Abstract

Vertical profiles of radiocesium (^{134}Cs and ^{137}Cs) were measured in the western subarctic area of the North Pacific in 2017. The highest concentration of ^{134}Cs , which was derived from the accident of the Fukushima Dai-ichi Nuclear Power Plant in 2011, was 0.14 Bq m^{-3} (or 1.19 Bq m^{-3} after the decay correction to the accident date). Although the vertical inventory of ^{134}Cs decreased between 2014 and 2017, the inventory in 2017 was larger than that expected. That was probably arose from the return of some portion of the high-concentration water mass along with the anticlockwise subarctic gyre current.

Keywords Fukushima Dai-ichi Nuclear Power Plant · Radiocesium · Seawater · North Pacific · Western subarctic area

Introduction

A massive earthquake in the North Pacific Ocean off Japan on 11 March 2011 resulted in serious damage to the Fukushima Dai-ichi Nuclear Power Plant (FNPP1) operated by Tokyo Electric Power Company (TEPCO). And the consequent giant tsunami enlarged the damage because the FNPP1 is located on the North Pacific shoreline of the Japanese island of Honshu. Radiocesium (^{134}Cs and ^{137}Cs) released from the damaged FNPP1 to the atmosphere in March and April 2011 was deposited on land in the eastern area of Honshu island and sea surface in the North Pacific [1, 2]. The total depositions of FNPP1-derived ^{134}Cs and ^{137}Cs on land

were equivalent [3] and have been estimated to be 2.4 PBq (10^{15} Bq), respectively [4]. On the other hand, the estimate of the total deposition of ^{134}Cs or ^{137}Cs in the ocean ranges between 10 and 20 PBq [5–9]. That suggests that 10–20% of the radiocesium released to the atmosphere was deposited on land in the eastern area of Honshu island and the rest (80–90%) was deposited in the North Pacific Ocean.

The radiocesium measurements in the coastal area by TEPCO [10] and the Japanese Government [11] revealed that another major source of radiocesium in the North Pacific was the direct discharge of radioactive water from the FNPP1 between late March and early April. The $^{134}\text{Cs}/^{137}\text{Cs}$ ratio in seawater collected during the coastal observations was almost 1, which suggests that the activity concentrations of ^{134}Cs and ^{137}Cs in the discharged water were also equivalent as same as those atmospheric-deposited. The total release of the directly-discharged radiocesium (^{134}Cs or ^{137}Cs) was estimated to be 2–6 PBq in many previous studies [5, 6, 12–14]. As a result, the total (atmospheric deposition and direct discharge) release of ^{134}Cs or ^{137}Cs into the North Pacific Ocean was calculated to be 12–26 PBq approximately.

The FNPP1 ($37.4^\circ\text{N}/141^\circ\text{E}$) is situated to the north of the Kuroshio Extension Current around 35°N , which corresponds to the Kuroshio Front (Fig. 1). The FNPP1-derived radiocesium directly-discharged and atmospheric-deposited north of the Kuroshio Front was transported eastward along with surface currents. In summer 2012,

Fig. 1 The sampling station (station CL1, 41°N/150°E) in June 2017 (the circle, this work). Those in previous works in June 2011 (the diamond) [18], February 2012 (the triangle) [19], September 2012 (the squares with a dot) [15], October 2012 (the square) [20], July 2014 (the inverted triangle) [21], and October 2014 (the inverted triangle with a dot) [22] are also shown in this figure. At the stations in September 2012 and October 2014, only surface seawater was collected. The star indicates the Fukushima Dai-ichi Nuclear Power Plant (FNPP1). This figure was drawn using Ocean Data View software [23]

about one and half years after the accident, High activity concentrations of radiocesium were observed at the sea surface around 165°E–170°W between 40°N and 50°N [15]. This high-concentration water mass then reached stations in the Gulf of Alaska or the eastern subarctic area in the North Pacific in 2015 [16]. A research paper recently published [17] suggested that the water mass had turned to the west and arrived in the northern Bering Sea by summer 2017 along with the anticlockwise subarctic gyre current.

As the high-concentration water mass was transported eastward from Japan to the North American Continent, the activity concentration and total inventory of the FNPP1-derived radiocesium increased in the eastern subarctic area of the North Pacific [16]. On the other hand, these in the western subarctic area decreased between 2011 and 2014 [21]. If the high-concentration water mass also returned to the western subarctic area along with the anticlockwise subarctic gyre current in 2017, the FNPP1-derived radiocesium concentration increased between 2014 and 2017. However, its temporal change after 2014 in the western subarctic area is unknown. Here we present vertical profiles of ^{134}Cs and ^{137}Cs in the western subarctic area of the North Pacific Ocean obtained in summer 2017. We discuss the temporal change in the FNPP1-derived radiocesium after 2014 and the time scale of the anticlockwise subarctic gyre circulation in the North Pacific. These discussions are conducive not only to the physical oceanography but also the ongoing monitoring of radionuclide concentrations in seawater at stations in the coastal area of the FNPP1 [10, 11].

Experimental

The seawater samples for radiocesium measurement were collected during a cruise of R/V Hakuho-maru, KH-17-3 in June 2017. Our sampling station locates in the western subarctic area of the North Pacific Ocean, about 1000 km away from the FNPP1 (Fig. 1). The seawater samples were collected from eight layers between the surface (23 m) to 782 m depth using a large-volume sampler (N12-1000, Nichiyu-Giken-Kogyo) that consists of four 250 L PVC samplers, a transponder, a motor-driven trigger, pressure/temperature sensors (RBRduo-TD-Ti sensor, RBR), and a battery unit. Thus, we conducted two casts with the large-volume sampler for shallow (23, 63, 102, and 152 m) and deep samplings (201, 396, 591, and 782 m). The salinity of the seawater sample was measured using a salinometer (Autosal Salinometer 8400B, Ocean Scientific International Ltd). The 250 L of seawater was pumped out using an impeller water pump and filtered through a 0.5 μm pore size wind-cartridge filter (TCW-05 N-PPS, Advantec). Then, about 40 L of seawater for the radiocesium measurement was collected in two plastic 20 L-containers.

To save the shipping costs of the seawater samples and the time for sample preparation in our on-shore laboratory, we conducted cesium separation from the 40 L seawater sample on board using a preparation device (Fig. 2). 1 mL of CsCl (07185-08, Kanto Chemical) solution (2.5 mg g^{-1}) was added into each container and the seawater in it was mixed well. The concentration of stable ^{133}Cs , as a carrier for radiocesium, was about 0.1 Cs-mg L^{-1} . The dissolved (stable and radioactive) cesium in the seawater sample was

Fig. 2 The preparation device on board. **a** The device contains four separation lines, each of which consists of a seawater sample (40 L) with the CsCl carrier, a resin bed (5 mL), a drain tank (50 L), and a peristaltic pump. **b** The two 20 L containers for the seawater sample were connected using a Y-shaped tube. **c** The KNiFC-PAN resin bed (5 mL or 1 g dry weight) in a 20 mL plastic cartridge (AC-20-R12, Triskem International)

separated using potassium nickel ferrocyanate-polyacrylonitrile resin (KNiFC-PAN Resin-B NC-B200-M, Lot FNCM170321, Triskem International) without adjustment of sample pH. The PAN resin has been used for the separation of radiocesium from seawater samples in previous studies [24–27]. The volume of the resin bed in a cartridge was about 5 mL (or about 1 g dry weight) and the flow rate of the seawater sample was 50 mL min⁻¹. The seawater sample was injected from the bottom of the cartridge to stir up the resin bed. Before and after the separation, a small volume aliquot (about 50 mL) of the seawater sample was withdrawn, respectively. After measurements of the volume and weight of the seawater sample in a drain tank (50 L), the seawater samples were spilled on board. And the resin in the cartridges and the small aliquots were carried back to our on-shore laboratory.

The carrier (stable cesium) concentration in the aliquot was measured using an ICP mass spectrometer (ELEMENT XR, Thermo Scientific). The difference in the concentration in the aliquot between before and after the separation determined the separation efficiency (or yield rate) of each resin

Fig. 3 The yield rate (%) of the ¹³³Cs carrier against the flow rate (mL min⁻¹) of 3%-NaCl solution (40 L). The concentrations of ¹³³Cs in the NaCl solution were 0.1 (circles), 0.4 (triangles), and 4.0 (squares) mg-Cs L⁻¹. The resin bed volume was about 5 mL (or 1 g dry weight)

bed. The yield rate depends on the resin bed volume, flow rate, and carrier concentration. Because we used well-type gamma-ray detectors, the bed volume should be less than 5 mL. We measured the yield rates in ranges of the flow rate (50–200 mL min⁻¹) and the carrier concentration (0.1–4 mg L⁻¹) for the 5 mL bed volume and got the highest yield rate (about 95%) at 50 mL min⁻¹ of the flow rate and 0.1 mg L⁻¹ of the carrier concentration (Fig. 3).

The resin in the cartridge was rinsed with pure water at 50 mL min⁻¹ using a peristaltic pump overnight and then dried at 50 °C in an oven. The dried resin was mixed well using a vibrator to avoid the inhomogeneous distribution of radiocesium in the resin. The radiocesium in the resin bed was measured using low-background gamma-ray spectrometers in the underground laboratory of Low Level Radioactivity Laboratory, Kanazawa University [28]. The well-type spectrometers were calibrated with gamma-ray volume sources (Eckert & Ziegler Isotope Products) certificated by Deutscher Kalibrierdienst. The activities of ¹³⁴Cs and ¹³⁷Cs were evaluated from gamma-ray peaks at 605 and 661 keV, respectively. The efficiency and background counting in the energy range was about 20% and less than 5 × 10⁻⁵ cps, respectively. The gamma counting time was about 10 days. For the peak from ¹³⁴Cs, the cascade summing effect was corrected. The factor for the effect was about 2, which was calculated as the difference between the ¹³⁴Cs/¹³⁷Cs ratios at a distance of 15 cm from the detector and in the well hole of the detector. The averages of the analytical uncertainties (standard deviations) for the ¹³⁴Cs and ¹³⁷Cs measurements were calculated to be about 26%

and 17%, respectively. This total uncertainty was the sum of those from the gamma counting, the calibration, and the correction for the summing effect. The large uncertainties more than 15% arose from the small number of the total gamma counting. The background concentrations of ^{134}Cs and ^{137}Cs in the KNiFC-PAN resin were below the detection limit (1.1 mBq g^{-1}) and 1.6 mBq g^{-1} , respectively. The detection limits of ^{134}Cs and ^{137}Cs measurements were about 0.05 and 0.01 Bq m^{-3} , respectively, which corresponds to about 0.4 and 0.01 Bq m^{-3} for the concentrations decay-corrected to the date of the FNPP1 accident (11 March 2011), respectively. The decay-corrected detection limit only depends on the half-life and corrects the underestimation of the detection limit for the decay-corrected activity concentration. The results of the radiocesium measurements are listed in Table S1.

Results

Before the FNPP1 accident, radiocesium was also released into the North Pacific Ocean by the atmospheric testing of nuclear weapons mainly in the 1950s and 1960s. The bomb-derived ^{137}Cs remained in the North Pacific at the time of the FNPP1 accident because its half-life is 30.0 y. The activity concentration at the surface in the western subarctic area just before the FNPP1 accident was about 1.5 Bq m^{-3} [29]. In contrast, virtually all the ^{134}Cs released into the North Pacific before the FNPP1 accident had disappeared because the half-life of ^{134}Cs is only 2.07 y. Consequently, ^{134}Cs is a more suitable tracer than ^{137}Cs for the FNPP1-derived radiocesium. Therefore, we discuss mainly the results of ^{134}Cs in the following sections.

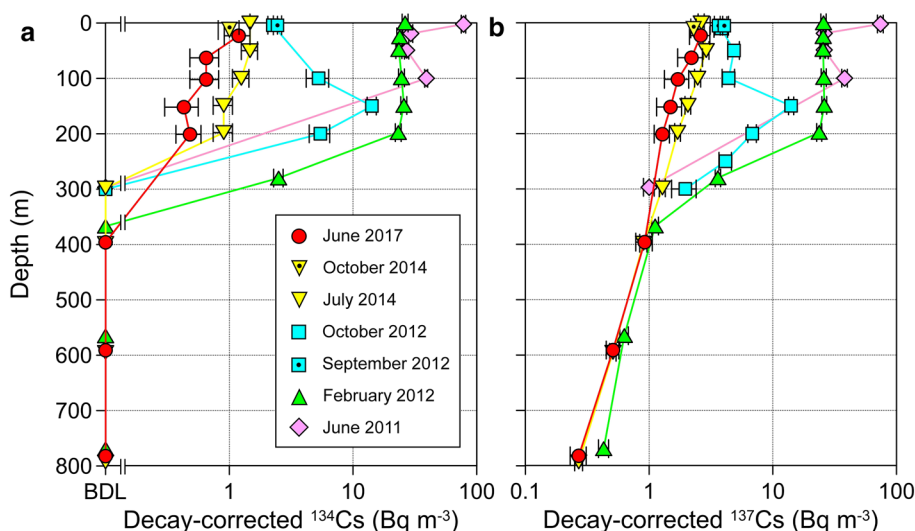

The FNPP1-derived ^{134}Cs was still observed in the western subarctic area in June 2017, about 6 years after

the FNPP1 accident. The highest (0.14 Bq m^{-3}) and lowest (0.05 Bq m^{-3}) activity concentrations were observed at the surface (23 m depth) and 152 m depth (Table S1), respectively. Below 201 m depth, the ^{134}Cs concentration was less than the detection limit (about 0.05 Bq m^{-3}). These low concentrations resulted from the radioactive decay and dilution due to the water mixing. The objective of this study is to elucidate the temporal change in the FNPP1-derived ^{134}Cs due to the water mixing and transport. Therefore, we discuss the activity concentration of ^{134}Cs (and ^{137}Cs) that decay-corrected to the date of the FNPP1 accident in the following sections.

The vertical profile of decay-corrected ^{134}Cs concentration in June 2017 is shown in Fig. 4a (the circles). The observed highest and lowest concentrations correspond to 1.19 and 0.43 Bq m^{-3} of the decay-corrected concentrations, respectively. Below 201 m depth, the decay-corrected ^{134}Cs concentration was less than the detection limit (about 0.4 Bq m^{-3}). The FNPP1-derived ^{134}Cs had penetrated to 200 m depth at least. The deeper penetration, however, was uncertain because the detection limit was high. This vertical profile observed in 2017 in the western subarctic area, north of the Kuroshio Front, was different from those in the western subtropical area, south of the Kuroshio Front. In the south, the FNPP1-derived ^{134}Cs had been penetrated to 600 m depth by 2017 [30]. The deeper penetration of the FNPP1-derived ^{134}Cs in the south was derived from the sinking (subduction) of the subtropical mode water into the subsurface layer (about 300–400 m) [31], which did not occur in the north of the front.

The decay-corrected ^{137}Cs activity concentration decreased with depth from 2.61 Bq m^{-3} at the sea surface to 0.27 Bq m^{-3} at 800 m depth in 2017 (the circles in Fig. 4b), which indicates that the bomb-derived ^{137}Cs had been penetrated to 800 m depth. In the layers shallower than

Fig. 4 Vertical profiles of decay-corrected ^{134}Cs (a) and ^{137}Cs (b) activity concentration (Bq m^{-3}) between June 2011 and June 2017 in the western subarctic area of the North Pacific Ocean. The symbols are the same as those in Fig. 1 (the new data in 2017 in this work are indicated by the circles). The activity concentrations are decay-corrected to the date of the FNPP1 accident. The error bar is the standard deviation of each measurement. BDL is the below detection level

200 m depth, where the FNPP1-derived ^{134}Cs was detected, the measured ^{137}Cs included both the bomb-derived and FNPP1-derived ^{137}Cs . The difference between the decay-corrected ^{134}Cs (Fig. 4a) and ^{137}Cs (Fig. 4b) activity concentrations indicates the decay-corrected concentration of the bomb-derived ^{137}Cs (Table S1) because the decay-corrected concentrations of the FNPP1-derived ^{134}Cs and ^{137}Cs were equivalent. The averaged decay-corrected concentration of the bomb-derived ^{137}Cs in the surface layer shallower than 100 m depth is about 1.3 Bq m^{-3} . The averaged value agrees with the observed concentrations just before the FNPP1 accident [29].

Discussion

Changes in the vertical profile

In Fig. 4a, the vertical profiles and surface concentrations of decay-corrected ^{134}Cs at stations about 500 km away from the FNPP1 (Fig. 1) in previous works [15, 18–22] are also shown. In June 2011, about 3 months after the accident, the FNPP1-derived ^{134}Cs concentration in the surface layer shallower than 100 m depth ranged between about 27 and 78 Bq m^{-3} . In April–May 2011, the similar high concentrations of decay-corrected ^{134}Cs between 20 and 80 Bq m^{-3} approximately were also observed at the sea surface between 143°E and 148°E in the western subarctic area [19]. These high concentrations observed within 2 months after the accident at the stations 500–1000 km away from the FNPP1 were probably derived from the atmospheric deposition. In June–August 2011, the decay-corrected concentration at the sea surface increased to $50\text{--}110 \text{ Bq m}^{-3}$ approximately due to the eastward transport of the high-concentration water mass of the directly-discharged ^{134}Cs from the coastal area of the FNPP1 to the sampling area [19]. Then those decreased to $10\text{--}40 \text{ Bq m}^{-3}$ approximately in September–December 2011 due to the further eastward transport of the high-concentration water mass [19]. Therefore, the ^{134}Cs observed in June 2011 probably has the two sources, the atmospheric-deposited and directly-discharged ^{134}Cs .

In February and September–October 2012, the decay-corrected ^{134}Cs concentrations in the mixed surface layer above 200 m depth were about 25 and $2\text{--}14 \text{ Bq m}^{-3}$, respectively (Fig. 4a). The decay-corrected concentration of ^{134}Cs in the shallower layers than 100 m depth in October 2012 was less than the detection limit. Therefore, we lined between the concentration at 100 m depth (5.27 Bq m^{-3}) in October 2012 and the surface concentration (2.25 Bq m^{-3}) in September 2012 at the station ($40.4^\circ\text{N}/146.8^\circ\text{E}$) close to the station in October 2012 (Fig. 1). In July 2014, the decay-corrected ^{134}Cs

concentration in the surface mixed layer above 200 m depth ranged between 0.90 and 1.47 Bq m^{-3} (Fig. 4a). These low concentrations resulted from that the main body of the high-concentration water mass had been transported to the central North Pacific Ocean by the summer of 2012 [15]. The stations between June 2011 and July 2014 were close to each other (Fig. 1). Thus, the observed changes in the vertical profile during this period indicate the temporal decrease of the FNPP1-derived ^{134}Cs concentration at the sampling area ($38\text{--}41^\circ\text{N}/146\text{--}147^\circ\text{E}$) in the western subarctic area.

Because our sampling station in June 2017 is about 500 km away from the stations in the previous studies (Fig. 1), we should consider the spatial variation when we compare the vertical profiles in June 2017 to those in the past. In September 2012, the spatial variation in decay-corrected ^{134}Cs concentration at the surface was small ($2.25\text{--}2.62 \text{ Bq m}^{-3}$) between 146 and 153°E (the squares with a dot in Fig. 1). Also, the decay-corrected concentrations at the surface in July and October 2014 were almost equal between 146 and 150°E (the inverted triangle and inverted triangle with a dot in Fig. 1, respectively). These results suggest a small spatial variation in decay-corrected ^{134}Cs concentration at the surface between our sampling station in 2017 and those in the previous studies. Therefore, we concluded that the decay-corrected ^{134}Cs in the surface mixed layer above 200 m depth in the western subarctic area decreased from $0.90\text{--}1.47 \text{ Bq m}^{-3}$ in July 2014 to $0.43\text{--}1.19 \text{ Bq m}^{-3}$ in June 2017 significantly (Fig. 4a).

The temporal change in the penetration depth of ^{134}Cs is not clear because the detection limits of the ^{134}Cs data in Fig. 4a are different. However, the small temporal variation in ^{137}Cs concentration in layers deeper than 400 m depth between 2012 and 2017 (Fig. 4b) implies that the FNPP1-derived ^{134}Cs have not penetrated to 400 m depth by June 2017. As seen in the vertical profile in February 2012, the surface mixed layer deepens to about 200 m depth in the midwinter in the western subarctic area. As a result, the FNPP1-derived radiocesium penetrates to the bottom of the surface mixed layer. However, the pycnocline between the surface mixed and deeper layers restricts the deeper penetration. In addition, no mode water transports the FNPP1-derived radiocesium to the subsurface layer below about 200 m depth in the western subarctic area. Thereby, the penetration depth and its temporal change in the western subarctic area have been shallower and smaller than those in the western subtropical area, respectively. The small temporal change in the penetration depth implies that the dilution of the FNPP1-derived radiocesium in the surface mixed layer above about 200 m depth in the western subarctic area has been primarily caused by the horizontal water mixing rather than the vertical mixing.

Changes in the vertical inventory

The vertical water-column inventory (or vertical-accumulated activity per square meter) of the decay-corrected ^{134}Cs activity concentration from the surface (0 m) to 800 m depth was calculated from the vertical profiles shown in Fig. 4a using a simple trapezoid method. The vertical inventory (Bq m^{-2}) is identical to an area surrounded by the lines of the ^{134}Cs concentration and zero (below detection level) in the figure. The vertical inventory decreased exponentially from $7459 \pm 239 \text{ Bq m}^{-2}$ in 2011 to $283 \pm 45 \text{ Bq m}^{-2}$ in 2014 (Fig. 5). The half-valued period for this decrease was calculated to be 227 days. If this exponential decrease had continued to 2017, the vertical inventory would have been about 10 Bq m^{-2} in 2017. However, a much larger vertical inventory, $186 \pm 45 \text{ Bq m}^{-2}$ was observed in June 2017, which suggests additional sources of the FNPP1-derived ^{134}Cs in the sampling area between 2014 and 2017. At stations closed to the FNPP1, ^{134}Cs activity concentration at the sea surface ranged from 10 to 100 Bq m^{-3} between 2014 and 2017 [11]. These concentrations near the FNPP1 were 10–100 times higher than those in our observational area (Fig. 4a). Although TEPCO denies any leakage of the radioactive water from the FNPP1 during that period, the higher concentrations could be explained by the continuous discharge of the contaminated water. However, these high concentration water at the stations near the FNPP1 probably cannot be the additional source at our sampling station about 1000 km away from the FNPP1 (Fig. 1).

Fig. 5 The temporal change in vertical water-column inventory of decay-corrected ^{134}Cs (Bq m^{-2}) between June 2011 and June 2017. The symbols are the same as those in Fig. 1 (the new data in 2017 in this work are indicated by the circle). The inventory in October 2012 was calculated using the data in September and October 2012. The inventories are decay-corrected to the date of the FNPP1 accident. The error bar at each station was calculated from the standard deviations of the data at each station (Fig. 4a)

The second candidate for the additional source of ^{134}Cs is the westward transport of the high- ^{134}Cs water mass into the western subarctic area. The main body of the high- ^{134}Cs water mass circulated along with the anticlockwise subarctic gyre current in the northern North Pacific. As mentioned above, that reached the eastern subarctic area in 2015 [16] and then the Bering Sea in 2017 [17]. If the forefront of the water mass had reached the western subarctic area by June 2017, that could be the additional source at our sampling station. In the eastern subarctic area, the arrival of the water mass in 2015 resulted in significant increases in the decay-corrected ^{134}Cs concentration and vertical inventory [16]. The concentration and vertical inventory in the western subarctic area, however, did not increase between 2014 and 2017 (Figs. 4a, 5). That suggests that the main body of the high- ^{134}Cs water mass had not reached the western subarctic area by summer 2017.

The North Pacific subarctic gyre consists of two anticlockwise circulations, the western and eastern gyres. The western gyre current circulates within the western subarctic area between 140°E and 180° approximately in a time scale of several years. That is shorter than the time scale of the whole (western and eastern) subarctic gyre circulation, about 10 years, which was suggested by the transport of the FNPP1-derived ^{134}Cs as discussed above [15–17]. Therefore, some portions of the high-concentration water mass probably circulated in the western subarctic area along with the anticlockwise western gyre current and returned our sampling area in the western margin of the gyre within several years after the FNPP1 accident. In the southern Okhotsk Sea, the FNPP1-derived ^{134}Cs concentration and inventory increased between 2013 and 2017 [32]. This increase in the Okhotsk Sea adjacent to the western subarctic area (Fig. 1) also suggests the return of the FNPP1-derived ^{134}Cs to the western margin of the western subarctic area and its consequent transport into the Okhotsk Sea by 2017. Therefore, we concluded that the smaller decrease in ^{134}Cs concentration than expected at our observational station in 2017 was probably derived from the return of some portions (not the main body) of the high- ^{134}Cs water mass in the western subarctic area about 6 years after the FNPP1 accident.

Conclusions

The radiocesium derived from the FNPP1 accident in 2011 was still observed in the surface mixed layer above about 200 m depth in the western subarctic area in June 2017, about 6 years after the accident. The decay-corrected activity concentration of the FNPP1-derived radiocesium decreased from $0.90\text{--}1.47 \text{ Bq m}^{-3}$ in 2014 to $0.43\text{--}1.19 \text{ Bq m}^{-3}$ in 2017 although its penetration depth did not change significantly. That implies that the FNPP1-derived radiocesium in the

subarctic area was diluted due to the horizontal water mixing rather than the vertical mixing. The vertical inventory of the decay-corrected FNPP1-derived radiocesium also decreased from $283 \pm 45 \text{ Bq m}^{-2}$ in 2014 to $186 \pm 46 \text{ Bq m}^{-2}$ in 2017. However, the inventory in 2017 was one-order larger than that expected by the exponential decrease of the inventory between 2011 and 2014, which indicates additional sources of the FNPP1-derived radiocesium in the western subarctic area in 2017. We concluded that the additional source was derived from the return of some portion of the high-concentration water mass to the western subarctic area about 6 years after the accident. The main body of the high-concentration water mass, however, had been circulating along with the whole (western and eastern) subarctic gyre current and had not returned yet to the western subarctic area by summer 2017.
