Abstract

Corporate boards, experts panels, parliaments, cabinets, and even nations all take important decisions as a group. Selecting an efficient decision rule to aggregate individual opinions is paramount to the decision quality of these groups. In our experiment we measure revealed preferences over and efficiency of several important decision rules. Our results show that: (1) the efficiency of the theoretically optimal rule is not as robust as simple majority voting, and efficiency rankings in the lab can differ from theory; (2) participation constraints often hinder implementation of more efficient mechanisms; (3) these constraints are relaxed if the less efficient mechanism is risky; (4) participation preferences appear to be driven by realized rather than theoretic payoffs of the decision rules. These findings highlight the difficulty of relying on theory alone to predict what mechanism is better and acceptable to the participants in practice.

1 Introduction

Before a group takes a decision—whether it is a corporate board thinking about investments, an expert panel considering different policies, a cabinet discussing reforms, or a nation considering who to appoint as president—the group has to select a decision rule that aggregates individual preferences into a group decision. With an inefficient decision rule, the group is likely to end up with less than optimal outcomes, e.g. bad investments, inefficient policies, unpopular presidential candidates, or simply deadlocked in discussions and forced to delay important decisions.¹ If a group finds its existing decision rule does not work well, its members could choose to replace it. Therefore, it is natural to expect inefficient rules to be replaced. In practice, however, we regularly see inefficient decision rules persist. Examples range from veto rules or restricted voting rights that limit the amount of information combined in corporate boards and shareholder meetings (De Jong et al., 2007; Grüner & Tröger, 2019), mechanisms that are hindered by reputational concerns in expert panels (Visser & Swank, 2007), the much criticized US electoral college (Rathbone, 2018), and remarkably stable electoral systems despite changing circumstances (Rahat, 2011). In this paper, we use an experiment to shed more light on when we can expect inefficient decision rules to (not) be replaced by efficient ones.

To improve group decision rules, we need to take two necessary steps: design and implementation. First, we need to design and test an efficient mechanism for the particular context. Given the decisions at hand and the composition of the group, it might be better to use simple majority voting or to aim for group consensus. Second, we need to ensure that group members are willing to use the efficient mechanism. The corresponding design and participation problems have been studied extensively both theoretically and experimentally in the literature on exchange mechanisms such as auctions, matching, and market design. In contrast, the experimental part of the literature on efficient mechanisms in social choice is limited. The overview of the experimental literature presented in Chen (2008) only found one paper that analyzes the efficiency of the theoretically optimal mechanism (Attiyah et al., 2000). Similarly, tests of the participation decision only seem to have occurred in the class of voting rules (Engelmann & Grüner, 2017; Bol et al., 2020; Engelmann et al., 2020).

Our paper addresses this gap in the literature on efficient social choice mechanisms in two ways. First, we use a revealed preference setup to measure subjects' willingness to participate in several mechanisms that appear repeatedly in theory. Second, we measure and compare the empirical efficiency of these mechanisms. Together, the revealed preferences and achieved efficiency levels allow us to show how private information, expected benefits, and outside options—all difficult to observe outside the lab setting—influence participation preferences. Our

---

¹ In our experiment all mechanisms are group decision and we use these terms interchangeably. For discussions and examples of the decision rules in the settings mentioned, see for instance: Malenko (2014), Gao and Huang (2018) about corporate boards; Swank et al. (2008), Hao and Suen (2009) about (expert) policy committees; and Colomer (2004), Benoit (2007), Goux and Hopkins (2008), Widgrén (2009), Warntjen (2010) for political examples.

experimental results thus shed light on the empirical efficiency and implementability of decision rules, both in a controlled lab environment.

Our results clearly show how outside options and private information shape subjects' revealed preferences over mechanisms. Subjects that know they dislike the public project prefer a mechanism that does not allow provision but provides a safe payoff over all other mechanisms, as is predicted by the Myerson–Satterthwaite impossibility theorem (Myerson & Satterthwaite, 1983). Subjects who know they like the public project are willing to flip a coin to decide on the project as long as this increases the likelihood of implementation. Furthermore, both subjects that approve the public project and those that want to stop it prefer having influence over the outcome over flipping a coin. Therefore, with risky alternative mechanisms, voluntary participation in more efficient mechanisms can be possible even in ad interim stages, as is predicted by Schmitz (2002), Segal and Whinston (2011) and Grüner and Koriyama (2012). However, our results also show that the mechanisms are not as efficient in the lab as theory predicts, and the difference between theoretical predictions and measured efficiency depends on the setting and the mechanism. In some settings, the predicted ranking is reversed and therefore theoretical expectations of (individual) preferences for mechanisms can be misleading.

In our experiment, we study four mechanisms: the theoretical optimal Arrow–d'Aspremont–Gérard–Varet (AGV) mechanism,² Simple Majority voting (SM), a Non-implementation mechanism that mimics the theoretical effects of forcing the Status Quo to persist by non-participation in the mechanism choice (NSQ), and flipping a coin (RAND, random decisions). The AGV mechanism is theoretically optimal in our public good setting. It is often used as the theoretical benchmark to which the efficiency other mechanisms are compared. However, the fact that the mechanism is optimal and efficient in theory does not necessarily translate to efficient outcomes in a laboratory or in practice. Despite its theoretical importance, the empirical performance of the AGV mechanism has not received much attention. To the best of our knowledge, the only direct test of its efficiency is in Attiyeh et al. (2000). They find that the AGV's empirical efficiency is no larger than the theoretical efficiency of sincere voting in SM.³ Our experiment allows us to directly compare AGV's and SM's achieved efficiency. The results show that the AGV mechanism is indeed more efficient than SM when the private valuations for the project are skewed. However, when the distribution is symmetric, SM is more efficient. We also show that SM is not as efficient as predicted in theory, but the difference between its predicted and

² The original mechanism was derived in Arrow (1979) and d'Aspremont and Gérard-Varet (1979). In our setting, the mechanism is part of the class of Vickrey–Clarke–Groves mechanisms that were derived from foundational work by Vickrey (1961), Clarke (1971), Groves (1973). It is also known as the expected externality mechanism, or pivot mechanism (Tideman & Tullock, 1976).

³ Several follow-up papers have examined possibilities to improve the empirical performance of mechanisms like the AGV, but do not compare the AGV to more empirically relevant mechanisms (Kawagoe & Mori, 2001; Cason et al., 2006).

achieved efficiency in the lab is much smaller and much more stable across settings than with the AGV. These findings highlight the importance of controlled tests for proposed mechanisms. Such tests are already the standard in auctions and matching (e.g. Roth, 2012) and in the related setting of Voluntary Contribution Mechanisms (VCM) (e.g. Bracht et al., 2008).⁴

The differences between theoretical and achieved efficiency of the mechanisms, mean that our subjects' preferences over mechanisms could be difficult to predict through theory alone. Remarkably, subjects can predict relative efficiency levels and select the mechanism that maximizes their expected payoff in the lab, even when the efficiency deviates from theoretic predictions. When SM is close to efficient, it is selected much more often than in settings where the AGV clearly outperforms SM in the lab. Furthermore, in a direct comparison, the empirical payoffs of the mechanisms more accurately predict mechanism choices than Bayes–Nash payoffs. Another difficulty of predicting the participation decisions and efficiency through theory alone, is the possibility that individuals attach value to non-monetary aspects. Group members that have other-regarding preferences attach a higher value to efficient mechanisms and might play differently within a given mechanism than narrowly self-interested group members (Engelmann & Grüner, 2017; Messer et al., 2010; Bierbrauer et al., 2017). However, in our setting, where we cleanly identify participation decisions *and* see the play in the selected mechanisms, narrow self-interest is the most important predictor. In fact, subjects prefer complete randomness over arguably fairer and more efficient mechanisms, as long as randomness gives them a better chance to obtain their preferred outcomes.

The rest of the paper is organized as follows: Sect. 2 discusses related literature. Sect. 3 outlines the experimental design and treatments. Section 4 states the predictions we test, Sect. 5 tests these predictions and discusses further findings. Section 6 concludes.

2 Related literature

Our experiment is closely related to the literature on social choice and the choice of voting rules or constitutions. This literature is riddled with impossibility theorems that show the difficulties of designing a mechanism that combines a set of desirable properties. Most famously, Arrow (1950) shows that non-dictatorship, Pareto efficiency, and independence of irrelevant alternatives cannot be obtained by any social choice rule for all potential preference profiles. In a similar vein, Myerson and Satterthwaite (1983) show that with two players and independent valuations, an

---

⁴ This literature is too large to survey here. Numerous contributions can be found in collections like Plott (2008), Kagel and Roth (1997, 2016). The difference between stylized theory and chaotic practice has caused the literature on market design to use an ever more integrated approach combining theory and experiments (Roth, 2012, 2015). In the related setting of the provision of divisible public goods, a similar literature has developed around (improvements to) VCM. For instance, Falkinger et al. (2000) test one such mechanism against the normal VCM, and Hamman et al. (2011) examine mechanism choice in the VCM setting.

efficient, ad interim incentive-compatible and budget-neutral mechanism for trade does not exist as long as players are guaranteed a sufficiently large payoff when not trading.⁵ Mailath and Postlewaite (1990) prove that individual rationality, incentive compatibility, and budget balance are also incompatible in an N-player public good setting like our experiment. Güth and Hellwig (1986, 1987) derive similar results for the private supply of a public good. In all these settings, it is impossible to achieve efficient production without a subsidy, if the mechanism choice is made through a veto rule (i.e. voluntary participation by all players). These impossibility results illustrate how participation constraints can stifle any chance of (efficient) mechanism change. For brevity, we will refer to this type of result as the Myerson–Satterthwaite impossibility theorem.

Our experiments recreate the conditions studied in several theoretic studies that show how (im-)possibility results depend on the relevant outside option. Cramton et al. (1987) and Schmitz (2002) show that an interim status quo—either shared ownership or a probabilistic distribution of outcomes—can make it possible to design a mechanism that is both ad interim incentive compatible and ex post efficient, without requiring subsidies. Under independent and identically distributed private valuations, these results imply that one can always find a status quo mechanism that allows voluntary participation in the efficient mechanism ad interim, both for Myerson and Satterthwaite's (1983) bargaining game for the public good setting of our experiment. Segal and Whinston (2011) make a similar point by demonstrating how background risk—a status quo that is not quite as secure as the no-trade outcome—can increase the willingness of individuals to accept mechanism changes. Their proposition 1 states that individuals are willing to accept an efficient mechanism if it has the same equilibrium distribution over allocations as the alternative mechanism. We recreate this risky alternative mechanism by flipping a coin in our experiment. Grüner and Koriyama (2012) illustrate that in some cases it is even possible for groups to shift from a (simple) majority voting system to the AGV mechanism without violating interim participation constraints. Although SM is quite efficient in binary choice situations, the efficiency gains of the AGV are large enough to compensate individuals for the potential loss in information rents in some settings.

A few recent experimental papers have examined the choice for group decision rules over indivisible public goods. Weber (2017) compares the performance of two normative design rules, Penrose's square root rule, and Shapley–Shubik power index in predicting subjects' preference over voting rules in an indirect democracy. The interpretation of the ex ante stage also differs between our setting and Weber's. In our setting, this stage refers to information about private payoffs of the decision, whereas in Weber's setting it revolves about group membership, and private preferences are never known when making the mechanism choice.⁶

⁵ An older, less general result can be found in Chatterjee (1982), and a more general statement of this result can be found in e.g. Segal and Whinston (2016). The interpretation in this paper is mostly due to Cramton et al. (1987).

⁶ The ex ante stage is often referred to as 'behind the veil-of-ignorance' in reference to Harsanyi (1955) and Rawls (1971). However, the definition of behind-the-veil differs depending on the setting. In this paper we therefore use ex ante and ad interim when talking about private information for clarity.

Bierbrauer et al. (2017) identify the theoretically optimal trade mechanism assuming players have other-regarding preferences. Their experiment shows that choices for a small but significant number of subjects are better explained by including other-regarding preferences. They also illustrate that if enough of such subjects are present, the social planner prefers a different mechanism than with narrowly self-interested agents. If social preferences play a role in our mechanisms, the theoretical predictions derived in models with narrowly self-interested agents might not hold.

The articles most closely related to ours are a small set of other experiments on mechanism choices for indivisible public goods. Engelmann and Grüner (2017), Engelmann et al. (2020) and Bol et al. (2020) also implement a two-stage group decision experiment for the provision of a public good. In Engelmann and Grüner's (2017) experiments, groups of five subjects select the number of votes required for implementation of the public good using a similar mechanism choice stage as our experiment. Narrowly self-interested, rational subjects always prefer the voting rule that requires only one (all five) vote(s) for implementation, if they have a positive (negative) valuation of the project. The same subjects should vote in favor of (against) implementation in the second stage to get their preferred outcome. However, subjects often choose intermediate thresholds (two, three, or four positive votes) indicating efficiency or prosocial concerns in the mechanism choice. A similar effect is found in Bol et al.'s (2020) experiments. Without information about private payoffs, the choice between the two voting mechanisms is strongly influenced by fairness concerns. In our experiments, ex post inequality is increased by AGV transfers in two treatments and decreased in another. However, our results do not indicate that the AGV is more attractive in the inequality reducing treatments. In Engelmann et al. (2020), the focus is on the efficiency of the voting rule choices in the ex ante stage. They find that the ex ante mechanism choices are influenced by concerns related to the protection of strongly influenced minorities. The inefficiency in mechanism choices is found to cost more than one third of (theoretical) expected surplus on average. Our results indicate that this efficiency loss varies considerably depending on the setting.

Attiyeh et al. (2000) directly test the efficiency of the AGV. In their experiment, groups of five or ten subjects play a direct revelation game for the provision of a public good. Each subject randomly draws a private valuation between $[-10, 10]$ and can report any cent value in this range. Interestingly, the authors find that only about 10% of the reported preferences exactly match the private values, and this is mostly driven by one very honest subject. Almost all reports match the sign subjects' preferences, indicating that many players tried to 'game the system' despite its truthful Nash equilibrium. Unlike in our experiment, subjects in Attiyeh et al.'s (2000) experiment did not play any other mechanism so that these authors cannot compare the empirical efficiency of different mechanisms.

3 Experimental design

We first describe the game and the mechanisms used. We then describe the treatments and the procedures of the experiment. Treatments differ only in potential private valuations for the public project. The underlying procedures, game, and all other details of the experiment, e.g., number of rounds, group size, and available mechanisms, are identical across all treatments.

3.1 The game

Subjects interact in groups of three and each group decides whether or not to implement an indivisible public project. Each of the 18 experimental rounds consists of two stages. First, a mechanism is selected for each group. Second, the group decides about the implementation of the public project through the chosen mechanism. If the project is implemented, all players receive a project payoff equal to their private valuation. Non-implementation results in a zero payoff for all subjects.

At the beginning of a round, subjects are informed about the two available mechanisms. They cannot influence which mechanisms are available in a round, and the order of the comparisons is randomly altered between sessions. Each subject privately chooses one of the mechanisms. After the choices have been recorded, the computer randomly selects one group member as the dictator, and executes the mechanism chosen by this subject. The computer determines whether the project is implemented through the selected mechanism, and payoffs are realized accordingly. All group members are informed of the selected mechanism before they play it, but they do not learn whose choice was selected or what mechanism the other two subjects selected. At the end of the round subjects are informed about the outcome and payoffs for the period.

The random dictator elicitation for the mechanism choice clearly differs from the theoretical mechanism-design setting in two important ways. First, we force subjects to choose between two given mechanisms, rather than from all potential mechanisms. This binary choice set clearly identifies subjects' outside option and allows us to manipulate it by changing the second mechanism. The drawback, a reduced choice set for participants, is unavoidable in any realistic empirical setting. Any other option would make identification of the outside option more difficult and would require subjects to choose between (infinitely) many mechanisms. Such choices are too demanding both on the experimental setup and for the subjects. Secondly, we follow the standard experimental methodology of randomizing the order of presentation in the mechanism choices rather than labeling one mechanism as the status quo or default. This randomization prevents response biases and thus allows a cleaner identification of preferences.

The experiment proceeds in two parts. In the first twelve rounds, subjects first choose their preferred mechanism in the *ex ante* stage and then learn their private valuation for the public project before the mechanism is played. In the last six rounds, subjects are informed about their private valuation for the project at the start of each round and therefore make mechanism choices in an *ad interim* stage.

Subjects are never informed about the valuations of other subjects. Our subjects face all six possible binary mechanism choices twice in the ex ante condition (rounds 1–12), before going to the ad interim rounds (rounds 13–18).

The evaluation of efficiency requires a clean comparison between the mechanisms. In the ex ante rounds, the private valuations that determine the efficiency of the project can not influence the mechanism chosen and played. Furthermore, we ensure the choices in the ex ante rounds are not influenced by previous experiences in the ad interim rounds by running them at the start of the experiment. Therefore, we use the ex ante rounds to determine behavioral strategies and to calculate efficiency. We begin with two blocks of ex ante rounds to ensure we have enough observations with different combinations of private valuations for these calculations.

The design is in many respects similar to the two-stage voting procedure studied by Engelmann and Grüner (2017) and Engelmann et al. (2020), but there are three important differences. First, in our study subjects choose between two mechanisms rather than five. This clearly identifies the outside option. Second, we have four very different mechanisms, rather than five mechanisms from the class of simple voting rules. The mechanisms allow us to make the same comparisons studied in the theoretical papers cited above. We describe the mechanisms in the next subsection. Third, we vary the amount of private information possessed by participants, whereas the amount of information is kept constant in those experiments. Bol et al. (2020) also focus on the effects of private information but exclusively in relation to voting mechanisms and value-driven preferences. We focus on testing the implementability and efficiency of the SM and AVG in different settings and compare the outcomes with theoretical predictions. Value-driven preferences are found more often in similar settings to ours. We test for such social preferences/concerns in Sect. 5.2.

3.2 The four mechanisms

We chose the following four mechanisms because of their theoretical implications and relevance for group decision-making.

Mechanism I AGV mechanism (AGV)

All group members report a valuation for the project. They can only report valuations that are present in the type space. If the sum of reported valuations is larger than zero, the project is implemented. If the sum is smaller than zero, the project is not implemented. Independent of project implementation, subjects pay or receive a transfer that depends on the vector of reported valuations.

Mechanism II Voting—Simple Majority (SM)

All group members vote for or against the project (no abstention). If two or more group members vote for implementation, the project is implemented, otherwise the project is not implemented.

Mechanism III Non-implementation Status Quo (NSQ)

The public project is not implemented.

Mechanism IV Random implementation (RAND)

Whether the public project is implemented depends on the flip of a fair coin. The project is implemented with 50% probability independent of subjects' valuations.

The AGV mechanism, or expected externality or pivot mechanism, is the theoretically optimal mechanism for decisions about indivisible public projects. It is incentive compatible, ex post budget balanced, and induces efficient implementation. It was first suggested by Arrow (1979) and d'Aspremont and Gérard-Varet (1979) who also give a formal proof of its properties. The AGV is a direct revelation game in which all individuals send a message from the type space (they can behave like other types but cannot invent new types). The expected surplus generated by the project is calculated based on the reports, and the project is implemented if and only if the reported surplus is positive. If individuals report truthfully, this leads to efficient project implementation. To ensure truthful reports, the mechanism calls for transfers equal to the expected externality an individual generates for the others.⁷ By including the externality in their payoffs, the mechanism forces individuals to take the expected surplus generated for the other players into account. As a result, all individuals are residual claimants of a value equal to the expected societal surplus they individually generate (their own surplus, plus the externality they impose on others). Consequently, they should send the message resulting in the highest expected social surplus. Since the AGV leads to first-best efficient implementation if all subjects report truthfully, this induces truthful reporting of all types. The AGV combines incentive compatibility with efficiency and budget balance and therefore the AGV provides the theoretical benchmark to which the performance of other mechanisms is compared. It is also an important benchmark for implementation. If it is impossible to switch from a given mechanism to the most efficient mechanism, the AGV, a switch to any other (less efficient) mechanism is unlikely.

The SM mechanism is chosen for two reasons. First, it is a common mechanism used in committee and small group decision-making and therefore provides a natural benchmark for the empirical performance of the AGV. Second, the comparison between AGV and SM is the focus of the possibility theorem in Grüner and Koriyama (2012), such that we can use it to reproduce the theoretical choice setting of that paper. The NSQ mechanism resembles the opportunity for individuals not to take part in a decision process and thereby prevent a group decision. It mimics the non-participation option that causes Myerson–Satterthwaite impossibility. The RAND mechanism introduces an uncertain status quo and reproduces the comparisons with intermediate allocations as studied in Schmitz (2002) and Segal and Whinston (2011).

⁷ The translated instructions for the Symmetric treatment in Online Appendix C include a table of all possible transfers.

3.3 Treatments

Treatments only differ in the distribution of private valuations for the public project. In all treatments, we use a uniform distribution over a type space with four possible valuations (in €) for the public project. The private valuations are drawn independently in each round. The distribution and its support are common knowledge and remain the same within a session.

The distribution of private valuations determines the expected payoff for the four mechanisms for each type. By varying the distributions, we thus vary the strength of the participation preferences over the mechanisms. For instance, theoretically AGV is always more efficient than SM, but the efficiency difference is much larger in skewed than in symmetric distributions. In the empirical analysis of the AGV, we find that subjects do not always truthfully reveal their private valuation. One suggested reason for such 'misreporting', is that subjects mistake valuation reports with the same absolute value (report '1' rather than '-1'). This type of mistake is excluded in the Robustness treatment where the absolute value of the project valuation is unique for all types (Table 1).

3.4 Procedures

The computerized experiments (zTree, Fischbacher, 2007) were conducted in the mLab of the University of Mannheim. Subjects were mostly undergraduate students from the University of Mannheim (recruitment through ORSEE, Greiner, 2015). Each session consisted of 18 rounds with random rematching of subjects in each matching group. In sessions with 18 or more participants there were two independent matching groups. All interactions were anonymous and subjects did not know who they were matched with in any round. To prevent income effects only one randomly selected round was paid in addition to a show up fee of €9. Each round was equally likely to be chosen for payment and the selected round was identical for all subjects within a session. We conducted nine sessions with 6–24 subjects, resulting in 150 participants in 15 matching groups. Of these, 85 (57%) subjects were male and the average age of participants was 23. Sessions lasted just under an hour on

Table 1 Distribution of valuations for the public project and number of observations by treatment

Treatment	Valuations (€)				Number of	
					Subjects	Match groups
Symmetric	-3	-1	1	3	45	4
Right-skewed (+7)	-3	-1	1	7	42	4
Left-skewed (-7)	-7	-1	1	3	45	5
Robustness	-3	-2	-1	7	18	2
Probability	25%	25%	25%	25%		

Probabilities are the same in all treatments. Subject types are drawn independently every round. A single treatment is used in each session

average, the average payment was €9.40, with a minimum of €2 and a maximum of €16.⁸

The 18 rounds were split into three six-round blocks: two blocks of *ex ante* rounds, followed by one block of *ad interim* rounds. Upon arrival in the lab, subjects received instructions for the first 12 rounds and were told about the existence of rounds 13–18. Subjects were only informed about the difference between rounds 1–12 and 13–18 (i.e., the revelation of private valuations before the mechanism choice in the *ad interim* rounds) after round 12. Subjects made each of the six possible binary mechanism choices once in each block, yielding three choices for each comparison. The order of the pairwise comparisons was randomized within each block and between sessions, and the order of the two mechanisms on subjects' screens was randomized between blocks. Initially we also planned to run sessions with *ad interim* rounds before the *ex ante* rounds. However, since we found no indications of order effects in the mechanism choices but had extra questions regarding the reporting strategy in the AGV, we ran an extra session with the Robustness treatment instead. In the next section, we explain the theoretical predictions for all treatments.

4 Predictions

To derive the theoretical predictions, we have to make assumptions about the level of rationality and the preferences of our subjects. We start with Predictions 1.1–1.4 that assume narrowly self-interested rationality, Prediction 2 allows for non-selfish preferences, and Prediction 3 allows for non-Nash money maximization. Derivations of our predictions can be found in “Appendix A.1”.

4.1 Narrowly self-interested and full rational predictions

By definition, all subjects are equal at the *ex ante* stage, and thus the payoff-maximizing mechanism for each individual also maximizes the expected group surplus. In the *ex ante* rounds, a rational, risk-neutral, and purely self-interested agent considers the Bayes–Nash equilibrium of each mechanism and selects the mechanism with the highest efficiency. Table 2 below displays the preference ordering over mechanisms in the *ex ante* rounds for each treatment.

Since the AGV and SM mechanisms are more efficient than NSQ and RAND, without private information subjects should prefer AGV and SM over NSQ and RAND in all treatments. Similarly, *ex ante* they should prefer AGV over SM if Nash equilibrium is played. If there are deviations from equilibrium, the preferred

⁸ Per treatment the average [minimum–maximum] payments were, Symmetric treatment €9.27 [5.75–12.00]; Right-skewed treatment €9.79 [5.16–16.00]; Left-skewed treatment €8.71 [2.00–11.96]; Robustness treatment €10.5 [6.00–16.00]. The translated instructions for the Symmetric treatment and screen shots from the original zTree program can be found in Online Appendix C.

Table 2 Predicted mechanism choices (ex ante)

Treatment	Ordering of mechanisms						
Symmetric	AGV	>	SM	>	NSQ	~	RAND
Right-skewed (+ 7)	AGV	>	SM	>	RAND	>	NSQ
Left-skewed (− 7)	AGV	>	SM	>	NSQ	>	RAND
Robustness	AGV	>	SM	>	RAND	>	NSQ

> and ~ indicate the preference ordering of the four mechanisms for a risk-neutral subject. The ordering of mechanisms corresponds to their expected payoffs in the respective treatments. The payoff calculations for the AGV and SM assume truthful valuation reports (AGV) and sincere voting (SM), both in accordance with their respective Bayes–Nash equilibrium

mechanism can depend on the realized efficiency of the two mechanisms. We will return to this issue in Prediction 3 and Sect. 5.3.

Prediction 1.1 *Without private information, all individuals prefer the more efficient of the two mechanisms in accordance with the ranking in Table 2.*

In the ad interim rounds, subjects should consider the expected value of each mechanism given their valuation and the strategies played by other players. A complete list of all the preference rankings therefore entails 84 ($4 \times 4 \times 6$) rankings between two mechanisms. The derivation of the following predictions and a table summarizing the 84 binary rankings can be found in “Appendix A.1”.

Theoretical work has identified several patterns in these binary rankings. Since the ranking of mechanisms depends directly on the valuation individuals have for the project, an individual with a negative valuation for the public project should choose the mechanism with the lowest implementation probability in Nash-equilibrium strategies. From this observation, we can conclude that the NSQ, with zero probability of implementation, dominates all other mechanisms for individuals with a negative project valuation. This is the application of the Myerson–Satterthwaite impossibility theorem in our setting: interim individual rationality makes all incentive compatible mechanisms less appealing than simply not participating for about half of our subjects.

Prediction 1.2 *With private information, individuals with a negative valuation prefer NSQ to all other mechanisms.*

Schmitz (2002) and Segal and Whinston (2011) show that the impossibility in prediction 1.2 can be overcome if the outside option has a similar distribution over final outcomes as the efficient mechanism, rather than providing a safe payoff like NSQ. In our experiment, their results translate to the prediction that subjects should prefer AGV and SM over RAND *even* with private information.

Prediction 1.3 *With private information:*

1. *all individuals prefer the AGV over the RAND mechanism;*
2. *all individuals prefer the SM over the RAND mechanism.*

Grüner and Koriyama (2012) demonstrate that individuals prefer the AGV over the SM as long as some conditions are met. In our experiment, their result translates to the following predictions:

Prediction 1.4 *With private information subjects prefer the AGV over the SM if:*

1. *they have a private valuation of -3 or $+3$ in the Symmetric treatment;*
2. *they have a private valuation of 7 or 1 in the Right-skewed treatment;*
3. *they have a private valuation of -7 or -1 in the Left-skewed treatment;*
4. *they have a private valuation 7 or -1 in the Robustness treatment.*

4.2 Empirically derived predictions

Empirical observations show that Bayes–Nash predictions can and do fail in empirical tests, but some regularities can be found. Based on the empirical observations in various papers, we make two more predictions.

4.2.1 Social concerns

In Engelmann and Grüner (2017), Bierbrauer et al. (2017) and Bol et al. (2020) the authors show that social concerns impact mechanism choices. In the Right-skewed and Robustness treatment, the AGV transfers are paid by subjects reporting high positive valuations. This “tax” thus reduces ex post inequality and increases the maximum payout to the type with lowest earnings without reducing the efficiency of the mechanism. In the Left-skewed treatment, a similar “tax” is levied from individuals with extremely negative valuations, increasing inequality. Thus, if we relax the assumptions on narrow self-interest and assume that utility increases in equality or the maxi-min criterion, the AGV should be more desirable in the Right-skewed and Robustness treatment than in the Left-skewed treatment. We expect this effect to be most visible in the ex ante rounds. In the ad interim rounds, we expect private benefits to dominate fairness concerns so that the later should not affect mechanism choices.

Prediction 2

1. *The AGV mechanism is chosen more often in the Right-skewed and Robustness treatments than in the Left-skewed treatment.*

2. *This preference is more pronounced in the ex ante rounds than in the ad interim rounds.*

4.2.2 Payoff maximization in the lab

Rational subjects are expected to maximize their own payoff *within the experiment*. However in the lab, the expected payoff of the SM and AGV mechanisms is not equal to their theoretical Nash-equilibrium payoff. Predictions about preferences over mechanisms based on Bayes–Nash equilibrium thus make incorrect assumptions and could incorrectly rank mechanisms. By varying the distribution of private valuations, we vary the payoff differences in the mechanism choice. This allows us to see if preferences over mechanisms indeed follow the payoff differences as expected. Furthermore, we expect the lab payoffs experienced by subjects to be better predictors of mechanism choices than theoretical Bayes–Nash equilibrium payoff.

Prediction 3

1. *Mechanisms with a higher personal payoff are selected more often.*
2. *This relation is stronger for lab payoffs than for Bayes–Nash equilibrium payoffs.*

5 Results

Before we look at the theoretical predictions about specific comparisons, we present an overview of the choice behavior over all treatments in Fig. 1.⁹ We then present our results on each of the predictions. We compare the efficiency of AGV and SM when we test Prediction 3.

In the summary overview of all binary choices in Fig. 1, we see some indications of the expected effects. In Fig. 1a, efficiency seems to matter in the ex ante mechanism choices. Subjects are close to indifferent between NSQ and RAND in the Symmetric and Robustness treatment where the ex ante expected value of implementation is (close to) zero, and more subjects favor NSQ (RAND) in the Left-skewed (Right-skewed) treatment that has a negative (positive) expected value. If we order the two treatments in terms of the relative efficiency of NSQ and RAND, we find the same order as on the lower axis of Fig. 1a. In line with Prediction 1.1, subjects overwhelmingly choose the more efficient, active mechanisms (SM and AGV) instead of the two passive ones. The choices between SM and AGV are close to the 50/50 distribution. SM is somewhat preferred in two treatments, whereas AGV is somewhat preferred in the Left-skewed treatment. In this last treatment, sending a message of -7 acts as a veto, which could provide a clear limit to the risk this mechanism poses to subjects.

⁹ Online Appendix B.1 shows a more detailed breakdown of all mechanism choices.

Fig. 1 Binary mechanism choices in the ex ante and the ad interim stage. Notes: Each of the six axes in the figures display the fraction of subjects choosing the mechanisms indicated at the corners. The scale of the diagonal axis can be read from both the vertical and horizontal axis. Separate sub-figures are drawn for choices in the ex ante rounds, the ad interim rounds with negative valuation, and ad interim rounds with positive valuation. Treatments are indicated by markers. The closer a marker is to a corner, the larger the fraction of subjects that chose that mechanism

The ad interim choices in Fig. 1b also appear largely in line with expectations. Prediction 1.2 states that subjects with a negative valuation prefer NSQ (Myerson–Satterthwaite impossibility). This is clearly visible in the agglomeration of markings in the south-west corner of Fig. 1b in the negative valuation panel. This choice pattern is completely absent for subjects with a positive valuation, and can also not be found in the ex ante choices of the same subjects. Striking is also that this clustering on the inefficient mechanism only happens if the mechanism is safe (NSQ). In line with Prediction 1.3, subjects are much more likely to choose the

SM or AGV over RAND, regardless of whether they have a positive or negative valuation.

Figure 1a shows that subjects prefer the AGV over SM most in the Left-skewed treatment. Whereas in the binary choice between NSQ and RAND no difference between treatments are found. This indicate that it is unlikely that Prediction 2 will be supported by our data. The figure does not show much about the other predictions.

5.1 Theoretical predictions, Prediction 1

In Table 3, we use logistic regressions to test Predictions 1.1–1.4. Throughout the paper, we cluster standard errors on the matching group (the largest group in the experiment that subjects could be matched with and thus could share some common history with) or treatment level and use a sandwich-estimator for the variance–covariance matrix based on Cameron et al. (2012).

To test Prediction 1.1, we first define a dummy variable that is set to 1 if the subject selected the mechanism that is theoretically most efficient (we code the comparison RAND-NSQ as missing in the Symmetric treatment as these mechanism have the same expected efficiency). Column (1) shows that subjects indeed do not respond to the valuation before they know their valuation. More importantly, the coefficients on the full set of treatment dummies are positive and highly significant, indicating that subjects in every treatment prefer the efficient mechanism in the ex ante stage, as stated in Prediction 1.1.

Column (2) relates to Prediction 1.2. It shows ad interim subject-periods with a choice between NSQ and some other mechanism. As predicted by Myerson–Satterthwaite impossibility, subjects with a negative valuation are much more likely to choose the NSQ. The hypothesis that the sum of the treatment-specific constant and the coefficient on *Negative Value* is equal to zero is rejected in all treatments (χ^2 -tests, $p < 0.001$ in all cases). Note the stark contrast with column (1) where both the treatment dummies and the Negative Value dummy have significantly smaller coefficient sizes. The Myerson–Satterthwaite theorem does not state that types with a negative value *on average* prefer NSQ, it states that *all types* with a negative valuation prefer the NSQ. Therefore, column (3) repeats the regression with a full set of valuation dummies (we drop the Symmetric treatment dummy for identification). The dummies for types -7 and -2 and corresponding observations are dropped because those types are perfectly predicted to select NSQ (see Fig. 1 and Online Appendix B.1.2). The coefficients on all negative valuations are positive and significant, whereas the coefficients on all positive valuations are negative and significant. Value -1 is the marginal type in the type space and has the smallest positive coefficient. In χ^2 -tests against the restriction that the treatment dummies and the coefficient on Value -1 add to zero, the null is rejected in all treatments (Right-skewed $p < 0.001$, Left-skewed $p = 0.005$, and Robustness $p = 0.039$). The pattern of Prediction 1.2 is clearly visible in the choices made by our subjects for all treatments and types.

In column (4), we look at the choice between flipping a coin or voting. Prediction 1.3 says that in these choices, all types should prefer AGV or SM to RAND.

Table 3 Prediction 1, money-maximizing under full rationality

Prediction	1.1	1.2	1.2	1.3	1.4
Stage	Ex ante	Ad interim	Ad interim	Ad interim	Ad interim
Choices	ALL	NSQ-Other	NSQ-Other	AGV-RAND SM-RAND	AGV-SM

Logistical regressions, dependent variables are dummies indicating that in a particular period this subject chose the indicated mechanism from the two available options. In column (4), two valuations and the 51 corresponding observations are not used in the regression because of colinearity issues and lack in variation, too many of the subjects with those types chose NSQ. Robust standard errors are in parentheses, *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$

Indeed, we find that the coefficients on all types are negative and highly significant, indicating that RAND is not preferred. We repeat the χ^2 -tests on the sum of the treatment dummy and the smallest coefficient for a type present in that treatment. The Symmetric treatment is the baseline, so the coefficients measure the marginal effects and they are all significant and negative as predicted. In the Right-skewed treatment, $Value - 3 + Right\ skewed = 0$ yields $\chi^2 = 11.24$, $p = < 0.001$. In the Left-skewed treatment, $Value - 3 + Left - skewed = 0$ yields $\chi^2 = 2.22$, $p = < 0.1364$. In the Robustness treatment, $Value - 3 + Robustness = 0$ yields $\chi^2 = 0.27$, $p = < 0.61$. Over all treatments, the pattern of Prediction 1.3 appears visible. However, if we check on the individual-type level on which the prediction is made, we find null results in two treatments.

In column (5), we examine which types prefer AGV to SM. To have enough statistical power, we create a single dummy that identifies the types that Grüner and Koriyama (2012) predict prefer the AGV over SM in the ad interim stage. The coefficient on the dummy *AGV-pref (GK)* is positive as predicted by Prediction 1.4 and is highly significant. Testing the restriction that the treatment dummies plus the coefficient *AGV-pref (GK)* equals zero yields: $\chi^2 = 52.78$, $p = < 0.001$ in the Symmetric treatment; $\chi^2 = 31.45$, $p = < 0.001$ in the Right-skewed treatment; $\chi^2 = 3.49$, $p = < 0.06$, in the Left-skewed treatment; $\chi^2 = 13.04$, $p = < 0.001$ in the Robustness treatment. The pattern suggested by Prediction 1.4 is clearly identified over the treatments, but is only marginally significant in the Right-skewed treatment.

The statistical noise we expect from our data asymmetrically affects theoretical predictions indicating implementation problems and potential solutions for two reasons. The first is directly observable in our data. In our statistical tests the problematic pattern of Prediction 1.2 is found very strongly. In fact, we have to drop some observations in column (3) because our statistics cannot deal with perfect identification. We do not see similarly strong patterns in the potential solutions to the impossibility in columns (4) and (5). In part, the fact that the later predictions are not as clear cut as the Myerson–Satterthwaite impossibility result is due to statistical power. We go from 1710 observation in 15 clusters in column (1) to only 150 observation in column (5). However, the theoretical predictions are made with certainty for all types, an expectation that is clearly not found in any real-world setting or the lab. Secondly, in many situations, we need all individual players or a qualified majority to accept a change in the rules. In a consensus or veto situation, we only need one opposing vote to prevent the implementation of efficient mechanisms. If we find a weak pattern in line with Prediction 1.2, this could be enough to prevent efficient mechanisms from being adopted. The opposite holds for Predictions 1.3 and 1.4. If we want the efficient mechanism to be voluntarily adopted, these predictions have to hold perfectly for all types. Any statistical noise around the prediction makes implementing efficient mechanisms more difficult. Since the results of these more qualified predictions are not as clear cut, empirical tests are needed to make sure such predictions are borne out in real life.

5.2 Social concerns, Prediction 2

In the Right-skewed and Robustness (Left-skewed) treatments, the AGV transfers are paid by subjects that have a valuation of 7 (– 7) for the public project to subjects that have a negative (positive) valuation for the public project. These payments reduce (increase) ex post inequality after implementation of the project. Based on the results in Engelmann and Grüner (2017), Bierbrauer et al. (2017), and Bol et al. (2020) that subjects value fairness, we could expect subjects to prefer the AGV more in the Right-skewed treatment and Robustness treatment than in the Left-skewed treatment. In Table 4 we test this prediction by looking at the choices for AGV in a logistic regression with dummy *Tax the winner* set to 1 for the Right skewed and Robustness treatments, and to 0 for the Left-skewed treatment. We interact *Tax the winner* with a dummy indicating the ad interim rounds to see if the social concerns matter more ad interim or ex ante. In column (1), we look at all decisions of all types and see that, ad interim, the AGV is chosen less often than ex ante. The main effect and the interaction effect of the *Tax the winner* dummy are insignificant (and of opposing sign). Since the strength of preferences depend directly on the valuation for the public project, the types with extreme preferences could drive the null result. In column (2), we therefore repeat the analysis using only types with a valuation of – 1 or + 1. This does not change the sign or significance of the coefficients on *Tax the winner*. Contrary to Prediction 2, there does not appear to be a prosocial tendency in the mechanism choices in our data.

Table 4 Effect of social concerns on mechanism choices

Variables	Chosen mechanism	
	AGV (1)	AGV (2)
Ad interim	– 0.835*** (0.254)	– 0.516 (0.326)
Tax the winner	– 0.275 (0.255)	– 0.271 (0.247)
Ad interim × Tax the winner	0.436 (0.286)	0.147 (0.407)

Logistical regressions, dependent variables are dummies indicating that in a particular period this subject chose the indicated mechanism from the two available options. Robust standard errors in parentheses, *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$

The difference between our findings and those experiments that do find social concerns can be explained by a number of factors. For instance, subjects might not perceive enough difference in fairness between the mechanisms since they all have similar procedural fairness. Alternatively, the one-third probability that the mechanism choice has direct effects on the experiment, and thus on monetary payoffs, might overwhelm social concerns. The random, anonymous rematching used in this experiment restricts personal relations, dynamic strategies, and direct reciprocity, further reducing the potential for social concerns. Random rematching and random dictator choices clearly reduce the scope of the social concerns, but they are common in similar experiments that do find social concerns in group decision settings.¹⁰ Our results thus put some bounds on the strength of these social concerns and/or the characteristics of the mechanisms that matter for the expression of social concerns by our subjects, but do not excluded social concerns per se.

5.3 Realized surplus, Prediction 3

Predictions 1.1–1.4 assume that all subjects play Bayes–Nash strategies when determining the relative payoffs of the mechanisms. However, as we know from other experiments and experience, individuals seldom perfectly adhere to Bayes–Nash strategies, and realized payoffs of the mechanisms are an empirical matter. With different valuations, we should expect different rankings of mechanisms for an income maximizing subject. Prediction 3 focuses on these differences between theoretic and empirical payoffs and how these affect mechanism choice.

We compare the realized payoff for each mechanism based on the behavioral strategies and the objective probability over the vector of types, rather than the average surplus in the lab. The surplus obtained in the lab is strongly influenced by the realizations of private valuation and the mechanism choices by the random dictator which can distort the comparison. Therefore, we use the observed distribution of reports/votes made by subjects to determine behavioral strategies for each treatment-type. Using these behavioral strategies, we calculate the payoffs and surplus (in €) that would have realized in the limit where all combinations of private valuations occur with their expected probabilities. Equivalently, the realized surplus can be interpreted as the expected value of the next, unobserved round given these behavioral strategies.¹¹

¹⁰ See for instance Feddersen et al. (2009), Botelho et al. (2005), Engelmann and Grüner (2017), Bierbrauer et al. (2017), or Bol et al. (2020).

¹¹ The calculations involve a direct comparison of the efficiency of AGV and SM on the same group of subjects. This comparison can be of independent interest for mechanism design in social choice. We therefore analyze the realized efficiency of these mechanisms in more detail in Online Appendix B.2. In this appendix we also show a table with the average payoff realized in the lab without correcting for the random draws in the experiment.

Table 5 Theoretical and realized group surplus with AGV and SM (ex ante)

Treatment	AGV			SM		
	Group surplus			Group surplus		
	Theory	Realized	Difference (%)	Theory	Realized	Difference (%)
Symmetric	1.59	1.18	− 0.41 (− 26%)	1.50	1.34	− 0.16 (− 11%)
Right-skewed (+ 7)	4.36	3.84	− 0.51 (− 12%)	3.75	3.68	− 0.07 (− 2%)
Left-skewed (− 7)	1.36	0.93	− 0.43 (− 32%)	0.75	0.66	− 0.09 (− 13%)
Robustness	3.28	2.93	− 0.35 (− 11%)	2.02	2.24	0.22 (11%)

Group surplus of an average round in Euro. Theoretical surplus is calculated based on Bayes–Nash equilibrium of the mechanisms. Realized surplus is based on behavioral strategies and can be interpreted as the expected value of the next round with this mechanism in the lab. The difference columns show by how much lab play differs from Nash equilibrium both in Euro and in percentages of theoretical surplus

Table 5 shows the Bayes–Nash surplus and the realized group surplus for the AGV and SM mechanisms in the ex ante rounds in all treatments.¹² Neither mechanism reaches its full theoretical efficiency level. Still, SM is almost as efficient in the lab as predicted by theoretical calculations with rational, self-interested agents. The AGV is perfectly efficient in theory but loses a lot of its efficiency in practice. It is still the most efficient mechanism ex ante in the two Skewed treatments and the Robustness treatment. In the Symmetric treatment, SM is theoretically very close to optimal, which reduces the advantage of AGV in theoretic calculations. Simultaneously, the realized efficiency of AGV is quite low in this treatment, causing the realized efficiency ranking to reverse. The reversal of the efficiency ordering of AGV and SM makes it very difficult to predict preferences over mechanisms in the lab for subjects that are sensitive to realized payoff.

In every round, each group faces an efficient project (group surplus > 0) or inefficient project with the same probability. In the ex ante rounds, the efficiency of the project cannot affect the mechanism choices. Therefore, we compare the number of efficient and inefficient provision decisions (one decision per three matched subjects per period) in the ex ante rounds in Table 6. We choose this comparison over a comparison of the surplus in Table 5 for two reasons. The values in Table 6 are determined at the level of treatments, so that we only have one observation per treatment. Furthermore, the size and variance of the surplus varies over treatments because of the changes in the type space and in behavior, so that comparisons of the average surplus are not directly informative. Over the four treatments combined, implementation is marginally more efficient in the AGV. However, if we look at the results per treatment, the only difference found is in the Robustness treatment, whereas the SM is non-significantly more efficient in the Symmetric treatment. The Robustness treatment is the least Symmetric treatment, so exactly the situation where the

¹² We concentrate on the ex ante rounds because in these rounds the private valuations, and thus the efficiency of the mechanisms, cannot influence the mechanisms played. Although they are noisier, results for the ad interim rounds are qualitatively similar.

Table 6 Efficient implementation in the AGV and SM mechanisms

Treatment	All		Symmetric		Right-skewed		Left-skewed		Robustness	
	AGV	SM	AGV	SM	AGV	SM	AGV	SM	AGV	SM
Inefficient	34	48	11	13	9	12	12	14	2	9
Efficient	189	164	50	62	53	48	62	38	24	16
Total	223	212	61	75	62	60	74	52	26	25
Odds ratio		0.615	1.049		0.681		0.528		0.15	
Fisher-Exact, p -value		0.051	1		0.478		0.18		0.0188	

Contingency table showing the numbers of efficient and inefficient project implementation decisions in the AGV and SM in each treatment. The lower part of the table shows the odds-ratio that compares the percentage of efficient implementation in both mechanisms as well as the corresponding p value from a two-sided Fisher's exact test against the null of no difference between the mechanisms

theoretically expected difference between AGV and SM is largest. In Online Appendix B.2.4 we show that similar results are obtained through logistical regressions with clustered standard errors. The same appendix shows these null results are not purely due to lack of statistical power, as we can clearly show that the AGV has more efficient implementation than the extremely noisy RAND mechanism.

Prediction 3 states subjects tend to select mechanisms with a higher expected payoff. After the ex ante rounds, subjects have experienced the mechanisms and thus have a feeling for the payoff they can obtain in the mechanisms in the lab. We create two proxies for these benefits by calculating the expected payoffs for each mechanism based on Bayes–Nash strategies and based on observed behavioral strategies for each treatment-type. We use the differences in expected utility between the two available mechanisms to explain the ad interim mechanism choices of each type in each treatment. This allows us to directly compare predictions based lab and Bayes–Nash payoffs for the second part of Prediction 3. Since strategies are determined at the treatment-type level, we aggregate our data to this level and determine the proportion of subjects with a given treatment-type that support mechanism A over mechanism B in a given choice.¹³ This yields one observation per treatment-type and correlated errors within treatment since strategies are interdependent. We estimate a quasi-binomial model against the fraction of subjects that prefer the mechanism using both the theoretic and lab payoff differences as explanatory variables. We cluster standard errors on the treatment level. Since we want to examine the difference lab-based and theory-based predictions, we do not use the comparison between RAND and NSQ where the lab and theoretic payoffs are the same by construction. The results are shown in Table 7.

In columns (1) and (2), we estimate the model using the lab and theory measures of incentives, respectively. In both columns, types that gain more from the mechanism are more likely to select it ad interim. If we look at the overall model fit, we

¹³ Mechanism A is defined as the AGV if available, or the SM mechanism otherwise. Online Appendix B.1.3 graphically displays the data and GLM model fit.

Table 7 Effect of utility differences on mechanism choice

	Proportion of support for mechanism A		
	(1)	(2)	(3)
Utility difference lab	1.670*** (0.572)		1.203** (0.572)
Utility difference theory		1.686*** (0.449)	0.528 (0.449)

Residual deviance	22.09	23.15	21.86
Prediction	3	3	3
Choices	AGV versus other, SM versus other	AGV versus other SM versus other	AGV versus other SM versus other

Generalized linear model for fractional response (quasibinomial with logistic link function). The dependent variable is the fraction of subjects selecting a mechanism A from the two offered. The independent variables measure the difference in expected utility between mechanism A and mechanism B. Expected utility calculations are based on lab play in the first 12 rounds (*Utility difference lab*) or theoretic Bayes–Nash equilibria (*Utility difference theory*). Standard errors (in parentheses) are clustered on the treatment level and calculated through a sandwich procedure based on Cameron et al. (2012). *** $p < 0.01$, ** $p < 0.05$, * $p < 0.1$

see a slightly better fit (lower residual deviance) for model (1) using lab predictions. In column (3), we pit the two predictors against each other directly. The positive correlation between the two independent variables decreases the coefficients' sizes, but the lab-based measure is the only significant predictor. The model with both variables has a marginally better fit than both other models, but the difference is not statistically significant (Rao score test, theory only $p = 0.849$, lab only $p = 0.937$). We looked at the ad interim rounds since we can see the choices made by each type individually there. We see something similar in the choice between AGV and SM in the ex ante rounds. In the Symmetric treatment, the realized surplus of the AGV is lower than that of SM in the lab. If we then look at Fig. 1a, we indeed see that support for the AGV is particularly low in that treatment. In fact, if we take the realized difference between AGV and SM in Table 5 and order the treatments accordingly, we find the exact same order as we see on the top axis of Fig. 1a. The expectations

of Prediction 3 are clearly found in our data. The expected benefits of the mechanisms drive choices, and subjects respond most clearly to the expected benefits they experience in actual play.

The pattern of efficiency differences is interesting in its own right. Consistent with theory, the voting mechanism underperforms relative to the AGV particularly in situations with skewed distributions. The inability to show the intensity of preferences is particularly costly in these situations. However, the realized differences are very small and therefore difficult to notice in real life. These small differences can therefore create difficulties in the implementation of this more efficient mechanism.

Deviations from theoretical efficiency predictions stem from subjects' second stage reporting (AGV) and voting (SM) strategies. Online Appendix B.2.1 shows that subjects that misreport the sign of their valuation in the AGV cause the largest loss in surplus. We show that the empirical best response of each type contains the truthful report and for most treatment-types it is unique. Reports with an incorrect sign could be caused by subjects that mistake -3 for 3 or vice versa. We removed this possibility in the Robustness treatment, but we still find a significant number of misreported signs. Furthermore, we find a pattern where subjects with a positive valuation almost never misreport the sign of their valuation, whereas subjects with a negative valuation do so more often. As such, there appears to be a bias by some of our subjects in favor of implementing the public project in the lab. Interestingly, this asymmetric pattern is present in all treatments and across a number of individuals. In Online Appendix B.3, we look at how individual differences in reporting and voting strategies relate to personal characteristics. The most consistent effect we identify is that those individuals that are more likely to follow the Nash strategies of truthful revelation (sincere voting) are also most likely to select the AGV (SM) if given the option. This seems to imply that beliefs about the mechanisms influenced both selection of and play within the mechanisms. We find little evidence that the deviations from Nash equilibrium, either in the AGV or in SM, are driven by understanding of the experiment.

6 Conclusion

In group decision problems with conflicting interest, selecting an efficient decision rule is a problem characterized by conflict. The conflict over outcomes spills over to the mechanism selection stage and can make inefficient mechanisms persist. To allow groups to use more efficient mechanisms, we need to design mechanisms that are both more efficient and implementable in practice. This paper presents the results of one of the first experimental studies in a social choice setting that combines the dual aspects of practical efficiency and implementability.

In our experiment, the patterns found in mechanism choices are largely, but not completely, consistent with narrowly self-interested rationality. In line with predictions going back to Harsanyi (1955), mechanism choices in an ex ante condition (behind-the-veil-of-ignorance) are efficient for the group. As the Myerson–Satterthwaite theorem and related impossibility results predict, the same subjects who prefer the theoretically optimal AGV ex ante, suddenly opt for the complete inertia of

zero-implementation after learning their private valuation is negative. We also found the more qualified predictions of Schmitz (2002), Segal and Whinston (2011) that subjects prefer AGV over flipping a coin (RAND) even after learning their private valuation, and that some types even prefer the AGV over SM *ad interim* (Grüner & Koriyama, 2012). However, theoretical predictions are not always accurate for all individual types or all possible situations. Not every subject prefers AGV over flipping a coin, and clear majorities for either AGV or SM often do not exist. Furthermore, a rational agent takes into account the realized payoff, including all deviations from Nash-equilibrium observed in reality. Since neither the optimal AGV nor SM are as efficient in the lab as in theory, theoretical predictions about the participation preferences of individuals are not always correct.

Our experiment highlights the difficulties of replacing a group decision rule with a more efficient one. This problem is fundamental to the socialist debate. It provides one possible answer to the question: “Why do centralized mechanisms like the state, and decentralized mechanisms like markets coexist?”. The difficulty to get even small groups with small stakes to accept efficient mechanisms, would translate to the near impossibility to get efficient mechanisms for a public project on the scale of a company, or nation (Mailath & Postlewaite, 1990). Centralized organizations with coercive power, like states or companies, bundle decisions and projects and take the individual projects away from purely decentralized mechanisms like open markets. In our experiment, groups would have been better off if they would have forced to use the AGV or SM for all projects, rather than possibly having the zero-implementation NSQ whenever someone objected. Similarly, in society and in companies, the efficiency gains from joint investment in (a set of) common projects are often large enough to compensate participants for their involvement in some projects that are not individually rational to them. In the words of one of the classics in this debate (Clarke, 1971, p. 17): “If policing and exchange costs associated with a market arrangement are too high, substitute non-market devices may be preferred”.

The choices in our experiment confirm the effects of background risk on participation, as predicted by Schmitz (2002), Segal and Whinston (2011), Grüner and Koriyama (2012). This forces us to consider the outside options used in mechanism design. Simply equating the outside option to constant (zero) utility can affect behavior in the game through participation choices. When participation matters, equating the outside option to zero is more than just a normalization, it is a modeling choice that impacts the results.

Our setup allows us to vary individual participation constraints and compare subjects’ revealed preference for mechanisms before and after private information is received. We believe similar methods could be fruitfully applied to experimentally investigate other questions related to participation constraints, for instance in optimal auctions, monopoly pricing, or matching settings.

A Appendix

A.1 Derivation of predictions

A.1.1 Prediction 1.1

Note that all mechanisms generate as much surplus as is generated by the public project, as the rest of the (experimental) budget is ex post balanced. From the four mechanisms, the AGV mechanism is the only mechanism that implements (in Bayes–Nash equilibrium) the project if and only if the generated surplus is larger than 0. The other mechanisms all have an efficiency loss from wrong implementation, or wrong non-implementations and therefore are less efficient in expectation. These differences in efficiency imply the preference of individuals without private information for the AGV over NSQ and RAND mechanism in Prediction 1.1. The SM mechanism implements if and only if at least two people vote in favor. If we assume that individuals vote in favor if they have a positive valuation and against if it they have a negative valuation, we can see when the loss of efficiency in implementation occurs. In the Symmetric treatment this happens in two cases (type vectors $\{-1, -1, 3\}$ and $\{1, 1, -3\}$), both of which cost 1€ and occur with a probability of 4.6875%, such that the expected loss of the SM mechanism relative to first-best efficiency is 0.09€, or 5.88% of the maximum efficiency.

In the Right-skewed treatment with the + 7 value there are four cases of inefficient implementation, type vectors $\{-3, -3, 7\}$, $\{-3, -1, 7\}$, $\{-3, 1, 1\}$ and $\{-1, -1, 7\}$, occurring with probabilities 4.6875%, 9.375%, 4.6875% and 4.6875% respectively. The expected loss is 0.61€, or 13.98% of maximum efficiency. In the Left-skewed treatment with the – 7 value there are four cases of inefficient implementation, type vectors $\{1, 1, -7\}$, $\{3, 1, -7\}$, $\{3, -1, -1\}$ and $\{3, 3, -7\}$, occurring with probabilities 4.6875%, 9.375%, 4.6875% and 4.6875% respectively. The expected loss is also 0.61€, but this is 44.82% of maximum efficiency in this setting, since the maximum efficiency delivers a much lower surplus.

The RAND mechanism has a zero expected surplus for the Symmetric treatment, a €– 1 expected surplus in the Left-skewed treatment (€– 7), and a €1 expected surplus in the Right-skewed treatment (€7). The loss of efficiency of the NSQ is always 100%. Since the efficiency loss in the SM mechanism is always lower than the loss in the NSQ or RAND mechanism, this proves Prediction 1.1.

A.1.2 Prediction 1.2

With known private values v_i , individuals can calculate their expected utility as a function of mechanism Γ :

$$E(U) = v_i * \Pr(Y = 1 | \Gamma = M).$$

With $Y = 1$ denoting implementation and $M \in \{\text{NSQ}, \text{RAND}, \text{SM}\}$. With a negative private value, v_i , the best response is to choose the mechanism with the lowest probability of implementation. Since $\Pr(Y = 1 | \Gamma = \text{NSQ}) = 0$, the NSQ (weakly)

dominates {RAND, SM} for these individuals. For the AGV mechanism, we also have to verify that the transfers do not change this prediction. The expected transfer, in truth-telling Bayes–Nash equilibrium in the Symmetric treatment is -0.125€ for the statements 3 and -3 and $+0.125\text{€}$ for -1 and 1 . For the AGV, the lowest implementation probability is achieved by any given subject by stating claiming the lowest type. Note, however, that this yields a probability of implementation that is strictly greater than 0 and a negative expected transfer, such that no rational individual with a negative valuation would choose this strategy over NSQ. Choosing AGV and playing claiming type -1 in the AGV yields an expected transfer of 0.13 [0.23] (0.23) € in the Symmetric [Left-skewed] (Right-skewed) treatment, but increases the implementation probability to 37.5% [37.5%] (50%) (assuming a truthful strategy of the other players). With any negative value, the expected implementation costs are therefore higher than the transfers. Since the transfers achieve their maximum at the -1 report, while the probability of implementation keeps increasing in the reported valuation, this also rules out any strategy with a higher reported type. Hence, selecting the AGV and lying cannot be preferred to selecting NSQ. In fact, the expected transfers for types with a negative valuation are never large enough to change the preferences over mechanisms. A similar line of reasoning proves the same result for types with positive valuations.

A.1.3 Predictions 1.3 and 1.4

For the AGV, assume that individuals report truthfully in the second stage when playing AGV, and vote in favor in case of positive valuation and against otherwise in SM. Each individual should then choose the mechanism that maximizes her expected payoff, which for $M \in \{\text{NSQ}, \text{RAND}, \text{SM}\}$ is as before:

$$E(U) = v_i * Pr(Y = 1 | \Gamma = M, v_i).$$

In the AGV the expected payoff is additionally influenced by the expected transfer each individual has to pay/receives, so it becomes:

$$E(U|AGV) = v_i * Pr(Y = 1 | \Gamma = AGV, v_i) + E(t_i | m_i = v_i).$$

where t_i is the transfer and m_i the message send by the subject about her type. Since the individuals possess private information, this can be either positive or negative. It is straightforward, albeit somewhat tedious, to calculate the expected utility of each type for each of the three mechanisms in all treatments. The results are displayed in Table 8 below.

Table 8 Expected utility by type and mechanism in Bayes–Nash equilibrium

Treatment	Mechanism: Valuation	AGV		SM		RAND	NSQ
		EV theory	EV lab	EV theory	EV lab	EV	EV
Symmetric	− 3	− 0.58	− 1.29	− 0.75	− 0.82	− 1.50	0.00
Symmetric	− 1	− 0.33	− 0.37	− 0.25	− 0.30	− 0.50	0.00
Symmetric	1	0.70	0.81	0.75	0.76	0.50	0.00
Symmetric	3	2.33	2.43	2.25	2.15	1.50	0.00
Right-skewed	− 3	− 1.14	− 1.79	− 0.75	− 0.99	− 1.50	0.00
Right-skewed	− 1	− 0.29	− 0.42	− 0.25	− 0.34	− 0.50	0.00
Right-skewed	1	0.84	0.87	0.75	0.76	0.50	0.00
Right-skewed	7	6.40	6.47	5.25	5.49	3.50	0.00
Left-skewed	− 7	0.00	− 0.96	− 1.75	− 1.84	− 3.50	0.00
Left-skewed	− 1	− 0.36	− 0.27	− 0.25	− 0.31	− 0.50	0.00
Left-skewed	1	0.52	0.73	0.75	0.74	0.50	0.00
Left-skewed	3	1.66	1.73	2.25	2.29	1.50	0.00
Robustness	− 3	− 0.94	− 0.94	− 0.19	− 0.31	− 1.50	0.00
Robustness	− 2	− 0.50	− 0.66	− 0.13	− 0.32	− 1.00	0.00
Robustness	− 1	− 0.06	− 0.14	− 0.06	− 0.18	− 0.50	0.00
Robustness	7	5.88	5.65	3.06	3.79	3.50	0.00

Expected value to a particular type in Euros for each treatment and types based on Bayes–Nash equilibrium strategy. Group surplus of an average round in Euro. The expected utility is based on Bayes–Nash equilibrium of the mechanisms

Like Segal and Whinston (2016) showed more generally, no single type prefers to flip a coin over playing the AGV (or SM in this case). For the predictions of Grüner and Koriyama (2012) we have a slightly more qualified result. In the skewed treatments the types − 3 and 3 prefer the SM mechanism, while all other types {− 7, − 1, 1, 7} prefer the AGV mechanism. In the Symmetric treatment the types − 1 and 1 are indifferent, while the types − 3 and 3 prefer AGV.

A.1.4 Preference ranking ad interim, full rationality and narrowly self-interested

Table 9 shows the order of the expected payoffs in the ad interim rounds per treatment and valuation, assuming the Bayes–Nash equilibrium is played.

Table 9 Predicted mechanism choices (ad interim)

Treatment	Valuation	Ordering of mechanisms						
Symmetric	3	AGV	>	SM	>	RAND	>	NSQ
	1	AGV	~	SM	>	RAND	>	NSQ
	-1	NSQ	>	SM	~	AGV	>	RAND
	-3	NSQ	>	AGV	>	SM	>	RAND
Right-skewed	7	AGV	>	SM	>	RAND	>	NSQ
	1	AGV	>	SM	>	RAND	>	NSQ
	-1	NSQ	>	SM	>	AGV	>	RAND
	-3	NSQ	>	SM	>	AGV	>	RAND
Left-skewed	3	SM	>	AGV	>	RAND	>	NSQ
	1	SM	>	AGV	>	RAND	>	NSQ
	-1	NSQ	>	AGV	>	SM	>	RAND
	-7	NSQ	>	AGV	>	SM	>	RAND
Robustness	7	AGV	>	RAND	>	SM	>	NSQ
	-1	NSQ	>	AGV	>	SM	>	RAND
	-2	NSQ	>	SM	>	AGV	>	RAND
	-3	NSQ	>	SM	>	AGV	>	RAND

> and ~ indicate the preferences ordering of the four mechanisms for a risk-neutral subject. The ordering of mechanisms corresponds to their expected payoffs given the respective treatment and valuation
