Abstract

Consecutive measurements performed on the same quantum system can reveal fundamental insights into quantum theory's causal structure, and probe different aspects of the quantum measurement problem. According to the Copenhagen interpretation, measurements affect the quantum system in such a way that the quantum superposition collapses after each measurement, erasing any memory of the prior state. We show here that counter to this view, un-amplified measurements (measurements where all variables comprising a pointer are in principle controllable) have coherent ancilla density matrices that encode the memory of the entire set of (un-amplified) quantum measurements that came before, and that the chain of this entire set is therefore non-Markovian. In contrast, sequences of amplified measurements (measurements where at least one pointer variable has been lost) are equivalent to a quantum Markov chain. We argue that the non-Markovian nature of quantum measurement has empirical consequences that are incompatible with the assumption of wave function collapse, thus elevating the collapse assumption into a testable hypothesis. Finally, we find that all of the information necessary to reconstruct an arbitrary non-Markovian quantum chain of measurements is encoded on the boundary of that chain (the first and the final measurement), reminiscent of the holographic principle.

1 Introduction

The physics of consecutive (sequential) measurements on the same quantum system has enjoyed increased attention as of late, as it probes the causal structure of quantum mechanics [7]. It is of interest to researchers concerned about the apparent lack of time-reversal invariance of Born’s rule [46, 53], as well as to those developing a consistent formulation of covariant quantum mechanics [45, 52], which does not allow for a time variable to define the order of (possibly non-commuting) projections [47]. Consecutive measurements on the same quantum system have also been used to test whether the statistics of the set of measurements is compatible with a macroscopic description of them [36].

Consecutive measurements can be seen to challenge our understanding of quantum theory in an altogether different manner, however. According to standard theory, a measurement causes the state of a quantum system to “collapse”, re-preparing it in an eigenstate of the measured operator so that after multiple consecutive measurements on the quantum system any memory about the initial preparation is erased. However, recent investigations of sequential measurements on a single quantum system with the purpose of optimal state discrimination have already hinted that quantum information survives the collapse [5, 43], and that information about a chain of sequential measurements can be retrieved from the final quantum state [25]. Such observations are incompatible with a Markovian—that is, memory-less—view of quantum measurement, which posits that for a set of detectors $X_1 \dots X_j$ that measure the state of a quantum system in j consecutive steps, the probability to obtain outcome x_j can only depend on the preceding state:

$$p(x_j|x_{j-1} \dots x_1) = p(x_j|x_{j-1}), \quad (1.1)$$

where $p(x_j|x_{j-1})$ is the conditional probability to observe outcome x_j for detector X_j if we previously had observed outcome x_{j-1} on detector X_{j-1} . In terms of the Shannon entropy of this chain, the Markov condition can be written succinctly as

$$H(X_j|X_{j-1} \dots X_1) = H(X_j|X_{j-1}), \quad (1.2)$$

where $H(X) = -\sum_i p(x_i) \log_2 p(x_i)$.

Here we investigate what circumstances confer the Markov property on chains of quantum measurements—meaning that each consecutive measurement “wipes the slate clean” so that retrodiction of quantum states [25] is impossible—and under what conditions the quantum trajectory remains coherent so that the memory of previous measurements is preserved. In particular, we study the *relative state* of measurement devices (both quantum and classical) in terms of quantum information theory, to ascertain how much information about the quantum state appears in the measurement devices, and how this information is distributed among them. We find that a crucial distinction refers to the “amplifiability” of a quantum measurement, that is, whether a result is encoded in the states of a closed or an open system. We also determine that a unitary relative-state description of quantum measurement makes predictions that are different from a formalism that assumes quantum state reduction, and that these differences can

be observed. But most importantly, we will argue that whatever the state of the measurement devices, the quantum state itself is *not* “projected”, so that all the initial amplitudes of the quantum state can continue to influence future measurements. Decoupling the state of the measurement device from the state of the quantum system—implying that one does not necessarily reflect the other even though one just measured the other—solves a number of long-standing paradoxes that have plagued quantum theory, but also opens up new puzzles about the nature of reality.

While the suggestion that the relative state description of quantum measurement [19] (see also [8, 10, 14, 22, 69]) and the Copenhagen interpretation of reduction of the wave function are at odds and may lead to measurable differences has been made before [14, 69], here we frame the problem of consecutive measurements in the language of quantum information theory, which allows us to make these differences manifest. We begin by outlining in Sect. 2 the unitary description of quantum measurement discussed previously [8, 10, 22], and apply it in Sect. 3 to a sequence of quantum measurements where the pointer—meaning a set of quantum ancilla states—remains under full control of the experimenter. In such a closed system, the pointer can in principle decohere if it is composed of more than one qubit, but this decoherence can be reversed in principle. We prove in Theorems 1 and 2 properties of the entropy of a chain of consecutive measurements that imply that the entropy of such chains resides in the last (or first and last) measurements, depending on whether or not the initial quantum state was known or not. We then show that for coherence to be preserved in such chains, measurements cannot be arbitrarily amplified—in contrast to the macroscopic measurement devices that are necessarily open systems.

In Sect. 4, we analyze sequences of amplifiable—that is, macroscopic—measurements and prove in Theorem 3 that amplified measurement sequences are Markovian. Corollary 1 asserts an information-theoretic statement of the general idea that two macroscopic measurements anywhere on a Markov chain must be uncorrelated given the state of all the measurement devices that separate them in the chain. This corollary epitomizes the essence of the Copenhagen idea of quantum state reduction in terms of the conditional independence of measurement devices that are not immediately in each other’s past or future. It is consistent with the notion that the measurements collapsed the state of the wave function, erasing any conditional information that a detector could have had about prior measurements. However, no irreversible reduction actually occurs, since all amplitudes in the underlying pure-state wave function continue to evolve unitarily.

Section 5 unifies the two previous sections by proving three statements (Theorems 4, 5, and 6) that relate information-theoretic quantities pertaining to unamplified measurements to the corresponding expressions for amplified measurements. We show that, in general, amplification leads to a loss of information.

After a brief application of the collected concepts and results to standards such as quantum state preparation, the double-slit experiment and the quantum Zeno effect, we close with conclusions in Sect. 6.

2 Theory of Quantum Measurement

2.1 The Measurement Process

Suppose a given quantum system is in the initial state

$$|Q\rangle = \sum_{x_1=0}^{d-1} \alpha_{x_1}^{(1)} |\tilde{x}_1\rangle, \quad (2.1)$$

where $\alpha_{x_1}^{(1)}$ are complex amplitudes. Here, Q is expressed in terms of the d orthonormal basis states $|\tilde{x}_1\rangle$ associated with the observable that we will measure. The von Neumann measurement is implemented with a unitary operator that entangles the quantum system Q with an ancilla A_1 ,¹

$$U_{QA_1} = \sum_{x_1=0}^{d-1} P_{x_1} \otimes U_{x_1}, \quad (2.2)$$

where $P_{x_1} = |\tilde{x}_1\rangle\langle\tilde{x}_1|$ are projectors on the state of Q . The operators U_{x_1} transform the initial state $|0\rangle$ of the ancilla to the final state $U_{x_1}|0\rangle = |x_1\rangle$, where $|x_1\rangle$ are the orthonormal basis states of the ancilla. The unitary interaction (2.2) between the quantum system and the ancilla leads to the entangled state [10]

$$|QA_1\rangle = U_{QA_1} |Q\rangle |0\rangle = \sum_{x_1} \alpha_{x_1}^{(1)} |\tilde{x}_1\rangle |x_1\rangle. \quad (2.3)$$

The coefficients $\alpha_{x_1}^{(1)}$ reflect the degree of entanglement between Q and A_1 : the number of non-zero coefficients is the Schmidt number [44] of the Schmidt decomposition.

Here we argue that this entanglement operation is sufficient to reproduce all experimental results for up to two consecutive projective measurements, without at the same time projecting the quantum state itself. The entanglement operation, already discussed by von Neumann [65], is often termed a “pre-measurement” or “latent measurement” [15], awaiting the second stage of measurement, namely the projection of the measurement device. However, it turns out that projecting the measurement device (by macroscopically recording its state) is not a necessary operation at this stage, as Dicke has shown [15]. Instead, a sequence of latent measurements can be performed on the quantum states in a coherent manner, projecting all measurement devices only after the last measurement has been performed. In fact, we will show below that as long as the density matrix of the measurement devices

¹ We focus here on orthogonal measurements, a special case of the more general POVMs (positive operator-valued measures) that use non-orthogonal states. What follows can be extended to POVMs, while at the same time Neumark’s theorem guarantees that any POVM can be realized by an orthogonal measurement in an extended Hilbert space.

Fig. 1 Entropy Venn diagrams [10] for the quantum system and ancilla. **a** For prepared quantum states, Q and A_1 are entangled according to Eq. (2.3). **b** For unprepared quantum states, Q and A_1 are correlated according to Eq. (2.12) when the reference R has been traced out. In this figure, we use the notation $S_1 = S(A_1)$ for the marginal entropy of ancilla A_1

are diagonal in the measurement basis, this final projection has no consequences for either the devices or the quantum state.

Tracing out the ancilla from (2.3), the density matrix of the quantum system can be written in the standard form,

$$\rho(Q) = \sum_{x_1} P_{x_1} |Q\rangle\langle Q| P_{x_1}, \quad (2.4)$$

where the probability to observe outcome x_1 is given by

$$q_{x_1}^{(1)} = \text{Tr}_Q [P_{x_1} \rho(Q)] = |\alpha_{x_1}^{(1)}|^2. \quad (2.5)$$

and P_{x_1} is a Kraus operator. This, of course, is just Born's rule.

Similarly, the density matrix of the ancilla A_1 is

$$\rho(A_1) = \text{Tr}_Q (|QA_1\rangle\langle QA_1|) = \sum_{x_1} |\alpha_{x_1}^{(1)}|^2 |x_1\rangle\langle x_1|. \quad (2.6)$$

From the symmetry of the state (2.3), the marginal von Neumann entropy of A_1 is the same as Q , which, in turn, is equal to the Shannon entropy of the probability distribution $q_{x_1}^{(1)} = |\alpha_{x_1}^{(1)}|^2$:

$$S(Q) = S(A_1) = H[q^{(1)}] = - \sum_{x_1} q_{x_1}^{(1)} \log_d q_{x_1}^{(1)}. \quad (2.7)$$

We denote the Shannon entropy of a d -dimensional probability distribution p_{x_i} by $H[p] = - \sum_{x_i=0}^{d-1} p_{x_i} \log_d p_{x_i}$. The von Neumann entropy of a density matrix $\rho(X)$ is defined as $S(X) = S(\rho(X)) = -\text{Tr} [\rho(X) \log_d \rho(X)]$, which on account of the logarithm to the base d , gives entropies the units “dits”.

The ancilla and quantum system are not classically correlated in (2.3) (as is required for decoherence models), but in fact are entangled. This entanglement is characterized by a negative conditional entropy [9, 10], $S(A_1|Q) = S(QA_1) - S(Q) = -S(A_1)$, where the joint entropy vanishes since (2.3) is pure. We illustrate the entanglement between A_1 and Q with an entropy Venn diagram [10] in Fig. 1a. The mutual entropy at the center of the diagram,

$S(Q : A_1) = S(Q) + S(A_1) - S(QA_1)$, reflects the entropy that is shared between both systems and is twice as large as the classical upper bound [1, 9, 10]. However, if mixed states are measured using the von Neumann measurement, the quantum system and the ancilla will appear classically correlated, but the joint system that includes the preparer is entangled, as we now show.

2.2 Unprepared Quantum States

In the previous section, we considered measurements of a quantum system that is prepared in a pure state (2.1) with amplitudes $\alpha_{x_1}^{(1)}$ (a “known” state). Suppose instead that we are given a quantum system about which we have no information, that is, where no previous measurement results could inform us of the state of Q . In this case, we should write the quantum system’s initial state as a *maximum entropy* mixed state

$$\rho(Q) = \frac{1}{d} \sum_{x_0=0}^{d-1} |\tilde{x}_0\rangle\langle\tilde{x}_0|, \quad (2.8)$$

with amplitudes that now correspond to a uniform probability distribution. We call this an *unprepared* quantum system. We can “purify” $\rho(Q)$ by defining a higher-dimensional pure state where Q is entangled with a reference system R [44],

$$|QR\rangle = \frac{1}{\sqrt{d}} \sum_{x_0=0}^{d-1} |\tilde{x}_0\rangle|x_0\rangle, \quad (2.9)$$

such that $\rho(Q)$ is recovered by tracing (2.9) over R . Here and earlier, the states of Q are written with a tilde, $|\tilde{x}_0\rangle$, to distinguish them from the states of R , which are denoted by $|x_0\rangle$.

To measure Q with an ancilla A_1 , we express the quantum system in the eigenbasis $|\tilde{x}_1\rangle$ (which corresponds to the eigenstates of the observable that ancilla A_1 will measure) using the unitary matrix $U_{x_0x_1}^{(1)} = \langle\tilde{x}_1|\tilde{x}_0\rangle$. The orthonormal basis states of the ancilla, $|x_1\rangle$, with $x_1 = 0, \dots, d-1$, automatically serve as the “interpretation basis” [14]. We then entangle [10] Q with A_1 , which is in the initial state $|0\rangle$, using the unitary entangling operation U_{QA_1} in Eq. (2.2),

$$|QRA_1\rangle = \mathbb{1}_R \otimes U_{QA_1} |QR\rangle |0\rangle = \frac{1}{\sqrt{d}} \sum_{x_0x_1} U_{x_0x_1}^{(1)} |\tilde{x}_1\rangle |x_0\rangle |x_1\rangle, \quad (2.10)$$

where $\mathbb{1}_R$ is the identity operation on R . We always write the states on the right hand side in the same order as they appear in the ket on the left hand side. Note that this entanglement operation is simply a generalization of the CNOT operation used explicitly in many quantum measurements (see, e.g. [2, 12, 16, 23, 30, 32, 34, 63]). We express the reference’s states in a new basis by defining $|x_1\rangle_R = \sum_{x_0} U_{x_1x_0}^{(1)} |x_0\rangle_R$ with the transpose of $U^{(1)}$, so that the joint system QRA_1 appears as

Fig. 2 Composition of the quantum ancilla. Dashed lines indicate entanglement between the quantum system, Q , and each of the n qudits, $A_1^{(1)}, \dots, A_1^{(n)}$, in the ancilla A_1

$$|QRA_1\rangle = \frac{1}{\sqrt{d}} \sum_{x_1} |\tilde{x}_1\rangle |x_1\rangle |x_1\rangle. \quad (2.11)$$

Note that (2.11) is a tripartite Schmidt decomposition of the joint density matrix $\rho(QRA_1) = |QRA_1\rangle\langle QRA_1|$, which is possible here because the entanglement operator U_{QA_1} ensures the bi-Schmidt basis ${}_R\langle x_1|QRA_1\rangle$ has Schmidt number one [49].

Tracing out the reference system from the full density matrix $\rho(QRA_1)$, we note that the ancilla is perfectly correlated with the quantum system,

$$\rho(QA_1) = \frac{1}{d} \sum_{x_1} |\tilde{x}_1 x_1\rangle \langle \tilde{x}_1 x_1|, \quad (2.12)$$

in contrast to Eq. (2.3) where A_1 and Q are entangled. Such correlations are indicated by a vanishing conditional entropy [10], $S(A_1|Q) = S(QA_1) - S(Q) = 0$. Tracing over (2.12), we find that each subsystem has maximum entropy $S(Q) = S(A_1) = 1$. In Fig. 1, we compare the entropy Venn diagrams that are constructed from the states (2.3) and (2.12). We note in passing that R can be thought of as representing all previous measurements of the quantum system that have occurred before A_1 .

2.3 Composition of the Quantum Ancilla

The ancilla A_1 may, in practice, be composed of many qudits $A_1^{(1)} \dots A_1^{(n)}$, which all measure Q in some basis, according to the sequence of entangling operations $U_{QA_1^{(1)}} \dots U_{QA_1^{(n)}}$ between Q and $A_1^{(i)}$ (see Fig. 2). In this case, Eq. (2.3), for example, is extended to

$$|QA_1\rangle = \sum_{x_1} \alpha_{x_1}^{(1)} |\tilde{x}_1\rangle |x_1\rangle_{A_1^{(1)}} \dots |x_1\rangle_{A_1^{(n)}}. \quad (2.13)$$

Tracing out the quantum system from Eq. (2.13), the joint state of the entire ancilla is $\rho(A_1) = \rho(A_1^{(1)} \dots A_1^{(n)}) = \sum_{x_1} |\alpha_{x_1}^{(1)}|^2 |x_1 \dots x_1\rangle \langle x_1 \dots x_1|$, that is, each component of A_1 is perfectly correlated with every other component, so that A_1 is internally self-consistent (“all parts of A_1 tell the same story”). However, while A_1 appears classical, and could conceivably consist of a macroscopic number of components, it is potentially *fragile*, in the sense that its entanglement with other devices may become hidden when any part $A_1^{(i)}$ of A_1 is lost (traced over). In the following, we will distinguish “amplifiable” from non-amplifiable devices: A state is termed amplifiable if

tracing over any of its components does not affect the correlations *between its subsystems*.

To do this, we will consider an additional step to the measurement process in our discussion of Markovian quantum measurements in Sect. 4.2, by introducing a macroscopic detector D_1 that measures the quantum ancilla A_1 . In other words, D_1 observes the quantum observer A_1 . This second system, which is also composed of many qudits, amplifies the measurement with A_1 , by *recording* the outcome on a macroscopic device. While A_1 may be fragile depending on the situation, D_1 is by definition robust: any part of D_1 could be traced over without affecting its correlations with other macroscopic measurement devices. While such a procedure (a quantum system observed by a quantum ancilla, which is observed by a classical device) may appear arbitrary, it merely represents a convenient way of splitting up the second stage of von Neumann's measurement [65] to better keep track of the fate of entanglement.

In the following sections, we formally define the concept of a quantum Markov chain that we use in the present article, in the context of consecutive measurements of a quantum system. We also further develop the formalism to describe series of un-amplified measurements with quantum ancillae A_i (which we will show to be non-Markovian) as well as amplified measurements with macroscopic detectors, D_i , which are Markovian. The relationship between amplifiability and the Markov property will be the subject of Theorem 3 in Sect. 4.4.

3 Non-Markovian Quantum Measurements

In the previous section, we introduced the concept of non-Markovian measurements as those sequences of measurements that are not amplified by macroscopic devices (latent measurements). In preparation for Theorem 3 in Sect. 4.4 that establishes this correspondence, we first consider consecutive measurements with quantum ancillae of prepared and unprepared quantum states, and demonstrate the non-Markovian character of the chain of ancillae. In particular, we will use entropy Venn diagrams to study the correlations between subsystems and the distribution of entropies during consecutive measurements.

3.1 Consecutive Measurements of a Prepared Quantum State

Building on the discussion from Sect. 2.1 where we described a single measurement of a quantum system, we now introduce a second ancilla A_2 that measures Q . This measurement corresponds to a new basis, $|\tilde{x}_2\rangle$, that is rotated with respect to the old basis, $|\tilde{x}_1\rangle$, via the unitary transformation $U_{x_1x_2}^{(2)} = \langle\tilde{x}_2|\tilde{x}_1\rangle$. Unitarity requires that

$$\sum_{x_2} U_{x_1x_2}^{(2)} U_{x'_1x'_2}^{(2)*} = \delta_{x_1x'_1}, \quad (3.1)$$

$$\sum_{x_1} U_{x_1x_2}^{(2)} U_{x_1x'_2}^{(2)*} = \delta_{x_2x'_2}. \quad (3.2)$$

Fig. 3 Entropy Venn diagram for the state (3.6). The presence of negative conditional entropies reveals that the quantum system, Q , is entangled with all three ancillae, $A_1A_2A_3$. In this figure, we use the notation $S_3 = S(A_3)$, which is the marginal entropy of the last ancilla A_3 in the measurement sequence. To generalize this diagram from three to n consecutive measurements of a prepared quantum system, S_3 is replaced by S_n , the entropy of the last ancilla A_n in the chain

After entangling Q and A_2 with an operator analogous to (2.2), the wavefunction (2.3) evolves to

$$|QA_1A_2\rangle = \sum_{x_1x_2} \alpha_{x_1}^{(1)} U_{x_1x_2}^{(2)} |\tilde{x}_2 x_1 x_2\rangle, \quad (3.3)$$

where the eigenstates of the second ancilla, A_2 , are $|x_2\rangle$.

Tracing out Q , the quantum ancillae are correlated according to the joint density matrix,

$$\rho(A_1A_2) = \sum_{x_1x'_1x_2} \alpha_{x_1}^{(1)} \alpha_{x'_1}^{(1)*} U_{x_1x_2}^{(2)} U_{x'_1x_2}^{(2)*} |x_1x_2\rangle\langle x'_1x_2|, \quad (3.4)$$

while A_1 and A_2 together are entangled with the quantum system. The marginal ancilla density matrices, obtained from (3.4), are

$$\rho(A_i) = \sum_{x_i} q_{x_i}^{(i)} |x_i\rangle\langle x_i|, \quad i = 1, 2 \quad (3.5)$$

where $q_{x_1}^{(1)} = |\alpha_{x_1}^{(1)}|^2$ is the probability distribution of ancilla A_1 , while the probability distribution of A_2 is the incoherent sum $q_{x_2}^{(2)} = \sum_{x_1} |\alpha_{x_1}^{(1)}|^2 |U_{x_1x_2}^{(2)}|^2$. We can compare this expression to the coherent probability distribution $\sum_{x_1} |\alpha_{x_1}^{(1)} U_{x_1x_2}^{(2)}|^2$ for A_2 , had the first measurement with A_1 never occurred. The marginal entropy of both A_1 and A_2 is the Shannon entropy $S(A_i) = H[q^{(i)}]$ of the probability distribution $q_{x_i}^{(i)}$.

A third measurement of Q with an ancilla A_3 yields

$$|QA_1A_2A_3\rangle = \sum_{x_1x_2x_3} \alpha_{x_1}^{(1)} U_{x_1x_2}^{(2)} U_{x_2x_3}^{(3)} |\tilde{x}_3 x_1 x_2 x_3\rangle, \quad (3.6)$$

where $U_{x_2x_3}^{(3)} = \langle \tilde{x}_3 | \tilde{x}_2 \rangle$, and $|x_3\rangle$ are the basis states of ancilla A_3 . The quantum system is entangled with all three ancillae in (3.6), as illustrated by the negative conditional entropies in Fig. 3. The degree of entanglement is controlled by the marginal entropy $S(A_3) = H[q^{(3)}]$ of ancilla A_3 , with the probability distribution $q_{x_3}^{(3)} = \sum_{x_1x_2} |\alpha_{x_1}^{(1)}|^2 |U_{x_1x_2}^{(2)}|^2 |U_{x_2x_3}^{(3)}|^2$. This procedure can be repeated for an arbitrary

number of consecutive measurements and can be used to succinctly describe the quantum Zeno and anti-Zeno effects (see Sect. 6.2).

3.2 Consecutive Measurements of an Unprepared Quantum State

Sequential measurements of an unprepared quantum system yield entropy distributions between the quantum system and ancillae that are different from those created by measurements of prepared quantum systems described in Sect. 3.1. In this section, we consider a sequence of measurements of an unprepared quantum system that is initially entangled with a reference system as in (2.9). Adding to the calculations in Sect. 2.2, we measure Q again in a rotated basis $U_{x_1x_2}^{(2)} = \langle \tilde{x}_2 | \tilde{x}_1 \rangle$, by entangling it with an ancilla A_2 . Then, with $|x_2\rangle$ the basis states of ancilla A_2 , the wavefunction (2.11) becomes

$$|QRA_1A_2\rangle = \frac{1}{\sqrt{d}} \sum_{x_1x_2} U_{x_1x_2}^{(2)} |\tilde{x}_2 x_1 x_1 x_2\rangle. \quad (3.7)$$

It is straightforward to show that the marginal ancilla density matrices are maximally mixed, $\rho(A_1) = \rho(A_2) = 1/d \mathbb{1}$, where $\mathbb{1}$ is the identity matrix of dimension d . It follows that A_1 and A_2 have maximum entropy $S(A_1) = S(A_2) = 1$.² The joint state of A_1 and A_2 is diagonal in the ancilla product basis,

$$\rho(A_1A_2) = \frac{1}{d} \sum_{x_1} |x_1\rangle\langle x_1| \otimes \sum_{x_2} |U_{x_1x_2}^{(2)}|^2 |x_2\rangle\langle x_2|, \quad (3.8)$$

in contrast to Eq. (3.4). Still, the quantum ancillae A_1 and A_2 are correlated. Equations (3.4) and (3.8) immediately imply that if the quantum system is measured repeatedly in the same basis ($U_{x_1x_2}^{(2)} = \delta_{x_1x_2}$) by independent devices, all of those devices will be perfectly correlated and will reflect the same outcome [8, 10].

Let us entangle a third ancilla, A_3 , with the quantum system such that $U_{x_2x_3}^{(3)} = \langle \tilde{x}_3 | \tilde{x}_2 \rangle$. We find that (3.7) evolves to

$$|QRA_1A_2A_3\rangle = \frac{1}{\sqrt{d}} \sum_{x_1x_2x_3} U_{x_1x_2}^{(2)} U_{x_2x_3}^{(3)} |\tilde{x}_3 x_1 x_1 x_2 x_3\rangle. \quad (3.9)$$

The entropic relationships between the variables Q , R , and $A_1A_2A_3$ are shown in Fig. 4. The vanishing ternary mutual entropy $S(Q : R : A_1A_2A_3) = 0$ indicates that the entropy $S(A_1A_3) = S_{13}$ that is shared by R and $A_1A_2A_3$ is in fact not shared with the quantum system. Tracing out the reference state, we find that the quantum system is still *entangled* with all three ancillae. However, this entanglement is now shared with the reference system, which yields a Venn diagram that is different from Fig. 3.

² Recall that all logarithms are taken to the base d , giving entropies the units *dits*. If $d = 2$, the units are *bits*.

Fig. 4 Entropy Venn diagrams for the pure state (3.9), where $S_{13} = S(A_1A_3)$ is the joint entropy of Eq. (3.12). **a** The entropy S_{13} that is shared by the reference state, R , and the chain of ancillae, $A_1A_2A_3$, is not shared with the quantum system Q , since the ternary mutual entropy must vanish: $S(Q : R : A_1A_2A_3) = 0$. **b** Tracing out the reference leaves Q entangled with all ancillae. To generalize these diagrams from three to n consecutive measurements of an unprepared quantum system, S_{13} is replaced by S_{1n} , the joint entropy of the first and last ancillae, A_1 and A_n , in the chain

Consecutive measurements provide a unique opportunity to extract information about the state of the quantum system from the correlations created between the ancillae, as we do not directly observe either the quantum system or the reference. Tracing out Q and R from the full density matrix associated with Eq. (3.9) yields the joint state of the three ancillae,

$$\begin{aligned} \rho(A_1A_2A_3) = & \frac{1}{d} \sum_{x_1} |x_1\rangle\langle x_1| \otimes \sum_{x_2x'_2} U_{x_1x_2}^{(2)} U_{x_1x'_2}^{(2)*} |x_2\rangle\langle x'_2| \\ & \otimes \sum_{x_3} U_{x_2x_3}^{(3)} U_{x'_2x_3}^{(3)*} |x_3\rangle\langle x_3|. \end{aligned} \quad (3.10)$$

Unlike the pairwise state $\rho(A_1A_2)$ in Eq. (3.8), the state of all three ancillae is *not* an incoherent mixture. Performing a third measurement has, in a sense, revived the coherence of the A_2 subsystem, and the set $A_1A_2A_3$ is now non-classical.

An apparent collapse has taken place after the second consecutive measurement in Eq. (3.8), as the corresponding density matrix has no off-diagonal terms. However, the third measurement seemingly *undoes* this projection, as can be seen from the appearance of off-diagonal terms in Eq. (3.10). This “reversal” is different from protocols that can “un-collapse” weak measurements [29, 35], because it is clear that the wavefunction (3.9) underlying the density matrix (3.10) was never projected in the first place. The presence of the cross terms in Eq. (3.10) has fundamental consequences for our understanding of the measurement process, and may open up avenues for developing new quantum protocols. In particular, the cross terms in Eq. (3.10) enable the implementation of disentangling protocols [22].

As mentioned in Sect. 2.3, the ancilla A_i may be composed of a large number of qudits. To account for a possibly macroscopic ancilla, we suppose that n qudits

$A_i^{(1)} \dots A_i^{(n)}$, which comprise the i th ancilla A_i , measure the quantum system in the same given basis. In this case, the joint density matrix (3.10) is extended to

$$\begin{aligned} \rho(A_1 A_2 A_3) = & \frac{1}{d} \sum_{x_1} |x_1 \dots x_1\rangle \langle x_1 \dots x_1| \otimes \sum_{x_2 x'_2} U_{x_1 x_2}^{(2)} U_{x_1 x'_2}^{(2)*} |x_2 \dots x_2\rangle \langle x'_2 \dots x'_2| \\ & \otimes \sum_{x_3} U_{x_2 x_3}^{(3)} U_{x'_2 x_3}^{(3)*} |x_3 \dots x_3\rangle \langle x_3 \dots x_3|. \end{aligned} \quad (3.11)$$

In principle, accounting for macroscopic ancillae does not destroy the coherence of the joint state (3.11), which is concentrated in the A_2 subsystem. The coherence is protected as long as no qudits in the intermediate ancilla A_2 are ‘lost’, implying a trace over their states, which removes all off-diagonal terms. In practical implementations, it may be effectively impossible to prevent decoherence when the number of qudits is sufficiently large. On the other hand, the pairwise density matrices $\rho(A_1 A_2)$, $\rho(A_2 A_3)$, and $\rho(A_1 A_3)$ are unaffected by a loss of qudits as they are already diagonal. In addition, it can be easily shown that the coherence in Eqs. (3.10) and (3.11) is fully destroyed if just the A_2 measurement is amplified by a detector D_2 (as we will see in Sect. 4.3). That is, amplification of the first and last ancillae has no effect on the coherence of (3.10) and (3.11).

From the joint ancilla density matrix (3.10), we now derive several properties of the chain of quantum ancillae and summarize them using an entropy Venn diagram between A_1 , A_2 , and A_3 . First, we construct all three pairwise ancilla density matrices and compute their entropies. Tracing out A_3 from the joint density matrix (3.10) recovers $\rho(A_1 A_2)$ in Eq. (3.8), as it should because the interaction between Q and A_3 does not affect the past interactions of Q with A_1 and A_2 . Tracing over A_2 in Eq. (3.10) gives

$$\rho(A_1 A_3) = \frac{1}{d} \sum_{x_1} |x_1\rangle \langle x_1| \otimes \sum_{x_2 x_3} |U_{x_1 x_2}^{(2)}|^2 |U_{x_2 x_3}^{(3)}|^2 |x_3\rangle \langle x_3|, \quad (3.12)$$

while tracing over A_1 yields

$$\rho(A_2 A_3) = \frac{1}{d} \sum_{x_2} |x_2\rangle \langle x_2| \otimes \sum_{x_3} |U_{x_2 x_3}^{(3)}|^2 |x_3\rangle \langle x_3|. \quad (3.13)$$

All three pairwise density matrices are diagonal in the ancilla product basis (see Theorem 2 in Sect. 3.3 for a general proof). We take “diagonal in the ancilla product basis” to be synonymous with “classical”. From Eqs. (3.8), (3.12), and (3.13), we can calculate the entropy of each pair of ancillae and of the joint state of all three ancillae from Eq. (3.10). The pairwise entropies are

$$S(A_1 A_2) = 1 - \frac{1}{d} \sum_{x_1 x_2} |U_{x_1 x_2}^{(2)}|^2 \log_d |U_{x_1 x_2}^{(2)}|^2, \quad (3.14)$$

Fig. 5 Entropy Venn diagram for three quantum ancillae that measured an unprepared quantum system. In this figure, we use the notation $S(A_i A_j) = S_{ij}$ for the pairwise entropy of any two ancillae A_i and A_j

$$S(A_2 A_3) = 1 - \frac{1}{d} \sum_{x_2 x_3} |U_{x_2 x_3}^{(3)}|^2 \log_d |U_{x_2 x_3}^{(3)}|^2, \quad (3.15)$$

$$S(A_1 A_3) = 1 - \frac{1}{d} \sum_{x_1 x_3} |\beta_{x_1 x_3}^{(13)}|^2 \log_d |\beta_{x_1 x_3}^{(13)}|^2. \quad (3.16)$$

where $|\beta_{x_1 x_3}^{(13)}|^2 = \sum_{x_2} |U_{x_1 x_2}^{(2)}|^2 |U_{x_2 x_3}^{(3)}|^2$. Furthermore, it is straightforward to show that $S(A_1 A_2 A_3)$, the entropy of $\rho(A_1 A_2 A_3)$ in Eq. (3.10), is equal to $S(A_1 A_3)$. This equality holds for any set of three consecutive measurements in an arbitrarily-long measurement chain as we will later prove in Theorem 2 of Sect. 3.3. With these joint entropies, we construct the entropy Venn diagram for the three ancillae that consecutively measured an unprepared quantum system, as shown in Fig. 5.

Let us apply the formalism presented thus far to the specific case of qubits (Hilbert space dimension $d = 2$). Measurements with ancilla A_2 at an angle θ_2 relative to the previous measurement with A_1 , and with ancilla A_3 at an angle θ_3 relative to A_2 , can each, without loss of generality, be implemented with a rotation matrix of the form³

$$U^{(i)} = \begin{pmatrix} \cos(\theta_i/2) & -\sin(\theta_i/2) \\ \sin(\theta_i/2) & \cos(\theta_i/2) \end{pmatrix}. \quad (3.17)$$

For measurements at orthogonal angles ($\theta_2 = \theta_3 = \pi/2$), for example, we have $|U_{x_1 x_2}^{(2)}|^2 = |U_{x_2 x_3}^{(3)}|^2 = 1/2$, and we expect each ancilla to be maximally entropic: $S(A_1) = S(A_2) = S(A_3) = 1$ bit. The joint entropy of each pair of ancillae is two bits, as can be read off of Eqs. (3.14–3.16). Because of the non-diagonal nature of $\rho(A_1 A_2 A_3)$ in Eq. (3.10), the joint density matrix of the three ancillae (using σ_z , the third Pauli matrix, and $\mathbb{1}$, the 2×2 identity matrix),

³ An arbitrary rotation by angle θ about the $\hat{n}$ axis is implemented with the operator $U(\theta) = e^{-i\theta \hat{n} \cdot \boldsymbol{\sigma}/2}$, where $\boldsymbol{\sigma}$ is the vector of Pauli matrices.

Fig. 6 Entropy Venn diagram for three qubit ancillae that measured an unprepared quantum system. Ancilla A_2 measured Q at an angle $\theta_2 = \pi/2$ relative to the basis of A_1 , and A_3 measured Q at $\theta_3 = \pi/2$ relative to the basis of A_2

$$\rho(A_1 A_2 A_3) = \frac{1}{8} \begin{pmatrix} 1 & -\sigma_z & 0 & 0 \\ -\sigma_z & 1 & 0 & 0 \\ 0 & 0 & 1 & \sigma_z \\ 0 & 0 & \sigma_z & 1 \end{pmatrix}, \quad (3.18)$$

has entropy $S(A_1 A_2 A_3) = 2$ bits, as can be checked by finding the eigenvalues of (3.18). Figure 6 summarizes the entropic relationships for un-amplified consecutive qubit measurements at $\theta_2 = \theta_3 = \pi/2$.

It is instructive to note that the Venn diagram in Fig. 6 is the same as the one obtained for a one-time binary cryptographic pad (the Vernam cipher [56]) where two classical binary variables (the source and the key) are combined to a third (the message) via a controlled-NOT operation [54] (the density matrices underlying the classical and quantum Venn diagrams are, however, very different). The Venn diagram implies that the state of any one of the three quantum ancillae can be predicted from knowing the *joint* state of the two others. However, the prediction of A_3 , for example, cannot be achieved using expectation values from A_2 's and A_1 's states separately, as the diagonal of Eqs. (3.10) and (3.18) corresponds to a uniform probability distribution. Thus, quantum coherence can be seen as encrypting classical information about past states.

3.3 Coherence of the Chain of Un-amplified Measurements

So far we have seen that the joint ancilla density matrices describing un-amplified measurements generally contain a non-vanishing degree of coherence. This suggests that coherence is not lost in the measurement sequence, but is actually contained in specific ancilla subsystems. In this section, we extend our unitary description of consecutive un-amplified measurements of a quantum system to an arbitrarily-long chain of ancillae, and derive several properties of the measurement chain.

Many of the joint ancilla density matrices that we have encountered in describing consecutive quantum measurements are so-called “classical-quantum states”. Such states have a block-diagonal structure of the form $\rho = \sum_i p_i \rho_i \otimes |i\rangle\langle i|$, where the density matrix ρ_i appears with probability p_i . However, the ancilla states that we derive here have the additional property that the density matrices ρ_i are always pure quantum superpositions.

For measurements of a prepared quantum system, classical-quantum states occur in the joint density matrices of two or more consecutive ancillae. For instance, recall the state $\rho(A_1 A_2)$ from Eq. (3.4) that resulted from two measurements of a prepared

quantum system. We can diagonalize this state with the set of non-orthogonal states $\alpha_{x_2}^{(2)} |\psi_{x_2}\rangle = \sum_{x_1} \alpha_{x_1}^{(1)} U_{x_1 x_2}^{(2)} |x_1\rangle$ for subsystem A_1 , so that (3.4) appears as

$$\rho(A_1 A_2) = \sum_{x_2} q_{x_2}^{(2)} |\psi_{x_2}\rangle \langle \psi_{x_2}| \otimes |x_2\rangle \langle x_2|, \quad (3.19)$$

where the normalization is equal to the probability distribution for the second ancilla A_2 ,

$$q_{x_2}^{(2)} = |\alpha_{x_2}^{(2)}|^2 = \sum_{x_1} |\alpha_{x_1}^{(1)}|^2 |U_{x_1 x_2}^{(2)}|^2. \quad (3.20)$$

On the other hand, classical-quantum states occur for measurements of unprepared quantum systems when there are at least *three* consecutive measurements, as the first measurement in that sequence can be viewed as the state preparation. For example, Eq. (3.10) can be diagonalized with the set of non-orthogonal states $\beta_{x_1 x_3}^{(13)} |\phi_{x_1 x_3}\rangle = \sum_{x_2} U_{x_1 x_2}^{(2)} U_{x_2 x_3}^{(3)} |x_2\rangle$ for the A_2 subsystem, so that

$$\rho(A_1 A_2 A_3) = \frac{1}{d} \sum_{x_1 x_3} p_{x_1 x_3}^{(13)} |x_1 x_3\rangle \langle x_1 x_3| \otimes |\phi_{x_1 x_3}\rangle \langle \phi_{x_1 x_3}|, \quad (3.21)$$

where the normalization is

$$p_{x_1 x_3}^{(13)} = |\beta_{x_1 x_3}^{(13)}|^2 = \sum_{x_2} |U_{x_1 x_2}^{(2)}|^2 |U_{x_2 x_3}^{(3)}|^2. \quad (3.22)$$

Evidently, from (3.19) and (3.21), each density matrix ρ_i in the general state $\rho = \sum_i p_i \rho_i \otimes |i\rangle \langle i|$ corresponds to a pure state in our ancilla density matrices. This leads to the interesting observation that the entropy of a chain of ancillae is contained in either just the last device, or in both the first and last devices together. In the first example above for $\rho(A_1 A_2)$, it is straightforward to show using Eq. (3.19) that $S(A_1 A_2) = S(A_2)$. That is, the entropy of the sequence $A_1 A_2$ is found at the end of the chain, A_2 . From the definition of conditional entropy [9], it follows that the entropy of A_1 vanishes (it is in the pure state $|\psi_{x_2}\rangle$), given the state of A_2 :

$$S(A_1 | A_2) = S(A_1 A_2) - S(A_2) = 0. \quad (3.23)$$

In the second example above for $\rho(A_1 A_2 A_3)$, we find from Eq. (3.21) that $S(A_1 A_3) = S(A_1 A_2 A_3)$. In other words, the entropy of the chain resides in the boundary, A_1 and A_3 . It follows that, given the joint state of A_1 and A_3 , A_2 's state has zero entropy (see the grey region in Fig. 5) and is fully determined (it is in the pure state $|\phi_{x_1 x_3}\rangle$):

$$S(A_2 | A_1 A_3) = S(A_1 A_2 A_3) - S(A_1 A_3) = 0. \quad (3.24)$$

In the following Theorems 1 and 2, we extend these results to an arbitrarily-long chain of quantum ancillae. These findings are important as they show that un-amplified measurement chains retain a finite amount of coherence. Specifically, for measurements on prepared quantum states, the coherence is contained in all ancillae up to

the last, while for unprepared quantum states coherence is maintained in all ancillae except for the boundary.

To begin, we define (ancilla) random variables A_i that take on states x_i with probabilities $q_{x_i}^{(i)}$. Each ancilla has d orthogonal states and the set of outcomes for the i th ancilla is labeled by the index x_i , where $x_i = 0, \dots, d - 1$.

Theorem 1 *The density matrix describing $j + 1$ ancillae that consecutively measured a prepared quantum system is a classical-quantum state such that its joint entropy is contained only in the last device in the measurement chain. That is,*

$$S(A_1 \dots A_{j+1}) = S(A_{j+1}). \quad (3.25)$$

Proof Generalizing the result (3.6), the wavefunction $|\Psi\rangle = |QA_1 \dots A_{j+1}\rangle$ for $j + 1$ consecutive measurements of a prepared quantum state is

$$|\Psi\rangle = \sum_{x_1 \dots x_{j+1}} \alpha_{x_1}^{(1)} U_{x_1 x_2}^{(2)} \dots U_{x_j x_{j+1}}^{(j+1)} |\tilde{x}_{j+1} x_1 x_2 \dots x_j x_{j+1}\rangle. \quad (3.26)$$

The first ket $|\tilde{x}_{j+1}\rangle$ in the joint state on the right hand side of (3.26) describes the quantum system, which is written in the basis corresponding to the last observable. Each A_i measures the quantum system in a basis that is rotated relative to the basis of the previous A_{i-1} , such that $U_{x_{i-1} x_i}^{(i)} = \langle \tilde{x}_i | \tilde{x}_{i-1} \rangle$. The unitarity of $U^{(i)}$ requires that

$$\begin{aligned} \sum_{x_{i-1}} U_{x_{i-1} x_i}^{(i)} U_{x_{i-1} x'_i}^{(i)*} &= \delta_{x_i x'_i}, \\ \sum_{x_i} U_{x_{i-1} x_i}^{(i)} U_{x'_{i-1} x_i}^{(i)*} &= \delta_{x_{i-1} x'_{i-1}}. \end{aligned} \quad (3.27)$$

Recasting expression (3.26) in terms of the following set of non-orthogonal states,

$$\alpha_{x_{j+1}}^{(j+1)} |\psi_{x_{j+1}}\rangle = \sum_{x_1 \dots x_j} \alpha_{x_1}^{(1)} U_{x_1 x_2}^{(2)} \dots U_{x_j x_{j+1}}^{(j+1)} |x_1 \dots x_j\rangle, \quad (3.28)$$

yields

$$|\Psi\rangle = \sum_{x_{j+1}} \alpha_{x_{j+1}}^{(j+1)} |\tilde{x}_{j+1} \psi_{x_{j+1}} x_{j+1}\rangle. \quad (3.29)$$

This is not a true tripartite Schmidt decomposition [49] as the states $|\psi_{x_{j+1}}\rangle$ are not orthogonal: the partial inner product $\langle \psi_{x_{j+1}} | \Psi \rangle$ does not give a state with a Schmidt number of one. Although the states $|\psi_{x_{j+1}}\rangle$ are not orthogonal, they are normalized according to

$$q_{x_{j+1}}^{(j+1)} = |\alpha_{x_{j+1}}^{(j+1)}|^2 = \sum_{x_1 \dots x_j} |\alpha_{x_1}^{(1)}|^2 |U_{x_1 x_2}^{(2)}|^2 \dots |U_{x_j x_{j+1}}^{(j+1)}|^2, \quad (3.30)$$

which is the probability distribution of ancilla A_{j+1} .

Fig. 7 Entropy Venn diagram for the un-amplified measurement sequence with ancillae $A_1, A_2, \dots, A_j, A_{j+1}$. According to (3.31), the joint entropy of the first j ancillae vanishes when given A_{j+1} , since the entropy resides only at the end of the chain. In this figure, we use the notation $S_j = S(A_j)$ for the marginal entropy of the j th ancilla

Tracing out the quantum system from the density matrix $|\Psi\rangle\langle\Psi|$ formed from (3.29), the state of all $j + 1$ ancillae can be written as

$$\rho(A_1 \dots A_{j+1}) = \sum_{x_{j+1}} q_{x_{j+1}}^{(j+1)} |\psi_{x_{j+1}}\rangle\langle\psi_{x_{j+1}}| \otimes |x_{j+1}\rangle\langle x_{j+1}|. \quad (3.31)$$

This state is non-diagonal in the ancilla product basis $|x_1 \dots x_{j+1}\rangle$, but is diagonalized by (3.28). The density matrix (3.31) is a classical-quantum state where the first j ancillae are in the pure state $|\psi_{x_{j+1}}\rangle$.

The appearance of classical-quantum states in the sequence of measurements leads to the interesting (and perhaps surprising) observation that the joint entropy of all ancillae in Eq. (3.31) resides only in the last device in the measurement chain. Since the joint state $|\psi_{x_{j+1}}\rangle \otimes |x_{j+1}\rangle$ is orthonormal, it is easy to see that the entropy of (3.31) is equal to the Shannon entropy of the probability distribution $q_{x_{j+1}}^{(j+1)}$. This is equivalent to the entropy of the last ancilla, so that

$$S(A_1 \dots A_{j+1}) = S(A_{j+1}). \quad (3.32)$$

□

Note that this implies that there is an upper bound to the joint entropy: $\max[S(A_1 \dots A_{j+1})] = \max[S_{j+1}] = 1$.

From this property it immediately follows that the entropy of the first j ancillae, conditional on the state of the last ancilla, vanishes,

$$S(A_1 \dots A_j | A_{j+1}) = S(A_1 \dots A_{j+1}) - S(A_{j+1}) = 0. \quad (3.33)$$

Therefore, if the state of the end of the measurement chain is known, then all preceding ancillae exist in a pure quantum superposition: The state of $A_1 \dots A_j$ is fully determined (a zero entropy state), given A_{j+1} . This implies that the entropy of all ancillae in an arbitrarily-long sequence of measurements resides only at the end of the chain.⁴ The entropy Venn diagram for these two subsystems is shown in Fig. 7.

⁴ It is worth noting that this is the essence of Hans Bethe's observation described in the Acknowledgements of [8], which gave rise to the latter reference, and ultimately to this work.

Theorem 2 For $j + 1$ consecutive measurements of an unprepared quantum system where the reference is traced out, the density matrix for three or more consecutive ancillae is a classical-quantum state such that its joint entropy is contained only in the first and last device of the measurement chain. That is,

$$S(A_{i-1}A_i \dots A_j A_{j+1}) = S(A_{i-1}A_{j+1}). \quad (3.34)$$

Proof Generalizing the result (3.9), the wavefunction $|\Psi'\rangle = |QRA_1 \dots A_{j+1}\rangle$ of $j + 1$ ancillae that consecutively measured an unprepared quantum state is

$$|\Psi'\rangle = \frac{1}{\sqrt{d}} \sum_{x_1 \dots x_{j+1}} U_{x_1 x_2}^{(2)} \dots U_{x_j x_{j+1}}^{(j+1)} |\tilde{x}_{j+1} x_1 x_2 \dots x_{j+1}\rangle. \quad (3.35)$$

Of the full set of consecutive measurements, consider the subset $A_{i-1}, A_i, \dots, A_j, A_{j+1}$, where $1 < i < j$. Tracing out Q , the reference, and all other ancilla states from the full density matrix $|\Psi'\rangle\langle\Psi'|$, and using the unitarity of each $U^{(i)}$ as stated in Eq. (3.27), the density matrix for this subset can be written as

$$\begin{aligned} \rho(A_{i-1} \dots A_{j+1}) &= \frac{1}{d} \sum_{\substack{x_{i-1} \\ x_{j+1}}} p_{x_{i-1} x_{j+1}}^{(i-1, j+1)} |x_{i-1}\rangle\langle x_{i-1}| \\ &\quad \otimes |\phi_{x_{i-1} x_{j+1}}\rangle\langle\phi_{x_{i-1} x_{j+1}}| \otimes |x_{j+1}\rangle\langle x_{j+1}|. \end{aligned} \quad (3.36)$$

This is a classical-quantum state with the intermediate ancillae $A_i, \dots, A_j$ in the pure state $|\phi_{x_{i-1} x_{j+1}}\rangle$. In the ancilla product basis $|x_{i-1} x_i \dots x_j x_{j+1}\rangle$, this matrix is block-diagonal due to the non-diagonality of the subsystem $A_i, \dots, A_j$. However, it is diagonalized by the non-orthogonal states

$$\beta_{x_{i-1} x_{j+1}}^{(i-1, j+1)} |\phi_{x_{i-1} x_{j+1}}\rangle = \sum_{x_i \dots x_j} U_{x_{i-1} x_i}^{(i)} \dots U_{x_j x_{j+1}}^{(j+1)} |x_i \dots x_j\rangle, \quad (3.37)$$

which are normalized according to

$$p_{x_{i-1} x_{j+1}}^{(i-1, j+1)} = |\beta_{x_{i-1} x_{j+1}}^{(i-1, j+1)}|^2 = \sum_{x_i \dots x_j} |U_{x_{i-1} x_i}^{(i)}|^2 \dots |U_{x_j x_{j+1}}^{(j+1)}|^2. \quad (3.38)$$

These normalization coefficients obey the sum rule

$$\sum_{x_{i-1}} p_{x_{i-1} x_{j+1}}^{(i-1, j+1)} = \sum_{x_{j+1}} p_{x_{i-1} x_{j+1}}^{(i-1, j+1)} = 1. \quad (3.39)$$

The density matrix for any two ancillae is already diagonal in the ancilla product basis (it is classical). For example, the joint state of A_{i-1} and A_{j+1} is

Fig. 8 Entropy Venn diagram for an un-amplified measurement sequence with ancillae $A_{i-1}, A_i, \dots, A_j, A_{j+1}$. According to (3.36), the entropy of all intermediate ancillae, $A_i, \dots, A_j$, vanishes when given A_{i-1} and A_{j+1} , since the entropy resides at the boundary of the chain. In this figure, we use the notation $S_{ij} = S(A_i A_j)$ for the pairwise entropy of any two ancillae A_i and A_j

$$\rho(A_{i-1}A_{j+1}) = \frac{1}{d} \sum_{\substack{x_{i-1} \\ x_{j+1}}} p_{x_{i-1}x_{j+1}}^{(i-1,j+1)} |x_{i-1}x_{j+1}\rangle \langle x_{i-1}x_{j+1}|, \quad (3.40)$$

so that its entropy reduces to the Shannon entropy $H[p^{(i-1,j+1)}/d]$ of the distribution $p_{x_{i-1}x_{j+1}}^{(i-1,j+1)}/d$. However, the density matrix for three or more consecutive ancillae corresponds to a classical-quantum state (3.36). This state has non-zero coherence that is contained in the subsystem of the intermediate ancillae, which are in the (non-orthogonal) pure state $|\phi_{x_{i-1}x_{j+1}}\rangle$. Since the joint state $|x_{i-1}\rangle \otimes |\phi_{x_{i-1}x_{j+1}}\rangle \otimes |x_{j+1}\rangle$ is still orthonormal, it is straightforward to show that the entropy of (3.36) is equal to the (Shannon) entropy of (3.40), despite the fact that the underlying state (3.36) is non-classical:

$$S(A_{i-1}A_i \dots A_j A_{j+1}) = S(A_{i-1}A_{j+1}). \quad (3.41)$$

□

It follows directly that the entropy of the intermediate ancillae $A_i, \dots, A_j$ vanishes when given the joint state of the ancillae A_{i-1} and A_{j+1} ,

$$S(A_i \dots A_j | A_{i-1}A_{j+1}) = S(A_{i-1}A_i \dots A_j A_{j+1}) - S(A_{i-1}A_{j+1}) = 0. \quad (3.42)$$

Evidently, if the state of the *boundary* of the chain is known, then the intermediate ancillae exist in a pure quantum superposition. The joint state of $A_i, \dots, A_j$ is fully determined (a zero-entropy state), given the joint state of A_{i-1} that measured Q in the past, together with A_{j+1} that measured Q in the future. Thus, for measurements on unprepared quantum systems, the entropy of an arbitrarily-long ancilla chain is found only in its boundary. The entropy Venn diagram for the boundary and the bulk of the measurement chain is shown in Fig. 8.

That the entropy of a chain of measurements is determined entirely by the entropy of the chain's boundary may seem remarkable, but is reminiscent of the holographic principle [58, 59, 62]. Indeed, it is conceivable that an extension of the one-dimensional quantum chains we discussed here to tensor networks [18] could make this correspondence more precise [60]. We contrast this result with the previous Theorem 1 for measurements on prepared quantum systems, where

the entropy resided only at the end of the chain since the preparation was already known.

4 Markovian Quantum Measurements

The non-Markovian measurements we have been discussing up to this point are potentially fragile: while the pointers can consist of many subsystems (even a macroscopic number), the entanglement they potentially display with other quantum systems will be lost even if only a single qudit escapes our control (and therefore, mathematically speaking, must be traced over). In this section we discuss a second step within von Neumann’s second stage of quantum measurement, where we observe the latent (fragile) quantum ancilla using a secondary observer. While this quantum “observer of the observer” also potentially consists of many different subsystems, it is robust by definition, in the sense that tracing over any of the degrees of freedom making up the pointer variable does not affect the relative state of the pointer and the quantum system or other devices.

4.1 Amplifying Quantum Measurements

To amplify a measurement, we observe the first quantum observer (denoted by A_1) by measuring A_1 in the same basis with a detector D_1 . This additional interaction with the first ancilla in (2.3) leads to the tripartite entangled state

$$|QA_1D_1\rangle = \mathbb{1}_Q \otimes U_{A_1D_1} |QA_1\rangle |0\rangle = \sum_{x_1} \alpha_{x_1}^{(1)} |\tilde{x}_1 x_1 x_1\rangle. \quad (4.1)$$

Tracing over the quantum system, we find that detector D_1 is perfectly correlated with the quantum ancilla A_1 according to the density matrix

$$\rho(A_1D_1) = \sum_{x_1} q_{x_1}^{(1)} |x_1 x_1\rangle \langle x_1 x_1|, \quad (4.2)$$

where $q_{x_1}^{(1)} = |\alpha_{x_1}^{(1)}|^2$. This implies that the detector states consistently reflect the same measurement outcomes as the ancilla states. Together, A_1 and D_1 are still entangled with the quantum system. In Fig. 9 we show the entropy Venn diagrams for the entangled state (4.1) and the correlated state (4.2). Since the underlying state (4.1) is pure, the ternary mutual entropy vanishes, $S(Q : A_1 : D_1) = 0$. In other words, the correlations that are created between the devices [the $S(A_1 : D_1)$ dits of information that are gained in the measurement] are not shared with the quantum system. It is worth pausing to digest this result: two measurement devices agree on a measurement outcome that, however, has no power of inference about the quantum state.

The macroscopic device D_1 is composed of many qudits $D_1^{(1)}, \dots, D_1^{(n)}$ that all measure the quantum ancilla A_1 according to the sequence of entangling operations $U_{A_1D_1^{(n)}} \dots U_{A_1D_1^{(1)}}$ (see Fig. 10). We can thus expand Eq. (4.1) to

Fig. 9 Entropy Venn diagram for **a** the tripartite entangled state (4.1). **b** Tracing over the quantum system, A_1 and D_1 are perfectly correlated as in Eq. (4.2). The $S(A_1 : D_1) = S_1$ bits of information gained in the measurement are not shared with the quantum system since the mutual ternary entropy vanishes, $S(Q : A_1 : D_1) = 0$. The quantity $S_1 = H[q^{(1)}]$ is the marginal entropy of each of the three subsystems, Q , A_1 and D_1

Fig. 10 Observing the quantum observer A_1 with a detector D_1 . Dashed lines indicate the entanglement created by the measurement between the ancilla A_1 and each of the n qudits $D_1^{(1)}, \dots, D_1^{(n)}$ that comprise the detector D_1

$$|QA_1D_1\rangle = \sum_{x_1} \alpha_{x_1}^{(1)} |\tilde{x}_1\rangle |x_1\rangle |x_1\rangle_{D_1^{(1)}} \dots |x_1\rangle_{D_1^{(n)}}. \quad (4.3)$$

The measurement outcome is read out from the state of the joint system

$$\rho(D_1^{(1)} \dots D_1^{(n)}) = \sum_{x_1} q_{x_1}^{(1)} |x_1 \dots x_1\rangle \langle x_1 \dots x_1|, \quad (4.4)$$

where it is clear that the device D_1 is self-consistent and all of its components reflect the same measurement outcome. This state is robust in the sense that it is not necessary to “keep track” of all qudits in the detector D_1 to observe correlations. Thus, tracing over any of the states in the expression above returns an equivalently self-consistent state.

In the following two sections, we amplify a chain of consecutive measurements of a prepared and an unprepared quantum system. Unlike our previous results for unamplified measurements, we will find that the joint state of detectors is now always classical (diagonal in the ancilla product basis), leading to entropy distributions that are significantly different from those of the un-amplified ancillae.

4.2 Amplifying Consecutive Measurements of a Prepared Quantum State

We begin by first considering the amplification of consecutive measurements of a prepared quantum state. Introducing a second pair of devices A_2 and D_2 , Eq. (4.1) evolves to

$$|QA_1D_1A_2D_2\rangle = \sum_{x_1x_2} \alpha_{x_1}^{(1)} U_{x_1x_2}^{(2)} |\tilde{x}_2 x_1 x_1 x_2 x_2\rangle. \quad (4.5)$$

Again, we find detector D_2 to be perfectly correlated with the quantum ancilla A_2 . The joint state of the detectors D_1 and D_2 is the classical density matrix

$$\rho(D_1D_2) = \sum_{x_1x_2} |\alpha_{x_1}^{(1)}|^2 |U_{x_1x_2}^{(2)}|^2 |x_1x_2\rangle\langle x_1x_2|. \quad (4.6)$$

This state is diagonal in the ancilla product basis, unlike the state (3.4) before amplification. Thus, the effect of amplifying the ancillae is a removal of all off-diagonal elements in the joint density matrices.

From (4.6), we see that for repeated measurements in the same basis ($U_{x_1x_2}^{(2)} = \delta_{x_1x_2}$) the results are fully correlated: when D_2 measures in the same basis as D_1 , the joint density matrix (4.6) reduces to $\rho(D_1D_2) = \sum_{x_1} |\alpha_{x_1}^{(1)}|^2 |x_1x_1\rangle\langle x_1x_1|$ so that the entropy of D_2 given D_1 vanishes, $S(D_2|D_1) = S(D_1D_2) - S(D_1) = 0$. The conditional probability to record the outcome x_2 , given that the first measurement yielded x_1 , is simply $p(x_2|x_1) = \delta_{x_1x_2}$. In other words, both devices agree on the outcome, as expected. It appears as if the quantum system had indeed collapsed into an eigenstate of the first device D_1 since the second device D_2 correctly confirms the measurement outcome. This result is consistent with the Copenhagen view of the quantum state during the measurement sequence as $|Q\rangle \rightarrow |\tilde{x}_1\rangle \rightarrow |\tilde{x}_1\rangle$. However, we see that no collapse assumption is needed for a consistent description of the measurement process, and in fact, all amplitudes of the quantum system are preserved. That is, (4.5) continues to evolve as a pure state, while the quantum system itself appears to be pure only conditional on the state of the measurement device: it is only “conditionally pure”.

In addition, the probability distribution for the second measurement with the pair A_2D_2 is consistent with a collapse postulate as it is given by the incoherent sum $q_{x_2}^{(2)} = \sum_{x_1} |\alpha_{x_1}^{(1)}|^2 |U_{x_1x_2}^{(2)}|^2$, instead of the coherent expression $\sum_{x_1} |\alpha_{x_1}^{(1)} U_{x_1x_2}^{(2)}|^2$, which is the result if the first measurement with A_1D_1 had never occurred.

4.3 Amplifying Consecutive Measurements of an Unprepared Quantum State

In this section, we study consecutive measurements of an unprepared quantum state, which will yield an entropy Venn diagram for the detectors that differs significantly from Fig. 5 for the quantum ancillae. To begin, we follow the procedure introduced in Sect. 4.1, and amplify the state (3.9) of three consecutive measurements of an unprepared quantum state.

Fig. 12 Entropy Venn diagram for amplification with detectors D_1 , D_2 , and D_3 in (4.9) of three qubit ancillae that measured an unprepared quantum system. Ancilla A_2 measured Q at $\theta_2 = \pi/2$ relative to the basis of A_1 , while A_3 measured Q at $\theta_3 = \pi/2$ relative to A_2 . In this case, all three detectors are uncorrelated. Amplification of A_2 with D_2 alone is sufficient to destroy the coherence in (3.18).

measurements with $\theta_2 = \theta_3 = \pi/2$, the joint density matrix of all three detectors, which we show for comparison to the un-amplified state (3.18), is diagonal:

$$\rho(D_1 D_2 D_3) = \frac{1}{8} \begin{pmatrix} 1 & 0 & 0 & 0 \\ 0 & 1 & 0 & 0 \\ 0 & 0 & 1 & 0 \\ 0 & 0 & 0 & 1 \end{pmatrix}. \quad (4.9)$$

As with the un-amplified state (3.18), the pairwise entropies for the detectors are also 2 bits. However, the tripartite entropy has increased to $S(D_1 D_2 D_3) = 3$ bits from the 2 bits we found for $S(A_1 A_2 A_3)$. Compare the resulting entropy Venn diagram in Fig. 12 to the diagram in Fig. 6 obtained for un-amplified qubit measurements.

The difference between the un-amplified density matrix $\rho(A_1 A_2 A_3)$ in Eq. (3.10) and the amplified state $\rho(D_1 D_2 D_3)$ in Eq. (4.8) can be ascertained by revealing the off-diagonal terms via quantum state tomography (see, e.g., [67]), by measuring just a single moment [61] of the density matrix, such as $\text{Tr}[\rho(A_1 A_2 A_3)^2]$, or else by direct measurement of the wavefunction [42].

The results in the two preceding sections are compatible with the usual formalism for orthogonal measurements [26, 50], where the conditional probability $p(x_2|x_1)$ to observe outcome x_2 , given that the previous measurement yielded outcome x_1 , is given by

$$p(x_2|x_1) = |U_{x_1 x_2}^{(2)}|^2. \quad (4.10)$$

Indeed, our findings thus far are fully consistent with a picture in which a measurement collapses the quantum state (or alternatively, where a measurement recalibrates an observer’s “catalogue of expectations” [17, 20, 55]).

To see this, we write the joint density matrix $\rho(D_1 D_2)$, found by tracing (4.8) over D_3 , in the collapse picture. For a detector D_1 that records outcome x_1 with probability $1/d$ and a detector D_2 that measures the same quantum state (at an angle determined by the rotation matrix $U^{(2)}$), the resulting density matrix is

$$\tilde{\rho}(D_1 D_2) = \frac{1}{d} \sum_{x_1} |x_1\rangle\langle x_1| \otimes \rho_{D_2}^{x_1}, \quad (4.11)$$

where the state $\rho_{D_2}^{x_1}$ of D_2 is defined using the projection operators $P_{x_1} = |x_1\rangle\langle x_1|$ on the state of D_1 ,

$$\rho_{D_2}^{x_1} = \frac{\text{Tr}_{D_1} [P_{x_1} \rho(D_1 D_2) P_{x_1}^\dagger]}{\text{Tr}_{D_1 D_2} [P_{x_1} \rho(D_1 D_2) P_{x_1}^\dagger]} = \sum_{x_2} |U_{x_1 x_2}^{(2)}|^2 |x_2\rangle\langle x_2|. \quad (4.12)$$

In other words, the state $\rho(D_1 D_2)$ that was obtained in a unitary formalism is equivalent to the collapse version $\tilde{\rho}(D_1 D_2)$. However, despite these consistencies with the collapse picture, we emphasize that the actual measurements induce no irreversible collapse and that all amplitudes in the underlying pure-state wavefunction (4.7) are preserved and evolve unitarily throughout the measurement process.

4.4 Quantum Markov Chains

One of the key differences between the entropy Venn diagrams in Figs. 5 and 11 is the vanishing conditional mutual entropy [10] for amplified measurements, $S(D_1 : D_3 | D_2) = 0$. Before amplification, the equivalent quantity for the quantum ancillae is in general non-zero, $S(A_1 : A_3 | A_2) \geq 0$. Evidently, the intermediate measurement with D_2 has, from the perspective of D_2 (meaning, given the state of D_2) *erased all correlations* between the first detector D_1 and the last detector D_3 in the measurement sequence. The vanishing of the conditional mutual entropy is precisely the condition that is fulfilled by quantum Markov chains as we will outline below.

Using the results for unprepared quantum states (this holds equally for prepared quantum states), we demonstrate that the chain of detectors, D_1, D_2, D_3 , which consecutively measured a quantum system is Markovian, as defined in [24] (see also [13] and references therein). We prove later in this section in Theorem 3 that this result can be extended to any number of consecutive measurements, not just three. To show that $S(D_1 : D_3 | D_2)$ is indeed zero, we compute the joint entropy $S(D_1 D_2 D_3)$ of all three detectors. From Eq. (4.8), we find

$$\begin{aligned} S(D_1 D_2 D_3) = & 1 - \frac{1}{d} \sum_{x_1 x_2} |U_{x_1 x_2}^{(2)}|^2 \log_d |U_{x_1 x_2}^{(2)}|^2 \\ & - \frac{1}{d} \sum_{x_2 x_3} |U_{x_2 x_3}^{(3)}|^2 \log_d |U_{x_2 x_3}^{(3)}|^2, \end{aligned} \quad (4.13)$$

or, $S(D_1 D_2 D_3) = S(D_1) + S(D_2 | D_1) + S(D_3 | D_2)$. However, using the chain rule for entropies [10], the tripartite entropy can also be written generally in the form $S(D_1 D_2 D_3) = S(D_1) + S(D_2 | D_1) + S(D_3 | D_2 D_1)$. From these two expressions, we see immediately that

$$S(D_3 | D_2 D_1) = S(D_3 | D_2). \quad (4.14)$$

Thus, the entropy of the detector D_3 is not reduced by conditioning on more than the state of the previous detector D_2 . This is the Markov property for entropies [13, 24].

The Markov property further implies that detectors D_1 and D_3 are independent from the perspective of D_2 , since the conditional mutual entropy [10] vanishes (see the grey region in Fig. 11),

$$S(D_1 : D_3 | D_2) = S(D_3 | D_2) - S(D_3 | D_2 D_1) = 0. \quad (4.15)$$

This result is consistent with the notion that the measurement with D_2 collapsed the state of the wavefunction, erasing any (conditional) information that detector D_3 could have had about the prior measurement with D_1 . The conditional mutual entropy does not vanish for un-amplified measurements, $S(A_1 : A_3 | A_2) \geq 0$, reflecting the fundamentally non-Markovian nature of the chain of quantum ancillae. In other words, as long as the measurement chain remains un-amplified (for example, the A_2 subsystem in (3.10)), the intermediate measurement does not erase the correlations between A_1 and A_3 (compare the gray region in Fig. 11 to the same region in Fig. 5).

We now provide a formal proof of the statement that the chain of detectors that amplified the quantum ancillae is equivalent to a quantum Markov chain.

Theorem 3 *A set of consecutive quantum measurements is non-Markovian until it is amplified. Specifically, the sequence of devices $D_i, \dots, D_j$ with $i < j$, that measure (amplify) the quantum ancillae $A_i, \dots, A_j$ (which themselves measured a quantum system Q) forms a quantum Markov chain:*

$$S(D_j | D_{j-1} \dots D_i) = S(D_j | D_{j-1}). \quad (4.16)$$

Proof We first show that the Markov property of probabilities implies the Markov property for entropies (see, e.g., Refs. [13, 24]). If consecutive measurements on a quantum system can be modeled as a Markov process, the probability to observe outcome x_j in the j th detector, conditional on previous measurement outcomes, depends only on the last outcome x_{j-1} ,

$$p(x_j | x_{j-1} \dots x_i) = p(x_j | x_{j-1}). \quad (4.17)$$

Inserting Eq. (4.17) into the expression for the conditional entropy [9] gives

$$\begin{aligned} S(D_j | D_{j-1} \dots D_i) &= - \sum_{x_i \dots x_j} p(x_i \dots x_j) \log_d p(x_j | x_{j-1} \dots x_i) \\ &= - \sum_{x_i \dots x_j} p(x_i \dots x_j) \log_d p(x_j | x_{j-1}). \end{aligned} \quad (4.18)$$

A partial summation over the joint probability distribution gives

$$p(x_{j-1} x_j) = \sum_{x_i \dots x_{j-2}} p(x_i \dots x_j), \quad (4.19)$$

so that the entropic condition satisfied by a quantum Markov chain is

$$\begin{aligned} S(D_j|D_{j-1} \dots D_i) &= - \sum_{x_{j-1}x_j} p(x_{j-1}x_j) \log_d p(x_j|x_{j-1}) \\ &= S(D_j|D_{j-1}), \end{aligned} \quad (4.20)$$

We now show that the chain of amplified measurements satisfies the entropic Markov property (4.20). For n consecutive measurements, the state $|\Psi\rangle = |QA_1 \dots A_n\rangle$ of Q and all ancillae is given by

$$|\Psi\rangle = \sum_{x_1 \dots x_n} \alpha_{x_i}^{(i)} U_{x_1 x_2}^{(2)} \dots U_{x_{n-1} x_n}^{(n)} |\tilde{x}_n x_1 \dots x_n\rangle. \quad (4.21)$$

After amplifying this state, we find that the density matrix for the joint set of sequential detectors, $D_i, \dots, D_j$, with $i < j$, is diagonal, as expected:

$$\begin{aligned} \rho(D_i \dots D_j) &= \sum_{x_i} q_{x_i}^{(i)} |x_i\rangle\langle x_i| \\ &\otimes \sum_{x_{i+1}} |U_{x_i x_{i+1}}^{(i+1)}|^2 |x_{i+1}\rangle\langle x_{i+1}| \\ &\dots \otimes \sum_{x_j} |U_{x_{j-1} x_j}^{(j)}|^2 |x_j\rangle\langle x_j|. \end{aligned} \quad (4.22)$$

The probability distribution $q_{x_i}^{(i)}$ of the i th device can be obtained from (3.30). The entropy of (4.22) is

$$\begin{aligned} S(D_i \dots D_j) &= - \sum_{x_i \dots x_{j-1}} \left(q_{x_i}^{(i)} |U_{x_i x_{i+1}}^{(i+1)}|^2 \dots |U_{x_{j-2} x_{j-1}}^{(j-1)}|^2 \right) \\ &\times \log_d \left(q_{x_i}^{(i)} |U_{x_i x_{i+1}}^{(i+1)}|^2 \dots |U_{x_{j-2} x_{j-1}}^{(j-1)}|^2 \right) \\ &- \sum_{x_{j-1} x_j} q_{x_{j-1}}^{(j-1)} |U_{x_{j-1} x_j}^{(j)}|^2 \log_d |U_{x_{j-1} x_j}^{(j)}|^2, \end{aligned} \quad (4.23)$$

where $q_{x_{j-1}}^{(j-1)}$ is the probability distribution of D_{j-1} . The first term in Eq. (4.23) is just the joint entropy $S(D_i \dots D_{j-1})$, so that the entropy of the j th detector, conditional on the previous detectors, is

$$\begin{aligned} S(D_j|D_{j-1} \dots D_i) &= S(D_i \dots D_j) - S(D_i \dots D_{j-1}) \\ &= - \sum_{x_{j-1} x_j} q_{x_{j-1}}^{(j-1)} |U_{x_{j-1} x_j}^{(j)}|^2 \log_d |U_{x_{j-1} x_j}^{(j)}|^2. \end{aligned} \quad (4.24)$$

All that remains is to show that (4.24) is equal to $S(D_j|D_{j-1})$. A simple calculation using the density matrix for two amplified consecutive measurements with D_{j-1} and D_j ,

$$\rho(D_{j-1}D_j) = \sum_{x_{j-1}x_j} q_{x_{j-1}}^{(j-1)} |U_{x_{j-1}x_j}^{(j)}|^2 |x_{j-1}x_j\rangle\langle x_{j-1}x_j|, \quad (4.25)$$

yields the joint entropy,

$$\begin{aligned} S(D_{j-1}D_j) = & - \sum_{x_{j-1}} q_{x_{j-1}}^{(j-1)} \log_d q_{x_{j-1}}^{(j-1)} \\ & - \sum_{x_{j-1}x_j} q_{x_{j-1}}^{(j-1)} |U_{x_{j-1}x_j}^{(j)}|^2 \log_d |U_{x_{j-1}x_j}^{(j)}|^2. \end{aligned} \quad (4.26)$$

The first term in this expression is the entropy of D_{j-1} (all marginal density matrices and entropies are the same for amplified and un-amplified ancillae; this is proved formally later in Lemma 2 of Sect. 5.1),

$$S(D_{j-1}) = H[q^{(j-1)}] = - \sum_{x_{j-1}} q_{x_{j-1}}^{(j-1)} \log_d q_{x_{j-1}}^{(j-1)}. \quad (4.27)$$

The conditional entropy $S(D_j|D_{j-1})$ is thus

$$\begin{aligned} S(D_j|D_{j-1}) &= S(D_{j-1}D_j) - S(D_{j-1}) \\ &= - \sum_{x_{j-1}x_j} q_{x_{j-1}}^{(j-1)} |U_{x_{j-1}x_j}^{(j)}|^2 \log_d |U_{x_{j-1}x_j}^{(j)}|^2, \end{aligned} \quad (4.28)$$

which is the same as (4.24). $\square$

We emphasize that the result that amplified measurements are Markovian holds for measurements of unprepared as well as prepared quantum states.

Corollary 1 *The Markovian nature of amplified measurements implies that the detectors D_i and D_j share no entropy (are independent) from the perspective of the intermediate detectors, $D_{i+1}, \dots, D_{j-1}$, since the conditional mutual entropy vanishes:*

$$S(D_i : D_j | D_{i+1} \dots D_{j-1}) = 0. \quad (4.29)$$

Proof The conditional mutual entropy is defined [10] as a difference between two conditional entropies,

$$\begin{aligned} S(D_i : D_j | D_{i+1} \dots D_{j-1}) &= S(D_j | D_{j-1} \dots D_{i+1}) \\ &\quad - S(D_j | D_{j-1} \dots D_i). \end{aligned} \quad (4.30)$$

From Theorem 3, the two quantities on the right hand side of this expression are both equal to $S(D_j | D_{j-1})$. Therefore the conditional mutual entropy vanishes [24]. $\square$

For three detectors, the Markov property is

$$S(D_{i-1} : D_{i+1}|D_i) = S(D_{i+1}|D_i) - S(D_{i+1}|D_i D_{i-1}) = 0. \quad (4.31)$$

We see that from the strong subadditivity (SSA) of quantum entropy [38, 39],

$$S(D_{i+1}|D_i D_{i-1}) \leq S(D_{i+1}|D_i), \quad (4.32)$$

and amplified measurements satisfy SSA with equality.

The previous theorem established that the sequence of amplified measurements is a quantum Markov chain. Now we will demonstrate that, conversely, un-amplified measurements are non-Markovian. In the following calculation, we use the state (3.35) for measurements of unprepared quantum states for simplicity. We will find that the Markov property (4.20) is violated in this case, so that in general un-amplified measurements are non-Markovian.

First, consider the joint density matrix for the sequence of quantum ancillae $A_i, \dots, A_j$ (with $i < j$), similarly to (3.35). As in Eq. (3.36), we find

$$\rho(A_i \dots A_j) = \frac{1}{d} \sum_{x_i x_j} p_{x_i x_j}^{(ij)} |x_i\rangle\langle x_i| \otimes |\phi_{x_i x_j}\rangle\langle \phi_{x_i x_j}| \otimes |x_j\rangle\langle x_j|, \quad (4.33)$$

where the coefficients $p_{x_i x_j}^{(ij)} = |\beta_{x_i x_j}^{(ij)}|^2$ and the normalized (but non-orthogonal) states $|\phi_{x_i x_j}\rangle$ were defined in Eq. (3.37). The joint states $|x_i \phi_{x_i x_j} x_j\rangle$ are orthonormal, so the entropy of Eq. (4.33) is simply

$$S(A_i \dots A_j) = 1 - \frac{1}{d} \sum_{x_i x_j} p_{x_i x_j}^{(ij)} \log_d p_{x_i x_j}^{(ij)}. \quad (4.34)$$

The coefficients $p_{x_i x_j}^{(ij)}$ can be equivalently expressed in terms of $U^{(j)}$ as

$$p_{x_i x_j}^{(ij)} = |\beta_{x_i x_j}^{(ij)}|^2 = \sum_{x_{j-1}} p_{x_i x_{j-1}}^{(i,j-1)} |U_{x_{j-1} x_j}^{(j)}|^2. \quad (4.35)$$

Inserting this into (4.34) and using the log-sum inequality⁵ with $b_{x_{j-1}} = 1$ and $a_{x_{j-1}} = p_{x_i x_{j-1}}^{(i,j-1)} |U_{x_{j-1} x_j}^{(j)}|^2$, we find that the joint entropy is bounded from below by

$$\begin{aligned} S(A_i \dots A_j) &\geq -\frac{1}{d} \sum_{x_i x_{j-1}} p_{x_i x_{j-1}}^{(i,j-1)} \log_d p_{x_i x_{j-1}}^{(i,j-1)} \\ &\quad - \frac{1}{d} \sum_{x_{j-1} x_j} |U_{x_{j-1} x_j}^{(j)}|^2 \log_d |U_{x_{j-1} x_j}^{(j)}|^2. \end{aligned} \quad (4.36)$$

⁵ The log-sum inequality [11] states that for non-negative numbers $a_1, \dots, a_d$ and $b_1, \dots, b_d$,

$$\sum_{x_i=1}^d a_{x_i} \log \frac{a_{x_i}}{b_{x_i}} \geq \left(\sum_{x_i=1}^d a_{x_i} \right) \log \frac{\sum_{x_i=1}^d a_{x_i}}{\sum_{x_i=1}^d b_{x_i}},$$

with equality if and only if $a_{x_i}/b_{x_i} = \text{const.}$

The first term on the right hand side of Eq. (4.36) is simply $S(A_i \dots A_{j-1}) - 1$, while the second term is $S(A_{j-1}A_j) - 1$. Given that $S(A_{j-1}) = 1$, it is straightforward to show that Eq. (4.36) can be rewritten as a difference between two conditional entropies,

$$S(A_j|A_{j-1}) - S(A_j|A_{j-1} \dots A_i) \leq 1, \quad (4.37)$$

with equality only when $p_{x_i x_{j-1}}^{(i,j-1)} |U_{x_{j-1} x_j}^{(j)}|^2$ is a constant. This occurs when $|U_{x_{j-1} x_j}^{(j)}|^2 = 1/d$ and $|U_{x_{\ell-1} x_\ell}^{(\ell)}|^2 = 1/d$ for one or more of the $\ell = i+1, \dots, j-1$ matrices. This shows that conditioning on more than just the state of the last ancilla A_{j-1} will reduce the conditional entropy of ancilla A_j (by at most 1). Since Eq. (4.37) is not equal to zero in general, we conclude that the sequence of un-amplified measurements is non-Markovian.

5 Effects of Amplifying Quantum Measurements

In the previous Sects. 3 and 4, we focused on consecutive measurements of a quantum system and discussed the concepts of non-Markovian (un-amplified) and Markovian (amplifiable) sequences, respectively. It is reasonable to ask whether there are entropic relationships between those two kinds of measurements. Introducing a second step to von Neumann's second stage serves precisely to establish such relationships. In this section, we establish the following three properties: Markovian detectors carry less information about the quantum system than non-Markovian devices; the shared entropy between consecutive non-Markovian devices is larger than the respective quantity for amplified measurements; the last Markovian detector in a quantum chain is inherently more random than its non-Markovian counterpart, given the combined results of all previous measurements.

5.1 Information About the Quantum System

We first calculate how much information about the quantum system Q is encoded in the last device in a chain of consecutive measurements of Q . To do this, we prove two Lemmas that state that the marginal entropy of the quantum system is always equal to the entropy of the last ancilla in the chain of measurements, and that the marginal entropy of a quantum ancilla is unaffected by amplification.

Lemma 1 *The entropy of the quantum system Q is equal to the entropy of the last ancilla, A_n , in the chain of measurements:*

$$S(Q) = S(A_n). \quad (5.1)$$

Proof Consider a series of consecutive measurements on a quantum system Q , with n ancillae. Following those measurements, in general the joint state of the quantum

system and all ancillae $|\Psi\rangle = |QA_1 \dots A_n\rangle$ is given by the pure state [see also Eq. (3.26)]

$$|\Psi\rangle = \sum_{x_1 \dots x_n} \alpha_{x_1}^{(1)} U_{x_1 x_2}^{(2)} \dots U_{x_{n-1} x_n}^{(n)} |\tilde{x}_n x_1 \dots x_n\rangle. \quad (5.2)$$

The density matrix for the quantum system is found by tracing out all ancilla states from the full density matrix associated with (5.2),

$$\rho(Q) = \text{Tr}_{A_1 \dots A_n} (|\Psi\rangle\langle\Psi|) = \sum_{x_n} q_{x_n}^{(n)} |\tilde{x}_n\rangle\langle\tilde{x}_n|, \quad (5.3)$$

where $q_{x_n}^{(n)}$ is the probability distribution for the last ancilla A_n that can be obtained generally from Eq. (3.30). Clearly, (5.3) is equivalent to the density matrix for the last ancilla, and so the corresponding entropies are the same: $S(Q) = S(A_n) = H[q^{(n)}]$. An alternative proof is to note that a Schmidt decomposition of the pure state $|\Psi\rangle\langle\Psi|$ implies that $S(Q) = S(A_1 \dots A_n)$. And, by Theorem 6 (see Sect. 5.2), $S(A_n) = S(A_1 \dots A_n)$, so that $S(Q) = S(A_n)$. $\square$

Lemma 2 *The entropy of a quantum ancilla A_i is unchanged if it is measured by an amplifying detector D_i , so that for all i in the chain of measurements*

$$S(A_i) = S(D_i). \quad (5.4)$$

Proof Amplifying the i th ancilla A_i in (5.2) with a detector D_i yields the joint density matrix for A_i and D_i

$$\rho(A_i D_i) = \sum_{x_i} q_{x_i}^{(i)} |x_i x_i\rangle\langle x_i x_i|, \quad (5.5)$$

where $q_{x_i}^{(i)}$ is the probability distribution for A_i , as defined in (3.30). The two subsystems are perfectly correlated so that the density matrix and marginal entropy of A_i is equivalent to D_i : $S(D_i) = S(A_i) = H[q^{(i)}]$. $\square$

In the remaining sections, we will use the shortened notation $S(A_i) = S(D_i) = S_i$ for the marginal entropies. Using Lemmas 1 and 2, we are now ready to prove the first theorem regarding information about the quantum system.

Theorem 4 *The information that the last device in a series of measurements has about the quantum system is reduced when the measurements are amplified, that is*

$$S(Q : D_n) \leq S(Q : A_n) \quad (5.6)$$

for n consecutive measurements of a prepared quantum state Q .

Proof We start with the state (5.2) for an un-amplified chain of consecutive measurements of a prepared quantum state Q , with n ancillae. Tracing out all previous

ancilla states from (5.2), the joint density matrix for the quantum system and the last ancilla is

$$\rho(QA_n) = \sum_{x_{n-1}x_nx'_n} q_{x_{n-1}}^{(n-1)} U_{x_{n-1}x_n}^{(n)} U_{x_{n-1}x'_n}^{(n)*} |\tilde{x}_n x_n\rangle \langle \tilde{x}'_n x'_n|, \quad (5.7)$$

where $q_{x_{n-1}}^{(n-1)}$ is A_{n-1} 's probability distribution. If we amplify the measurement chain (or, equivalently, just the last measurement) the state (5.7) becomes diagonal:

$$\rho(QD_n) = \sum_{x_{n-1}x_n} q_{x_{n-1}}^{(n-1)} |U_{x_{n-1}x_n}^{(n)}|^2 |\tilde{x}_n x_n\rangle \langle \tilde{x}_n x_n|. \quad (5.8)$$

Note that the amplification is equivalent to a completely dephasing channel [4, 28, 40] since we can write

$$\rho(QD_n) = \sum_{x_n} P_{x_n} \rho(QA_n) P_{x_n}, \quad (5.9)$$

where $P_{x_n} = |x_n\rangle \langle x_n|$ are projectors on the state of A_n . In other words, $\rho(QD_n)$ is formed from the diagonal elements of $\rho(QA_n)$. To show that the amplified mutual entropy is reduced as in Eq. (5.6), it is sufficient to show that the joint entropy is increased. The mutual entropy for two subsystems is defined [10] as $S(Q : A_n) = S(Q) + S(A_n) - S(QA_n)$ and similarly for $S(Q : D_n)$. Since, by Lemma 2, the marginal entropies are unchanged by the amplification, $S(A_n) = S(D_n)$, we have

$$S(Q : D_n) = S(Q : A_n) + S(QA_n) - S(QD_n). \quad (5.10)$$

Therefore, we just need to show that $S(QD_n) \geq S(QA_n)$, which is easiest by considering the relative entropy of coherence [3, 68]. This quantity, $C_{\text{rel.ent.}}(\rho) = S(\rho_{\text{diag}}) - S(\rho)$, is the difference between the entropies of a density matrix ρ and a matrix ρ_{diag} that is formed from the diagonal elements of ρ . It is derived by minimizing the relative entropy $S(\rho \parallel \delta) = \text{Tr}(\rho \log \rho - \rho \log \delta)$ over the set of incoherent matrices δ . By Klein's inequality, the relative entropy is non-negative so that $S(\rho_{\text{diag}}) \geq S(\rho)$, with equality if and only if ρ is an incoherent matrix. In our case, ρ and ρ_{diag} are given by $\rho(Q : A_n)$ and $\rho(Q : D_n)$, respectively. Therefore, it follows that $S(QD_n) \geq S(QA_n)$ and

$$S(Q : D_n) \leq S(Q : A_n), \quad (5.11)$$

with equality if and only if $\rho(QA_n)$ is already diagonal in the ancilla product basis. $\square$

To directly compute the mutual entropies in Theorem 4, we first diagonalize the density matrix (5.7) with the orthonormal states $|\Phi_{x_{n-1}}\rangle = \sum_{x_n} U_{x_{n-1}x_n}^{(n)} |\tilde{x}_n x_n\rangle$, so that

$$\rho(QA_n) = \sum_{x_{n-1}} q_{x_{n-1}}^{(n-1)} |\Phi_{x_{n-1}}\rangle \langle \Phi_{x_{n-1}}|. \quad (5.12)$$

Fig. 13 The entropy Venn diagrams for **a** the quantum system and the un-amplified ancilla according to Eq. (5.7), and **b** the quantum system and the amplifying detector according to Eq. (5.14). The information that the last device has about the quantum system is reduced when the measurement is amplified. That is, $S(Q : D_n) \leq S(Q : A_n)$

The joint entropy of this state is simply the marginal entropy of A_{n-1} [$S(QA_n) = S(A_{n-1}) = S_{n-1}$], which can also be derived using the Schmidt decomposition and the results of Theorem 6 (see Sect. 5.2). Thus, using Lemma 1, the information that the last ancilla has about the quantum system is

$$S(Q : A_n) = 2S_n - S_{n-1}. \quad (5.13)$$

If we now amplify the measurement chain (or, equivalently, just the last measurement) the information that D_n has about Q will be reduced from (5.13). From Eq. (5.8), the joint density matrix of Q and D_n can also be written as

$$\rho(QD_n) = \sum_{x_n} q_{x_n}^{(n)} |\tilde{x}_n x_n\rangle \langle \tilde{x}_n x_n|, \quad (5.14)$$

which leads to $S(QD_n) = S(D_n) = S_n$. Therefore, amplifying the measurement reduces the quantity (5.13) to

$$S(Q : D_n) = S_n, \quad (5.15)$$

where we used Lemmas 1 and 2 to write $S(Q) = S(A_n) = S(D_n) = S_n$. This quantity depends explicitly on only the last measurement, unlike (5.13), which depends on the last two. The amount of information (5.13) that the last device has about the quantum system before amplification is related to the information after amplification (5.15), by

$$S(Q : D_n) = S(Q : A_n) + S_{n-1} - S_n. \quad (5.16)$$

Thus, the marginal entropies in a chain of consecutive measurements never decrease, $S_n \geq S_{n-1}$, since $S(Q : D_n) \leq S(Q : A_n)$. The entropy Venn diagrams for the devices A_n and D_n and the quantum system are shown in Fig. 13.

We can illustrate this loss of information about the quantum system by considering consecutive qubit measurements. Suppose that ancilla A_{n-1} measures Q at an angle $\theta_{n-1} = 0$ relative to A_{n-2} and that A_n measures Q at an angle $\theta_n = \pi/2$ relative to A_{n-1} . In this case, the marginal entropies are $S_{n-1} = S_{n-2} = H[q^{(n-2)}]$ and $S_n = 1$

bit. The last detector, D_n , has one bit of information about quantum system, which is less than that of the un-amplified ancilla: $S(Q : A_n) = 2 - H[q^{(n-2)}] \geq 1$. Interestingly, how much we know about the state of Q prior to amplification is controlled by the entropy of an ancilla, A_{n-2} , located two steps down the measurement chain.

5.2 Information About Past Measurements

We now calculate how much information is encoded in a measurement device about the state of the measurement device that just preceded it in the quantum chain. In particular, we will show that the shared entropy $S(A_n : A_{n-1})$ between the last two devices in the measurement chain is reduced by the amplification process so that $S(D_n : D_{n-1}) \leq S(A_n : A_{n-1})$. These calculations have obvious relevance for the problem of quantum retrodiction [25], but we do not here derive optimal protocols to achieve this.

Theorem 5 *The information that the last device has about the previous device is reduced when that measurement is amplified, that is,*

$$S(D_n : D_{n-1}) \leq S(A_n : A_{n-1}). \quad (5.17)$$

Proof From the wavefunction (5.2), the density matrix for the last two ancillae in the measurement chain is

$$\begin{aligned} \rho(A_{n-1}A_n) = & \sum_{\substack{x_{n-2}x_{n-1} \\ x'_{n-1}x_n}} q_{x_{n-2}}^{(n-2)} U_{x_{n-2}x_{n-1}}^{(n-1)} U_{x_{n-2}x'_{n-1}}^{(n-1)*} \\ & \times U_{x_{n-1}x_n}^{(n)} U_{x'_{n-1}x_n}^{(n)*} |x_{n-1}x_n\rangle\langle x'_{n-1}x_n|. \end{aligned} \quad (5.18)$$

Amplification removes the off-diagonals of $\rho(A_{n-1}A_n)$ so that

$$\rho(D_{n-1}D_n) = \sum_{x_{n-1}} P_{x_{n-1}} \rho(A_{n-1}A_n) P_{x_{n-1}}, \quad (5.19)$$

where $P_{x_{n-1}} = |x_{n-1}\rangle\langle x_{n-1}|$ are projectors on the state of A_{n-1} . Note that from (5.18), it is sufficient to amplify just the second-to-last measurement with A_{n-1} . Since the marginal entropies are unchanged by the amplification (Lemma 2), the amount of information before amplification, $S(A_n : A_{n-1})$, and after, $S(D_n : D_{n-1})$, is related by

$$S(D_n : D_{n-1}) = S(A_n : A_{n-1}) + S(A_{n-1}A_n) - S(D_{n-1}D_n). \quad (5.20)$$

In a similar fashion to the calculations in Theorem 4, it is evident from (5.19) that the joint entropy is increased, $S(D_{n-1}D_n) \geq S(A_{n-1}A_n)$. It follows that the information that the last device has about the device that preceded it in the measurement sequence is reduced:

$$S(D_n : D_{n-1}) \leq S(A_n : A_{n-1}), \quad (5.21)$$

with equality if and only if $\rho(A_{n-1}A_n)$ is already diagonal in the ancilla product basis. $\square$

Let us show how amplification reduces the amount of information about past measurements in the case of qubits. In this example, suppose that the last two measurements in the chain are each made at the relative angle $\pi/2$. As expected, the amplified density matrix (5.19) in that case becomes uncorrelated, $\rho(D_{n-1}D_n) = \frac{1}{2} \mathbb{1}_{D_{n-1}} \otimes \frac{1}{2} \mathbb{1}_{D_n}$, where $\mathbb{1}$ is the 2×2 identity matrix, and the shared entropy vanishes $S(D_n : D_{n-1}) = 0$. In other words, the last detector has no information about the detector preceding it. In contrast, prior to amplification the density matrix (5.18) is coherent with joint entropy $S(A_{n-1}A_n) = 1 + S_{n-2}$. Therefore, the corresponding shared entropy is nonzero, $S(A_n : A_{n-1}) = 1 - S_{n-2} = 1 - H[q^{(n-2)}]$, revealing that information about the previous measurement survives the sequential $\pi/2$ measurements (as long as A_{n-1} is not amplified).

The calculations described above can be extended to include the information that the last device has about *all* previous devices in the measurement chain. We claim in Theorem 6 that the amplification process reduces this information by a specific minimum (calculable) amount. To prove this statement, we make use of Theorem 1, where we showed that the joint entropy of all quantum ancillae that measured a prepared quantum system is simply equal to the entropy of last ancilla in the un-amplified chain.

Theorem 6 *For n consecutive measurements of a quantum system, the information that the last device has about all previous measurements is reduced by amplification by at least an amount Σ_n :*

$$S(D_n : D_{n-1} \dots D_1) \leq S(A_n : A_{n-1} \dots A_1) - \Sigma_n, \quad (5.22)$$

where $\Sigma_n = S(A_{n-1}|A_n) \geq 0$ is a non-negative conditional entropy that quantifies the uncertainty about the prior measurement given the last.

Proof We begin by recognizing that the amplified mutual entropy $S(D_n : D_{n-1} \dots D_1)$ for the full measurement chain is equal to $S(D_n : D_{n-1})$ by the Markov property (see Theorem 3). Then, by Theorem 5 we can place an upper bound on the amplified information

$$S(D_n : D_{n-1} \dots D_1) = S(D_n : D_{n-1}) \leq S(A_n : A_{n-1}), \quad (5.23)$$

where $S(A_n : A_{n-1})$ is the mutual entropy before amplifying the measurement. Next, we will relate $S(A_n : A_{n-1})$ to $S(A_n : A_{n-1} \dots A_1)$. From Theorem 1, the latter quantity can be written simply as

$$S(A_n : A_{n-1} \dots A_1) = S_{n-1}, \quad (5.24)$$

so that with the definition of $S(A_n : A_{n-1})$, we come to

$$S(A_n : A_{n-1} \dots A_1) = S(A_n : A_{n-1}) + \Sigma_n, \quad (5.25)$$

where $\Sigma_n = S(A_{n-1}|A_n)$ represents the information gained by conditioning on all previous measurements. Inserting (5.25) into the inequality (5.23), we obtain

$$S(D_n : D_{n-1} \dots D_1) \leq S(A_n : A_{n-1} \dots A_1) - \Sigma_n. \quad (5.26)$$

The information is reduced as long as $\Sigma_n \geq 0$. To show this, we recall the joint density matrix (5.18) for A_{n-1} and A_n . This state can be written as a classical-quantum state

$$\rho(A_{n-1}A_n) = \sum_{x_n} q_{x_n}^{(n)} \rho_{x_n} \otimes |x_n\rangle\langle x_n|, \quad (5.27)$$

where

$$q_{x_n}^{(n)} \rho_{x_n} = \sum_{x_{n-2}} q_{x_{n-2}}^{(n-2)} p_{x_{n-2}x_n}^{(n-2,n)} |\phi_{x_{n-2}x_n}\rangle\langle\phi_{x_{n-2}x_n}|, \quad (5.28)$$

and the non-orthogonal states $|\phi_{x_{n-2}x_n}\rangle$ were previously defined in Eq. (3.37). In this block-diagonal form, the entropy is

$$S(A_{n-1}A_n) = S_n + \sum_{x_n} q_{x_n}^{(n)} S(\rho_{x_n}), \quad (5.29)$$

so that the quantity of interest, Σ_n , can be written as

$$\Sigma_n = S(A_{n-1}|A_n) = \sum_{x_n} q_{x_n}^{(n)} S(\rho_{x_n}) \geq 0. \quad (5.30)$$

This quantity is clearly non-negative since both $q_{x_n}^{(n)} \geq 0$ and $S(\rho_{x_n}) \geq 0 \forall x_n$. Therefore, with $\Sigma_n \geq 0$, we find that the information is indeed reduced by the amplification process, and by at least an amount equal to Σ_n . $\square$

Continuing with our qubit example that followed Theorem 5, if the last two measurements were each made at the relative angle $\pi/2$, the ancilla A_n has 1 bit of information about the joint state of all previous ancillae. That is, $S(A_n : A_{n-1} \dots A_1) = 1$ bit, while the amplifying detector D_n has no information at all, $S(D_n : D_{n-1} \dots D_1) = 0$.

Corollary 2 *Amplifying the measurement chain increases the entropy of the last device conditioned on all previous devices by at least an amount Σ_n :*

$$S(D_n|D_{n-1} \dots D_1) \geq S(A_n|A_{n-1} \dots A_1) + \Sigma_n. \quad (5.31)$$

Proof By definition, the mutual entropy and conditional entropy are related by

$$S(D_n : D_{n-1} \dots D_1) = S_n - S(D_n|D_{n-1} \dots D_1), \quad (5.32)$$

which, from Theorem 6, is bounded from above by $S(A_n : A_{n-1} \dots A_1) - \Sigma_n = S_n - S(A_n|A_{n-1} \dots A_1) - \Sigma_n$. Therefore,

Fig. 14 Entropy Venn diagrams **a** before amplification with n ancillae that consecutively measured a quantum system Q , and **b** after amplification with macroscopic detectors

$$S(D_n|D_{n-1} \dots D_1) \geq S(A_n|A_{n-1} \dots A_1) + \Sigma_n, \quad (5.33)$$

and the uncertainty in the last measurement is increased by at least an amount Σ_n . $\square$

This section quantified a number of unsurprising—but nevertheless important—results: amplifying measurements reduces information, and increases uncertainty. The key quantity that characterizes the difference between un-amplified and amplified chains is Σ_n , which quantifies how much we do *not* know about the state preparation, A_{n-1} , given the state determination, A_n . Depending on the relative state between A_{n-1} and A_n , we may know nothing ($\Sigma_n = 1$), or everything ($\Sigma_n = 0$). We summarize the results presented in this section with the entropy Venn diagrams in Fig. 14.

6 Applications of Consecutive Quantum Measurements

In this section we apply the formalism developed in this article to several paradigmatic measurement scenarios, specifically the double-slit experiment, the quantum Zeno effect, and quantum state preparation.

6.1 The Double-Slit Experiment

Suppose a photon in the state

$$|\Psi\rangle = |h\rangle_P \otimes |\psi\rangle_Q \quad (6.1)$$

is incident on a double-slit apparatus. Initially, the state's polarization (P) degree of freedom is h , while the spatial (Q) degree of freedom is ψ . Once past the slits, the quantum state's spatial state evolves to the superposition

$$|\Psi\rangle = |h\rangle_P \otimes \frac{|\psi_1\rangle_Q + |\psi_2\rangle_Q}{\sqrt{2}}, \quad (6.2)$$

where $|\psi_j\rangle_Q$ is the state corresponding to the photon passing through slit j . The photon is then detected by a CCD camera D_X , which acts as an interference screen. This interaction can be modeled as a von Neumann measurement of the spatial states by the screen. Writing the spatial states of the photon in terms of the position basis of the screen yields

$$|\psi_j\rangle_Q = \sum_{x=1}^n \psi_j(x) |x\rangle_Q, \quad (6.3)$$

where $j = 0, 1$ labels each slit. The states $|x\rangle$ can be discretized into n distinct locations according to

$$\begin{aligned} |x=1\rangle &= |100 \dots 0\rangle, \\ |x=2\rangle &= |010 \dots 0\rangle, \\ &\vdots \\ |x=n\rangle &= |0 \dots 001\rangle, \end{aligned} \quad (6.4)$$

which denote the location x at which a photon is detected by D_X . Inserting this basis into the expression (6.2) and performing the measurement of Q with D_X (which starts in the initial state $|x=0\rangle = |0 \dots 0\rangle$), we arrive at

$$|\Psi'\rangle = |h\rangle_P \otimes \sum_{x=1}^n \frac{\psi_1(x) + \psi_2(x)}{\sqrt{2}} |xx\rangle_{QD_X}. \quad (6.5)$$

Tracing out the photon states, the density matrix describing the screen is

$$\rho(D_X) = \frac{1}{2} \sum_{x=1}^n |\psi_1(x) + \psi_2(x)|^2 |x\rangle_{D_X} \langle x|, \quad (6.6)$$

where the probability to detect the photon at a position x is a coherent superposition of probability amplitudes and leads to the standard double-slit interference pattern.

We can extend this description to the case of multiple measurements in the context of the quantum eraser experiment. We first tag the photon's path in order to obtain information about which slit it passed through. In practice, we can implement the tagging operation by placing different wave plates in front of each slit. As a simple example, we assume the tagging takes the form of a controlled-NOT operation so that horizontal polarization h is converted to vertical polarization v if the photon traverses the second slit. Thus, instead of (6.2), the polarization (P) and spatial (Q) degrees of freedom are now entangled, leading to

$$|\Psi\rangle = \frac{|h\rangle_P \otimes |\psi_1\rangle_Q + |v\rangle_P \otimes |\psi_2\rangle_Q}{\sqrt{2}}. \quad (6.7)$$

Of course, the entanglement in (6.7) destroys the interference pattern on the screen. The fringes can be restored by measuring the photon's polarization with a detector D_P in a rotated basis, before the photon hits the screen. Rewriting the polarization states in the new basis, $|0\rangle$ and $|1\rangle$, which are rotated by an angle θ with respect to $|h\rangle$ and $|v\rangle$ [see (3.17)],

$$|v\rangle_P = U_{00} |0\rangle_P + U_{01} |1\rangle_P, \quad (6.8)$$

$$|h\rangle_P = U_{10} |0\rangle_P + U_{11} |1\rangle_P, \quad (6.9)$$

and measuring P with the detector D_P yields

$$\begin{aligned} |\Psi'\rangle &= \frac{1}{\sqrt{2}} \left(U_{10} |\psi_1\rangle_Q + U_{00} |\psi_2\rangle_Q \right) \otimes |00\rangle_{PD_P} \\ &\quad + \frac{1}{\sqrt{2}} \left(U_{11} |\psi_1\rangle_Q + U_{01} |\psi_2\rangle_Q \right) \otimes |11\rangle_{PD_P}. \end{aligned} \quad (6.10)$$

The angle at which we measure the polarization determines the coherence of the spatial states Q , which is reflected in the visibility of the recovered interference patterns. Repeating the measurement with the screen, (6.10) becomes

$$\begin{aligned} |\Psi''\rangle &= \frac{1}{\sqrt{2}} \sum_{x=1}^n \left[\left(U_{10} \psi_1(x) + U_{00} \psi_2(x) \right) |00\rangle_{PD_P} \right. \\ &\quad \left. + \left(U_{11} \psi_1(x) + U_{01} \psi_2(x) \right) |11\rangle_{PD_P} \right] \otimes |xx\rangle_{QD_X}. \end{aligned} \quad (6.11)$$

The density matrix for the screen is, as expected, still completely mixed and describes two intensity peaks on the screen. However, an interference pattern can be extracted if we condition on the outcome of the polarization measurement, as we now show. Consider

$$\rho(QD_P) = \frac{1}{2} \sum_{i=0}^1 \rho_Q^{(i)} \otimes |i\rangle_{D_P} \langle i|, \quad (6.12)$$

where

$$\rho_Q^{(i)} = \sum_{x=1}^n |U_{1i} \psi_1(x) + U_{0i} \psi_2(x)|^2 |x\rangle_{D_X} \langle x|, \quad (6.13)$$

is the state of Q , given that the polarization measurement yielded the outcome i . The probability distribution of this state is a coherent sum of amplitudes and describes an interference pattern with a visibility that is controlled by the measurement angle,

θ . In particular, measuring at $\theta = 0$ leads to no interference, while $\theta = \pi/2$ recovers the standard fringe (or anti-fringe) pattern.

We refer the reader to Ref. [22] for a detailed information-theoretic analysis of the Bell-state quantum eraser experiment, where the degree of erasure is controlled by an entangled photon partner, even after the original photon has hit the screen.

6.2 Quantum Zeno and Anti-Zeno Effects

The quantum Zeno effect [57] (see also the review [27]) has been called a “paradox” because of the perceived back-reaction of the measurement devices on the quantum state. In the original formulation, an atom undergoing radioactive decay was shown to be prevented from decaying by measuring it repeatedly [57]. Here we derive the standard results of the quantum Zeno and anti-Zeno effects in the context of unitary consecutive measurements without resorting to a collapse assumption, and without a need of amplifying measurements (as all the measurement devices are stable and amplifiable).

Instead of a time-varying quantum state controlled by quantum measurements in the same basis, we can equivalently study a static quantum state consecutively measured by quantum detectors whose basis change with their position in the sequence [27, 50]. In particular, we focus on the case where n consecutive measurements are performed in such a way that each measurement device has the same relative angle with the preceding device but all angles adding up to $\pi/2$, compared to the case where the last measurement occurs at an angle $\pi/2$ with respect to the preparation.

The quantum Zeno effect is usually derived by assuming that the wave function is collapsed at each measurement, removing (“by hand”, as it were, see e.g., [50, p. 392]) the off-diagonal elements of the density matrix at every measurement. We will see that we can derive the “freezing” of the quantum state using von Neumann measurements only, without state reduction. Instead, all amplitudes continue to be present in the joint density matrix, even though the density matrix of every single detector and that of the quantum state is diagonal.

To study the Zeno effect using von Neumann measurements, we assume that an initial quantum two-state system is in the state $\rho(Q) = p|0\rangle\langle 0| + (1-p)|1\rangle\langle 1|$, with arbitrary p , which was prepared by a measurement with detector D_0 . It is then subsequently measured by detectors $D_1 \dots D_n$, each at an angle $\pi/(2n)$ relative to the previous detector, completing a full $\pi/2$ rotation after n observations (see Fig. 15). The density matrix for the preparation (detector D_0) is $\rho(D_1) = p|0\rangle\langle 0| + (1-p)|1\rangle\langle 1|$, which has an entropy $S(D_0) = H[p]$, where $H[p] = -p \log_2 p - (1-p) \log_2 (1-p)$ is the binary entropy function. The density matrix for the first detector, expressed in a basis that is rotated with the unitary matrix U , is

$$\rho(D_1) = \sum_j (p |U_{0j}|^2 + (1-p) |U_{1j}|^2) |j\rangle\langle j|, \quad (6.14)$$

where the unitary matrix is given by

Fig. 15 A sequence of n measurements of a quantum state, where each detector D_j measures the quantum state at a relative angle $\theta/2n$ with respect to the preceding detector, or angle $\theta_j = j\theta/2n$ with respect to the preparation. After n such measurements, the angle between the preparation and the last detector is $\theta/2$

$$U = \begin{pmatrix} \cos(\frac{\pi}{4n}) & -\sin(\frac{\pi}{4n}) \\ \sin(\frac{\pi}{4n}) & \cos(\frac{\pi}{4n}) \end{pmatrix}. \quad (6.15)$$

Using consecutive von Neumann measurements we can calculate the entropy of the first detector to be $S(D_1) = H[q]$ with $q = 1/2 + (p - 1/2) \cos(\frac{\pi}{2n})$,

In general, following the preparation, the probability $q^{(n)}$ to observe the state $|0\rangle$ after n measurements is

$$q^{(n)} = \frac{1}{2} + \left(p - \frac{1}{2}\right) \cos^n\left(\frac{\pi}{2n}\right) \rightarrow p \text{ as } n \rightarrow \infty. \quad (6.16)$$

with entropy

$$S(D_n) = H\left[1/2 + \left(p - \frac{1}{2}\right) \cos^n\left(\frac{\pi}{2n}\right)\right], \quad (6.17)$$

Figure 16a shows the preparation $S(D_0)$ as well as detector entropies $S(D_1), S(D_2)$ for $n = 2$, while Fig. 16b shows the case $n = 10$. As n becomes large, the entropies appear “frozen”, so that the density matrix of the n th detector is equal to that of the preparation with D_0 .

Had we measured the preparation directly at angle $\theta = \pi/2$, the entropy of that detector would be one: this outcome should be completely random. For polarization measurements for example, this results in perfect transmission of the initially polarized beam even though the n detectors rotate the plane of polarization by 90° [33].

It is instructive to study the Zeno effect in terms of the detector correlation function $K_{0n} = \langle D_0 D_n \rangle$ which quantifies the correlation between the preparation and last detector. If every detector is rotated by an angle θ with respect to the previous detector, it is easy to show that $K_{i,i+1} = \cos(\theta)$, so if for example a detector is rotated by $\theta = \pi/2$, we expect $K_{12} = 0$. Now let us perform n such measurements, such that

Fig. 16 **a** The detector entropies for two consecutive measurements D_1 and D_2 , after the preparation with D_0 , of the quantum state $\rho(Q) = p|0\rangle\langle 0| + (1-p)|1\rangle\langle 1|$, for $n = 2$. Each detector is at an angle of $\pi/4$ relative to the previous detector. **b** Detector entropies D_5 and D_{10} for a Zeno experiment with $n = 10$. Each detector is rotated by an angle $\theta = \pi/20$ with respect to the preceding one

the angle between each subsequent pair is $\pi/2n$. After n measurements we have performed a total rotation of $\pi/2$. The correlation between the first and last measurement, however, turns out to be $K_{0n} = \cos^n(\pi/2n)$, which tends to 1 as $n \rightarrow \infty$. If the intermediate measurements from $n = 1$ to $n - 1$ had not been carried out, the correlation function would be $K_{0n} = \cos(n\pi/2n) = 0$ instead.⁶

Finally, let us study for completeness the anti-Zeno effect, which is often described as the complete destruction of a quantum state due to incoherent consecutive measurements [31, 37, 41]. In the present language, this corresponds to the randomization of a given (prepared) quantum state after consecutive measurements at random angles with respect to the initial state. We begin again with the prepared mixed state $\rho(Q) = p|0\rangle\langle 0| + (1-p)|1\rangle\langle 1|$, but now observe it consecutively using measurement devices D_k at angles θ_k drawn from a uniform distribution on the interval $[0, \pi/2]$. The probability to observe Q in state $|0\rangle$ after n measurements with random phases is now

$$q^{(n)} = \frac{1}{2} + \left(p - \frac{1}{2}\right) \prod_{k=1}^n \cos(\theta_k). \quad (6.18)$$

In order to obtain the most likely state probability for random dephasing, we calculate the expectation value,

$$E\left[\prod_{k=1}^n \cos(\theta_k)\right] = \prod_{k=1}^n E[\cos(\theta_k)] = \left(\frac{2}{\pi}\right)^n, \quad (6.19)$$

⁶ After completion of this manuscript, we discovered that the same set of arguments were made by Dicke using latent measurements in his unheralded publication [15].

so that $E[q^{(n)}] \rightarrow 1/2$ as $n \rightarrow \infty$. Thus, any quantum state is randomized via consecutive quantum projective measurements in random bases. A similar result was derived for the dephasing of photon polarization in Ref. [33].

6.3 Preparing Quantum States

For our final application, we discuss how to prepare quantum states by considering consecutive measurements on unprepared quantum states. Suppose a quantum system is prepared in the known state

$$\rho(Q) = \sum_{x=0}^{d-1} p_x |\tilde{x}\rangle\langle\tilde{x}|, \quad (6.20)$$

which we already wrote in the eigenbasis of the first observable measured after the preparation. We can always prepare a state like (6.20) by measuring an unprepared quantum state (2.9), with the pair $A_1 D_1$ in a given (but arbitrary) basis. Then, a second measurement with $A_2 D_2$ at a relative angle θ_2 gives rise to the state

$$|QRA_1 D_1 A_2 D_2\rangle = \frac{1}{\sqrt{d}} \sum_{x_1 x_2} U_{x_1 x_2}^{(2)} |\tilde{x}_2\rangle_{x_1} |x_1 x_1 x_2 x_2\rangle. \quad (6.21)$$

From this we can compute the operator [10] describing the state of the quantum system, conditional on the state of the first detector, D_1 ,

$$\begin{aligned} \rho(Q|D_1) &= \rho(QD_1) \left(\rho(D_1)^{-1} \otimes \mathbb{1}_Q \right) \\ &= \sum_{x_1} \rho_Q^{x_1} \otimes |x_1\rangle\langle x_1|, \end{aligned} \quad (6.22)$$

where $\rho(D_1)^{-1}$ is the inverse of the density matrix. The density matrix $\rho_Q^{x_1}$ is the prepared state (6.20) of the quantum system, given that the outcome x_1 was observed in the first measurement,

$$\rho_Q^{x_1} = \frac{\text{Tr}_{D_1} [P_{x_1} \rho(QD_1) P_{x_1}^\dagger]}{\text{Tr}_{QD_1} [P_{x_1} \rho(QD_1) P_{x_1}^\dagger]} = \sum_{x_2} |U_{x_1 x_2}^{(2)}|^2 |\tilde{x}_2\rangle\langle\tilde{x}_2|. \quad (6.23)$$

Here, $P_{x_1} = |x_1\rangle\langle x_1|$ are projectors on the state of detector D_1 . If we choose for the quantum state preparation the outcome $x_1 = 0$, for example, then $p_{x_2} = |U_{0x_2}^{(2)}|^2$ provides the probability distribution for the quantum system, and we arrive at the desired prepared state (6.20) from (6.23).

The purification of (6.20) in terms of the basis of ancilla A_2 is

$$|QA_2\rangle = \sum_{x_2} \sqrt{p_{x_2}} |\tilde{x}_2\rangle |x_2\rangle, \quad (6.24)$$

which is an entangled state with the marginal entropies $S(Q) = S(A_2) = H[p]$. If we rename A_2 to A_1 , then expression (6.24) is equivalent to (2.3). Equipped with this state preparation, we can now make the usual consecutive (amplified or un-amplified) measurements of Q with A_2D_2 , A_3D_3 , etc.

7 Conclusions

Conventional wisdom in quantum mechanics dictates that the measurement process collapses (“reduces”) the state of a quantum system so that the probability that a particular detector fires depends only on the state preparation and the measurement chosen. This assertion can be tested by considering sequences of measurements of the same quantum system. If a “memory” of the first measurement (the state preparation) persists beyond the second measurement, then a reduction of the wave packet can be ruled out. We studied this question using two classes of quantum measurement: those performed within a closed system where every part of a measurement device (every qudit of the pointer) is under control (latent measurements), and those performed within an open system, where part of the pointer variable is ignored. We found that sequences of quantum measurements in closed systems are non-Markovian (retaining the memory of past measurements) while sequences of open-system measurements obey the Markov property. In the latter case, the probability distribution of future measurement results only depends on the state preparation and the measurement chosen. It is important to note here that our construction shows unequivocally that the Markovian measurements are a *special case* of the non-Markovian ones, and that the loss of memory is not a fundamental property of quantum measurements, but is merely a consequence of the loss of quantum information when tracing over degrees of freedom that participated in the measurement. We quantified this loss by calculating the amount of information lost when observing coherent quantum detectors using incoherent devices.

We have found that the entropy of coherent chains of latent measurements is entirely determined by the entropy at the boundary of the chain, namely the entropy of the state *preparation* (the first measurement in the chain) and the last measurement. If the chain is started on a known state, then the entropy of the chain is contained in the last measurement only. This property is a direct consequence of the unitarity of quantum measurements, and signifies that any quantum measurement outcome is constrained by its immediate past and its immediate future. It has not escaped our attention that this property of quantum chains is reminiscent of the holographic principle, which posits that the description of a system can be encoded entirely on its boundary alone. Because the holographic principle is often thought to have its origin in an information-theoretic description of space-time [66], it is perhaps not surprising that an information-theoretic analysis of chains of measurements would yield precisely such an outcome. In particular, it is not too hard to imagine that the past-future relationship that consecutive quantum measurements entail create precisely the partial order required for the “causal sets” program for quantum gravity [6]. Of course, to recover space-time from sets of measurements we would

need to consider not just sequential measurements on the same system, but multiple parallel chains that are entangled with each other, creating a network rather than a chain (we have recently shown that the unitary formalism deployed here can be extended to parallel measurements when discussing the Bell-state quantum eraser [22]). In that respect, the network of quantum measurements is more akin to van Raamsdonk's [64] tensor networks, created using entangling and disentangling operations (see also [48]). Incidentally, the present formalism implies the existence of a disentangling operation that “undoes” quantum measurements, and that can serve as a powerful primitive for controlling quantum entanglement [21].

Using a quantum-information-theoretic approach, we have argued that a collapse picture makes predictions that differ from those of the unitary (relative state) approach if multiple consecutive non-Markovian measurements are considered. Should future experiments corroborate the manifestly unitary formulation we have outlined, such results would further support the notion of the reality of the quantum state [51] and that the wavefunction is not merely a bookkeeping device that summarizes an observer's knowledge about the system [17, 20]. We hope that moving discussions about the nature of quantum reality from philosophy into the empirical realm will ultimately lead to a more complete (and satisfying) understanding of quantum physics.
