REVIEW

A review on the genetic resources, domestication and breeding history of spinach (*Spinacia oleracea* L.)

Abstract This paper addresses the genetic resources, domestication and breeding history of spinach as a comprehensive review of these crop aspects is currently unavailable. It is shown that the availability of genetic resources of wild relatives belonging to the primary gene pool is currently very limited, which hampers breeding and research activities. Therefore, new collecting expeditions are clearly warranted. The domestication of spinach is discussed on the basis of its presumed migration routes and the traits that were probably involved in the domestication syndrome. Spinach is thought to have domesticated in former Persia. Migration then occurred eastwards to China and westwards to Europe, but additional genetic data are needed to reveal the most likely migration routes. Morphological changes in pistillate flowers and loss of dormancy are identified as the main traits involved in the domestication syndrome of spinach. To a large extent we could re-construct the relationships between spinach cultivars that were developed until the 1950s, but this appeared difficult for the more recent cultivars due to intellectual property protection

by breeding companies. Resistance against downy mildew has been the main breeding target in spinach. The introgression of NBS-LRR resistance genes from wild relatives is the major strategy to develop downy mildew resistant cultivars. However, the use of loss-of-function alleles of susceptibility genes may provide a more durable strategy to develop resistant cultivars. So far, abiotic resistance and quality traits have received minor attention in spinach research and breeding. This is expected to change considering the potential effects of climate change on these traits.

Keywords Breeding history · Crop wild relatives · Domestication · Plant breeding · Spinach

Introduction

Cultivated spinach (*Spinacia oleracea* L., $2n = 2x = 12$) is one of the most nutritious vegetables consumed worldwide (Morelock and Correll 2008). It is a leafy vegetable from the family Amaranthaceae, which includes other important crops such as beet, quinoa and amaranth (Hassler 2018). Spinach is an annual plant with distinct vegetative and reproductive phases. Typically, at the end of the winter or in early spring seeds are sown after which seedlings grow to form a rosette of leaves (Krarup and Moreira 1998; Van der Vossen 2004). The arrival of warmer and longer summer days induces bolting, hence

spinach plants start their reproductive phase by growing a peduncle of about one metre tall (Krarup and Moreira 1998), generally with terminal staminate flowers and/or pistillate flowers at bract axils (Uotila 1997). Nowadays, many cultivars exist with distinct leaf attributes, from round to hastate leaves and from flat to crinkly (savoy) texture (Morelock and Correll 2008). Adaptation to different photoperiods and climatic conditions is also present, thus some cultivars possess bolting resistance to longer and warmer days to make them compatible with summer cultivation (Van der Vossen 2004).

Spinach is a wind-pollinated dioecious species, although monoecious plants also exist (Khattak et al. 2006). Spinach sex expression is flexible as different classes of spinach have been described based on sex and morphology (Rosa 1925). Some dioecious plants may show sex reversion resulting in gynomonocy and andromonocy, in the case of female and male plants respectively (Komai and Masuda 2004; Morelock and Correll 2008).

The global production of spinach reached more than 26.7 million tonnes in 2016, representing a production value of 18 billion USD (FAOSTAT 2018). Approximately 91.5% of this global spinach production is accounted for by China alone. Due to favourable environmental conditions, especially long daylength, spinach seed production is mainly based in Denmark (Morelock and Correll 2008; Deleuran 2010; Correll et al. 2011), covering more than 70% of the world's supply.

Spinach is rich in mineral elements and vitamins (Roberts and Moreau 2016), including substantial levels of the carotenoids vitamin A, lutein and zeaxanthin (Bunea et al. 2008) and other molecules with high antioxidant properties such as vitamin C, vitamin E and phenolic compounds including flavonoids (Chun et al. 2005; Pandjaitan et al. 2005). Roberts and Moreau (2016) investigated the health-related effects of spinach, including studies of its antioxidant, anti-inflammatory, antitumoral, anti-obesity and lipid-lowering effects in animal models and humans. On the other hand, spinach is known for its high content in oxalic acid when compared to other crops (Mou 2008a). Oxalic acid can form insoluble salts with certain elements (Noonan and Savage 1999) and has been shown to reduce calcium, magnesium and zinc bioavailability in humans (Kelsay and Prather 1983; Heaney et al. 1988; Noonan and Savage 1999;

Bohn et al. 2004). Oxalic acid may also lead to the formation of kidney stones (Noonan and Savage 1999; Ermer et al. 2016). In addition to oxalic acid, spinach is also rich in nitrate (Santamaria 2006), which can be converted into nitrite in the digestive system (Tiso and Schechter 2015) and the latter can react with haemoglobin to form methaemoglobin, potentially causing methaemoglobinaemia (Santamaria 2006).

Despite the economical and nutritional importance of spinach, knowledge about the crop history is rather limited. Here we review the available publication sources regarding the related wild species, the domestication process and the breeding history of spinach. In addition, we summarize recent developments that are expected to open up a new era of spinach breeding.

Wild relatives

Currently, 11 species from the genus *Blitum* and two species from the genus *Spinacia* are considered to be part of the gene pool of cultivated spinach (Table 1; Vincent et al. 2013). While the *Blitum* species are classified in the tertiary gene pool, *Spinacia tetrandra* Steven ex M. Bieb and *Spinacia turkestanica* Iljin are assigned to the primary gene pool of cultivated spinach. Interestingly, Fujito et al. (2015) found that

Table 1 Wild species included in the spinach gene pool

Primary gene pool

<i>Spinacia tetrandra</i> Steven ex M. Bieb
Tertiary gene pool ^a
<i>Blitum asiaticum</i> (Fisch. & C.A. Mey.) S. Fuentes et al.
<i>Blitum atriplicinum</i> F. Müll.
<i>Blitum bonus-henricus</i> (L.) Rechb.
<i>Blitum californicum</i> S. Wats.
<i>Blitum capitatum</i> L.
<i>Blitum hastatum</i> Rydb.
<i>Blitum korshinskyi</i> Litv.
<i>Blitum litwinowii</i> (Paulsen) S. Fuentes et al.
<i>Blitum nuttallianum</i> Roem. & Schult.
<i>Blitum spathulatum</i> (A. Gray) S. Fuentes et al.
<i>Blitum virgatum</i> L.

^a*Blitum petiolare* Link (Vincent et al. 2013) is also listed as a spinach wild relative, but the species is considered a synonym of *Blitum capitatum* L. (Hassler 2018)

hybrids of *S. oleracea* × *S. tetrandra* and *S. tetrandra* × *S. oleracea* showed a highly diminished pollen fertility, which might question the primary gene pool position of *S. tetrandra*. Additionally, recent studies (Fujito et al. 2015; Xu et al. 2017) indicated that *S. oleracea* is phylogenetically closer to *S. turkestanica* than to *S. tetrandra*, suggesting that *S. turkestanica* is the wild ancestor of cultivated spinach.

While *S. turkestanica* is autochthonous in Central and Southern Asia, *S. tetrandra* is autochthonous in the Middle East and Transcaucasia (Fig. 1; Hassler 2018). Collecting of wild spinach by local inhabitants was observed during collecting expeditions of the Centre for Genetic Resources, the Netherlands (CGN; Kik 2008). This seems to occur in parallel to the growing of cultivated spinach, although commercial cultivation was found to be rare in Armenia, Azerbaijan, Uzbekistan and Tajikistan, countries in which wild spinach is present (Van Treuren et al. 2019).

At the morphological level, *S. turkestanica* and *S. tetrandra* are very similar and both species resemble cultivated spinach to a large extent (Fig. 2). However, some differences between the species can be observed in the inflorescences. While *S. turkestanica* shows only cauline clusters of flowers in the inflorescences and short petioles in its bracts, *S. tetrandra* shows both cauline and basal clusters of flowers, and the bracts lack a petiole (Uotila 1997). Interestingly, Kik (unpublished data) observed bracts of *S. tetrandra* with petioles on basal positions but not on apical ones.

Fig. 1 Presumed distribution area of *S. turkestanica* (blue) and *S. tetrandra* (green). (Color figure online)

Furthermore, sexual dimorphism is more pronounced in *S. tetrandra*, as male plants are considerably smaller than females (Fig. 2).

Both *S. turkestanica* and *S. tetrandra* are of large interest to the breeding industry as they are used as source material for agronomically relevant traits, especially in case of resistance breeding against spinach downy mildew, caused by the oomycete *Peronospora farinosa* f. sp. *spinaciae* (Pfs), also referred to as *Peronospora effusa* (Greville) Rabenhorst (Correll et al. 1994; Qian et al. 2016). As new Pfs races appear continuously (Feng et al. 2018), breeders benefit from potential new resistance sources present in wild spinach germplasm.

Out of the nearly 2097 accessions of the genus *Spinacia* maintained in genetic resources collections worldwide 1959 are classified as *S. oleracea*, indicating the poor availability of wild spinach in gene banks (Table 2). In 2012, only 14 accessions of *S. turkestanica* and 12 of *S. tetrandra* were available in gene bank collections (Van Treuren et al. 2012). Due to this poor representation, CGN collected a total of 66 new accessions of *S. turkestanica* in 2008 and 36 new accessions of *S. tetrandra* in 2011 (Van Treuren et al. 2019). To date, 89 accessions of *S. turkestanica* and 49 accessions of *S. tetrandra* are included in genetic resources collections (Table 2), while an additional 10 accessions of *S. tetrandra* will become available by the end of 2020 (Van Treuren et al. 2019). Spinach collections could be further improved by introducing accessions from thus far unexplored regions, such as *S. tetrandra* from the Middle East and South-West Asia and *S. turkestanica* from South and South-West Asia. However, organising collecting expeditions on a legal basis has become increasingly difficult for many countries, not in the least due to more stricter requirements regarding access and benefit sharing.

Domestication

Geographical spread

Spinach is considered to have been domesticated first in the region of present Iran (Boswell 1949) and to have spread to other regions late in history (Fig. 3) as no evidence of the presence of the crop in the ancient Greek or Roman civilizations has been found (Heine 2018). The oldest available records indicate that

Fig. 2 Illustrations of both sexes of *S. turkestanica* and *S. tetrandra*

spinach was consumed in Mesopotamia in the 4th century AD (El Faïz 1995, as cited in Hallavant and Ruas 2014). The earliest written evidence of cultivated spinach is from China and dates back to the 7th century, showing that spinach arrived in China via Nepal (Laufer 1919). Even though Rolland and Sherman (2006) state that the Saracens introduced spinach to Sicily in the 9th century, the first written records mentioning cultivation around the Mediterranean region date back to the 10th century in Muslim territories (Sneep 1983) and the first written record in continental Europe dates back to the 12th century in Moorish Spain (El Faïz 2000). This latter document mentions spinach cultivation in the Iberian Peninsula since at least the 11th century. The first European archaeobotanical evidence was found in a French Pyrenean village and dates back to the end of the 12th or the beginning of the 13th century (Hallavant and Ruas 2014). Considering the proximity of this location to Spain, it seems plausible that spinach spread to Europe from the Iberian Peninsula, even though the migration routes throughout Europe are still unresolved (Hallavant and Ruas 2014).

The aforementioned historical evidence suggests that the spread of spinach followed two separate directions, one to Southern and Eastern Asia and another one to Africa, the Mediterranean and Northern Europe, from which it was later introduced in the Americas. A distinction is often made between two main groups of spinach cultivars, namely Asian-type and Western-type cultivars (Simoons 1990; Van der Vossen 2004), which have probably resulted from the different selection regimes applied in the two regions. Recent phylogenetic studies have shown an

association between genetic relationship and geographical origin of spinach accessions, with consistent differences between Asian and Western cultivars (Shi et al. 2017; Xu et al. 2017). At the morphological level, Asian cultivars preserved the narrow, hastate and smooth leaf shape and the long petioles of wild spinach, whereas Western cultivars changed the hastate leaf shape to a round form, while leaves were enlarged and the savoy leaf texture appeared (Van der Vossen 2004).

Domestication syndrome

Domestication syndrome traits are not obvious in spinach because *S. oleracea* largely resembles both wild *Spinacia* species. According to Sneep (1983) the oldest available spinach descriptions and botanical drawings are from Leonard Fuchs (1543) and Hieronymus Bock (1539, 1546). Comparison of these drawings with a wild *Spinacia* plant clearly illustrates the similarity (Fig. 4). Therefore, leaf shape and plant morphology were probably not part of the domestication syndrome of spinach. Interestingly, wild spinach species are dioecious (Astley and Ford-Lloyd 1981) even though both Fuchs' (1543) and Bock's (1546) drawings depict monoecious plants. This raises the question whether monoecism was a potential domestication trait or not.

The main difference between cultivated spinach and wild *Spinacia* species is the morphology of the pistillate flowers. Wild species show clusters of fused flowers, which progress into spiny aggregated fruits containing multiple seeds (Fig. 5). Astley and Ford-Lloyd (1981) suggested that having both sexes

Passport data of individual accessions and information on the holding institutes can be obtained from these data repositories

enclosed in one single fruit is valuable in nature to avoid isolation of the sexes and ensure reproduction of dioecious plants. Cultivated spinach shows clusters of ununited flowers, resulting into separate round and slightly flattened fruits. As the presence of separate fruits may probably have eased the sowing and seed collecting tasks, this trait may have been selected to reduce manual labour and may have become fixed during the domestication of spinach.

The smooth fruit trait seems to have appeared in Europe at the end of the Middle Ages or at the

beginning of the Modern History. In fact, the first written evidence of smooth fruits dates back to 1539 (Bock 1539), indicating that this trait was not part of the domestication syndrome of spinach. Multiple emergences of the smooth phenotype may have independently occurred as the presence or absence of prickles is controlled by a single gene, with spines being dominant over smoothness (Pandey and Kalloo 1993). The smooth phenotype has also been observed in landraces from the Middle East (Sabaghnia et al. 2014; Mohebodini et al. 2017).

Seed dormancy was reduced during the domestication of spinach as germination is typically high in cultivated spinach but low in wild *Spinacia* (Van Treuren et al. 2019). Loss of dormancy is a common domestication trait and has been selected in parallel in multiple crop families (Rendón-Anaya and Herrera-Estrella 2018; Wang et al. 2018a). Although dormancy is advantageous for plant survival in the wild by avoiding potentially unsuitable environmental conditions (Bentsink and Koornneef 2008), uniformity and reliability in germination are preferred for cultivation (Finch-Savage and Bassel 2016).

Crop breeding

Early breeding history

Studying how spinach looked like in previous times and how new cultivars arose is difficult due to scarce documentation. During the 1950s, Sneep collected evidence regarding the domestication and breeding history of spinach. A paper about his results was published in 1957 as a communication from the former IVT (Institute for Horticultural Plant Breeding, Wageningen, the Netherlands) and was subsequently translated into English and published in 1983. Sneep's paper is probably the best and most complete source

regarding the breeding history of spinach until the 1950s. The modern breeding history of spinach from 1950 onwards is difficult to reveal as breeding companies usually keep their breeding information confidential. A summary of the main events in the breeding history of spinach is shown in Fig. 6.

Based on current knowledge, Bock (1539) was the first author to differentiate between two spinach cultivars. While one cultivar had spiny seeds and leaves with hastate shape, the other one showed smooth seeds and broader leaves with a less pronounced hastate shape (Bock 1539; Sneepe 1983). Evidence of additional spinach cultivars was absent from the literature until publication of the books

‘Paradisi in Sole Paradisus Terrestris’ in 1629 (Parkinson 1904) and ‘The Gardeners Dictionary’ (Miller 1731, 1768).

Around the 19th century more information concerning spinach and many other crops became available (Sneepe 1983). This was due to the fact that breeding companies and seed merchants started to denominate cultivars and to add a brief description to these products, indicating their qualities and marketable traits. The French seed company Vilmorin-Andrieux started to play a major role in spinach breeding during the 19th century, and important information can be extracted from this company’s pricelists, starting as early as 1771 (Vilmorin-

Fig. 6 Summary of the breeding history of spinach. The years in which new downy mildew (Pfs) races were observed are marked in red colour

Andrieux 1855, 1883; Sneeep 1983). Gibault (1912) and Sneeep (1983) considered that some of Vilmorin-Andrieux's cultivars represented the precursors of European cultivars. Gibault emphasized that Vilmorin-Andrieux's cultivars 'Épinard d'Angleterre' and 'Épinard de Hollande' became the two most relevant cultivars by the end of the 18th century, the former being a prickly-seeded and the latter a smooth-seeded cultivar. From 'Épinard de Hollande' Vilmorin-Andrieux produced the cultivar 'Épinard de Flandre' in 1829 (Gibault 1912), referred to as

'Vlaamse' in the Netherlands (Sneeep 1983), which was described as the most common cultivar at that time (Vilmorin-Andrieux 1883).

Since the end of the 19th century, Dutch breeders have played a leading role in spinach breeding (Sneeep 1983). In particular, the role of Sluis & Groot (currently part of Syngenta) and Rijk Zwaan has been significant in the breeding history of spinach.

Different improved cultivars were selected from 'Épinard d'Angleterre', 'Épinard de Hollande' and 'Épinard de Flandre' (Fig. 7). These selections

Fig. 7 Breeding history and ancestry of spiny-seeded spinach

showed the improved characteristics in response to the main breeding targets of spinach selection until the mid-20th century, namely larger, fleshier and darker green leaves with a rounder shape and a reduced tendency to bolt. Moreover, many cultivars were selected against leafless males, resulting in new cultivars that were mostly female or monoecious (Sneep 1983). Even though spiny-seeded cultivars were diversified, and new selections appeared during the 20th century (Fig. 7), the general trend was to breed for smooth-seeded rather than for spiny-seeded cultivars.

Supposedly, smooth-leaved cultivars were mainly derived from two selections of ‘Épinard de Flandre’, namely ‘Gaudry’ and ‘Monstrueux de Viroflay’, or simply ‘Viroflay’ (Fig. 8). ‘Gaudry’ was released in 1843 and ‘Viroflay’ was commercialized for the first time in 1873 by Vilmorin-Andrieux. Both ‘Gaudry’ and ‘Viroflay’ served as a source for many new

selections and crossing programmes, which interestingly resulted in late-bolting summer cultivars, such as ‘Nobel’ in 1926 and ‘Viking’ in 1933, as well as winter-hardy cultivars, such as ‘Géant d’Hiver’ in 1927 (Sneep 1983).

Savoy-leaved cultivars, also called Bloomsdale-type spinach, followed a separate breeding history (Fig. 9). Due to their leaf shape, these were preferred over smooth-leaved cultivars in regions where vegetables needed transportation over long distances (Sneep 1983; Rubatzky and Yamaguchi 1997). Crinkles kept spinach less compact during packing and transport, resulting in an extended shelf life.

The initial savoy cultivar was called ‘Savoy-leaved’, ‘Norfolk’ and ‘Bloomsdale’ later on (Fig. 9). The cultivar may have been derived from the ‘Épinard de Flandre’ or a similar cultivar (Kinney 1896), while also the year of introduction is not exactly known. The year of introduction may have

Fig. 8 Breeding history and ancestry of smooth-leaved, smooth-seeded spinach. See the box in Fig. 7 for explanation

been around 1874 (Kinney 1896; Sneep 1983) but in other sources 1828 is mentioned (Sneep 1983; Decoteau 2000). Several selections were made from ‘Bloomsdale’, improving the colour to dark-green and delaying the time to bolt.

Breeding for biotic stress tolerance

Spinach blight

In 1920, the spinach industry in the USA was threatened by a virulent outbreak of spinach blight

(Cucumber Mosaic Virus or CMV; Kaplan 1998). Smith (1920) found that spinach accessions from Manchuria in China, collected during an expedition of the United States Department of Agriculture (USDA) 20 years earlier, were distasteful to the aphids that transmitted the virus. Smith was able to transfer this advantageous trait to American cultivars and selected ‘Virginia Savoy’ in 1921 when he crossed CMV-resistant plants with ‘Bloomsdale’ (Fig. 9). This was the first documented case of resistance breeding in spinach. Cook et al. (1947) reported the development of a wilt resistant line by positive selection of ‘Virginia

Downy mildew

name ‘Califlay’, which resulted from a cross between PI 140467 and ‘Viroflay’ and the subsequent four-times-backcrossing to ‘Viroflay’ (Fig. 8; Smith and Zahara 1956).

After the arrival of the USDA hybrids, F₁ hybrid spinach became the standard in the spinach seed industry. In the beginning, hybrid production was laborious due to the need to rogue male plants from the normally dioecious female seed-producing plants. Nowadays, the process requires less input since the industry uses gynomonoecious and andromonoecious plants in order to enable development and maintenance of the parental lines used for hybrid production (Janick 1998; Morelock and Correll 2008).

In 1958, some ‘Califlay’ plants were infected by downy mildew in the USA and Europe because of the appearance of a new race of the pathogen, denominated as Pfs2 (Zink and Smith 1958; Smith et al. 1961). Interestingly, ‘Early Hybrid #7’ and ‘Dixie Market’ were resistant to Pfs2 even though both hybrids and ‘Califlay’ had been developed using the same initial resistant accession PI 140467 (Jones et al. 1956; Smith et al. 1961). Later it was found that the source of resistance to Pfs2 was PI 140462, a Persian accession that had also been used to develop the parental lines for the hybrids. It was hypothesized that

at least two genes were involved in the resistance, namely *M1*, present in ‘Califlay’ and the hybrids, and *M2*, only present in the hybrids (Smith et al. 1962). Later, Eenink (1976) found that *M1* and *M2* were closely linked genes involved in downy mildew resistance and were weakly linked with the gene involved in spinach blight resistance.

After the start of downy mildew resistance breeding in the late 1950s, the entire spinach breeding industry focused on introgressing both resistance genes into existing cultivars. ‘Resistoflay’, a new ‘Viroflay’-derived cultivar with both downy mildew resistances was developed (Koopmans 1965). In the Netherlands, the spinach industry boomed during the 1960s and many new and resistant cultivars derived from ‘Resistoflay’ or USDA resistant accessions were introduced to the market (Banga 1960; Banga and Koopmans 1962).

The downy mildew resistance lasted until 1976 when Pfs3 appeared in the Netherlands. However, ‘Califlay’ and its derived cultivars appeared resistant to this new race (Eenink 1976). This suggested the presence of a third resistance gene (*M3*) in ‘Califlay’ (Jones and Dainello 1982) and breeding efforts were directed to the development of cultivars with all three resistance genes. In 1978, new spinach cultivars resistant to all three races of downy mildew were introduced to the market (Morelock 1999).

It was not until 1990 that Pfs4, which was able to infect commercially available cultivars, appeared in California (Correll et al. 1990). Resistant cultivars entered the market as early as in 1991 (Morelock 1999). Brandenberger et al. (1991) stated that regarding the spinach breeding program in Arkansas the perspective had shifted from single-gene qualitative resistance to polygenic quantitative resistance against downy mildew. By 1994, horizontal resistance was reported for several cultivars released by the University of Arkansas during the 1980s, which had been selected from lines that displayed horizontal resistance to white rust (Brandenberger 1994; Morelock 1999). Parallel to the efforts on horizontal resistance breeding, screening of spinach germplasm was continued to identify resistance genes against Pfs4 (Brandenberger et al. 1992). Two accessions with high resistance against Pfs4 were found, namely *S. oleracea* SPI 82/87 originating from Iraq, and *S. turkestanica* CGN09546 from Uzbekistan (Morelock and Correll 2008).

Breeding for new downy mildew resistant cultivars is a continuous concern as new races of the pathogen keep appearing. In fact, downy mildew is still the main and one of the most destructive diseases of spinach at the global scale (Correll et al. 1994, 2011). To be able to respond to the rapid evolution of the pathogen, wild germplasm was increasingly being explored by breeders to find new resistance genes, which formed the basis of CGN’s expeditions to collect *S. turkestanica* in 2008 and *S. tetrandra* in 2011 (Van Treuren et al. 2019).

The International Working Group on Peronospora (IWGP), supported by the University of Arkansas and the University of California, is a consortium of seed companies and the Netherlands Inspection Service for Horticulture (Naktuinbouw). The IWGP monitors the emergence and development of new spinach downy mildew races and decides on their official denomination (Plantum 2009). To date 17 races have been denominated by the IWGP, the most recent one in 2018 (Naktuinbouw 2018).

The introgression of qualitative resistance genes (R-genes) from germplasm is common procedure in breeding for downy mildew resistance in spinach (Correll et al. 2011). These R-genes, predominantly ‘nucleotide binding site leucine-rich repeats’ (NBS-LRR) genes (Marone et al. 2013), confer pathogen resistance by encoding proteins specialized in recognizing pathogen-related molecules, which can trigger R-mediated defence (Gururani et al. 2012). Xu et al. (2017) identified 139 different NBS-LRR genes in the spinach genome, while Correll et al. (2011) hypothesized that 6 loci are controlling known downy mildew resistances. These loci are referred to as *RPF* loci, but to date none have been identified nor cloned (She et al. 2018). Currently, up to 13 different *RPF* loci have been described (Dijkstra 2015a, b, 2016). The IWGP members use a common differential set of cultivars that have different *RPF* loci (Table 3) to characterize and identify new downy mildew isolates (International Seed Federation 2018; Feng et al. 2018). Some of these differentials are near-isogenic lines (NILs) that each contain a single *RPF* locus (RPF1–6). Recently, comparative genomics research resulted in the identification of the RPF1 region and the inference of three potential candidate genes (Xu et al. 2017). Further experiments using similar approaches may help to identify the genomic location and DNA sequence of other *RPF* genes. Moreover, more detailed insight in

the structure of R proteins would contribute to a better understanding of the mechanisms underlying the interaction with their ligands.

R-gene resistance follows a gene-for-gene interaction. Consequently, their effectiveness is rapidly lost when a new virulent race appears, as the pathogen has a large selective advantage and will spread quickly among genetically similar plants (Brown 2015). Although methods exist that can slow down the breakdown of R-genes, such as gene stacking and cultivating mixtures of cultivars with different resistance genes (Brown 2015), the emergence of hyper-virulent races or races without a matching resistance locus can be disastrous for spinach cultivation (Kapos et al. 2019). As currently the major approach to obtain downy-mildew resistance relies on temporary solutions, there is an urgent need to find durable resistance.

A compatible host–pathogen interaction requires the expression of specific host genes, the so-called susceptibility genes (S-genes; Pavan et al. 2010; Van Schie and Takken 2014). Mutation or loss of an S-gene can lead to recessive durable resistance (Brown 2015). S-genes associated with downy mildew susceptibility, denoted as Downy Mildew Resistance (*DMR*) genes, have been found in *A. thaliana* (*DMR1-6*; Van Damme et al. 2005, 2008). These genes probably have a conserved function across plant species. Schouten et al. (2014) and Porterfield and Meru (2017) used *DMR1* and *DMR6* to search for novel *DMR* candidate genes in the Cucurbitaceae family. Huibers et al. (2013) studied the *DMR1* orthologue in *S. lycopersicum* (*SIDMR1*) and found that gene silencing was associated with resistance against late blight caused by the oomycete *Phytophthora infestans*, although it also caused detrimental effects on plant growth. Sun et al.

(2016) reported six susceptibility genes for late blight in potato. Although no records of S-genes in *Spinacia* species have been found in the literature, breeding for mutant S-genes could be a promising approach to develop spinach cultivars that are resistant to rapidly evolving pathogens such as downy mildew.

White rust

White rust, caused by the oomycete *Albugo occidentalis*, is another disease affecting spinach cultivation. White rust is mainly present in the spinach producing areas east of the Rocky Mountains in the United States (Correll et al. 1994; Koike et al. 2006), although outbreaks have occurred also in Iran (Ebrahimi and Afzali 2000), Greece (Vakalounakis and Doulis 2013), Mexico (Correll et al. 2017) and Turkey (Soylu et al. 2018). Geographical expansion of white rust may form a potential threat to spinach cultivation.

White rust was recognized as a serious disease during the 1930s and 1940s in the USA (Brandenberger et al. 1992). However, the first cultivars with partial resistance to white rust were not released until 1975 by the USDA (Brandenberger 1994). In contrast to downy mildew, no qualitative resistance against white rust has been reported (Correll et al. 2017) and quantitative approaches have been used to mitigate the effects of the disease. According to Bowers (1972), the commercial 'Hybrid 178' and the USDA breeding line 'WRG 70-5' formed the basis to develop resistant cultivars. In 1987, the improved open-pollinated cultivar 'Fallgreen' with a high resistance level was released by the University of Arkansas (Morelock 1999). Although new open-pollinated resistant cultivars were developed, the former materials were used by the spinach breeding industry to create white rust resistant hybrids (Morelock and Correll 2008).

Leaf spot diseases

Ascomycete fungi are the main causal agents for the emergence of leaf spot diseases (Koike et al. 2006). The main ascomycetes responsible for leaf spots in spinach are *Colletotrichum dematium*, causing anthracnose, *Stemphylium botryosum* and *Cladosporium variable* (De Visser 2015; Liu et al. 2018). In addition, *Cercospora beticola*, *Colletotrichum coccoodes*, *C. truncatum* and *Myrothecium verrucaria* are

minor agents causing leaf spot diseases in spinach (Liu et al. 2018).

Although literature on breeding for resistance against leaf spot pathogens is scarce, variation in tolerance to *C. dematium* isolates among different spinach cultivars has been reported (Correll et al. 1993). Also partial resistances to *S. botryosum* and *C. variable* have been observed in spinach germplasm (Mou et al. 2008). Furthermore, molecular markers associated with resistance against *S. botryosum* have been identified (Shi et al. 2016a).

Soilborne diseases

Soilborne diseases are commonly expressed as root rot and damping off at very early plant stages. The major causal agents of soilborne diseases are fungi, such as *Fusarium oxysporum*, other *Fusarium* species and *Rizoctonia solani* and oomycetes, such as *Aphanomyces cochlioides* and several *Pythium* species (Correll et al. 1994; Koike et al. 2006; De Visser 2015). As *Pythium* spp. are the main agents for damping off in spinach, available germplasm is being investigated for variation in resistance to these species (Magnée et al. 2017).

Wilt caused by *Fusarium oxysporum* and *Verticillium* spp. (e.g. *V. dahliae*) is also threatening spinach cultivation (Correll et al. 1994; Koike et al. 2006). Regarding *V. dahliae*, molecular markers associated with resistance to the fungus have been identified (Shi et al. 2016b).

Insects

Damage to spinach cultivation by insects has been reported for green peach aphids, garden webworms, Hawaiian beet webworms, southern beet webworm, seed-corn maggots, cabbage loopers, cucumber beetles, grasshoppers and leafhoppers (Morelock and Correll 2008). However, our literature survey did not reveal any genetic studies or breeding programs regarding resistance against these pests.

The leafminer *Liriomyza langei* is considered a serious threat to spinach production in the United States. Adult flies of this species feed on the plant sap after puncturing of the leaves, while feeding by larvae causes the typical winding mines in leaves. The resulting reduction in photosynthetic capacity negatively affects the marketability of spinach. As the use

of insecticides is still common practice, host genetic resistance would offer an efficient strategy to control the disease. Screening of 345 accessions of the US spinach collection has shown genetic variability for leafminer resistance (Mou 2008b), and a subsequent genetic study revealed five SNPs associated with this trait (Shi and Mou 2016). It was concluded from these studies that leafminer resistance can be improved and combined with yield traits in cultivars and that the identified SNP markers may be useful for marker-assisted selection in spinach breeding programs. To date, highly resistant commercial cultivars have not yet been developed.

Breeding for abiotic stress tolerance

Spinach has been investigated for its tolerance to abiotic factors such as water stress (Zuccarini and Savé 2016; Ors and Suarez 2017), salinity and osmotic stress (Bagheri et al. 2015; Ors and Suarez 2016, 2017; Ferreira et al. 2018), heavy metal stress (Fagioni et al. 2009; Bagheri et al. 2015) and temperature stress (Mogren et al. 2015; Chitwood et al. 2016; Ors and Suarez 2016). Two genes involved in tolerance to osmotic stress have been identified (Weretilnyk and Hanson 1988; Burnet et al. 1995; Hibino et al. 2002), but in general the genetics of tolerance against abiotic stresses is rather understudied in spinach.

Adaptation to low nitrogen availability is an important aspect in the development of sustainable and more efficient agriculture (Witcombe et al. 2008). In this context, the two QTL regions related to growth in nitrogen-poor conditions identified by Chan-Navarrete et al. (2016) will contribute to the improvement of nitrogen use efficiency in spinach.

To date, abiotic stress improvement is largely unexplored in spinach as the available literature on this topic is rather scarce. As climate change is expected to pose serious challenges to agriculture (Pereira 2016), research on abiotic stress tolerance will most likely gain considerable importance in spinach breeding in the near future.

Breeding for quality

The chemical composition of spinach has been shown to differ significantly between cultivars, including oxalic acid, nitrate, vitamin C, lutein, carotenoid and phenolic content (Murphy and Morelock 2000;

Murphy 2001; Howard et al. 2002; Pandjaitan et al. 2005; Solberg et al. 2015; Wang et al. 2018b). Although nutritional composition is known to be influenced by factors such as cultivation method and storage procedures (Lester et al. 2010; Koh et al. 2012), the large variation observed among cultivars indicates a genetic basis, suggesting that nutritional quality can be improved by plant breeding (Howard et al. 2002; Morelock and Correll 2008; Wang et al. 2018b).

Maximizing health-related compounds and minimizing oxalic acid and nitrate content are important targets in improving the quality of spinach cultivars. Shi et al. (2016c) identified SNP markers associated with oxalate concentration in spinach, while Qin et al. (2017) identified SNP markers associated with 13 different mineral elements. In both studies, the identified materials with breeding potential were cultivated spinach accessions from diverse origins, including both landraces and modern cultivars. Additionally, the two QTLs related to nitrogen use efficiency (Chan-Navarrete et al. 2016) could be helpful to reduce nitrate levels in spinach leaves by minimizing the amount of applied fertilizer.

Differences in the concentration of phenolics and flavonoids between modern cultivars differing in the level of resistance against downy mildew and white rust have been detected by Howard et al. (2002). In addition, Pandjaitan et al. (2005) reported that the level of phenolics and flavonoids in spinach leaves depended on the maturity stage, mid-mature leaves showing the highest levels in comparison with baby and adult leaves. Recently, a red spinach cultivar with an increased antioxidant content was released (Mou 2019). This cultivar is rich in betacyanin and has been selected from a red-veined spinach cultivar.

Morphological traits are highly important for a better appearance and easier processing of spinach plants. Recently, Cai et al. (2018) identified a major QTL and three candidate genes associated with leaf colour. Ma et al. (2016) identified SNP markers related to petiole colour, leaf texture and leaf margin shape, while Chitwood et al. (2016) reported SNP markers associated with leaf erectness, plant size and bolting. A better understanding of the mechanisms involved in bolting time is important in spinach breeding as it would enable the development of bolting-resistant cultivars with an extended period of leaf production.

Cultivar development would highly benefit from an improved insight how monoecism and dioecism are controlled. Several markers associated with these reproductive characters have been found (Khattak et al. 2006; Onodera et al. 2011; Yamamoto et al. 2014), while Qian et al. (2017) identified two potential genomic regions harbouring the X/Y sex-determining gene. Nevertheless, as sex expression in spinach is still not well understood, further research is needed before this character can be exploited in spinach breeding.

Future perspectives

Genetic resources

Current data suggest that *Spinacia tetrandra* belongs to the secondary rather than to the primary gene pool of spinach. To substantiate this finding crossing experiments with cultivated spinach are needed along with more detailed molecular analyses to reveal species relationships.

The underrepresentation of crop wild relatives in genetic resources collections is limiting future spinach research and breeding. As many wild species are under pressure in their natural habitat, for instance due to climatic changes, valuable genetic resources for crop breeding may go extinct. The stricter requirements regarding access and benefit sharing are hampering new collecting expeditions to enrich genetic resources collections. It is therefore imperative that access and benefit issues are soon adequately arranged by the international political community in order to open up countries for the collecting of valuable genetic resources that can be exploited in crop breeding.

Domestication

Although spinach is considered to have spread from its presumed domestication area in Iran to China and Europe, the exact migration routes are not completely clear. For example, spinach cultivation may have been introduced in Europe via North Africa but also via the Balkan. Data on the genetic structure of landraces originating from alternative routes are needed to reveal the most probable migration routes of spinach after domestication.

Crop breeding

In 2017, an assembly of the spinach genome was published (Xu et al. 2017), which is available from SpinachBase (<http://www.spinachbase.org>). The spinach genome has an estimated size of ~ 1000 Mb, containing 74.4% of repetitive sequences and an approximate number of 25,500 protein-coding genes. Previous research revealed a total of 93 genomic regions associated with wild species introgressions that are potentially related with spinach domestication and breeding (Xu et al. 2017). Comparative genomics approaches between cultivated spinach and its main wild relatives are currently hampered by the fact that genome assemblies of *S. turkestanica* and *S. tetrandra* are lacking. In cooperation with several breeding companies, we have initiated research to develop reference genomes for these two species. In addition, this study will include the resequencing of available genetic resources of the species. It is anticipated that the results of this study will greatly facilitate the exploitation of the genetic diversity of the wild species in spinach breeding for new robust cultivars that are more resilient to biotic and abiotic stresses.

Breeding for downy mildew resistance using NBS-LRR genes has been shown to provide only short-term solutions as these genes are usually broken down by new races of the disease. Therefore, more durable strategies for downy mildew resistance are clearly needed. An interesting new approach is the inactivation of S-genes as this strategy has been reported to be effective against downy mildew infection, such as in case of the DMR genes in *Arabidopsis*.

Climate change is expected to have a large negative impact on global crop cultivation. The increase in global temperatures poses major challenges to spinach cultivation because of unpredictable heat and drought periods. In addition to heat and drought stress, also salt stress is expected to become a problem due to increases in soil water evaporation resulting in the increase of mineral salts in topsoil layers. As severe declines in crop yield can be expected, the breeding of new spinach cultivars that are more resilient to these abiotic stresses is clearly needed.
