Abstract

Most mitigation scenarios compatible with a likely change of holding global warming well below 2 °C rely on negative emissions technologies (NETs). According to the integrated assessment models (IAMs) used to produce mitigation scenarios for the IPCC reports, the NET with the greatest potential to achieve negative emissions is bioenergy with carbon capture and storage (BECCS). Crucial questions arise about where the enormous quantities of biomass needed according to the IAM scenarios could feasibly be produced in a sustainable manner. Africa is attractive in the context of BECCS because of large areas that could contribute biomass energy and indications of substantial underground CO₂ storage capacities. However, estimates of large biomass availability in Africa are usually based on highly aggregated datasets, and only a few studies explore future challenges or barriers for BECCS in any detail. Based on previous research and literature, this paper analyses the pre-conditions for BECCS in Tanzania by studying what we argue are the applications of BECCS, or the components of the BECCS chain, that are most feasible in the country, namely (1) as applied to domestic sugarcane-based energy production (bioethanol), and (2) with Tanzania in a producer and re-growth role in an international BECCS chain, supplying biomass or biofuels for export to developed countries. The review reveals that a prerequisite for both options is either the existence of a functional market for emissions trading and selling, making negative emissions a viable commercial investment, or sustained investment through aid programmes. Also, historically, an important barrier to the development of production capacity of liquid biofuels for export purposes has been given by ethical dilemmas following in the wake of demand for land to facilitate production of biomass, such as sugarcane and jatropha. In these cases, conflicts over access to land and mismanagement have been more of a rule than an exception. Increased production volumes of solid biomass for export to operations that demand bioenergy, be it with or without a CCS component, is likely to give rise to similar conflicts. While BECCS may well play an important role in reducing emissions in countries with high capacity to act combined with existing large point sources of biogenic CO₂ emissions, it seems prudent to proceed with utmost caution when implicating BECCS deployment in least developed countries, like Tanzania. The paper argues that negative BECCS-related emissions from Tanzania should not be assumed in global climate mitigation scenarios.

1 Introduction

Most climate scenarios compatible with a likely change of holding global warming well below 2 °C rely on negative emissions technologies (NETs). According to the integrated assessment models (IAMs) used to produce climate scenarios for the Intergovernmental Panel on Climate Change (IPCC) reports, the NET with the greatest potential to achieve negative emissions is bioenergy with carbon capture and storage (BECCS) (Beck and Mahony 2018; Fuss et al. 2014; Gough et al. 2018a, b; Harper et al. 2018). This method features in the scenarios despite only experimental scale experiences and acknowledged major uncertainties related to, for example, technological capacity, maturity and the availability of sustainable biomass. Fuss et al. (2014) estimate the required quantities of removed carbon, if guided by the estimates from the IPCC's Working Group III, to be in the range between 2 and 10 Gt annually in 2050. Such a huge deployment would, among other things, entail serious land-use trade-offs with possibly long-lasting impacts on food security, fibre production, biodiversity and fresh water and fertilizer supply (Creutzig et al. 2015; Fuss et al. 2014; Harper et al. 2018).

Crucial questions arise about where the enormous quantities of biomass needed according to the IAM scenarios could be produced in a sustainable manner. Many IAMs deploy large amounts of BECCS in sub-Saharan Africa, and according to the *Carbon Mitigation Initiative* at Princeton University, Africa is attractive in the context of BECCS because of large areas that could contribute biomass energy and indications of substantial underground carbon dioxide (CO₂) storage capacities. The initiative has presented the idea that the USA could meet ambitious national emissions targets in 2050 by buying offsets from African BECCS projects, while also providing opportunities for co-benefits in Africa, such as sustainable fuels for cooking and transport (Williams and Larsen 2012).

However, estimates of large biomass availability in Africa are usually based on highly aggregated datasets, and only a few studies explore future challenges or barriers for BECCS in any detail. Technical and social challenges for the rapid up-scaling of BECCS in different socio-economic and geographical contexts have not yet been satisfactorily explored (Anderson and Peters 2016; Buck 2016; Carton 2019; Creutzig et al. 2015; Fuss et al. 2014; Geden 2015; Gough et al. 2018a, b). Buck (2016) has further argued that context-dependent factors such as national politics, land characteristics and social relations are likely to significantly determine the feasibility of BECCS, and that such factors are missing from highly generalized mitigation scenarios. This paper thus seeks to contribute to more context-sensitive knowledge about the feasibility of BECCS, with an in-depth analysis of socio-economic, geographical and institutional preconditions in Tanzania, a developing country identified by IAMs as having a large potential for large-scale BECCS deployment (Harper et al. 2018). Following Buck's (2016) suggestion that analogue cases may be the most accessible route for understanding the feasibility of BECCS, given the lack of real-world experiences of large-scale BECCS, we will explore large-scale biofuel investments in Tanzania as an entry point for a more general discussion about the feasibility of large-scale BECCS in sub-Saharan Africa.

Based on the previous research and literature, this paper analyses the preconditions for BECCS in Tanzania by studying what we argue are the applications of BECCS, or the components of the BECCS chain, that are most feasible in the country, namely (1) as applied to domestic sugarcane-based energy production (bioethanol), and (2) with Tanzania in a producer and re-growth role in an international BECCS chain, supplying biomass or biofuels for export to developed countries.

2 Background

The core idea of BECCS is the growth and utilization of biomass for different industrial and energy purposes and subsequent storage of the resulting CO₂ by-product in geological formations while also re-growing biomass. Because CO₂ is stored both in the biomass through photosynthesis and after the biomass has been processed, the technology allows for the potential of net negative CO₂ emissions. Due to its significant capital costs, it is regarded as applicable only to large point sources, primarily the paper and pulp industry, biofuel producers or combined heat and power plants. A huge drawback of BECCS is its heavy energy penalty, which means it significantly lowers the efficiency of the industrial process it is applied to (Bui et al. 2017; Jönsson and Berntsson 2012).

Tanzania is theoretically well suited for biomass generation on an industrial scale. It has long been considered a forerunner in sub-Saharan Africa in carbon forestry management (Blomley et al. 2008), and even termed an “African poster child for policy reform” with regard to forest management (Koch 2017: p. 181), while also taking the lead in the production of jatropha biofuel and influencing the international debate that followed (Arora et al. 2013; Gasparatos et al. 2015). The country has several characteristics that suggest it is also suitable for BECCS deployment, as evidenced by the recent history of Western investments in liquid biofuels and other land-based projects (Harnesk and Brogaard 2016). These projects have been motivated by the fact that 46% of the country is covered with forests, and that it possesses an abundance of unused land, a large available workforce and governmental structures that are generally perceived to be stable and supportive of foreign investment (Habib-Mintz 2010; Mwakaje 2012). Even though BECCS is currently absent as a political issue in Tanzania, its vast biomass resources, beneficial preconditions according to many IAMs (e.g. Harper et al. 2018), recent history of foreign investments, and central position in international debates on biofuels and forest management make it arguably one of the most suitable objects for a case-based investigation into the feasibility of BECCS in sub-Saharan Africa. Furthermore, it is the only African country that has been targeted for claimed investments aimed at a development of BECCS (Kemper 2015; Swedish Radio 2009).

2.1 Analytical framework and method

Due to the fact that BECCS lacks both a technology/science push and market pull, it can be said to lack the main determinants of emerging technologies succeeding in breaking through (Bellamy and Healey 2018; Freeman 1986). This, in addition to the fact that it does not yet exist on a commercial scale, poses challenges for how to study its hypothetical future development, thus studies of system innovations, the emergence of sustainable technologies and socio-technical transitions (Edquist 1997; Geels 2012; Metcalfe and Cantner 2003; Smith et al. 2005) are likely to be of limited value. Yet, some theoretical premises for novel technology development can be derived from such literature, and we will employ a basic analytical framework suggested by Jacobsson and Lauber (2006) for the analysis of BECCS’ potential in Tanzania. As Markard et al. (2012) note, there is also a value in expanding studies of sustainable transitions to countries outside the OECD core, not least to highlight unequal power relations in technological development, that are of crucial importance for the potential implementation of BECCS in sub-Saharan Africa (Hansen et al. 2018; Lawhon and Murphy 2012; Wieczorek 2018).

The analytical framework suggested by Jacobsson and Lauber (2006) assumes that large-scale technological transformations presuppose and entail economic, social and infra-structural transformations at different scales. First, they require *institutional change*, which includes the creation of policies, legislation, regulatory standards, knowledge and political structures that facilitate the emergence of a new technology and its access to technological expertise and markets. Here, we would also add the importance of informal institutions to complement and operate in the void between incomplete or inadequate formal institutions, and that may include historical memory and trust (van Assche et al. 2014). Because informal institutions are harder to detect, they may be easy to overlook, but they are often crucial in determining path dependencies of different kinds, something that Wieczorek (2018) highlights as key to understanding socio-technical innovation in developing countries.

Secondly, a new technology is dependent on *the formation of markets* for its breakthrough, something that is in itself closely connected to institutional change. New markets often need a period of protection, during which crucial learning processes help the technology reach commercial maturity, and incentive structures of different kinds may induce firms to enter. Here, in line with Karnøe and Garud (2012), we would highlight that institutions not only act as limiting factors or structural determinants of path dependency, but may also be seen in an alternative light as preconditions for *path creation*, perhaps especially so if they are weak or malleable.

Thirdly, the *creation of broader constituencies and advocacy coalitions* beyond purely commercial actors is necessary for technological development. Such constituencies involve non-market actors like NGOs and universities, who contribute to fostering both material preconditions and softer structures like acceptance and legitimacy. Fourthly, the entrance of new firms into the interplay of institutions, market forces and advocacy coalitions will decide the success of an emerging technology. In the context of developing countries, Marquardt et al. (2016), Nygaard and Bolwig (2018) and Sixt et al. (2018) have highlighted the importance of support and advocacy from international actors, while van Welie and Romijn (2018) stress the need to embed technological development in the local culture. Because of the still highly hypothetical nature of BECCS development as a technological system, we treat these third and fourth steps as a single step in the concluding discussion. This framework should be seen as a simple set of criteria against which we evaluate the possibilities of BECCS development in Tanzania in the concluding discussion, and it is not employed in the main literature review, which follows in the next section.

The paper is based on secondary literature that was found through the Unisearch web application. We selected literature based on its relevance according to our analytical framework and assumptions about BECCS' feasibility in Tanzania, i.e. that it is most likely to be applied in relation to ethanol production or with Tanzania acting as a provider of solid biomass for export. Thus, we included literature that pertained to geographical conditions of relevance for industrial biomass production, land-use trade-offs, case studies of biofuel projects, and formal institutional frameworks regulating biofuel production and foreign investments, all geographically limited to Tanzania.

The vast majority of texts are peer-reviewed scientific publications, but some items of particular relevance from the grey literature and from news sources were also included. The search (which included the search strings "Tanzania", "LDC", "BECCS", "bioenergy with carbon capture and storage", "SEKAB", "ethanol production", "biofuel" and "REDD+" in various combinations) generated around 60 texts which were deemed relevant after an initial brief overview and reading of the abstracts. Further texts were included using the reference lists. This first selection was then closely read and cross-analysed by all authors, allowing us to make a number of key points in relation to our research problem

and analytical framework. It should be noted that we have used the literature review as a basis for an analysis of formal and informal institutional preconditions for large-scale BECCS in Tanzania, and that our aim has neither been to perform a comprehensive literature review nor an overview of the field or bibliometric analysis. While certain papers of potential relevance might therefore not have been included, we are confident that our main arguments are sustained by and firmly anchored in relevant literature.

3 Background

3.1 Path creation preconditions for BECCS in Tanzania: ethanol or solid biomass for export

The more recent mitigation scenarios, described by Riahi et al. (2017), which deliver a climate forcing of 2.6 W/m^2 in 2100 (i.e. compatible with the 2°C goal), deploy BECCS in all world regions, including the region “Africa and the Middle East”. As early as mid-century, the average deployment rate of BECCS in this region is 6.3 EJ (i.e. 1700 TWh). By 2060, all 2°C scenarios deploy BECCS to some extent, averaging 27.4 EJ (see Fig. 1). For comparison, 0.022 EJ (i.e. 6 TWh) of electricity was produced in Tanzania in 2014.

The electricity grid in Tanzania is severely underdeveloped, with the majority of its population living in rural, off-grid or isolated grid areas (Felix and Gheewala 2012; Msyani 2013). Electricity makes up a fraction of the country’s primary energy supply (Msyani 2013; Odhiambo 2009), and only approx. 15–30% of the Tanzanians have access to electricity, a vast majority of them are living in urban areas (Amars et al. 2017; Aly et al.

Fig. 1 Use of BECCS in the Middle East and Africa in the Shared Socio-economic Pathways Database’s scenarios ($n=19$) compatible with a forcing of 2.6 W/m^2 in 2100 (i.e. 2°C compatible)

2017). At present, the Tanzanian energy system is dominated by biomass as a cooking fuel, which represent well over 80% of total energy consumption (AfDB 2015; Odhiambo 2009). At the same time, biomass contributes well below 1% to electricity generation; most electricity is instead generated from natural gas fired thermal power plants and hydropower (Amars et al. 2017). Increasing the level of access to electricity is highly prioritized for the Tanzanian government. However, government plans for electrification centre on fossil fuels and an ambition to vastly expand the country's large-scale hydroelectric resources (Amars et al. 2017; Bhati and Koshy 2018; Kichonge 2018). The official generation expansion plan assumes that in 2025, 75% of the power production will be supplied by fossil fuel fired power plants, 20% by hydro and 5% by other renewables (Aly et al. 2017). Part of the plans for a 75% fossil fuel based electricity generation, approx. 26 percentage points, is coal-based. Up to 8% of this could potentially be co-fired with biomass without necessitating separate fuel system preparation or delivery systems (Demirbas 2003). Yet in general, the prospects for a development of a domestic bioenergy-based power system in Tanzania seem slim. Furthermore, because the paper and pulp industry is limited to a single facility, this avenue for BECCS is also restricted.

In general, the prospects for CO₂ storage are deemed to be low in the onshore sub-Saharan Africa, but suitable geological CO₂ storage basins may exist onshore in the coastal areas of Tanzania. Storage potentials are not well explored, however, due to a lack of experience of oil and gas extraction in those areas (Haszeldine 2006). It has been suggested that the neighbouring country in the south, Mozambique, has extensive storage capacity, more than enough for its future domestic needs. The northern region of Mozambique has been identified as one of the most promising areas for extracting natural gas and coal, especially the Rovuma basin (235–470 Mt CO₂) (Global CCS Institute 2015), but none of the major extractive industrial actors have been promoting geological CO₂ storage here. Sasol, the major South African chemical and energy company, is investing heavily in natural gas extraction in Mozambique and acknowledges climate change as a paramount challenge. It has an active interest in carbon capture and storage (CCS) as partners of “The South African Centre for Carbon Capture and Storage” and as stakeholders in “CCS forerunners Technology Centre Mongstad” in Norway. The viability for geological storage of CO₂ is currently claimed to be investigated by Sasol, but only domestically in South Africa. Natural gas extraction in Mozambique is presented by the company as an opportunity to displace more carbon intensive fuels like coal, rather than enabling CO₂ storage (Sasol 2018).

Very large natural gas resources (37 trillion cubic feet) were discovered off-shore in 2010, in the south eastern regions of Tanzania, bordering Mozambique. These resources vastly outnumber the domestic demand for natural gas, and consequently, the gas resources can only be fully monetized through exports of liquefied natural gas. Several major international energy companies have been invited by the government to form joint ventures, to facilitate the construction of the multi-billion dollar infrastructure needed to exploit the resources. This would constitute one of the continent's most capital-intensive infrastructure projects, estimated to cost at least US\$ 20–30 billion. However, since the discoveries were made in 2010, the government's view on revenues and ownership structures has changed towards a more nationalistic stance, with more control left to domestic and state-controlled companies and a shift in focus from institutional capacity building to maximizing benefits for Tanzania (Hundsbaek Pedersen and Bofin 2019). According to Hundsbaek Pedersen and Bofin (2019), the driver for the radical change was the anxiety that foreign actors would extract the resources without contributing to the Tanzanian economy, as has

been the case historically. This shift in focus was formalized in the Petroleum Act of 2015 and three Sovereignty Acts of 2017,¹ which among other things declared national sovereignty over natural resources and disallowed companies to take disputes to international arbitration. Consequently, several major international actors have ongoing disputes with the Tanzanian government. Certainly, the unpredictability that has followed the publication of the Sovereignty Acts has made Tanzania less attractive for foreign investments in large-scale infrastructure (Hundsbaek Pedersen and Bofin 2019), and will most likely also keep the integration of carbon storage in the slowly emerging Tanzanian fossil fuel sector off the table for the foreseeable future.

Instead, in the following, we discuss the avenues ahead for the arguably least problematic options for integrating Tanzania in a future BECCS system. First, in spite of the acknowledged challenges of taking advantage of suitable storage sites in the region, we discuss the technically least complex and least costly option for capturing relatively large amounts of CO₂, and secondly, we discuss the growth of biomass for export within an international BECCS system, which would reposit the challenges and main responsibility of storage to developed countries.

As the fermentation of sugar gives rise to almost pure CO₂ fumes (99% purity in the reactor), capturing CO₂ from ethanol production is generally considered among the cheapest options for BECCS (Moreira et al. 2016). The techno-economic potential for ethanol production in Tanzania, in different scenarios, has been assessed at 6–26 million litres (l) annually from sugarcane molasses (a by-product from the production of sugar) and an additional 15–79 million l annually from sugarcane juice, i.e. a combined potential of 21–105 million l annually (Quintero et al. 2012). As ethanol weighs approx. 0.8 kg/l, the production potential corresponds to 17–84 million kg of ethanol annually. Fermentation resulting in 1 kg ethanol releases approximately 0.96 kg CO₂ (Moreira et al. 2016). The scenarios for ethanol production, thus, correspond to releasing approx. 0.016–0.081 million metric tonnes (Mt) of biogenic CO₂ annually. This can be compared to Tanzania's total emissions in 2014 of 290 MtCO_{2eq} including land use, land use change and forestry (LULUCF), and 80 MtCO_{2eq} excluding LULUCF. However, there are possibilities to combine different scenarios to further increase production (Quintero et al. 2012). Thurlow et al. (2016) conclude that the economic incentives for ethanol production in Tanzania are strong, indicating that ethanol production could expand relatively rapidly under the right market conditions. Eshton and Katima (2015) show that under the right market conditions and optimization of cultivation practices, reducing the need for chemical fertilizers, biofuels may, if not exported, reduce the GHG emissions by 70% compared with fossil fuels, while also increasing Tanzanian energy security. However, they also emphasize that Tanzania has low food productivity, and consequently, large investments in bioenergy crops could have negative socio-economic implications. Figure 2 shows total sugar production in Tanzania from 2007/2008 to 2016/2017 indicating annual variability in total sugar production, with a slightly positive trend starting from 2011/2012.

Potentially, ethanol could also be used for cooking, which could prove to be a crucial improvement from an environmental perspective. Both rural and urban Tanzanian households are heavily dependent on firewood or charcoal for heating and cooking, with Felix and Gheewala (2011) reporting 94% of all households and 78% of households in Dar es

¹ The Natural Wealth and Resources (Permanent Sovereignty) Act, the Natural Wealth and Resources (Review and Re-Negotiation of Unconscionable Terms) Act and The Written Laws (Miscellaneous Amendments) Act.

Fig. 2 Total sugar production from 2007/2008 to 2016/2017

Salaam to be reliant on the fuel. In 2000, total consumption of charcoal in the country was estimated at 750,000 tonnes (Sheya and Mushi 2000), and Odhiambo (2009) has reported 90% of total energy consumption to be biomass-based. Apart from causing health problems through air pollution, this enormous level of charcoal production puts heavy pressure on the forest, with deforestation increasingly being acknowledged as a problem. Government attempts to impose fines on charcoal production have largely failed due to difficulties in regulating this unofficial economy, and substituting charcoal for liquefied petroleum gas (LPG) is only an option for the relatively rich (Felix and Gheewala 2011).

Thus, there is a potential side-benefit to be found in implementing BECCS in relation to expanded use of ethanol domestically in Tanzania. Just as importantly, however, increased production of biomass for biofuel purposes risks results in positive emissions when all factors are considered, and thus further environmental degradation (Harper et al. 2018; Romijn 2009). Apart from causing biodiversity stress, deforestation is the major source of greenhouse gases in Tanzania. Agriculture, forestry and other land uses (AFOLU) in Tanzania account for 93.2% of total emissions, which dwarfs the emissions from the other sectors. Energy contributes to 3.8%, waste management to 1.5%, and industrial processes and product use to 0.5%. Deforestation and forest degradation account for the largest emissions in the AFOLU sector, with approximate annual emission of 37 MtCO_{2eq} (URT 2014, 2017).

A BECCS supply chain does not need to be confined to one single country. Peters and Geden (2017) illustrate a potential BECCS system with biomass harvesting in Cameroon exported to the UK for combustion and carbon capture and subsequent permanent storage in Norway. Given that BECCS necessitates a long-term perspective, spanning decades or even centuries, the prospect of involving several countries with vastly different motives and governance cultures would be likely to pose major challenges for the creation of a robust and reliable system for measurement, reporting and verification. Nevertheless, the division of the system components of BECCS across several countries is mentioned frequently in the BECCS literature (Gough et al. 2018a, b; Grönkvist et al. 2010; Peters and Geden 2017; Williams and Larsen 2012). Honegger and Reiner (2018) analyse at length how international policy instruments, primarily Article 6.4 of the Paris Agreement, could mobilise the

financial support needed for deploying NETs in developing countries, in a least-cost and flexible way that take the partaking countries' various stages of development into account.

The idea of African countries acting as suppliers of biofuels or a source for biomass re-growth has already raised concerns. In Bonn in May 2016, at the first session of the UN Framework Convention on Climate Change after the Paris Agreement was concluded, an intense debate took place when a few African networks raised fears that negative emissions technologies would result in land-grabs on the African continent (Guillemot 2017). Anderson and Peters (2016) raise concerns over global inequity from another angle. They claim that an eventual failure to deliver NETs, as envisioned in most IAMs, would strike the vulnerable low-emitting countries hardest. If prioritizing equity, risk aversion and aspiring to avoid moral hazard, they claim, the global climate mitigation agenda should instead rest on the premise that NETs will not deliver at scale (see also Carton 2019). Implementing BECCS would therefore entail serious difficulties and risks.

From an optimistic viewpoint, it could be argued that a path creation for BECCS would create an opportunity for regulatory improvement, given that the current forest and land management situation in Tanzania is precarious (Bhati and Koshy 2018; Karnøe and Garud 2012). To better understand the preconditions of such an optimistic scenario coming to fruition, we will therefore summarize findings from the literature about the formal institutional framework relevant for a future BECCS system in Tanzania, as well as empirical evidence from biofuel projects that point towards the existence of important informal institutions (van Assche et al. 2014).

4 Formal institutions governing biomass development

4.1 International formal institutions related to climate change

Internationally, the expectations on developing countries to contribute to global mitigation efforts have increased over the last decade. The Paris Agreement is perhaps the most prominent example of this trend, as it is the first globally applicable climate agreement expecting all contracting parties to contribute to emissions reductions and to undertake adaptation measures to avoid dangerous anthropogenic interference with the climate system. The Paris Agreement thus provides a policy objective clearly relevant to BECCS: to hold global warming well below 2 °C by 2100 and, in the second half of the century, to balance global emissions and uptakes. This goal will require changing societies on transformational scales, building societal and ecosystem resilience by, among other things, achieving net-zero emissions of greenhouse gases sometime after 2050. However, being labelled a least developed country (LDC), Tanzania is subject to relatively low pressure from international politics to adopt decarbonization leadership; mitigation actions in Tanzania are expected to primarily be supported by international means of implementation. Thus, the international level provides contradictory incentives for BECCS in Tanzania: while the Paris Agreement has created pressures globally to stimulate the development of NETs, international mechanisms do little to facilitate the establishment of national-level institutional structures that are conducive to foreign investment in such technological developments. The IPCC's accounting methodologies and guidelines for emissions are developed for national entities, and have difficulties capturing and mirroring the complexity of multinational or even global BECCS systems and supply chains (Gough et al. 2018a, b). Gough et al. (2018a, b) have further

identified goal conflicts between the targets concerning loss of natural habitats and restoration of degraded areas adopted by the Convention on Biological Diversity in 2010—targets which are not considered in the land-use scenarios applied in the IAMs—and mitigation targets premised on expanded biofuel use. Gasparatos et al. (2015) similarly argue that knowledge about the multitude of targets and indicators that exist on different policy levels is incomplete and fragmented, making management of the significant trade-offs difficult.

The incentives gap between policy levels can be illuminated by looking at the most central components in the international toolbox for technology development and resilience building in LDCs. The most relevant of these is the Kyoto Protocol's Clean Development Mechanism (CDM), which is an instrument of tradable emissions credits. Developed countries may invest in CDM projects in developing countries, prove emissions reductions compared to a baseline and generate tradable emission rights. In 2011, the UNFCCC decided to include CCS in the CDM. However, thus far, not one single methodology for a CCS CDM project has been approved. Such approval is also unlikely in the future for at least two reasons: (1) the market for certified emission reductions from CDM has virtually collapsed with the decline in demand, and (2) the requirements for approval of CCS methodologies under the CDM are unusually strict, involving host country domestic regulations covering, e.g. site selection and characterization, access rights to storage sites, redress for affected entities and liability (Dixon et al. 2013). As noted by Zakkour et al. (2014), the approval of CCS CDM rules in late 2011 coincided with a downturn in interest in the CDM, which in turn undercut the potential to spur the development of BECCS in Tanzania. At present, discussions are under way on how a new market mechanism, similar to the CDM of the Kyoto Protocol, should be operationalized under the Paris Agreement (e.g. Greiner et al. 2017).

Similarly, Nationally Appropriate Mitigation Actions (NAMAs) and REDD+, which are both instruments used for incentivizing various types of biomass operations, are driven more by donor than by market logic. The same applies to climate-related official development aid. The problem with this logic regarding BECCS in Tanzania is that donors generally seek to avoid institutionalizing aid (Fridahl et al. 2015), while BECCS would necessitate long-term commitment of capital for both initial investments and operation. BECCS is generally characterized by high operational costs and few, if any, benefits beyond its contribution to the global mitigation effort. Even the most promising low-cost alternatives for BECCS, i.e. ethanol production, would require capital to cover the cost added to normal operations (Moreira et al. 2016). As long as the option to sell carbon credits in an international market remains unfeasible and donors are unwilling to provide long-term aid to cover operational costs, the pressure from international law on Tanzania to implement BECCS will remain low and unconvincing. In other words, while the international policy objectives have become clearer, the instruments for fulfilling such objectives in LDCs do not support BECCS.

Yet, accounting rules developed by the IPCC and agreed by the UNFCCC can incentivize BECCS. In the national greenhouse gas inventories, negative emissions resulting from BECCS can be used to offset positive emissions by pooling within or between sectors. As such, BECCS can be used to comply with international commitments. However, even if the accounting rules may incentivize BECCS at national level, the typical operator, i.e. subnational entities or businesses, is not given incentives from national accounting rules since it is governments—not subnational entities—that are responsible for compliance under the UNFCCC. Furthermore, using such an option for compliance also requires that the mitigation target is extremely ambitious and that low-cost mitigation options have been

exhausted, rendering higher cost options such as BECCS viable. Neither of these conditions have been fulfilled in Tanzania. Given the country's other overriding priorities and its low international responsibilities for mitigating climate change, it seems highly unlikely that these international factors will incentivize the Tanzanian government to direct investments into BECCS.

4.2 Domestic formal institutions related to climate change

Domestically, a large package of climate-related strategies, policies and laws have been adopted in Tanzania. The most immediately relevant is the 2012 Climate Change Strategy, preceded by Tanzania's 2007 National Adaptation Program of Action and subsequently followed by the 2013 Agriculture Climate Resilience Plan (sectorial response to the strategy) and the National REDD+ Strategy (forestry conservation and sustainable management). Soon after, in 2015, Tanzania also submitted its Intended Nationally Determined Contribution (INDC) to the UN Paris Agreement. All of these are structured under the Tanzanian Development Vision 2025, agreed in 1999 with the aim of transforming Tanzania into a middle-income, semi-industrialized country by 2025. The vision was first detailed in parallel strategies for economic development and eradication of poverty together with five-year development plans focusing more on investments in human resources and capital, the first having been initiated in 2011, all of which informs the Climate Change Strategy and its sectorial responses. By 2016, the different strategies had become sufficiently similar to be merged into a coherent second five-year development plan, now organized under a long-term perspective plan initiated to provide a clearer direction for the short- and mid-term strategies, later enabled by the brief and relatively abstract Vision 2025 (Government of Tanzania 2012). Vision 2025 sets domestic goals aspiring to become a middle-income and semi-industrialized country by 2025. This goal requires a transformational change of Tanzania's socio-technical systems through, for example, policy development, eradication of energy poverty, expansion of its educational system and diversification of the economy to avoid overdependence on primary resources, especially in climate-sensitive sectors (Government of Tanzania 1999).

The Climate Change Strategy constitutes significant progress in the much-needed work of identifying Tanzania's climate vulnerabilities and possible response measures, and to start making the general 1997 National Environmental Policy and 2004 Environmental Management Act more climate specific. There are still several steps to take to turn the strategy into policy and possibly law, especially when it comes to being more specific and prioritizing interventions (Yanda et al. 2013).

4.3 Formal institutions regulating ethanol, other biofuels and solid biomass

A BECCS ethanol technical system in Tanzania would, if not intended purely for domestic appliances, have to be adapted to international market standards. Tanzania is exempted from import tariffs, which means that Tanzanian ethanol would be competitive with Brazilian ethanol despite higher production costs. However, access to the EU market is also dependent on Tanzanian producers' ability to meet the EU's sustainability criteria. This holds both for ethanol and for solid biomass fuels (Widengård et al. 2018). Among other things, this means that bioethanol must achieve greenhouse gas savings of 60% for new production plants and 50% for old plants in comparison with fossil fuels. It also means that converting land with high carbon stocks to grow biomass intended for biofuel production is

prohibited. In Tanzania, this means that accessing the EU market requires limiting production to converted grassland in combination with mitigation measures to combat process-related emissions.

This legislation would conflict with the immediate domestic economic incentives for ethanol production. Thurlow et al. (2016) have evaluated the economic potential for ethanol production in Tanzania, including scenarios under emission constraints, and found great potential for economic growth and poverty reduction, especially in scenarios where smallholders in outgrower schemes are used. However, if the emission constraints are also factored in, to contribute less to climate change and to try to meet sustainability criteria to access the EU export market, it would make more economic sense for Tanzania to use mixed farming systems including large-scale plantations with higher productivity and, thus, less need for clearing land for the purpose of cultivating sugarcane (Thurlow et al. 2016).

The global market price for ethanol is also dependent on legislation external to Tanzania. For example, it has been shown that the global market price for ethanol in 2002–2010 was largely determined by a tax credit to fuel blenders for each entity of biofuel mixed with fossil fuels in the USA as well as consumer biofuels tax exemption in Brazil (Rajcaniova et al. 2013). Whether Tanzanian ethanol is competitive on a global market therefore depends not only on achieving low production and transportation costs but also on subsidies provided in other ethanol producing countries. Such complex market dynamics ought to hold true for solid biomass, too.

Furthermore, the world market price of ethanol or solid biomass is vulnerable to environmental changes. Sugarcane, for example, is very sensitive to variable climate (Everingham et al. 2002). If climate change impacts negatively on the production of sugar in, for example, the large Brazilian sugar and ethanol district of São Paulo, this could drive global market prices up. Therefore, climate change can affect biomass and biofuel production in Tanzania both directly, and indirectly through global market swings following impacts in other parts of the world. Such effects may work both positively and negatively in terms of producer opportunities.

In Tanzania, the acquisition of land for biofuel development purposes is regulated by the Land Act and the Village Land Act, both adopted in 1999 and implemented in 2001. Together they regulate the use of village land, which constitutes 70% of the total land area, and general land, constituting 2%. For an investor to be able to acquire village land for plantations of biofuel, the land must first be transformed into general land by an act of government, and then leased for a maximum of 99 years (Arora et al. 2013; Massay 2016).

Reclassifying village land into general land can be done by the president in accordance with section 4 of the Land Act. This involves transparent and participatory processes, adequate compensation and assurances that the land will be reverted to villagers in the event of, for example, failure to carry out investments as planned. In practice, however, the process of reclassifying land is often deemed intransparent, compensation inadequate and monitoring of the investors' compliance with the planned land use changes unsatisfactory. Several examples exist of situations when land is reclassified and leased to international biofuel investors, but the investments are not carried out as promised. In these situations, it has proven hard for farmers and villages to reclaim their rights to manage the land for farming, grazing or other original purposes (Kijazi et al. 2017; Tenga 2015).

Domestic laws and guidelines have also been developed to regulate the production of biofuels. In 2006, A National Biofuels Task Force was established aiming at developing legislation and policies for the rapidly expanding biofuel market. The energy sector in Tanzania is guided by the National Energy Policy of 2015. The policy fosters sustainable

technology for energy development and discourages unsustainable practices such as deforestation for energy development. Despite its broad coverage of various energy sources, the policy does not provide clear policy statements or strategies for bioenergy development (Boesen et al. 2017). In addition, electricity policy is formulated in master plans, most recently the electricity master plan of 2016. From six scenarios, one with an electricity mix dominated by gas and coal is deemed to be the most economically viable by the government. Nonetheless, significant uncertainties remain around how such a scenario could be implemented as the plan is lacking in feasibility studies, not least regarding how to transmit electricity from large energy sources located in southwest and southeast to load centres in the northwest and northeast, and most of the projects envisioned by the 2012 plan have never made progress (Bhati and Koshy 2018).

Despite the lack of a focused energy policy, biofuel development in Tanzania gained momentum after 2010 with the government and other key stakeholders being keen to make use of the investment opportunities provided by international mitigation efforts. At least since 2012, official visions have circulated that designate a future role for Tanzania as a world leader in biofuel production and export (Mwakaje 2012). These visions have been aligned to neoliberal policies pursued ever since the mid-1980s, aimed at reconfiguring Tanzania as a market open for international capital (Arora et al. 2013). Pressure for investments in bioenergy has been increasing steadily primarily due to international interest, and not due to local market demand or the national policy frameworks. The launch in 2010 of the Southern Agricultural Growth Corridor of Tanzania (SAGCOT) is one direct result of such international interest and pressure. This investment programme, established with the aim of combining profitable farming and safeguarding ecosystem services, was developed amid growing interest from international donors in ambitious private–public partnerships in Africa, typically involving big multinational investors and aiming to facilitate capital inflows to large-scale projects (Arora et al. 2013; Brüntrup et al. 2016; Engström 2018; Willoughby 2014). Furthermore, the Ministry of Energy and Minerals has developed guidelines to facilitate biofuel developments, on the assumption of the existence of 4 million hectares suitable for biofuel investment (Mshandete 2011).

Nevertheless, studies point to the domestic guidelines and regulations being vague and difficult to implement, to the detriment of both local populations and foreign investors (Arora et al. 2013; Brüntrup et al. 2016; Sulle and Nelson 2009; Vermeulen and Cotula 2010). As a result, biofuel development in Tanzania can be said to have been advancing in the absence of national policies (Mshandete 2011; Boesen et al. 2017), and the experiences of biofuel developments in Tanzania can therefore be understood as determined to a large extent by informal institutions that complement, modify or supersede weak formal institutions (e.g. Greif 2006; North 2005). In the following, we will turn to a number of such experiences and reflect on what they reveal in terms of informal institutions in Tanzania.

5 Experiences from commercial projects and aid: the importance of informal institutions for biofuel and biomass production projects

Biofuel-related projects, mainly biodiesel and bioethanol, have been present in Tanzania for a long period, and over the years many investors have shown an interest in increasing their level of financial commitment in bioenergy related activities (Mshandete 2011; Okonko et al. 2009). It should, however, be stressed that as Martin et al. (2009) point out, many of these initiatives have been poorly documented and that, therefore, there is

significant uncertainty surrounding the extent of the country's biofuel endeavours (see also Mwansasu and Westerberg 2014). Nevertheless, the projects that have been documented do provide some important experiences in relation to a potential BECCS system based on ethanol or solid biomass production in Tanzania.

Most of the investments have been motivated by international policy shifts related to fossil fuel replacement, and the developments in Tanzania have therefore been determined largely by external forces (Martin et al. 2009; Mshandete 2011). Such externally driven projects include the British-owned CAMS Agri-Energy Tanzania Ltd and the Spanish Abengoa Bioenergy that in the early 2000s announced plans to jointly produce 250 million l of ethanol annually from sweet sorghum (Locher and Sulle 2013), corresponding to about 0.2 MtCO₂ annually.

The international interest in biofuel production has caused severe strain on local communities in Tanzania due to the gap between, on the one hand, vague official policies aimed at facilitating foreign investment, and, on the other hand, local institutional capacity. A lack of central oversight and monitoring, projects with little backing from local stakeholders, and local authorities lacking the necessary expertise have often meant that biofuel projects result in conflicts over competing land uses and inferior technology choices (Jumbe et al. 2009; Mshandete 2011; Mwansasu and Westerberg 2014; Rascack 2014; Boesen et al. 2017). Brüntrup et al. (2016) further claim that the success rate for projects implemented under the SAGCOT programme has been very low, with an unfavourable business environment, abusive bureaucracy, lengthy and complicated communication with authorities and fraud cited as reasons. Bergius et al. (2018) conclude that SAGCOT had a flawed design from the start, with smallholders assumed to be ineffective and in need of modernization.

The biofuel boom has further revealed severe problems with the official statistics related to land use in Tanzania. What was assumed to be unoccupied land suitable for biofuel plantations has often been found to be occupied and used, albeit sometimes in a low-intensive fashion (Olwiga et al. 2015). In an extensive assessment of land statistics in Tanzania, Exner et al. (2015) conclude that the terms "marginal land" and "unused land" are misleading and even manipulative. The terms emanate from either capitalistic-economic or state-bureaucratic narratives, and obscure what are considered irrelevant user groups. These findings contradict the explicit and sometimes implicit assumptions of the World Bank and the Food and Agriculture Organization of the United Nations (FOA) that large areas of unused land are available in sub-Saharan Africa for commercial agriculture and integration into the global trade (Exner et al. 2015), and arguably also the land-use scenarios applied by the IAMs.

While the Village Land Act constituted an attempt to safeguard local communities against land grabbing, the formal institutions adopted under it have proven to be vastly underequipped to handle the increasing number of land conflicts between communities and investors, as well as between farmers and pastoralists. In April 2015, the District Land and Housing Tribunals had 18,033 cases pending and received on average 11,542 new ones each year, while the responsible governmental department, the Ministry of Lands, has been severely under-resourced, receiving zero funds for the budget year 2014/2015 (Massey 2016). At the same time, the fragmented structure of the judiciary system has meant that regulations are enforced and interpreted unevenly across institutions (Kashaigili and Nzunda 2010; Lund et al. 2006; Massey 2016; Sulle and Nelson 2009). In the absence of formal institutions regulating permission processes, applications have been approved and denied on an ad hoc basis (Martin et al. 2009), and land transactions have proven problematic both for local communities and for investors, despite the existence of a formally progressive land transactions legislation (Brüntrup et al. 2016; Sulle and Nelson 2009;

Vermeulen and Cotula 2010; Zirulnick 2015). The lack of clear regulatory structures compromises project planning, as important steps such as application writing, permission granting and taxation are governed through informal institutions (Mshandete 2011).

The recent hype surrounding *jatropha* plantations is illustrative of how a sudden interest from foreign investors may cause a wave of development projects that subsides quickly when the technology fails to take off (van Eijck et al. 2014; Habib-Mintz 2010; Mwansasu and Westerberg 2014; Romijn and Caniels 2011; Sulle and Nelson 2009, 2013). Evaluations have shown that contrary to the plans to use marginal land, many agrofuel investors chose to locate their plantations on well-watered fertile land, which reportedly increased food prices (Mshandete 2011). Renzaho et al. (2017) further conclude that *jatropha* plantations often resulted in irreversible environmental damage. Expectations were initially great from both international investors and the Tanzanian government, but implementation revealed crucial gaps between different institutional levels that acted as barriers to technological learning, which was aggravated by a lack of trust from local communities in investors. The failure of the government to pursue a consistent policy favouring *jatropha* plantation that went beyond facilitating foreign investments meant that the Tanzanian *jatropha* industry eventually ground to a halt in the face of growing criticism of individual projects and the risk of competition for agricultural land (Arora et al. 2013).

Furthermore, the focus on ambitious private–public partnerships has, in the absence of sufficient institutional protection for small-scale farmers, given disproportional structural benefits to centralized and already privileged farms, and has risked increasing the rural poor's vulnerability to market swings (Willoughby 2014). The regulatory framework has often proven insufficient to protect local inhabitants against being evicted to make space for biofuel projects, leading to resentment and resistance towards business models involving centralized plantation strategies (Hultman et al. 2012; Boesen et al. 2017).

Similar scepticism towards aid-driven projects has been reported elsewhere, with local stakeholders viewing aid as a form of neo-colonial endeavour involving teams of foreign experts who are insensitive to cultural differences (Fridahl et al. 2015). Koch (2017) argues that in the case of aid-driven, forest related projects in Tanzania, the discrepancy between the formal policy framework and the actual experiences on the ground is usually explained by deficient resources (that responsible authorities lack qualified staff, funding or facilities to make sure the existing regulations and policies are pursued), corruption or conflicts of interest. In contrast to the conventional explanation that deficient budgets and capacity shortfalls are the main reasons for failure, Koch (2017) finds that development aid often leads to implementation failure due to the fact that decision-makers adopt a strategy of tactical manoeuvring, by which they officially adjust their agendas according to donors' aspirations but lack a genuine ambition to implement the new policies, thus leveraging resource flows and securing autonomy. In line with this, Tanzania's REDD+ policy is claimed to be another "conservation fad" serving the purpose of reinforcing and benefitting the local elite, and maintaining business as usual (Lund et al. 2017). Jacob and Brockington (2017) and Nantongo (2017) draw similar conclusions, but maintain that new modes of forest governance, besides primarily benefitting the elite, can also provide a fair share of the benefits to most of the villagers (cf. also Brüntrup et al. 2016; Renzaho et al. 2017). However, Nantongo (2017) emphasizes that the outcome is highly context dependent, which makes flexibility in implementation vital.

5.1 The case of SEKAB

An illustrative case in relation to a potential BECCS system in Tanzania is the project developed by Sweden's SEKAB (Svensk Etanol kemi AB). The case displays most of the problems touched upon above, and furthermore, it is the only project in Africa to date that has been designated as a BECCS project (Kemper 2015).

In 2005, the Swedish municipal company Norrlands Etanolkraft AB bought a majority of the shares in SEKAB, after which the company embarked on an international expansion.² In 2006, it signed an agreement with the government of Tanzania to lease 20 000 hectares of supposedly abandoned land outside the city of Bagamoyo in the Rufiji District, with the prospect of following this with additional investments in the Rufiji Delta in the southern parts of the country, totalling more than 200,000 ha (Bergius et al. 2018). The Rufiji Delta has many characteristics typical of Tanzania, and the challenges are thus likely to be similarly reflected in other regions of the nation, according to Mwakaje (2012). Initially, 10 000 ha would be used for an ethanol plantation that would yield 1 million tonnes of harvested sugarcane within 10 years of starting operation (Franke et al. 2010, Zirulnick 2015). Using the potential for ethanol production as specified by Thurlow et al. (2016) and process emission data from Moreira et al. (2016),³ this corresponds to production of about 69.4 million l ethanol and process emissions of about 0.05 MtCO₂ annually. The more ambitious, long-term plan was to export 10 million tonnes of ethanol to Sweden by 2030 and build one factory every year between 2010 and 2025.

Swedish law restricts municipalities to only doing business within their borders, with a few exceptions for exporting knowledge and services and for international aid, and questions about the legality of SEKAB's investment in Tanzania were therefore raised. Although the Swedish administrative court ruled to allow the SEKAB investment on the basis that it was related to electricity production and could therefore be allowed as an exception according to the municipal legislation,⁴ the legal doubts dissuaded continued municipal financial support. Thus, in 2009, the municipality withdrew from Tanzania by selling its share of SEKAB to EcoEnergy Africa AB (in turn owned by EcoDevelopment in Europe AB, a minority shareholder in SEKAB) for 400 SEK (approx. €40). The concurrent downturn in global ethanol prices also influenced the municipal decision, as did a domestic debate in Sweden about the negative socio-environmental effects of large-scale ethanol production (e.g. Bergius et al. 2018).

It also became evident that the land was not abandoned as was first assumed, and even though local farmers were consulted by the company, they claimed they had not received compensation for their loss of land (Zirulnick 2015). Around the same time, the company African Green Oil (AGO) negotiated with six villages in the Rufiji District on 30,000 ha of land, ending up with just 2800 ha for the company, an episode which further reveals the gap between investors' ambitions and the amount of land actually available. In a thorough review of methods for assessing land availability, Mwansasu and Westerberg (2014) concluded that biofuel investments in the district are only possible if it is assumed that

² See Engström (2018) for a comprehensive and critical analysis of the case.

³ That is, an ethanol conversion ratio of 69.4 l/t sugarcane, a density of ethanol of 0.8 kg/land and process emissions of 0.96 kg CO₂/kg ethanol.

⁴ Law 1997:857 on Electricity; Law 2009:47 on Certain municipal authorities; the Municipal Act 2017:725; Law 2001:151 on Municipal export of services and municipal international aid.

available land is unused and unoccupied and that the investors have applied adequate methods for assessing available land.

Complaints from NGOs and local farmers saw the project grind to a halt, and the long delay eventually resulted in the Swedish International Development Cooperation Agency (SIDA) withdrawing its conditional credit guarantee support (Zirulnick 2015). Criticism was also directed at SEKAB for influencing the Tanzanian government in setting up its National Biofuels Task Force in 2006, in parallel with the project initiation. The task force was accused of not being neutral and of including SEKAB staff as advisors (Martin et al. 2009; Sosovele 2014). It was also amid this climate of growing criticism that the CEO of SEKAB started to describe the project in terms of a BECCS system (Swedish Radio 2009), something which had not been part of the original plans, and the authors of this paper have been unable to find documents or project plans that can verify any concrete measures being taken towards that end.

The long delays, the land conflicts and the withdrawal of key investors meant that the project never got off the ground. Thus, the SEKAB case highlights the vulnerability of both investors and local communities to the vicissitudes of the market and other external forces, as well as the difficulties in fulfilling the theoretical potential of large-scale biofuel plantations in practical action.

All in all, the experiences of biofuel developments, and also large-scale agro investments in general, in Tanzania in recent years have been largely negative (Engström 2018). They thus risk compounding a legacy of distrust among local communities towards large-scale industrial projects that stems from the experiments with “scientific agriculture” under Nyerere, the first President of independent Tanzania (Arora et al. 2013). The government received severe criticism for prioritizing foreign interests over domestic development (Sosovele 2014). Indications of a policy reorientation under the new President Magufuli towards increased state control over natural resources and active industrial policy could be understood as a backlash against the neoliberal policies that have been geared towards easing the access of foreign capital (Jacob and Pedersen 2018; Woodroffe et al. 2017).

6 Discussion

In this concluding discussion, we will reconnect the literature review to our analytical framework and reflect on the preconditions for BECCS systems in Tanzania, with focus on the ethanol industry and the country as a supplier of biomass to developed countries, in terms of institutions, market formation and advocacy groups (Jacobsson and Lauber 2006).

6.1 Institutions

Despite theoretically good preconditions for BECCS in Tanzania (e.g. Harper et al. 2018; Mwansasu and Westerberg 2014) and a stable regime of governance compared to many developing countries (Wieczorek 2018), the dynamic between formal and informal institutions is presently not conducive to the kind of large-scale biofuel/biomass operations that a BECCS system would necessitate. Among important informal institutions that the literature points to are the lack of trust towards both government and foreign investors as well as ad hoc and informal governance in the absence of formal institutions, which makes land planning processes unpredictable and prone to conflict. The inadequacy of formal institutions in the regulation of land use poses a serious question about the viability of BECCS

in Tanzania, given that the theoretical potential for net negative emissions can easily translate into net positive emissions due to land use change (Harper et al. 2018). The experiences from large-scale biofuel projects to date indicate a great risk of projects proving to be counterproductive, from both a mitigation perspective and a poverty reduction perspective (see also Engström 2018; Newell and Phillips 2016).

Several formal institutions that offer theoretical support for BECCS are less promising when viewed from practical experience. The CDM mechanism has so far failed to support any CCS project, while REDD+ projects have a low rate of success (Koch 2017; McAfee 2016). The IPCC accounting guidelines could incentivize BECCS as it allows accounting for negative emissions in national greenhouse gas inventories. However, the government of Tanzania is under no pressure to deliver ambitious emissions reductions. Therefore, the implementation of a BECCS system in Tanzania, and other developing countries, would be most likely to emanate from initiatives in developed countries (Honegger and Reiner 2018), driven by either aid or commercial logic. As the literature review shows, aid programmes in their current structure are unlikely to facilitate BECCS in Tanzania. NAMAs, REDD+ and climate-related official development aid are characterized by a donor logic that is unfit for BECCS purposes. BECCS demands long-term capital commitments both for initial investments and to compensate for the additional operational costs (Moreira et al. 2016), but donors generally seek to avoid institutionalizing and sustaining aid over longer periods of time (Fridahl et al. 2015). Furthermore, Marquardt et al. (2016) argue that aid organizations are unlikely to drive energy transitions in developing countries if the programme is not closely aligned with the overarching governmental energy strategy (see also Kamp and Vanheule 2015; Verbong et al. 2010). At present, BECCS is a poor fit in this context, even though expanding the domestic demand of ethanol for cooking and transport theoretically could add momentum to BECCS development supported by international aid.

6.2 Market formation

Commercial logic seems similarly unlikely to drive BECCS implementation in Tanzania under current conditions. The only potential value of BECCS lies in its “production” of negative emissions, and its commercial viability is therefore dependent on a functional market for carbon credits that also includes negative emissions. At present, the prospect of a carbon market with prices high enough to justify the large capital and operational costs associated with BECCS on a purely commercial basis seems distant.

Large-scale ethanol production for export is vulnerable to external regulation and market swings, and would be more commercially appealing if there was also a domestic market demand in Tanzania. Here, the government could move to create demand by stimulating domestic use of ethanol as a fuel for cooking and transportation. Arora et al. (2013) point to the absence of governmental support through market subsidies as one important reason why *jatropha* production failed (see also Nygaard and Bolwig 2018). The willingness of the current government to pursue an active industrial policy, including by banning the import of sugar, points to such a market formation being possible (The Citizen 2016). However, the question remains how BECCS could be implemented in such a technical system as anything but a burden on production.

Historically, an important barrier to the development of production capacity of liquid biofuels for export purposes has been given by ethical dilemmas following in the wake of demand for land to facilitate production of biomass, such as sugarcane and *jatropha*. In these cases, conflicts over access to land and mismanagement have been more of a rule

than an exception. Increased production volumes of solid biomass for export to operations that demand bioenergy, be it with or without a CCS component, is likely to give rise to similar conflicts.

6.3 Advocacy groups and entry of firms

Even though the IPCC accounting guidelines allow negative emissions to be accounted for in national greenhouse gas inventories, providing an opportunity for states to use BECCS for compliance with international obligations, the typical BECCS operator, i.e. subnational entities or businesses, is not incentivized to do so by national demand side policy. This fact would make it all the more difficult to generate the kind of market and learning dynamics that the entry of new firms into the formation process of a new technical system brings in relation to BECCS. Furthermore, given the recent history of poorly executed and controversial biofuels projects in Tanzania and the risk of land or forest degradation, it would be difficult to garner the kind of broad-based support among stakeholders that is important for a new technical system to take hold (Hansen and Nygaard 2014; van Welie and Romijn 2018). On a more general level, it is also important to highlight that BECCS lacks a strong advocacy group overall, and perhaps most importantly among the industries and actors that would supposedly be the first to implement it, such as pulp and paper and biofuel producers. This latter fact makes its vast deployment in even the more recently published and updated IAM studies (Harper et al. 2018) all the more conspicuous.

7 Conclusions

To conclude, the most viable path creation options for large-scale BECCS deployment in Tanzania would be either in the context of ethanol production, or with Tanzania acting as supplier of biomass in an international BECCS system. The external preconditions for either option—commercial or regulatory incentives for negative emissions, or sustained investments through aid programmes or other international sources of finance—are currently lacking. More importantly, the review of historical experiences from biofuel investments in Tanzania reveals that the lack of adequate domestic institutions often occasions land-grabs, land-use conflicts, corruption, technical challenges, lacking infrastructure and resource trade-offs. The institutional vacuum, or dysfunctionality, would further make the needed monitoring and verification of dedicated biomass plantations difficult.

On the basis of our review, we would therefore argue that negative BECCS-related emissions from Tanzania should not be assumed in global climate mitigation scenarios. Furthermore, assuming Tanzania to contribute to negative emissions in estimations of the global carbon budget has problematic spatial and temporal ethical implications. First, it entrenches a view of sub-Saharan African soil as open for appropriation by developed countries in a global system of uneven exchange. As experiences from previous biofuel projects show, local livelihoods are jeopardized both by mistaken assumptions of marginal land and by being connected to a volatile world market.

Second, because scenarios can shape perceptions of what is politically feasible (Beck and Mahony 2018; also Anderson and Peters 2016; Geden 2015), setting climate policy objectives on the basis of assuming Tanzania and other similar countries to play a role in delivering negative emissions risks leads to carbon lock-in and delaying more urgent emissions reductions. Vulnerable countries like Tanzania are the ones most directly at risk

for climate change induced hazards. Thus, implicating LDCs in a role of delivering negative emissions in the global carbon budget amounts to nothing less than collateralising the countries' future in what Carton (2019) has termed "the political economy of delay" (p. 765).

While BECCS may well play an important role in reducing emissions in countries with high capacity to act combined with existing large point sources of biogenic CO₂ emissions (Gough et al. 2018a, b), it seems prudent to proceed with utmost caution when implicating BECCS deployment in LDCs, like Tanzania. It also seems reasonable to argue that large-scale biomass-based energy supply, be it for use with or without CCS, implicating massive land use in LDCs should not be assumed other than in cases that are grounded in deeper contextual case-by-case analysis.
