracking problem. The present work is focusing on providing a control strategy for the position tracking problem.

To be able to localize a robot by another robot while executing tasks, both robots have to be controlled in a cooperative manner. There is extensive literature regarding such cooperative control scenarios. A comprehensive overview of the subject is given by Gazi and Passino (2011) and (Zhang and Mehrjerdi 2013). Gazi and Passino (2011) is discussing the theory of swarm mechanics and interaction constraints while Zhang and Mehrjerdi (2013) is providing a survey on formation control and coordination of multiple robots. According to Zhang and Mehrjerdi (2013) the coordination and control algorithms can be classified in leader-follower, behavioral based, virtual structure, graph based and potential field based approaches. The leader-follower principle is a well-established approach for non-holonomic mobile robots (Consolini et al. 2008; Cui et al. 2009), particularly regarding decentralized controllers in order to maintain the flexibility of a distributed system. These decentralized controllers are typically based on feedback linearization (Ge and Cui 2002; Desai et al. 1998) or backstepping and can be adapted to different tasks by switching the control law (Das et al. 2002). The same control approaches can also be found in behavioral (Lawton et al. 2003), virtual structure (Beard et al. 2001; Mehrjerdi et al. 2011), graph theory based (Fax and Murray 2004; Cai and Queiroz 2015; Dong and Farrell 2008) and artificial potential (Nascimento et al. 2014, 2013) based control approaches.

A more generic tool for multi-robot control is *MPC* which is based on formulating the control scenario as optimization problem. One typical example of *MPC* for UAVs is trajectory tracking in formation flight while considering collision avoidance constraints. Examples of a centralized *MPC* of cooperative control scenarios is given in Shin and Kim (2009) and Alrifaaee et al. (2014). In Shin and Kim (2009) a leader-follower mode is used to perform airplane formation flight with collision avoidance using nonlinear *MPC*. For this purpose Shin and Kim (2009) compares centralized, sequential decentralized and fully decentralized methods of nonlinear *MPC*. Alrifaaee et al. (2014) is presenting a non-convex *MPC* for cooperative control. Here, the first objective is to tackle collision avoidance while the secondary performance objective is to deal with the quality of the collision-free trajectory. Examples of the use of decentralized *MPC* is given by

Shin and Kim (2009), Fukushima et al. (2013), Turpin et al. (2012) and Bemporad and Rocchi (2011). The considered scenario in Fukushima et al. (2013) is formation control of a multi-vehicle system with collision avoidance and input constraints. For this purpose a feedback linearization controller is integrated with *MPC*. The application of Turpin et al. (2012) is trajectory tracking of aerial robots under formation constraints using decentralized *MPC*. In Bemporad and Rocchi (2011) a decentralized linear time-varying *MPC* is used for formation control of multiple UAVs using a leader-follower approach.

The generality and the high control performance of *MPC* come with a high computational burden. Hence, the real-time capability is a crucial aspect of *MPC* which has led to a variety of fast optimization algorithms to minimize the related computational effort. A theoretically well-established and widely used fast *MPC* algorithm is sequential quadratic programming (*SQP*) in combination with Newton-type solvers with e.g. Gauß-Newton or Broyden-Fletcher-Goldfarb-Shannon (*BFGS*) Hessian approximation. A comprehensive framework with a wide variety of related algorithms is *ACADO* (Diehl et al. 2009). The computational efficiency and real-time feasibility for fast mobile robot systems have been validated experimentally, as for example in collision avoidance scenarios with an aerial manipulator (Geisert and Mansard 2016) under use of *BFGS*. A computationally efficient non-*SQP* variation of a Newton-type method is the continuation generalized minimal residual (*CGMRES*) method as presented in Ohtsuka (2004). Its underlying concept is introduced in Sect. 3. A compact version in C++ code is freely available under (Ohtsuka 2015). The low computational burden of *CGMRES* makes it particularly suitable to control fast systems, such as e.g. gasoline engines (Kang et al. 2014), hover crafts (Seguchi and Ohtsuka 2003) and Eco cruise control scenarios (Sajadi-Alamdari et al. 2016). To increase the numerical stability, the condensed multiple shooting derivative *CMSCGMRES* has been developed in Shimizu et al. (2009, 2006). In the previous publication (Dentler et al. 2016a), *CMSCGMRES* has been successfully implemented to control a commercial quadrotor. The low computation time and real-time capability of *CMSCGMRES* has been confirmed experimentally for the given scenario. For this reason, this contribution is also based on *CMSCGMRES*. To reduce the implementational effort of additional inter-robot communication and consensus mechanisms and to compute a globally optimal solution, this contribution is computing the *MPC* centrally. Yet, in order to maintain the modularity of the distributed system in the central *MPC* scheme, the modularization scheme from previous work (Dentler et al. 2016b) is utilized in the form of the *DEN-MPC* framework, as published in Dentler et al. (2017) (more details are given in Sect. 3).

so called optimal control problem. In this work, *OCPs* of the form

$$\begin{aligned} \min_{\mathbf{u}} \quad & J = \int_{\tau_0}^{\tau_f} l(\mathbf{x}, \mathbf{u}, \tau) d\tau \\ \text{s.t.} \quad & \dot{\mathbf{x}} = \mathbf{f}(\mathbf{x}, \mathbf{u}, \tau) \\ & \mathbf{x}_0 = \mathbf{x}(\tau_0) \end{aligned} \quad (1)$$

are considered. The desired behavior is defined by the cost function J which is consisting of an integral cost term. It is subjected to the prediction model dynamics $\mathbf{f}(\mathbf{x}, \mathbf{u}, \tau)$. The initial state condition $\mathbf{x}_0$ is representative for the measurement at each control update interval. A common way to solve *OCPs* in real-time applications is to derive the Hamiltonian for (1)

$$H(\mathbf{x}, \mathbf{u}, \tau) = l(\mathbf{x}, \mathbf{u}, \tau) + \boldsymbol{\lambda}^\top \mathbf{f}(\mathbf{x}, \mathbf{u}, \tau), \quad (2)$$

with the Lagrange multipliers $\boldsymbol{\lambda}$. $\boldsymbol{\lambda}$ can then be computed via backward integration from $\mathbf{0}$ over the horizon using

$$\dot{\boldsymbol{\lambda}} = - \frac{\partial H(\mathbf{x}, \mathbf{u}, \tau)}{\partial \mathbf{x}}. \quad (3)$$

The controls are then typically determined by solving the first order optimality condition

$$0 = \frac{\partial H(\mathbf{x}, \mathbf{u}, \tau)}{\partial \mathbf{u}} = \frac{\partial l(\mathbf{x}, \mathbf{u}, \tau)}{\partial \mathbf{u}} + \boldsymbol{\lambda}^\top \frac{\partial \mathbf{f}(\mathbf{x}, \mathbf{u}, \tau)}{\partial \mathbf{u}}. \quad (4)$$

There is a wide variety of methods to solve (4), whereas for real-time *MPC* common approaches are gradient [e.g. *GRAMPC* (Graichen and Käpernick 2012)] or Newton-type [e.g. Gauß-Newton in *ACADO* (Diehl et al. 2009)] line search methods.

Within this work, a continuation generalized minimal residual method *CGMRES* derivative is used which has been already successfully applied in previous work (Dentler et al. 2016a, b). The continuation idea is to look at the continuous closed loop dynamics of the stabilized system

$$\dot{H}(\mathbf{x}, \mathbf{u}, \tau) = \xi_u H(\mathbf{x}, \mathbf{u}, \tau) \quad (5)$$

which can then be used to approximate $\dot{\mathbf{u}}$

$$\dot{\mathbf{u}} = H_u^{-1} (\xi_u H - H_x \dot{\mathbf{x}} - H_t). \quad (6)$$

$\dot{\mathbf{u}}$ can be computed efficiently with a *GMRES* method under use of a forward difference approximation of H_u^{-1} . The controls $\mathbf{u}$ are finally gained by integrating $\mathbf{u}$ from the previous time step with $\dot{\mathbf{u}}$

$$\mathbf{u}[t_k + 1] = \mathbf{u}[t_k] + \dot{\mathbf{u}}[t_k] \Delta t. \quad (7)$$

More detailed information about the *CGMRES* algorithm can be found in Ohtsuka (2004). By making the continuation assumption (5) also for the states $\mathbf{x}$, a multiple shooting method can be derived to increase numerical stability. This increases the problem dimension, as the corresponding equation to (5) for the inputs $\mathbf{u}$ has also to be solved for the predicted system states within the horizon. An additional condensing addresses this issue by reducing the problem dimension again. A detailed overview of the *CMSCGMRES* method is given in Shimizu et al. (2006). The major advantage of using the continuation approach is the low computation time of the *CGMRES* method which makes it particularly interesting for real-time *MPC*, as already discussed in previous work (Dentler et al. 2016a).

Within this work, a modularization of *MPC* for cooperative control scenarios is applied, as presented in Dentler et al. (2016b). For cooperative scenarios with two entities (*agent0* : x_0, u_0 and *agent1* : x_1, u_1) a cost function can have the form

$$\begin{aligned} l(\mathbf{x}_0, \mathbf{u}_0, \mathbf{x}_1, \mathbf{u}_1) \\ = l_0(\mathbf{x}_0, \mathbf{u}_0) + l_1(\mathbf{x}_1, \mathbf{u}_1) + l_c(\mathbf{x}_0, \mathbf{u}_0, \mathbf{x}_1, \mathbf{u}_1), \end{aligned} \quad (8)$$

where l_0 and l_1 represent tracking cost functions, while l_c is defining some interaction costs. Under this assumption the optimality condition 6 yields to

$$\begin{aligned} 0 = & \frac{\partial l_0(\mathbf{x}_0, \mathbf{u}_0, \tau)}{\partial \mathbf{u}_0} + \frac{\partial l_1(\mathbf{x}_1, \mathbf{u}_1, \tau)}{\partial \mathbf{u}_1} \\ & + \frac{\partial l_c(\mathbf{x}_0, \mathbf{u}_0, \mathbf{x}_1, \mathbf{u}_1)}{\partial \mathbf{u}_0} + \frac{\partial l_c(\mathbf{x}_0, \mathbf{u}_0, \mathbf{x}_1, \mathbf{u}_1)}{\partial \mathbf{u}_1} \\ & + \boldsymbol{\lambda}_0^\top \frac{\partial \mathbf{f}_0(\mathbf{x}_0, \mathbf{u}_0, \tau)}{\partial \mathbf{u}_0} + \boldsymbol{\lambda}_1^\top \frac{\partial \mathbf{f}_1(\mathbf{x}_1, \mathbf{u}_1, \tau)}{\partial \mathbf{u}_1} \end{aligned} \quad (9)$$

With the optimality condition (9) l_c will influence u_0 through $\frac{\partial l_c(\mathbf{x}_0, \mathbf{u}_0, \mathbf{x}_1, \mathbf{u}_1)}{\partial \mathbf{u}_0}$ and u_1 through $\frac{\partial l_c(\mathbf{x}_0, \mathbf{u}_0, \mathbf{x}_1, \mathbf{u}_1)}{\partial \mathbf{u}_1}$. The modularization allows to switch off the influence of l_c on e.g. u_1 by neglecting $\frac{\partial l_c(\mathbf{x}_0, \mathbf{u}_0, \mathbf{x}_1, \mathbf{u}_1)}{\partial \mathbf{u}_1}$ in the optimality condition (9). This is useful, if one central *MPC* is used to control the complete cooperation scenario, but some interaction tasks shall just influence one drone (e.g. the use case scenario of this work). The further advantage of this centralized approach is its high performance, as not just the measured, but also the predicted future system states are taken into consideration. In the *OCP* the exclusion of cost derivatives (e.g. with respect to u_0) will be marked by an index $\setminus \{u_0\}$, e.g.

$$l^{\setminus \{u_0\}}(\mathbf{x}_0, \mathbf{u}_0, \mathbf{x}_0, \mathbf{u}_0, \tau) \quad (10)$$

To finally apply a *MPC* in a mobile robot scenario, a prediction model is required. For real-time applications the complexity of this prediction model is crucial for the per-

Fig. 3 AR.Drone 2.0¹ coordinate frame definition

formance of the *MPC* solver. Hence, a very compact model is preferable which is developed in the next section.

4 Direction vector prediction model and validation

Most mobile robots are designed to move in a planar space. Their position is defined in a xy -plane and the height of this plane (z). Accordingly, their attitude is defined by the rotation angle Ψ around the plane normal vector. This description does not only fit for most wheeled ground robots, but can also be applied to multi-rotor unmanned aerial vehicles. Multi-rotor UAVs are typically operated around their static equilibrium. By assuming that rotations around x (roll) and y (pitch) are so small to be neglected, the quadrotor attitude can be linearized. This yields to a hover controller (Corke 2013), as implemented in most commercial multi-rotor UAVs. As a result, the pose can be described by a single yaw angle Ψ , representing the rotation around the z axis. To address the modeling of such systems, this section is introducing a modeling method for hover controlled multi-rotor systems. This model has furthermore the advantage to contain all elements from which omnidirectional and unidirectional ground robot motion models can also be derived.

To derive the generalized multi-rotor model, the coordinate frames, given in Fig. 3 are considered. A standard approach is to model the system's behavior in the state-space and to give the system function as an Ordinary Differential Equation (*ODE*). The state vector $\mathbf{x}$ of such a system

$$\mathbf{x}(t) = [x_{\mathcal{G}}(t), y_{\mathcal{G}}(t), z_{\mathcal{G}}(t), \Psi(t), \dot{x}_{\mathcal{V}}(t), \dot{y}_{\mathcal{V}}(t)]^{\top} \quad (11)$$

is composing $x_{\mathcal{G}}, y_{\mathcal{G}}, z_{\mathcal{G}}$ position in the global frame $\mathcal{G}$, the $\Psi_{\mathcal{G}}$ rotation around $z_{\mathcal{G}}$ and the forward $\dot{x}_{\mathcal{V}}$ and sideward $\dot{y}_{\mathcal{V}}$ velocity in the vehicle frame $\mathcal{V}$. Under use of the forward, sideward, upward and heading velocity as input

$$\mathbf{u}(t) = [u_f(t), u_s(t), u_z(t), u_{\Psi}(t)]^{\top}, \quad (12)$$

the system dynamics $\mathbf{f}(\mathbf{x}(t), \mathbf{u}(t))$ can be approximated by a semi-nonlinear state-space model (Dentler et al. 2016a)

$$\dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}(t), \mathbf{u}(t)) \quad (13)$$

$$\dot{\mathbf{x}}(t) = \left\{ \begin{array}{l} \left. \begin{array}{l} \dot{x}_{\mathcal{V}}(t) \cos(\Psi(t)) - \dot{y}_{\mathcal{V}} \sin(\Psi(t)) \\ \dot{x}_{\mathcal{V}}(t) \sin(\Psi(t)) + \dot{y}_{\mathcal{V}} \cos(\Psi(t)) \\ b_z \cdot u_z(t) \\ b_{\Psi} \cdot u_{\Psi}(t) \end{array} \right\} \text{Map: } \mathcal{V} \rightarrow \mathcal{G} \\ \left. \begin{array}{l} a_f \cdot \dot{x}_{\mathcal{V}}(t) + b_f \cdot u_f(t) \\ a_s \cdot \dot{y}_{\mathcal{V}}(t) - b_s \cdot u_s(t) \end{array} \right\} \text{Linear model.} \end{array} \right. \quad (14)$$

For low-cost quadrotors the velocity inputs are typically just related to an attitude displacement, e.g. increase pitch angle to increase forward velocity. Accordingly the inputs are not expressing the exact velocity in m s^{-1} . The identification of the linear model parameters helps to describe this attitude control behavior and to accommodate such unnormalized system inputs. Representatively for such low-cost mobile robotic systems, the quadrotor *AR.Drone 2.0* is applied as example within this work.

4.1 Angle discontinuity effect on UAV control

The attitude of mobile robots which are moving in a planar plane is typically defined by a single angle Ψ on the interval

$$\Psi := \{\Psi \in \mathbb{R} \mid -\pi < \Psi \leq \pi\}. \quad (15)$$

For a full rotation of the mobile robot, Ψ is changing the sign between $\pm\pi$. By artificially limiting the angle on the interval (15) a discontinuity is introduced into the model of the angle. This is problematic, if the attitude is controlled by means of velocity or acceleration. To show the problematic behavior, a model predictive controller is applied to an *AR.Drone 2.0* quadrotor under use of the prediction model (11) with

$$\begin{aligned} & (b_z, b_{\Psi}, a_f, b_f, a_s, b_s)^{\top} \\ & = (1, 1.6, -0.5092, 1.458, -0.5092, 1.458)^{\top} \end{aligned} \quad (16)$$

The resulting trajectory is given in Fig. 4. To control the quadrotor attitude, traditionally the error $e_{\Psi} = \Psi_{des} - \Psi$ to the desired yaw angle Ψ_{des} is minimized. The yaw angle plot in Fig. 4 shows a step in the desired angle from $\Psi_{des}(0\text{ s}) = \frac{\pi}{2}$ to $\Psi_{des}(2.8\text{ s}) = \pi$. To minimize e_{Ψ} , the controller is applying a positive angular velocity to converge asymptotically towards $\Psi_{des} = \pi$. As real mobile robotic systems are exposed to disturbance, the robot is likely to overshoot $\Psi_{des} = \pi$ which leads to a change of sign to $\Psi = -\pi$. This can be seen in Fig. 4 at $t \approx 5.4\text{ s}$. Hence, the quadrotor will again try to reach the desired value from the new angle

Fig. 4 Angle discontinuity problem regarding the control trajectories of a real *AR.Drone 2.0* quadrotor

$\Psi_{des} = -\pi$. As a result, positions close to $\Psi_{des} = \pm\pi$ cannot be stabilized which leads to a repetitive rotational movement.

The main use of angle Ψ is the mathematical description for the mapping of the vehicle coordinate frame $\mathcal{V}$ to the global coordinate frame $\mathcal{G}$. This is typically done by means of a rotation matrix, as shown in (14). For the planar case the rotation matrix yields

$$\mathbf{p}_{\mathcal{V}} = \begin{bmatrix} \cos(\Psi) & -\sin(\Psi) \\ \sin(\Psi) & \cos(\Psi) \end{bmatrix} \mathbf{p}_{\mathcal{G}} = \mathbf{T}_{\mathcal{G}}^{\mathcal{V}} \mathbf{p}_{\mathcal{G}} \text{ with } \mathbf{p} = [x \ y]^{\top}. \quad (17)$$

To overcome the described angle discontinuity in the transformation, a continuous way to describe the robot attitude has to be used. One way to do so is to use a direction vector. For

Fig. 5 Unit circle

3D-space this is well established in the form of quaternions $\mathbf{q} \in \mathcal{R}^4$ which consist of a real part q_0 and three imaginary parts q_1, q_2, q_3 to describe rotations $\mathbf{q} = \langle q_0, q_1, q_2, q_3 \rangle$. In state space models these four elements are treated as separate states. For real-time *MPC* the related increase in the *OCF* dimension is significant. For the considered robots, the pose control is only based on a rotation in the 2D *xy*-plane. Accordingly, a direction vector approach is sufficient to describe the attitude, as discussed in the next Sect. 4.2.

4.2 Direction vector approach

As previously discussed, the direction of a vector can be used to describe a robot attitude. Each position vector of the points on the unit circle can accordingly be used which is directly related to complex number theory. These vectors are uniquely defined by their projections onto the coordinate axis x and y as shown in Fig. 5. In comparison to a single angle description with yaw Ψ , this transformation is bijective. In the context of this work, the combination of these two projections (d_x and d_y) is called direction vector $\mathbf{d}$. The direction vector $\mathbf{d}$ can be written in vector form

$$\mathbf{d} = \begin{bmatrix} d_x \\ d_y \end{bmatrix} = \begin{bmatrix} \cos(\Psi) \\ \sin(\Psi) \end{bmatrix} \quad \begin{aligned} d_x &:= \{d_x \in \mathbb{R} \mid -1 < d_x \leq 1\} \\ d_y &:= \{d_y \in \mathbb{R} \mid -1 < d_y \leq 1\} \end{aligned} \quad (18)$$

As the direction vector is expressing the projection from the unit circle, d_x and d_y are fulfilling the circle constraint

$$1 = d_x^2 + d_y^2 \quad (19)$$

To receive the state space description, $\dot{\mathbf{d}}$ yields under use of (18) to

$$\dot{\mathbf{d}} = \begin{bmatrix} \dot{d}_x \\ \dot{d}_y \end{bmatrix} = \begin{bmatrix} -\sin(\Psi) \\ \cos(\Psi) \end{bmatrix} \dot{\Psi} = \begin{bmatrix} -d_y \\ d_x \end{bmatrix} \dot{\Psi} \quad (20)$$

This is intuitive, as the derivative $\dot{\mathbf{d}}$ has to be orthogonal to $\mathbf{d}$ to force $\mathbf{d}$ to stay on the unit circle.

The system input u_ψ is expressing the angular velocity $\dot{\psi}$ in (20) with the constant factor b_ψ . Hence, the derivative yields to

$$\dot{\mathbf{d}} = \begin{bmatrix} -d_y \\ d_x \end{bmatrix} b_\psi \cdot u_\psi(t) \quad (21)$$

Transformation matrix (17) is transformed with (18) to

$$\mathbf{T}_{\mathcal{G}}^{\mathcal{V}} = \begin{bmatrix} d_x & -d_y \\ d_y & d_x \end{bmatrix} \quad (22)$$

To transform the system dynamics (14) into a direction vector model, Ψ is substituted by the direction vector in the state vector

$$\mathbf{x}(t) = [x_{\mathcal{G}}(t), y_{\mathcal{G}}(t), z_{\mathcal{G}}(t), d_x(t), d_y(t), \dot{x}_{\mathcal{V}}(t), \dot{y}_{\mathcal{V}}(t)]^T. \quad (23)$$

Using the direction vector (18), the derivative (21) with u_ψ and the coordinate transformation (22), the system dynamics (14) finally leads to

$$\dot{\mathbf{x}}(t) = \mathbf{f}(\mathbf{x}(t), \mathbf{u}(t)) = \begin{bmatrix} \dot{x}_{\mathcal{V}}(t) d_x(t) - \dot{y}_{\mathcal{V}}(t) d_y(t) \\ \dot{x}_{\mathcal{V}}(t) d_y(t) + \dot{y}_{\mathcal{V}}(t) d_x(t) \\ b_z \cdot u_z(t) \\ -d_y(t) \cdot b_\psi \cdot u_\psi(t) \\ d_x(t) \cdot b_\psi \cdot u_\psi(t) \\ a_f \cdot \dot{x}_{\mathcal{V}}(t) + b_f \cdot u_f(t) \\ a_s \cdot \dot{y}_{\mathcal{V}}(t) - b_s \cdot u_s(t) \end{bmatrix} \quad (24)$$

To track attitude $\mathbf{d}$, a simple quadratic penalty can be used

$$J_{\mathbf{d}} = (\mathbf{d}_{des} - \mathbf{d})^T \begin{bmatrix} q_{dx} & 0 \\ 0 & q_{dy} \end{bmatrix} (\mathbf{d}_{des} - \mathbf{d}) \quad (25)$$

under the assumption, that numerical errors of the MPC solver avoid the singular problem of opposing attitudes, e.g. $\mathbf{d}_{des} = [1, 0]^T$ with $\mathbf{d} = [-1, 0]^T$, or $\mathbf{d}_{des} = [0, 1]^T$ with $\mathbf{d} = [0, -1]^T$.

4.3 Experimental validation of direction vector approach

To validate the direction vector quadrotor model (24), the desired drone attitude is rotated anti-clock-wise in steps of $\psi = \frac{\pi}{2}$. The Ψ plot in Fig. 6 shows the desired and actual attitude of the system. In contrast to the previous instability at $\psi = \pm\pi$ (Fig. 4), Fig. 6 is showing the desired asymptotic approaching of the desired trajectory. The oscillations

Fig. 6 Experimental Validation of direction vector quadrotor model

in x, y, z around the desired point are caused by disturbance. This includes airflow disturbance, modeling errors, numerical errors and the trade-off between energy optimality and position tracking. Hence, the direction vector approach is resolving the angle discontinuity problem stated in Sect. 4.1. The proposed approach is a trade-off between the continuous attitude description, the computational effort, regarding the quaternion approach (4 states) and the standard angle description (1 state). Regarding the generality of the direction vector model, the same approach can be easily applied also to other planar robots with single angle attitude description. For example ground robots can be modeled by neglecting the z component of (24) with $u_z = 0$. For unidirectional robots, the sideward movement can be neglected by setting $u_s = 0$. Based on the resulting direction vector based system dynamics, the next sections describe the application of

the model in a sensor constrained model predictive control scenario.

5 Sensor based control with potential functions

One major difficulty to control complex tasks autonomously is the mathematical formulation of such tasks. A generic way to do so are inequality constraints. MPC can take such constraints into consideration. In this work, they are considered in the MPC as weakened constraints. This refers to the substitution of hard inequality constraints by a cost function, that imposes a repulsive behavior from a violation of the constraint. This implementation in the cost function equals to a potential function. In this section, a generic procedure to create such potential functions is presented. The formulation of a sensor constraint serves as example. In the example scenario an object is tracked with a sensor attached to a quadrotor. The sensor perception space is thereby shaped like a cone (e.g. ultrasonic distance sensor). How to describe this sensor limitation is shown in the following section.

5.1 Sensor constraints

The considered use case is an *AR.Drone 2.0* quadrotor with the presented dynamics (24). With the example of a cone-formed sensor perception space, the robot/sensor system can be illustrated as shown in Fig. 7. The first step to implement the sensor based control is, to formulate the perception space limitation in terms of constraints. For this purpose, a target object is defined in the sensor frame with the position vector $\mathbf{p}_S \in \mathcal{S}$

$$\mathbf{p}_S = [x_{pS} \ y_{pS} \ z_{pS}]^T \in \mathbb{R}^3. \quad (26)$$

Regarding the position of the trackable object in the sensor frame $\mathbf{p}_S$, the field of view of the sensor can be expressed by the constraints

$$0 \geq c_1(\mathbf{p}_S, \alpha) = y_{pS}^2 + z_{pS}^2 - (x_{pS} \sin(\alpha))^2 \quad (27)$$

$$0 \geq c_2(\mathbf{p}_S) = -x_{pS}, \quad (28)$$

where (27) is representing a double cone. To receive a single cone perception space, constraint (28) is limiting the cone to the positive half plane of x_{pS} . In contrast to just pointing the quadrotor into the target's direction, the formulation of the perception area offers more flexibility to the MPC to optimize the energy consumption and to adapt the scenario to other constraints e.g. obstacles. The question of how to consider the sensor constraint (27) and (28) in an optimal control problem is described in the next section.

Fig. 7 Use case scenario: tracking with cone shaped sensor perception of a quadrotor

5.2 Potential function constraint handling

Considering the constraints (27) and (28) as hard constraints is problematic, because their violation would lead to an infeasible optimization problem. In the sensor based tracking scenario this would be the case, if the object is outside the sensor perception space. Such a violation is possible due to disturbance or an infeasible initial pose. For this reason, the sensor constraints are designed as weakened constraints by imposing a repulsive behavior from constraint violation. One way to accomplish this is to add an additional penalty term to the OCP's integral costs l . Due to the fact that OCPs are typically defined as minimization problems with the optimum $l = 0$, a constraint violation has to be penalized with a higher cost. An intuitive approach to translate the constraint $c \leq 0$ to the weakened constraint l_c is therefore to penalize the compliant area with $l = 0$ and the constraint violation area with $l = 1$. This can be described by using a unit step ϵ , such that

$$c \leq 0 \quad \Rightarrow \quad l_c = \epsilon(c). \quad (29)$$

For the cone constraint (27) and (28) this leads to

$$\begin{aligned} l_c(\mathbf{p}_S, \alpha) &= \epsilon(c_2(\mathbf{p}_S)) + \epsilon(c_1(\mathbf{p}_S, \alpha)) \epsilon(-c_2(\mathbf{p}_S)) \\ &= \epsilon(-x_{pS}) + \epsilon(y_{pS}^2 + z_{pS}^2 - (x_{pS} \sin(\alpha))^2) \epsilon(-x_{pS}) \end{aligned} \quad (30)$$

c_2 is used to distinguish between the negative and positive half-space of x_{pS} :

$$l_c(c_2(\mathbf{p}_S) > 0 \rightarrow x_{pS} \in \mathbb{R}^-) = 1 \quad (31)$$

$$l_c(c_2(\mathbf{p}_S) \leq 0 \rightarrow x_{pS} \in \mathbb{R}^+) = c_1(\mathbf{p}_S, \alpha) \quad (32)$$

To initially use the unit step approximation (29) for the constraint transformation has proven to be particularly helpful regarding potential functions developed from nested constraints. More complex approximation functions lead to

Fig. 8 Unit step penalty function values of cone constraint)

Fig. 9 Unit step penalty function of cone constraint in the xy -plane)

larger mathematical expression and reduce the readability of the behavior of the potential function. Furthermore, the behavior of the developed potential function can be easily validated visually by plotting the areas with potential value $l_c = 0$ and $l_c = 1$. For the example of the weakened cone constraint (30), this results in the characterizing cone area with potential value $l_c = 0$ and the corresponding infeasible area outside with $l_c = 1$ as shown in Fig. 8.

5.3 Addressing vanishing gradient

The resulting cost function for the xy -plane is shown in the left plot of Fig. 9. As expected, the figure shows that the gradient satisfies

$$\nabla l_c(\mathbf{p}_S, \alpha) = \mathbf{0} \quad \forall c_1(\mathbf{p}_S, \alpha) \neq 0 \quad (33)$$

As most approaches for searching the minimum of the defined cost function l_c are based on a gradient descent, this property becomes problematic, as the convergence of the search algorithm cannot be guaranteed. To address this issue a cost slope can be added around the cone as shown in the right illustration of Fig. 9. To impose a gradient, a simple quadratic penalty can be added in the undesired regions. Hence, (30) can be extended to

$$\begin{aligned} l_c(\mathbf{p}_S, \alpha, \kappa_G) &= (-x_{pS}) \left(1 + \kappa_G (x_{pS}^2 + y_{pS}^2 + z_{pS}^2) \right) \\ &\quad + \epsilon \left(y_{pS}^2 + z_{pS}^2 - (x_{pS} \sin(\alpha))^2 \right) \\ &\quad \cdot \epsilon(x_{pS}) \left(1 + \kappa_G (y_{pS}^2 + z_{pS}^2) \right), \end{aligned} \quad (34)$$

Fig. 10 Sigmoid approximation of unit step with corresponding derivatives

whereby parameter κ_G is controlling the steepness of the gradient derivative. As a remark, gradient-based solvers typically require convex *OC* problems to ensure convergence. Naturally, most sensor perception spaces are convex. However this should be kept in mind for development of more complex constraints or the combination of multiple constraints.

5.4 Addressing differentiability of the potential function

The second problematic property of the proposed unit step constraint translation (29) is that the derivative of the unit step is not an analytical function. Yet, most fast optimal control problem solvers require the differentiability of the cost function. To address this problem, the switching behavior of the unit step, with respect to the constraints, can be approximated by means of a sigmoid function. This has been already validated in previous work for a collision avoidance constraint (Dentler et al. 2016a) and is similar to the tanh approximation, as introduced in Bertrand et al. (2014). Accordingly, the unit step can be approximated with

$$\epsilon(c) \approx \text{sig}(c, \kappa_A) = \frac{1}{1 + e^{-\kappa_A c}}, \quad (35)$$

where κ_A is a design parameter. The derivative of $\text{sig}(c, \kappa_A)$ can be determined analogously

$$\frac{\partial \text{sig}(c, \kappa_A)}{\partial c} = \frac{\kappa_A (1 + e^{-\kappa_A c})}{(1 + e^{-\kappa_A c})^2}. \quad (36)$$

Figure 10 is showing the behavior of the sigmoid function and its derivative for a variation of κ_A .

For increasing κ_A , $\text{sig}(c, \kappa_A)$ is converging towards a step function $\epsilon(c)$. Its derivative is accordingly converging towards a δ impulse

$$\lim_{\kappa_A \rightarrow \infty} \text{sig}(c, \kappa_A) \rightarrow \epsilon(c) \quad (37)$$

$$\lim_{\kappa_A \rightarrow \infty} \frac{\partial \text{sig}(c, \kappa_A)}{\partial c} \rightarrow \delta(c). \quad (38)$$

Factor κ_A is therefore determining the trade-off between quality of the approximation and condition number of the

Fig. 11 Extended weakened cone constraint transformed with sigmoid

function. A bad-conditioned problem for high κ_A is numerically more difficult to solve. The transformation of the extended weakened cone constraint (34) by means of a sigmoid function (35), finally yields to

$$\begin{aligned} l_c(\mathbf{p}_S, \alpha, \kappa_G, \kappa_A) &= \text{sig}(-x_{pS}, \kappa_A) \left(1 + \kappa_G (x_{pS}^2 + y_{pS}^2 + z_{pS}^2) \right) \\ &\quad + \text{sig}(y_{pS}^2 + z_{pS}^2 - (x_{pS} \sin(\alpha))^2, \kappa_A) \\ &\quad \cdot \text{sig}(x_{pS}, \kappa_A) \left(1 + \kappa_G (y_{pS}^2 + z_{pS}^2) \right) \end{aligned} \quad (39)$$

which is shown in Fig. 11 for $\kappa_A = 10$.

To be able to track an object with known position in the global coordinate system, $\mathbf{p}_S$ in (30) has to be determined by its counterpart $\mathbf{p}_G$ in the global coordinate system. The required coordinate transformation is explained in the following section.

5.5 Coordinate transformation

The coordinate transformation from the global coordinate frame to the sensor frame can be described as a sequential transformation with homogeneous transformation matrices. For a matrix that transforms a point $\mathbf{p}$ from the global coordinates $\mathcal{G}$ into the sensor frame coordinates $\mathcal{S}$ we use the following nomenclature

$$\begin{bmatrix} \mathbf{p}_S \\ 1 \end{bmatrix} = \mathbf{T}_{\mathcal{G}}^{\mathcal{S}} \begin{bmatrix} \mathbf{p}_G \\ 1 \end{bmatrix}. \quad (40)$$

This transformation matrix can consist of the position displacement of coordinate systems

$$\mathbf{T}(\mathbf{x}) = \begin{bmatrix} 1 & 0 & 0 & x \\ 0 & 1 & 0 & y \\ 0 & 0 & 1 & z \\ 0 & 0 & 0 & 1 \end{bmatrix} \quad \text{with } \mathbf{x} = [x \ y \ z]^T, \quad (41)$$

the rotational displacement expressed by an angle β e.g. around y

$$\mathbf{T}_y(\beta) = \begin{bmatrix} \cos(\beta) & 0 & -\sin(\beta) & 0 \\ 0 & 1 & 0 & 0 \\ \sin(\beta) & 0 & \cos(\beta) & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}, \quad (42)$$

and a direction vector e.g. around z

$$\mathbf{T}_z(\mathbf{d}) = \begin{bmatrix} d_x & d_y & 0 & 0 \\ -d_y & d_x & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{bmatrix}. \quad (43)$$

With the

robot position $\mathbf{p}_{rG} = (x_{rG}, y_{rG}, z_{rG})^T$ and

robot orientation $\mathbf{d}_{rG} = (d_{xG}, d_{yG})^T$

the transformation matrix from the global frame $\mathcal{G}$ into the vehicle frame $\mathcal{V}$

$$\begin{aligned} \mathbf{T}_{\mathcal{G}}^{\mathcal{V}}(\mathbf{d}_{rG}, \mathbf{p}_{rG}) &= \mathbf{T}_{zG}(\mathbf{d}_{rG}) \mathbf{T}(-\mathbf{p}_{rG}) \\ &= \begin{bmatrix} d_{xG} & d_{yG} & 0 & -d_{xG}x_{rG} - d_{yG}y_{rG} \\ -d_{yG} & d_{xG} & 0 & d_{yG}x_{rG} - d_{xG}y_{rG} \\ 0 & 0 & 1 & -z_{rG} \\ 0 & 0 & 0 & 1 \end{bmatrix} \end{aligned} \quad (44)$$

and then to the sensor frame $\mathcal{S}$

$$\begin{aligned} \mathbf{T}_{\mathcal{V}}^{\mathcal{S}}(\beta, [d_s, 0, 0]^T) &= \mathbf{T}_{yV}(\beta) \mathbf{T}(-[d_s, 0, 0]^T) \\ &= \begin{bmatrix} \cos(\beta) & 0 & -\sin(\beta) & -d_s \cos(\beta) \\ 0 & 1 & 0 & 0 \\ \sin(\beta) & 0 & \cos(\beta) & -d_s \sin(\beta) \\ 0 & 0 & 0 & 1 \end{bmatrix} \end{aligned} \quad (45)$$

leads to the transformation matrix

$$\begin{aligned} \mathbf{T}_{\mathcal{G}}^{\mathcal{S}}(\beta, d_s, \mathbf{d}_{rG}, \mathbf{p}_{rG}) &= \mathbf{T}_{\mathcal{V}}^{\mathcal{S}}(\beta, [d_s, 0, 0]^T) \mathbf{T}_{\mathcal{G}}^{\mathcal{V}}(\mathbf{d}_{rG}, \mathbf{p}_{rG}) \\ &= \begin{bmatrix} d_{xG} \cos(\beta) & d_{yG} \cos(\beta) & -\sin(\beta) & z_{rG} \sin(\beta) - v \cos(\beta) \\ -d_{yG} & d_{xG} & 0 & d_{yG}x_{rG} - d_{xG}y_{rG} \\ d_{xG} \sin(\beta) & d_{yG} \sin(\beta) & \cos(\beta) & -z_{rG} \cos(\beta) - v \sin(\beta) \\ 0 & 0 & 0 & 1 \end{bmatrix} \\ &\quad \text{with } v = d_s + d_{xG}x_{rG} + d_{yG}y_{rG}, \end{aligned} \quad (46)$$

Fig. 12 Tracking of global position with weakened cone constraint

and the inverse transformation

$$\begin{aligned} \mathbf{T}_S^G(\beta, d_s, \mathbf{d}_{rG}, \mathbf{p}_{rG}) &= \left(\mathbf{T}_G^S(\beta, d_s, \mathbf{d}_{rG}, \mathbf{p}_{rG}) \right)^{-1} \\ &= \begin{bmatrix} d_{xG} \cos(\beta) & -d_{yG} & d_{xG} \sin(\beta) & d_s d_{xG} + x_{rG} \\ d_{yG} \cos(\beta) & d_{xG} & d_{yG} \sin(\beta) & d_s d_{yG} + y_{rG} \\ -\sin(\beta) & 0 & \cos(\beta) & z_{rG} \\ 0 & 0 & 0 & 1 \end{bmatrix}. \end{aligned} \quad (47)$$

The global coordinates in the sensor frame is accordingly given by (40) and leads to

$$\begin{aligned} \begin{bmatrix} \mathbf{p}_S \\ 1 \end{bmatrix} &= \mathbf{T}_G^S(\beta, d_s, \mathbf{d}_{rG}, \mathbf{p}_{rG}) \begin{bmatrix} \mathbf{p}_G \\ 1 \end{bmatrix} \\ &= \begin{bmatrix} x_{pS} \\ y_{pS} \\ z_{pS} \\ 1 \end{bmatrix} = \begin{bmatrix} (z_{rG} - z_{pG}) \sin(\beta) - \eta \cos(\beta) \\ d_{yG}(x_{rG} - x_{pG}) + d_{xG}(y_{pG} - y_{rG}) \\ (z_{pG} - z_{rG}) \cos(\beta) - \eta \sin(\beta) \\ 1 \end{bmatrix} \end{aligned} \quad (48)$$

with $\eta = d_s + d_{xG}(x_{rG} - x_{pG}) + d_{yG}(y_{rG} - y_{pG})$

Finally the target position in the sensor coordinate frame can be expressed in global coordinates by (48) and applied in $l_c(\mathbf{p}_S, \alpha, \kappa_G, \kappa_A)$ (39). Due to its complexity, the resulting equation is not given here. Figure 12 is showing the resulting costs in the xy -plane for a quadrotor at position $\mathbf{p}_{rG} = (-1, -1, 0)^T$ and orientation $\mathbf{d}_{rG} = (0.71, 0.71)^T \equiv \Psi = 45^\circ$. The triangular base form of the cone is oriented as expected from the UAV origin in $\mathbf{p}_{rG} = (-1, -1, 0)^T$.

6 Safety constraints

To validate the derived potential function experimentally, additional safety measures are necessary. The most important safety constraint is treating collision avoidance and ensures that a safety distance d_{min} between object and drone is not violated. Second, the maximum distance d_{max} of the sensor has to be considered. This can be accomplished by implementing a cohesion constraint which introduces a repulsive behavior from large distances between object and robot. Both constraints are derived according to the workflow presented for the sensor constraint in Sect. 5.

6.1 Collision avoidance constraint

Considering that $\mathbf{p}_G$ could also represent an obstacle to avoid, a potential function for obstacle avoidance can be formulated as penalty of a distance below a limit d_{min} :

$$d_{min} \leq \|\mathbf{p}_G - \mathbf{p}_{rG}\|. \quad (49)$$

The norm can be reformulated by means of quadrature

$$0 \leq c_{minD} = (\mathbf{p}_G - \mathbf{p}_{rG})^T (\mathbf{p}_G - \mathbf{p}_{rG}) - d_{min}^2 \quad (50)$$

which then is transformed into a potential function with unit steps

$$\begin{aligned} l_{minD} &= \epsilon(c_{minD}) \\ &= \epsilon\left((\mathbf{p}_G - \mathbf{p}_{rG})^T (\mathbf{p}_G - \mathbf{p}_{rG}) - d_{min}^2\right). \end{aligned} \quad (51)$$

To improve the convergence properties, (51) is extended by a quadratic penalty term

$$\begin{aligned} l_{minD} &= \epsilon\left((\mathbf{p}_G - \mathbf{p}_{rG})^T (\mathbf{p}_G - \mathbf{p}_{rG}) - d_{min}^2\right) \\ &\quad \cdot \left(\kappa_H - \kappa_G \left((\mathbf{p}_G - \mathbf{p}_{rG})^T (\mathbf{p}_G - \mathbf{p}_{rG})\right)\right) \end{aligned} \quad (52)$$

Here, κ_H is defining the maximum height and κ_G the decent of the gradient of the potential function. Finally, (52) can be transformed to an analytical function with the help of the sigmoid function (36)

$$l_{minD}(\mathbf{p}_G, \mathbf{p}_{rG}, d_{min}, \kappa_H, \kappa_G, \kappa_A) \quad (53)$$

$$\begin{aligned} &= \text{sig}\left((\mathbf{p}_G - \mathbf{p}_{rG})^T (\mathbf{p}_G - \mathbf{p}_{rG}) - d_{min}^2, \kappa_A\right) \\ &\quad \cdot \left(\kappa_H - \kappa_G \left((\mathbf{p}_G - \mathbf{p}_{rG})^T (\mathbf{p}_G - \mathbf{p}_{rG})\right)\right). \end{aligned} \quad (54)$$

κ_A is describing the quality of the unit step approximation as before. The final result of the potential function is shown in Fig. 13 which shows a high penalty for the area with distance d_{min} around the origin. The form of the convex top

Fig. 13 Collision avoidance constraint potential function over xy -plane

Fig. 14 Collision avoidance constraint potential function in global perspective

can be adjusted with κ_G . Figure 14 is showing penalty values $l_{minD} > 0.5$ for an obstacle in position $\mathbf{p}_G = (x, y, z)^T$ with robot placed at $\mathbf{p}_{rG} = (-1, -1, 0)^T$. As desired any violation of d_{min} (49) is addressed with a high penalty. This yields a repulsive behavior between robot and object.

6.2 Cohesion constraint

Cohesion can be seen as inversion of the collision avoidance problem (49), where distances bigger than d_{max} to an object should be avoided. The constraint can therefore be formulated as

$$d_{max} \geq \|\mathbf{p}_G - \mathbf{p}_{rG}\|. \quad (55)$$

As before, the norm can be expressed with the help of a quadrature

$$0 \leq c_{maxD} = d_{max}^2 - (\mathbf{p}_G - \mathbf{p}_{rG})^T (\mathbf{p}_G - \mathbf{p}_{rG}) \quad (56)$$

and transformed into a cost function with a unit step function

$$\begin{aligned} l_{maxD} &= \epsilon(c_{maxD}) \\ &= \epsilon(d_{max}^2 - (\mathbf{p}_G - \mathbf{p}_{rG})^T (\mathbf{p}_G - \mathbf{p}_{rG})). \end{aligned} \quad (57)$$

To manipulate the curvature of the given penalty function, κ_H is introduced to define the maximum height. κ_G is describing the ascent of the gradient of the potential function

$$\begin{aligned} l_{maxD} &= \epsilon(d_{max}^2 - (\mathbf{p}_G - \mathbf{p}_{rG})^T (\mathbf{p}_G - \mathbf{p}_{rG})) \\ &\quad \cdot (\kappa_H + \kappa_G ((\mathbf{p}_G - \mathbf{p}_{rG})^T (\mathbf{p}_G - \mathbf{p}_{rG}))) \end{aligned} \quad (58)$$

The final analytical cost function is gained from an approximation of the unit step ϵ with the sigmoid function (36). Which yields

$$\begin{aligned} l_{maxD}(\mathbf{p}_G, \mathbf{p}_{rG}, d_{max}, \kappa_H, \kappa_G, \kappa_A) \\ = \text{sig}(d_{max}^2 - (\mathbf{p}_G - \mathbf{p}_{rG})^T (\mathbf{p}_G - \mathbf{p}_{rG}), \kappa_A) \\ \cdot (\kappa_H + \kappa_G ((\mathbf{p}_G - \mathbf{p}_{rG})^T (\mathbf{p}_G - \mathbf{p}_{rG}))). \end{aligned} \quad (59)$$

Figure 15 is showing the desired inverse behavior as for the collision avoidance behavior in Fig. 13. The cohesion constraint leads to a high penalty for distances greater than d_{max} around the origin. Figure 16 is showing penalty values $l_{maxD} > 0.5$ for an obstacle in position $\mathbf{p}_G = (x, y, z)^T$ with the robot placed at $\mathbf{p}_{rG} = (-1, -1, 0)^T$. The figure validates that the whole area of $\|\mathbf{p}_G - \mathbf{p}_{rG}\| \geq d_{max}$ is highly penalized which leads to an attracting behavior between object and robot.

With the developed safety constraints (53) and (59), the cone constraint has been validated as discussed in the following section.

7 Validation of the sensor based control with potential functions

The validation scenario is a visual quadrotor tracking scenario, where one quadrotor is equipped with a camera and tracking a target quadrotor. The task is to keep the target quadrotor in the camera frame as shown in Fig. 17.

The control of both quadrotors is accomplished with a central MPC controller (Dentler 2016) and extended by the

Fig. 15 Cohesion constraint function over xy -plane

Fig. 16 Cohesion constraint potential function in global perspective

Fig. 17 Visual tracking of quadrotor from camera-equipped quadrotor

potential functions that are defining the tracking task. The combination of cone (39), collision avoidance (53) and cohesion (59) constraint with the coordinate transformation (48) and quadrotor dynamics (14) with parameters (16) in an OCF results in

$$\begin{aligned} \min_{\mathbf{u}} J &= \int_{t_0}^{t_f} l_0(\tau) + l_1(\tau) \\ &+ k_{00} l_c^{\setminus\{u_1\}}(\mathbf{p}_{uav1S}, \alpha, \kappa_{G0}, \kappa_{A0}) \\ &+ k_{01} l_{maxD}^{\setminus\{u_1\}}(\mathbf{p}_{uav1G}, \mathbf{p}_{uav0G}, d_{max}, \kappa_{H1}, \kappa_{G1}, \kappa_{A1}) \\ &+ k_{02} l_{minD}^{\setminus\{u_1\}}(\mathbf{p}_{uav1G}, \mathbf{p}_{uav0G}, d_{min}, \kappa_{H2}, \kappa_{G2}, \kappa_{A2}) d\tau \\ \text{s.t. } \mathbf{c}_0(\tau) &\leq \mathbf{0}, \mathbf{c}_1(\tau) \leq \mathbf{0} \\ \mathbf{0} &= \mathbf{f}_0(\mathbf{x}_0, \mathbf{u}_0, t), \mathbf{0} = \mathbf{f}_1(\mathbf{x}_1, \mathbf{u}_1, t) \end{aligned}$$

with

$$\begin{aligned} \begin{bmatrix} \mathbf{p}_{uav1S} \\ 1 \end{bmatrix} &= \mathbf{T}_G^S(\beta, -d_s, \mathbf{d}_{uav0G}, -\mathbf{p}_{uav0G}) \begin{bmatrix} \mathbf{p}_{uav1G} \\ 1 \end{bmatrix} \\ l_i(\tau) &= (\mathbf{x}_i^*(\tau) - \mathbf{x}_i(\tau))^T \mathbf{Q}_i (\mathbf{x}_i^*(\tau) - \mathbf{x}_i(\tau)) \\ &+ \mathbf{u}_i(\tau)^T \mathbf{R}_i \mathbf{u}_i(\tau) \end{aligned} \quad (60)$$

The index $\setminus\{u_1\}$ of the cost functions l_c , l_{maxD} and l_{minD} reflects, that the influence of the cost functions on UAV_1 is neglected, as explained in (10). This means that the cone, collision avoidance and cohesion constraint is only affecting UAV_0 . The advantage of this modular approach of a central control for such a scenario is, that future states of both systems are considered for the computation of the optimal controls, while the effect of the tracking costs can be limited to one quadrotor.

The parameters of (60) for the experimental validation are given as

$$\mathbf{Q}_0 = \text{Diag}([0, 0, 0, 0, 0, 0.7, 0.7]) \quad (61)$$

$$\mathbf{R}_0 = \text{Diag}([1, 1, 1, 1]) \quad (62)$$

$$\mathbf{Q}_1 = \text{Diag}([1.5, 1.5, 1.6, 1, 1, 0, 0]) \quad (63)$$

$$\mathbf{R}_1 = \text{Diag}([1, 1, 1, 1]) \quad (64)$$

$$\begin{aligned} p_c : d_s &= 0.17, \alpha = 0.5, \beta = 0.5, \\ k_{00} &= 0.4, k_{G0} = 0.01, k_{A0} = 2.0 \end{aligned} \quad (65)$$

$$\begin{aligned} p_{minD} : d_{min} &= 1, k_{01} = 0.4, \\ k_{H1} &= 4.5, k_{G1} = 0.001, k_{A1} = 3.0 \end{aligned} \quad (66)$$

$$\begin{aligned} p_{maxD} : d_{max} &= 2, k_{02} = 0.4, \\ k_{H2} &= 1.5, k_{G2} = 0.001, k_{A2} = 3.0 \end{aligned} \quad (67)$$

$$\begin{aligned} p_{cgmr} : n_{hor} &= 20, T_{hor} = 1 \text{ s}, \epsilon_T = 10^{-8}, \zeta = 10 \\ \Delta t &= 0.01 \text{ s}, k_{max} = 30, \alpha_{hor} = 2 \end{aligned} \quad (68)$$

Fig. 18 Numerical validation of the use case scenario with V-REP

The parameters p_{cgmres} are referring to the *CMSCGMRES* solver and are given in a coherent notation to the previous work (Dentler et al. 2016a). To examine the dynamic behavior of the proposed control solution, the target position of UAV_1 is moving in a circular trajectory. For UAV_0 , the choice of $\mathbf{Q}_0$ leads to a tracking of zero forward velocity $\dot{x}_{uav0V}(t) = 0$ and sideward velocity $\dot{y}_{uav0V}(t) = 0$ which yields to the desired states

$$\mathbf{x}_0^* = \text{Diag}([0, 0, 0, 0, 0, 0.0, 0.0]) \quad (69)$$

$$\mathbf{x}_1^* = \text{Diag}([\frac{1}{2} \cos(0.3t), \frac{1}{2} \sin(0.3t), 1, 0, 0, 0.0, 0.0]). \quad (70)$$

Based on the given parameters and target trajectories, the scenario is validated in the following sections.

7.1 Numerical validation

For the numerical validation, two *AR.Drone 2.0* models have been implemented in the simulation environment V-REP (Fig. 18). The position information of quadrotors and target trajectories is shared via a Robot Operating System (ROS) interface.

Figure 19 is showing the trajectories of both UAVs. UAV_1 is following the circular moving target which is reflected by sinusoidal position trajectories. UAV_0 is tracking UAV_1 with the developed sensor constraints which is indicated by likewise sinusoidal position trajectories of UAV_0 . The form and position of the resulting trajectory is depending on the initial UAV positions. As the position of UAV_0 is just dependent on the applied constraints, UAV_0 can rotate freely around UAV_1 . This explains the drift of the sinusoidal position trajectory of UAV_0 . The control trajectories of UAV_1 and UAV_0 are showing that the input limits are respected. The distance d stays in the defined limits $d_{min} \leq d \leq d_{max}$ with one exception at the initial phase of the simulation. Here the repulsive

Fig. 19 Numerical simulation: Trajectories of use case scenario

behavior of the collision avoidance constraint can be seen, where the controller increases the distance to fulfill $d \geq d_{min}$. On one hand, the disadvantage of the weakened constraint is, that d can violate the given constraint depending on the parametrization of the potential function and the smoothness of the unit step approximation by the sigmoid (35). On the other hand, the advantage is, that a constraint violation does not lead to an infeasible *OCP*. To conclude, the distance trajectory is validating the active collision avoidance and cohesion constraint.

To validate that the tracked UAV_1 stays within the sensor beam width angle α , Fig. 19 is therefore also showing the absolute tracking angle α_t

$$\alpha_t = \left\| \arccos \left(\frac{\mathbf{p}_S \cdot (1, 0, 0)^T}{|\mathbf{p}_S|} \right) \right\|. \quad (71)$$

which is describing the angle between the UAV_0 sensor orientation vector and the distance vector to UAV_1 in the sensor frame. The resulting α_t plot in Fig. 19 is validating, that the cone constraint keeps the tracking angle α_t smaller than the sensor beam width angle $\alpha_t \leq \alpha = 0.5$ rad. It can be seen that the tracking angle α_t is in fact much smaller. This is caused by the smooth approximation of the unit steps by sigmoids (35) which leads to a convergence towards the center of the cone. Especially for undisturbed systems, this yields to a smaller tracking angle α_t than the beam width angle α . To reduce this effect κ_A can be increased.

A more intuitive access to the UAV behavior is gained by plotting the UAV positions and the orientation of UAV_0 by means of a vector as shown in Fig. 20. To be able to associate both UAV positions, time-related UAV positions are connected with a line. It is visible that UAV_1 is following the desired circular trajectory, while UAV_0 is tracking UAV_1 in an ellipsoidal movement. The orientation vectors are displayed at each $\Delta t \approx 1.68$ s for means of visualization.

To resume, Figs. 19 and 20 validate the desired behavior of the proposed sensor constrained *MPC* controller in simulation. The next section is discussing the extension of this numerical validation to the real scenario.

7.2 Experimental validation

The use case scenario with real *AR.Drone 2.0* quadrotors, as shown in Fig. 21, is subject to a variety of disturbance which is not considered in the numerical validation. Light-weight *UAVs* like an *AR.Drone 2.0* quadrotor are particularly responsive to airflow disturbance. In addition, their flight dynamics are very volatile, as their body consist of deformable Styrofoam. These and more influences (communication latency, prediction model errors, measurement uncertainty) are not considered in the *MPC* model and simulation environment. For this reason an experimental val-

Fig. 20 xy -plot with UAV_0 orientation of the numerical simulation of the use case scenario (direction samples each $\Delta t \approx 1.67$ s)

Fig. 21 Experimental validation of the use case scenario with real quadrotors

idation is necessary to assess the robustness of the proposed control approach. The position data of the real *AR.Drone 2.0* quadrotors is hereby measured by a motion capture system.

The resulting system trajectories are given in Fig. 22. In contrast to the numerical simulation, the real *AR.Drone 2.0* trajectories are subject to significant disturbance. Especially the mutual airflow disturbance is causing low-frequency oscillations ≈ 0.5 Hz which are visible in the y -position of UAV_0 and UAV_1 . As the airflow disturbance error is propagating from the UAV_1 position to the UAV_0 response, the resulting oscillations are particularly visible in the controls of UAV_0 .

To evaluate the control performance, the distance d and absolute tracking angle α_t are given in Fig. 22. The distance plot is stating that UAV_1 is tracked within the given distance limitations. At $t \approx 55$ s the behavior of the weakened constraint is visible which is allowing a minor violation of d_{min} in return for avoiding infeasible solutions and ease of implementation. The absolute tracking angle (71) in Fig. 22 is measured between the UAV_0 orientation vector and the

Fig. 22 Trajectories of real use case scenario

Fig. 23 xy -plot with UAV_0 orientation of real use case scenario (Direction samples each $\Delta t \approx 1.68$ s)

distance vector to UAV_1 . Due to the initial conditions, α_t is violating the applied cone constraint at the beginning, but is tracked within the given beam width angle $\alpha_t \leq \alpha = 0.5$ rad for $t \geq 6$ s. Hence, the trajectories in Fig. 22 confirm the desired tracking behavior.

Figure 23 is showing the resulting xy -trajectory with samples of the UAV_0 orientation vector. For means of visualization, the orientation sample time is reduced to $\Delta t \approx 1.68$ s. Due to different initial conditions (positions, velocities, etc.), the xy -trajectory is not directly comparable with the numerical simulation. However, it visualizes the closed-loop UAV position response to mutual airflow disturbance in the form of small oscillation. In comparison to the simulation trajectory, the rejection of these oscillations (input costs) dominate the minor gradient within the compliant area of the sensor constraint. As a result the absolute tracking angle α_t and distance d plots in Fig. 22 go closer to their constraint limits and the xy -plot does not follow the ellipsoidal pattern of UAV_0 in Fig. 20. In order to evaluate the tracking without the mutual airflow disturbance and under different initial conditions, a further analysis of the robustness is shown in the experimental discussion (Sect. 7.3).

For the evaluation of the computational efficiency of the proposed approach, Fig. 24 is giving the MPC computation time on a standard computer (*Dell Latitude E5440*). The peaks in the computation time of $t_{comp} \approx 20$ ms are not directly related to the solver, but are caused by CPU interrupts by other processes. The resulting average computation time $t_{av,comp} = 2.5$ ms is very low in comparison to the control update interval of $\Delta t = 10$ ms and states the real-time feasibility of the MPC .

To conclude, the experimental results are validating the computational efficiency and effectiveness of the MPC control based on potential functions.

Fig. 24 Computation time of real use case scenario

7.3 Experimental discussion

In order to discuss the robustness to disturbance and initial conditions, the previous experiment of Sect. 7.2 is altered by substituting UAV_1 by a target with constant position $\mathbf{p}_{uav0\mathcal{G}} \rightarrow \mathbf{p}_{t\mathcal{G}} = [0.04, -0.05, 0.96]^\top \text{ m}$. The disturbance is introduced manually by means of an obstacle with the position $\mathbf{p}_{O\mathcal{G}}$ and a related collision avoidance constraint (52) $l_{minD}(\mathbf{p}_{O\mathcal{G}}, \mathbf{p}_{uav0\mathcal{G}}, d_{O,min}, \kappa_{H3}, \kappa_{G3}, \kappa_{A3})$. In order to make the evasive behavior visible in the xy -plane, the z -axis action of UAV_0 is reduced by increasing the input penalty for u_z . The resulting OCP (72)–(78) does consider the obstacle and target position within the prediction horizon as constant

$$\begin{aligned} \min_{\mathbf{u}} J = & \int_{t_0}^{t_f} \mathbf{u}_0(\tau) \mathbf{R}_0 \mathbf{u}_0(\tau) \\ & + k_{00} l_c(\mathbf{p}_{t\mathcal{S}}, \alpha, \kappa_{G0}, \kappa_{A0}) \\ & + k_{01} l_{maxD}(\mathbf{p}_{t\mathcal{G}}, \mathbf{p}_{uav0\mathcal{G}}, d_{max}, \kappa_{H1}, \kappa_{G1}, \kappa_{A1}) \\ & + k_{02} l_{minD}(\mathbf{p}_{t\mathcal{G}}, \mathbf{p}_{uav0\mathcal{G}}, d_{min}, \kappa_{H2}, \kappa_{G2}, \kappa_{A2}) \\ & + k_{03} l_{minD}(\mathbf{p}_{O\mathcal{G}}, \mathbf{p}_{uav0\mathcal{G}}, d_{O,min}, \kappa_{H3}, \kappa_{G3}, \kappa_{A3}) d\tau \\ \text{s.t. } & \mathbf{c}_0(\tau) \leq \mathbf{0}, \mathbf{c}_1(\tau) \leq \mathbf{0} \\ & \mathbf{0} = \mathbf{f}_0(\mathbf{x}_0, \mathbf{u}_0, t) \end{aligned} \quad (72)$$

with

$$\begin{aligned} \begin{bmatrix} \mathbf{p}_{t\mathcal{S}} \\ 1 \end{bmatrix} = & \mathbf{T}_{\mathcal{G}}^{\mathcal{S}}(\beta, -d_s, \mathbf{d}_{uav0\mathcal{G}}, -\mathbf{p}_{uav0\mathcal{G}}) \begin{bmatrix} \mathbf{p}_{t\mathcal{G}} \\ 1 \end{bmatrix} \\ \mathbf{R}_0 = & \text{Diag}([1, 1, 10, 1]) \end{aligned} \quad (73)$$

$$\begin{aligned} p_c : & d_s = 0.17, \alpha = 0.5, \beta = 0.5, \\ & k_{00} = 0.4, k_{G0} = 0.01, k_{A0} = 2.0 \end{aligned} \quad (74)$$

$$\begin{aligned} p_{minD} : & d_{min} = 0.7, k_{01} = 0.4, \\ & k_{H1} = 4.5, k_{G1} = 0.0001, k_{A1} = 3.0 \end{aligned} \quad (75)$$

$$\begin{aligned} p_{maxD} : & d_{max} = 2, k_{02} = 0.4, \\ & k_{H2} = 1.5, k_{G2} = 0.0001, k_{A2} = 3.0 \end{aligned} \quad (76)$$

$$\begin{aligned} p_{OminD} : & d_{O,min} = 1, k_{03} = 0.6, \\ & k_{H3} = 1.5, k_{G3} = 0.001, k_{A3} = 3.0 \end{aligned} \quad (77)$$

$$\begin{aligned} p_{cgmres} : & n_{hor} = 20, T_{hor} = 1 \text{ s}, \epsilon_T = 10^{-8}, \zeta = 10 \\ & \Delta t = 0.01 \text{ s}, k_{max} = 30, \alpha_{hor} = 2. \end{aligned} \quad (78)$$

The experimental outline is shown in Fig. 25. As in Sect. 7.2, the pose of UAV_0 is measured with a motion capture system. The constant target position is indicated as green diamond in the center of the pictures. In its initial pose, UAV_0 is not necessarily fulfilling the underlying inequality constraints of the sensor cone constraint (39). The activation of the controller therefore initially leads to a convergence towards a compliant pose. As a next step, an obstacle (red star) is introduced manually by means of the motion capture system. UAV_0 (blue circle) is evading the approaching obstacle by moving in the opposite direction. This evasion maneuver shows the form of an arc due to the active target tracking constraints. Following UAV_0 with the obstacle consequently leads to a circular trajectory around the tracked target point $\mathbf{p}_{t\mathcal{G}}$. The corresponding UAV_0 orientation is indicated by a blue arrow.

To cope different initial conditions and obstacle patterns, a set of 10 experiments is conducted. Figure 26 is showing the resulting xy -trajectory of UAV_0 (blue line), obstacle (dashed red line) and the fixed target position (green diamond). To visualize the system at different time instances, the position of the obstacle (red star) and pose of UAV_0 (blue circle with arrow) is marked every $\Delta t = 4.2 \text{ s}$. The distances between UAV_0 and target is signalized as light grey line at each of these time instances. Accordingly, the distance between UAV_0 and the obstacle is indicated as light red line. The resulting circular patterns validates the target tracking during the evasion maneuver. Furthermore, the direction of the drone is pointing to the center which is indicating the tracking of the target. In this context, in plot 7 center left and plot 9 center up the drone orientations which are not pointing towards the target are representing initial conditions. These initial poses of UAV_0 have been chosen arbitrarily within the spacial limitations of the laboratory and its exact values can be exerted from the UAV_0 pose plots in Fig. 27. In this initial phase a typical increase in the altitude (z) can be observed which is caused by the inclination angle β of the sensor cone constraint. The steps in the Ψ values in Fig. 27 are based on the limited Ψ -angle interval. The sinusoidal trajectories in x and y evidence the circular evasion maneuver of UAV_0 . Figure 28 is showing measurements of the corresponding obstacle position. Also here the sinusoidal trajectory, in order to follow the UAV_0 and provoke an evasion, is visible. The steps in the obstacle position at the beginning are caused by entering the detection zone of the motion capture system.

To analyze the influence of the obstacle collision avoidance constraint l_{minD} (53), Fig. 29 is showing the distance between UAV_0 and obstacle. The plots show how the obstacle is moved close to d_{Omin} to provoke an evasion maneuver of UAV_0 . The measured minimal distances are given in Table 1.

Fig. 25 UAV_0 trajectory—tracking target with constant position while obstacle is avoided

Fig. 26 UAV_0 x - y -trajectory with pose markers every $\Delta t = 4.2$ s showing circular evasion maneuver pattern

As the collision avoidance design is based on weakened constraints, violations are feasible. For all 10 experiments the highest violation of the obstacle distance d_O appears in run 5 with $\min(d_O) = 0.601$ m. The violation generally depends on UAV_0 and obstacle speed as well as cost gradient design of the collision avoidance constraint. For the here considered UAV and obstacle speeds, the cost gradient is chosen less steep (77)

in order to show a smooth repulsive behavior while showing the desired evasion. In reverse conclusion higher violations are accepted. For higher system velocities this cost gradient has to be chosen steeper. Its repulsive behavior can be observed as oscillation around the constraint border in Fig. 29 run 6, 7 and 9.

Fig. 27 UAV₀ pose trajectory with steps in the Ψ -trajectory due to the limited yaw angle interval

Fig. 28 Manually introduced obstacle position showing circular pattern in order to follow UAV₀ on its evasion trajectory. Any steps are caused by entering the obstacle into the field of detection of the motion caption system

Fig. 29 UAV₀ distance to obstacle d_O stays above the defined minimum distance of $d_{O,min} = 1.0\text{m}$

The influence of the target collision avoidance and cohesion constraints can be evaluated using the Euclidean distance of UAV₀ to the target, as shown in Fig. 30. Both constraints restrict the distance to $d_{min} = 0.7\text{m} \leq d \leq 2.0\text{m} = d_{max}$. The measured distance d lies in the interval $0.941\text{m} \leq d \leq 1.966$ and therefore complies to the target distance constraints for all 10 experiments. The peak distance values are given in Table 1. The minimum tracking distance $\min(d) = 0.941\text{m}$ appears in run 2 and its maximum value $\max(d) = 1.966\text{m}$ in run 10.

Finally, the behavior of the developed sensor cone constraint (39) is validated. For this purpose the absolute tracking angle α_t (71) is shown in Fig. 31. The sensor constraint (39) is restricting the absolute tracking angle to $\alpha_t \leq \alpha_{t,max} = 0.5$. For the set of experiments, the initial conditions do typically not satisfy this constraint due to a low initial UAV₀ altitude z and in compliant orientation ψ . This is directly shown by the controller counteraction as shown in Fig. 32. In the initial phase experiment 1–5 show a direct reaction in the altitude by $|u_z| \gg 0$, while a significant adjustment in the ψ -axis by $|u_\psi| \gg 0$ is dominating in experiment 5–10. The resulting convergence towards the constraint compliance $\alpha_t \rightarrow \alpha_{t,max}$ can be seen in all plots of Fig. 30 and is followed by a period of low action, as all constraints are satisfied and the obstacle is not considered yet. With the approaching obstacle $d_O \rightarrow d_{O,min}$ in Fig. 29, the control action in Fig. 32 is increased due to the evasion maneuver. As a result, also the tracking angle α_t in Fig. 31 is disturbed. To measure the constraint violation the maximal absolute tracking angle in the nominal state $\max(\alpha_{t,ns})$ is given in Table 1. For this purpose, $\max(\alpha_{t,ns})$ takes into consideration the absolute tracking angle peak values after the initial convergence phase. $\alpha_t \leq \alpha_{t,max} = 0.5$ rad holds after the initial phase for all the experiments. The measured maximum appears in run 2 with $\max(\alpha_{t,ns}) = 0.438$ rad.

The experimental results validate the desired behavior of sensor based tracking also under the influence of disturbance introduced as obstacle. The sensor field of view limitations are respected and collisions are avoided. Furthermore, the set of experiments shows the robust convergence towards a compliant state under differing initial conditions and constraint violations.

8 Conclusion and perspective

The present paper focuses on the presentation of a workflow for the generation of potential functions for sensor constrained MPC. The workflow is tested in simulation and a real-world implementation of a sensor constraint tracking scenario with quadrotors.

For this purpose a compact motion model for multi-rotor UAVs has been developed. To be able to control the robot's

Fig. 30 UAV_0 distance to target d stays within the defined minimum distance of $d_{\min} = 0.7\text{m}$ and maximum distance of $d_{\max} = 2.0\text{m}$

Fig. 31 UAV_0 absolute tracking angle α_t stays within the defined maximum of $\alpha_{t,\max} = 0.5\text{ rad}$ of the sensor cone constraint

Fig. 32 UAV₀ actuation

yaw angle orientation in 360° , the problem of the discontinuously defined yaw angle $-\pi < \psi \leq \pi$ has been addressed. The MPC of the resulting direction vector model has been validated experimentally with an *AR.Drone 2* quadrotor.

Based on the developed system dynamic description, the workflow for a sensor constrained MPC control has been presented. The *AR.Drone 2* quadrotor with attached sensor has served as platform for the sensor based tracking scenario. The first step in the workflow is to formulate the sensor perception space within a sensor coordinate frame by means of inequality constraints. For the use case, the cone shape of the sensor perception space has been described by a combination of two inequality constraints. As second step, these constraints have been transformed into a potential function with the help of unit steps. The idea is to introduce a repulsive behavior for a violation of the constraints which leads to a weakening of the constraints. This allows a small violation to maintaining feasibility of the OCP. The transformation into a weakened constraint with the help of unit steps helps to verify the cost functions without having to deal with the increased complexity of sigmoids. In addition, it allows a simple graphical verification of the potential function with visualization tools. To improve the solvability of the problem for gradient based solvers, the next step has been the introduction of a gradient in the undesired area of the potential function which is pointing away from the target region. Subsequently, the previously introduced unit steps in the potential function are approximated with sigmoids which leads to a continuous gradient around the constraint borders. As a result the potential function becomes analytical and therefore solvable by standard real-time MPC solvers.

In order to validate the derived potential function for the cone constraint, additional safety measures have been necessary. Therefore, a collision avoidance and a cohesion constraint have been developed, using the previously described workflow. In the validation scenario an *AR.Drone 2.0* is used to track another *AR.Drone 2.0* quadrotor which is following a circular trajectory. The tracking by means of the sensor constraint has been tested experimentally in simulation and a real-world implementation. To further discuss the influence of obstacles, utilized constraints and different initial conditions, a series of real-world collision avoidance scenarios has been presented. In the presented scenarios an *AR.Drone 2.0* is tracking a fixed target using the developed constraints for the cooperative control scenario while disturbance is introduced in form of an obstacle. The results show the desired collision evasion maneuver while maintaining sensor tracking for different initial conditions. The results have validated the developed multi-rotor prediction model as well as the sensor constraint potential function.

Table 1 Peak distance values for the set of 10 conducted experiments

Run	1	2	3	4	5
$\min(d_O)$ (m)	0.976	0.950	0.945	1.038	0.601
$\min(d)$ (m)	1.064	0.941	1.176	1.203	0.950
$\max(d)$ (m)	1.785	1.931	1.827	1.791	1.834
$\max(\alpha_{t,ns})$ (rad)	0.371	0.438	0.345	0.183	0.350
Run	6	7	8	9	10
$\min(d_O)$ (m)	0.754	0.773	0.915	0.879	1.083
$\min(d)$ (m)	1.091	0.633	1.082	1.191	0.984
$\min(d)$ (m)	1.922	1.815	1.791	1.823	1.966
$\max(\alpha_{t,ns})$ (rad)	0.260	0.307	0.220	0.225	0.271

Maxima, respectively minima are indicated in bold

Future work will focus on the solution of the localization problem with cameras. A further development will be the analysis of the energy efficiency of the proposed sensor constraint, in contrast to a simple orientation tracking. Particularly interesting would be a statistical analysis of large numbers of real-world experiments. Another direction of future studies is to distribute the presented central MPC and to explore the applicability of cloud computing. In addition, the application of the tracking scenario in heterogeneous systems e.g. ground robots and UAVs, will also be addressed in future work.

Jan Dentler is a Ph.D. candidate in the field of nonlinear real-time optimization in the Automation and Robotics Research Group of the University of Luxembourg. His interest is towards the development and application of real-time model predictive control algorithms for fast nonlinear distributed systems and cooperative aerial manipulation scenarios with quadrotors. Jan Dentler studied industrial electronics at the Ulm University of Applied Sciences which he finished in 2012 with

honours. His thesis was focusing on signal processing of ultrasonic signals. During his master studies at the Ulm University he focused on control engineering and automation particularly model predictive control. In 2014 he received the Master of Science (M.Sc.) degree in electrical engineering for his thesis about distributed model predictive control of cooperating unmanned aerial vehicles.

Somasundar Kannan received his Ph.D. degree in 2011 from Arts et Métier ParisTech, France with specialization in Automatic Control with a Thesis focused on Adaptive Model Predictive Control. He received his MS degree in Aerospace Engineering: Dynamics and Control from Korea Advance Institute of Science and Technology (KAIST), Republic of Korea and Bachelor of Engineering Degree in Electronics and Instrumentation from University of Madras, India. He joined the

Interdisciplinary Center for Security Reliability and Trust (SnT) at the University of Luxembourg in 2013, as Associate Researcher in the Automation and Robotics Research Group. Prior to working at SnT Dr. Somasundar Kannan was a researcher at the Automatic Control lab in Supélec- Rennes in 2012. The research focus of Dr. Somasundar Kannan spans over the fields of Control Engineering, Aerial and Space Robotics, Multibody Dynamics and System Identification. He has authored and coauthored several publications in technical journals and referred conferences.

Souad Bezzaoucha graduated from “Ecole Nationale Polytechnique”, Algeria, and received a Master of Science in Electrical Engineering in 2005 and 2007, respectively. She received a Master degree in Computer Science Engineering from “Ecole Polytechnique”, France in 2010 (“Excellence Scholarships” from the Foundation of Ecole Polytechnique) and spent 1 year from 2007 to 2008 as a research student at the “Graduate School of Engineering”, Kyoto University, Japan (Japanese

Government—Monbukagakusho Scholarship). She received her Ph.D. from Université de Lorraine, France, in 2013. From January 2014 to May 2015 she was a postdoctoral fellow and lecturer at Laboratoire de l’Intégration du Matériau au Système (IMS), Bordeaux, France and Bordeaux Polytechnic National Institute (INP) Enseirb-MatMeca. Since June 2015 she joined the Interdisciplinary Center for Security, Reliability and Trust (SnT), University of Luxembourg as a Research Associate. Her research interests are in the robust control theory, observers design and cyber security.

Miguel Angel Olivares-Mendez received the Diploma in Computer Science Engineering in 2006 from the University of Malaga (UMA), Spain. He received the M.Sc. degree in Robotics and Automation and Ph.D. degree in Robotics and Automation at the Industrial Engineering Faculty in the Technical University of Madrid (UPM), Spain, in 2009 and 2013, respectively. He was distinguished with the Best Ph.D. Thesis award of 2013 by the European Society for Fuzzy Logic and Technology

(EUSFLAT). He joined the Interdisciplinary Center for Security Reliability and Trust (SnT) at the University of Luxembourg on May 1, 2013, as Associate Researcher in the Automation and Robotics Research Group. Since May 1, 2013, he is acting as Associate Editor for Journal of Intelligent and Robotic Systems (JINT). In December 1, 2015, he was selected to be Reviewer Editor for the Robotic Control Systems, part of the journal(s) Frontiers in Robotics and AI. Dr. Olivares-Mendez’s research interests are focused in the areas of Unmanned Systems, Computer Vision, Vision-Based Control, Soft-Computing Control Techniques, Fuzzy control, Sensor Fusion, Robotics and Automation. He has been working in robotics and control with unmanned systems since 2006. He has published over 50 book chapters, technical journals and referred conference papers.

Holger Voos studied Electrical Engineering at the Saarland University and received the Doctoral Degree in Automatic Control from the Technical University of Kaiserslautern, Germany, in 2002. From 2000 to 2004, he was with Bodenseewerk Gerätetechnik GmbH, Germany, where he worked as a Systems Engineer in aerospace and robotics. From 2004 to 2010, he was a Professor at the University of Applied Sciences Ravensburg-Weingarten, Germany, and the head of the

Mobile Robotics Lab there. Since 2010, he is a Professor at the University of Luxembourg in the Faculty of Science, Technology and Communication, Research Unit of Engineering Sciences. He is the head of the Automatic Control Research Group and also the head of the Automation and Robotics Research Group in the Interdisciplinary Centre of Security, Reliability and Trust (SnT) at the University of Luxembourg. His research interests are in the area of perception and control for autonomous vehicles and mobile robots as well as distributed and networked control.
