Abstract This review represents the first attempt to define the origins of the major P450-containing pathways in plants. Comparative genomics with five complete P450 gene sets from *Chlamydomonas reinhardtii* with 39 sequences, *Physcomitrella patens* (moss) with 71 sequences, rice with 356 sequences, Arabidopsis with 246 sequences and Populus with 312 sequences is used to estimate how old each gene family is and to identify the most ancient P450s and their pathways. The pathways included are the phenylpropanoid and lignin pathways, the gibberellin pathway, the oxylipin/jasmonate pathway, the basic flavonoid pathway, the brassinosteroid pathway, the abscisic acid pathway and the cutin synthesis pathway. An effort is made to identify at least some examples of P450s that have emerged at many different levels of the evolutionary bush, from the base to the tips.

Keywords Cytochrome P450 · Pathway · Evolution · Plants · Moss · Populus

Introduction

Genome sequencing projects are rapidly expanding outward from the first model organisms in each Kingdom of life. From the first bacterial genome in 1995, there are now more than 360 complete bacterial genomes and more than 25 archaeal genomes (National Microbial Pathogen Data Resource Center 2005). The Joint Genome Institute sequenced 15 bacterial genomes in October 2000 (Microbial Month) to demonstrate a sequencing rate of one bacterial genome every working day and a half. The Venter Institute has announced plans to sequence 100 marine microbial genomes in one year (Venter Institute marine microbial genome project 2006) and this has been increased to 150 bacterial and 5 archaeal genomes (Gordon et al. 2006). Fungal genomes are also accumulating with the goal of comparative genomics of highly similar genomes, as in six species of *Saccharomyces*: *S. cerevisiae*, *S. mikatae*, *S. kudriavzevii*, *S. bayanus*, *S. castellii*, and *S. kluyveri* (Kellis et al. 2003; Cliften et al. 2003). Additional disparate fungal genomes are being sequenced to cover a broader phylogenetic range. The National Human Genome Research Institute NHGRI is funding three fungal genome initiatives to sequence 18 species (Fungal Genome Sequencing 2006), of which 16 are already assembled and released as of June 2006 (Government list of genome projects 2006;

Fungal Genome Initiative 2006). Numerous non-fungal eukaryotic microbes, mostly pathogens like *Giardia* (GiardiaDB 2006), *Plasmodium* (PlasmoDB 2006), *Trypanosoma* (El-Sayed et al. 2005) and *Toxoplasma* (ToxoDB 2006) are completed or well underway.

Animals have larger genomes and are more difficult to assemble due to the numerous highly repeated sequences that they contain. There has been emphasis on mammals, with human leading the way, followed by mouse, rat, chimp, dog, cow and pig. Many other mammals will follow. Already (June 2006), there are 41 million sequence traces for the laboratory opossum *Monodelphis domestica*, 29 million for the duck-billed platypus *Ornithorhynchus anatinus*, 12 million for purple sea urchin *Strongylocentrotus purpuratus*, 10 million for African savanna elephant *Loxodonta africana*, and 9 million for the nine-banded armadillo *Dasypus novemcinctus* at the NCBI Trace Archive (Ensembl Trace Repository Statistics 2006) Rabbit, European common shrew and the Lesser hedgehog or tenrec have two-fold genome sequence coverage completed. Two species of pufferfish are sequenced and zebrafish assembly *Zv5* contains 1.63 Gb of about 1.8 Gb in the genome (90%). Purple sea urchin has been sequenced and is assembled at the UCSC genome browser (UCSC Genome Browser 2006) and at Baylor College of Medicine (“Baylor College of Medicine sea urchin BLAST server” 2006). Two species of tunicate or sea squirts are now available as well as 12 species of *Drosophila* (Assembly/Alignment/Annotation of twelve related *Drosophila* species, two species of mosquitos, two species of roundworms, and simpler animals like hydra. The NHGRI maintains a web list of proposed sequencing projects, their white papers and current status (Government list of genome projects 2006).

Information on plant genomes has been more slowly collected. Arabidopsis and two strains of rice have been sequenced, with Arabidopsis and the japonica rice strain reaching a highly polished “gold standard” of completion and assembly (Haas et al. 2005; International Rice Genome Sequencing Project 2005). These genomes are now moving into the post-genomic or functional genomic era focusing on annotation of the 20–25 thousand genes that exist in these species (Bevan

and Walsh 2005; NSF 2006; Ohyanagi 2006). Recently, *Populus trichocarpa* (black cottonwood) became the first tree to have its genome sequenced (Joint Genome Institute 2006). At the other end of the plant spectrum, the moss *Physcomitrella patens* is being sequenced with over 7 million traces in the Trace Archive (“Why sequence *Physcomitrella patens*?” 2006). Sequence data on Gemmiferous spike moss (*Selaginella moellendorffii*) is now released to the Trace Archive with 1.9 million reads or about 10 × coverage for this small plant genome (Community Sequencing Project plans 2005). These genomes should make it possible to follow plant evolution by genome comparison from *Chlamydomonas reinhardtii* (Joint Genome Institute 2006) to an angiosperm tree. Even so, there will be significant gaps in this evolutionary progression, since some plant genomes are prohibitively large for complete sequencing. Ferns have a genome size of about 160 Gb compared to humans at a paltry 3 Gb. Even with these large genomes, EST sampling, as has already been done with pine and spruce (NSF Genomics of Loblolly Pine Embryogenesis Project 2006; Lorenz et al. 2006; Pavy et al. 2005), can provide some measure of the range of transcripts expressed in vivo. In fact, 20 of the top 50 organisms listed in the ESTdb at Genbank are plants (“ESTdb release 012006” 2006).

Plants adaptation to land, the development of water barriers, vascular systems, and lignin for structural support, and their production of long range signaling mechanisms for defense responses, flower color and fragrance for attraction of pollinators, defense toxins to repel herbivores and pathogens have all required new biochemistries and novel pathways. Due to the usefulness of oxygen in building complex molecules, cytochrome P450 enzymes are often found in these pathways. In fact they are extremely abundant, comprising about 1% of the genes in some plant genomes such as Arabidopsis, rice and poplar. At least a part of plant evolution can be tied to the appearance of these novel pathways and in turn, to the emergence of P450s that are essential to these pathways. This article compares whole genome sets of cytochrome P450s or CYP genes from the moss to rice, Arabidopsis and

poplar to begin the process of identifying the origins of the P450s and thus the pathways themselves. The Cytochrome P450 Homepage (“Cytochrome P450 homepage” 2006) has information on the complete gene sets.

Chlamydomonas as a beginning point

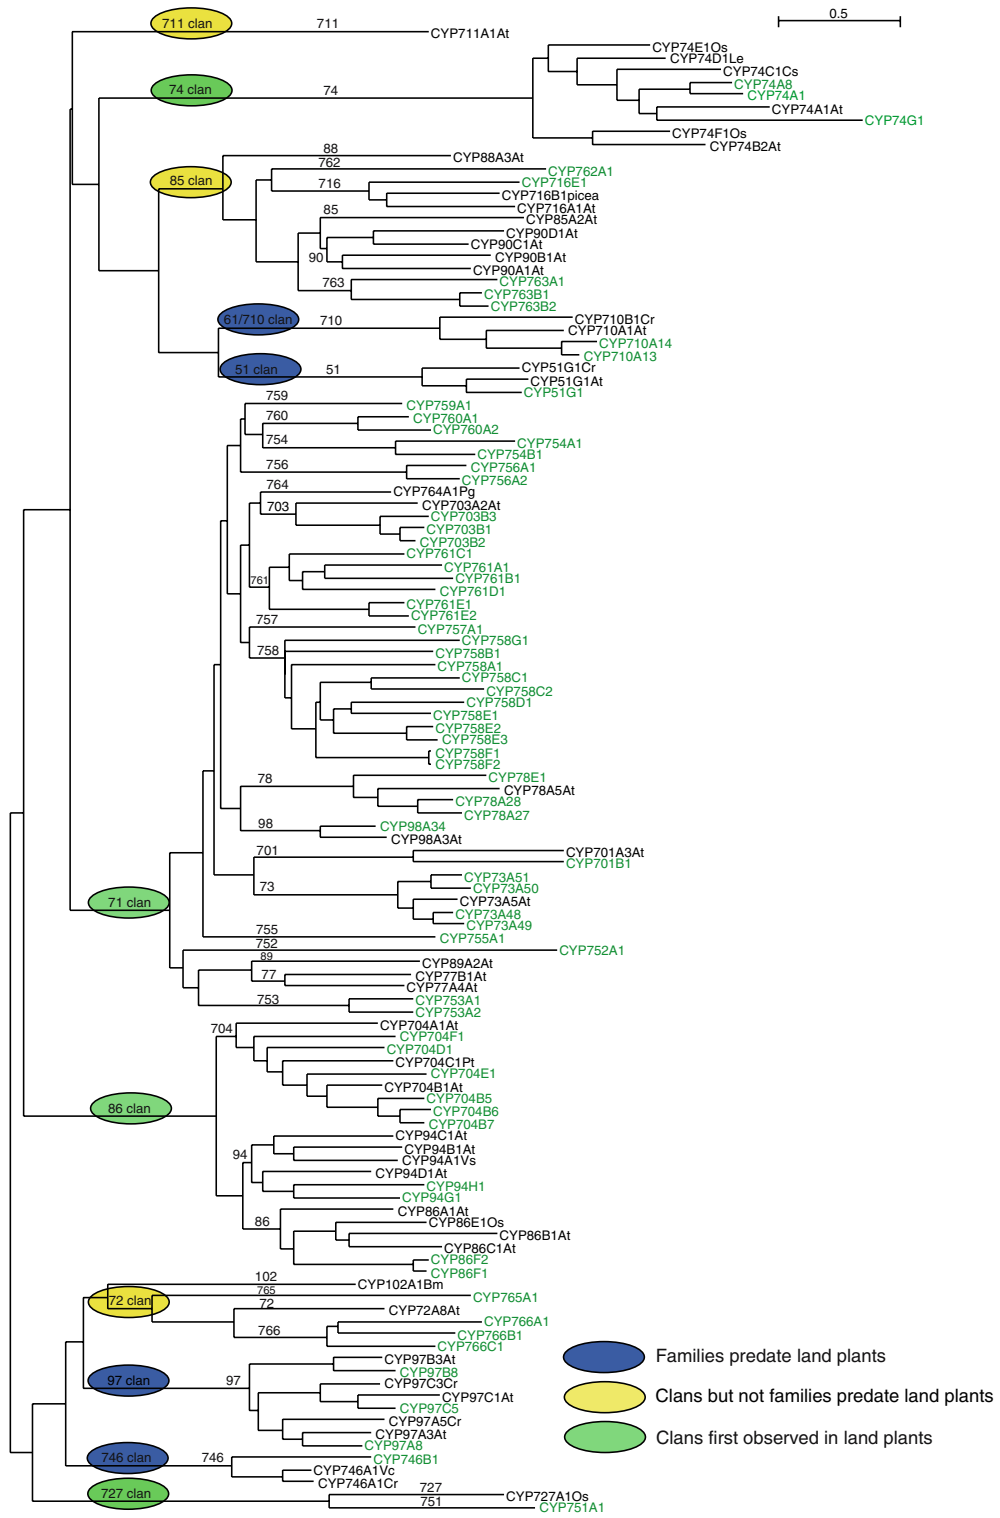

The green alga *Chlamydomonas* has as long an evolutionary history as any living member of the Viridiplantae or green plants. However, it has retained a single-celled, aquatic lifestyle and is considered to be a good model of the clade founder. Analysis of the CYP genes in *Chlamydomonas reinhardtii* finds 39 genes (“*Chlamydomonas reinhardtii* cytochrome P450s” 2006). These 39 genes are distributed in 21 families according to the CYP nomenclature. Only four of these families had been seen previously. CYP51, which is the sterol 14 α -demethylase found in most eukaryotes, exists in the green alga as expected. CYP97 is found in *Chlamydomonas*, pine, rice, *Arabidopsis* and poplar with three orthologous subfamilies in each species. Notably, each subfamily has only one member suggesting a unique highly conserved function for each. Of the individual genes within this family CYP97C1 of *Arabidopsis* is a carotenoid ϵ -hydroxylase involved in the formation of lutein from α -carotene (Tian et al. 2004). CYP97A3 is a carotenoid β -hydroxylase (Kim and DellaPenna 2006). CYP97B also is likely to metabolize carotenoids, a function that was present in algae before plants came onto the land. Another subfamily CYP97E is found in the diatoms *Skeletonema costatum* and *Thaliossira pseudonana*. CYP710 exists in *Arabidopsis* and rice as multiple genes, and in poplar as a single gene in the CYP710A subfamily. *Chlamydomonas* has only one gene CYP710B1. The different subfamily designation is due to sequence divergence, but this is the probable ortholog to the CYP710A sequences. Comparison to other eukaryotic P450s shows that CYP710 belongs to the CYP61 clan found in the ergosterol pathway of all fungi. In fact some fungi only have two CYPs, CYP51 and CYP61, with CYP61 serving as a C-22 sterol desaturase that acts after CYP51 in ergosterol biosynthesis. CYP710A1 in

Arabidopsis, is also a C-22 sterol desaturase acting on β -sitosterol (Morikawa et al. 2006). The last conserved family in *Chlamydomonas* is CYP55, a fungal P450 family. CYP55 is nitric oxide reductase in some fungi (Kizawa et al. 1991). CYP55 is unique among eukaryotic P450s in that it is a soluble P450 not associated with any membrane or subcellular structures. Sequence comparisons to other CYPs show a high similarity to a bacterial family CYP105 from *Streptomyces* and this probably represents the origin of this family via lateral gene transfer to fungi. Since CYP55 is not seen in land plants, it is likely to have been acquired in algae from fungi after land plants diverged from their common ancestor. The algal CYP55B1 shares one intron-exon boundary with CYP55A6 of *Neurospora crassa*, so it had to share a common ancestor with the fungal gene and not the CYP105s of bacteria.

All plant CYP families except CYP51, CYP97, CYP710 and CYP746 are new in land plants

Before the moss genome was sequenced, all known plant P450s fell into 63 families (Nelson et al. 2004). Annotation of moss adds 16 new families that are not radically different from other plant CYPs. All 71 moss CYPs except one belong in the 10 existing plant CYP clans (Fig. 1). One sequence, which is ambiguous and sorts with the CYP72 clan or the CYP97 clan, has been given its own clan. This sequence, CYP746B1, is 51% identical to the *Chlamydomonas* sequence CYP746A1.

All plant clans except CYP711 are found in moss. The fact that several CYP711-like sequences are seen in *Chlamydomonas* (CYP743 and CYP744), suggest that these genes may have been lost in moss. This implies that all the major innovations of sequence at the CYP clan level were already found in moss but not in algae. There must have been a burst of evolution in the interval between emergence on land and arrival at the moss stage of complexity. During this period the CYP71, CYP74, CYP86 and CYP727 clans evolved. Among present-day angiosperms, the CYP71 clan is by far the largest, with one-third to one-half of the plant P450s in any one

◀ **Fig. 1** A neighbor-joining tree of 119 plant P450 sequences including all 71 from moss. CYP102A1 from *Bacillus megaterium* is included for the PHYLIP neighbor-joining algorithm to choose as an outgroup. The sequence alignment was created using ClustalW. Moss P450s are labeled in green. Non-moss sequences have initials after the name. At, *Arabidopsis thaliana*; Cs, *Cucumis sativa*; Cr, *Chlamydomonas reinhardtii*; Le, *Lycopersicon esculentum*; Pg, *Panax ginseng*; Os, *Oryza sativa*; Picea glauca, Pt, *Pinus taeda*; Vc, *Volvox carteri*; Vs, *Vicia sativa*. Families existing in green algae and land plants are CYP51, CYP97, CYP710 and CYP746 (blue ovals). These families and clans predate land plants. The additional plant CYP clans found in algae are CYP72, CYP85 and CYP711 (yellow ovals). These clans existed before land plants, but no CYP families in them are shared between land plants and algae. The CYP clans CYP71, CYP74, CYP86 and CYP727 (green ovals) are only found in land plants. The 120 sequences and the alignment used are posted at <http://www.drnelson.utmem.edu/mosstreeseqs.html> and <http://www.drnelson.utmem.edu/mosstreealn.html>

genome. The CYP71 clan is also the largest clan in moss with 41 sequences. This fact suggests that CYP71 was one of the earliest plant CYP clans, aside from the solo-function CYPs like CYP51, CYP97A, CYP97B, CYP97C, and CYP710. Even these genes are showing recent signs of expansion, though it may only be for expression of the same function in different tissues as seen with CYP710A1, A2, A3 and A4 in *Arabidopsis*. These four highly similar CYP710 genes occur in two clusters of two genes each. According to the P450 tissue profiling data at the Functional Genomics of *Arabidopsis* P450s site (“Tissue profiling expression data for *Arabidopsis* P450 genes” 2006), CYP710A1 is more highly expressed in root than in other tissues, while CYP710A2 is more evenly expressed in shoot, root and stem. However, Poplar has only one CYP710 gene, so a single function may still be the norm for CYP710, with a recent series of duplications in *Arabidopsis*. The existence of CYP51G1 (CYP51A2) and CYP51G2 (CYP51A1) in *Arabidopsis* suggested two CYP51 genes had evolved in this species, but recently, the CYP51G2 sequence was shown to be an expressed pseudogene and thus non-functional (Kim et al. 2005). Rice has eight full length CYP51H genes and these presumably have taken on some new functions. *Arabidopsis* has only one CYP711 gene, but Poplar has two (due to a very recent genome duplication) and rice has five. The single CYP711 gene in *Arabidopsis* suggests a

single conserved function. Recently, CYP711 has been identified as MAX1, a gene making a carotenoid-derived branch-inhibiting hormone (Booker et al. 2005). Other than matches to CYP711 members, CYP711 has its best BLAST hits to CYP5, thromboxane A2 synthase in vertebrates. CYP5 is a member of the CYP3 clan in animals that includes CYP3 and CYP5 in vertebrates and CYP6 and CYP9 in insects. CYP711 may share a common ancestor with the CYP3 clan.

Emergence of ancient P450-containing pathways

Moss has 71 CYPs (Fig. 1) with more than half in the CYP71 clan, sometimes referred to as the plant group A P450s (center of Fig. 1). This expansion of the CYP71 clan sequences is noted in other plant genomes and seems to have begun early in land plants (Durst and Nelson 1995). However, most of the plant families in the CYP71 clan are not the same in moss and angiosperms or pine. The five CYP71 clan families that are clearly present in moss and other plants including *Arabidopsis*, rice and pine are CYP73, CYP78, CYP98, CYP701 and CYP703. Two of these CYPs have well defined roles in the phenylpropanoid pathway: CYP73 is cinnamate 4-hydroxylase (C4H) in the core pathway (Batard et al. 1997), and CYP98 is coumaryl shikimic acid 3'-hydroxylase (C3H), in the branch pathway forming G-lignols (Franke et al. 2002; Humphreys and Chapple 2002). Moss which is not a woody plant lacks CYP84 (F5H) for making S-lignol monomers in higher plants (Osakabe et al. 1999). The absence of this gene in the moss genome suggests that the evolution of the lignin synthetic pathway is only partly complete in the moss genome, or less likely, that other enzymes fulfill this role in moss. CYP701 is another interesting case. Another interesting example of the limited pathway evolution in moss is CYP701 that is the ent-kaurene oxidase enzyme at the beginning of the gibberellin biosynthetic pathway (Helliwell et al. 1999). In the complete pathway found in higher plants, there is a kaurenoic acid oxidase CYP88, that forms GA₁₂ from ent-kaurenoic acid (Winkler and Helentjaris 1995; Helliwell et al. 2001)

but this enzyme is missing in moss. Again, moss is showing the first part of a pathway for molecules critical for higher plants.

Gibberellins have been shown to affect sex determination in some fern gametophytes in schizaeaceous taxa (*Anemia*, *Lygodium*) but not in non-schizaeaceous taxa (*Ceratopteris*, *Dryopteris*, *Polypodium*) (Warne and Hickok 2005). GA_9 methyl ester has been found in the fern *Lygodium japonicum*, where it acts as an antheridiogen (Yamane et al. 1979). The GA_9 structure is similar to the GA_{12} structure and probably derived from GA_{12} . That would mean that CYP701 and CYP88 would be present in *Lygodium* and probably other schizaeaceous fern taxa. Therefore, CYP88 must have been present in the last common ancestor of ferns and higher plants. The evolution of CYP88 is a prerequisite for gibberellin GA_{12} biosynthesis in green plants, but not by the independent pathway of *Gibberella fujikuroi* (Malonek et al. 2005). As such CYP88 becomes a clade marker or synapomorphy for this important plant signaling precursor.

CYP78, also in the CYP71 clan, is not as well characterized except for CYP78A11 which is the *Plastochron1* gene in rice that controls the timing of lateral organ formation from the apical meristem (Miyoshi et al. 2004) and CYP78A1 in *Zea mays* which is a lauric acid ω -hydroxylase expressed in developing inflorescences (Imaishi et al. 2000). The pathway for these important developmental roles have not yet been determined, but the existence of related genes in moss suggests that it is an ancient plant pathway possibly involving fatty acid hydroxylations. Another family within this clan, CYP703, is also expressed in flowers and capable of hydroxylating fatty acids (Imaishi et al. 1999). The cellular function of CYP703 is not known, though it is plainly conserved in moss (Fig. 1).

The CYP72 clan has at least two members CYP734A1 and CYP72C1 that inactivate brassinolide (Turk et al. 2005). One might expect parallel evolution of these sequences with the CYP85 and CYP90 families that are involved in synthesizing brassinolide (Kim et al. 2005; Nomura et al. 2005; Bancos et al. 2002). Although there are no clear CYP72 or CYP734 family sequences in moss, three moss sequences in the

CYP766 family cluster with CYP72A8. These three sequences are placed in the CYP72 clan. Recently, a third CYP72 clan member, CYP714D1 has been identified as EU11 (elongation of uppermost internode 1) in rice and suggested to have a role in inactivating GA signalling in the growing rice plant. A mutation in this gene led to excessive levels of an active form of GA in the uppermost internode (Luo et al. 2006). This result has linked the CYP72 clan to inactivation of both brassinosteroids and gibberellins. Blast searches in fern ESTs identified a sequence 45% identical to CYP72A18 over 276 amino acids (CV735871 *Ceratopteris*) showing that the CYP72 family probably exists in ferns. The CYP72 clan is diverse, with eight established families and two new families in moss, CYP765 and CYP766. Ferns have at least one more EST with 53% identity to CYP709C9 (BP914549 *Adiantum capillus-veneris*) indicating the presence of at least two known CYP72 clan families in ferns with probable precursors in the last common ancestor of ferns and moss.

The CYP74 family is important in modifying unsaturated fatty acid hydroperoxides derived from linoleic or α -linolenic acids and includes at least three classes of enzymes, allene oxide synthases, hydroperoxide lyases and divinyl ether synthases. The CYP74A subfamily contains the allene oxide synthases in the oxylipin pathway to jasmonic acid and methyl jasmonate, that act as signals in plant defense pathways. These products have been likened to the arachidonic acid metabolites found in animals (Howe and Schillmiller 2002). The CYP74A subfamily first appears in phylogenetic trees in moss and has related sequences in gymnosperms (*Picea glauca*), monocots and dicots. The CYP74B subfamily includes hydroperoxide lyases. However, as one moves farther back in phylogeny to rice and moss, the number of CYP74 subfamilies increases as the sequences diverge, and it becomes less clear which subfamilies encode hydroperoxide lyases and which encode divinyl ether synthases. Of the three members in the CYP74 clan of moss, one has been identified as allene oxide synthase (CYP74A1 GenBank AJ316566 and potentially CYP74A8) and one as hydroperoxide lyase CYP74G1 GenBank AJ316567. The CYP74

genes do not use molecular oxygen in their mechanism, so they have lost conservation of the I-helix oxygen binding region. This and other changes gives them a very long branch on the usual phylogenetic tree of plant P450s (Fig. 1).

The CYP85 clan has several functions, one is the previously mentioned CYP88 kaurenoic acid oxidase (Winkler and Helentjaris 1995; Helliwell et al. 2001) that is absent from moss and acts after CYP701 in the gibberellin pathway in higher plants. Other CYP85 clan members are involved in brassinosteroid metabolism. CYP85 and CYP90 members are required to make these particular growth inducing compounds (Kim et al. 2005; Nomura et al. 2005; Bancos et al. 2002). While these two families are not recognized as separate families in moss, the CYP763 family is closely related and probably shares a common ancestral gene with CYP85 and CYP90. It is not yet clear if moss produces brassinosteroids. BLAST searches for CYP genes in the EST database show a strong CYP90A-related sequence in the fern *Adiantum capillus-veneris* (BP916923, 48% to 90A1, 37% to 90B1). This provides evidence that brassinosteroid synthesis may exist in ferns with emergence of a clear precursor to the CYP90A subfamily.

The CYP86 clan has three families, CYP86, CYP94 and CYP704, in moss that are seen in Arabidopsis, poplar, pine and rice (Nelson et al. 2004). The functions of these families appear to have been established very early in plant evolution with land plants needing to protect themselves against water loss. This is accomplished by forming a waxy water barrier referred to as the cuticle. The monomers of cutins that make up this barrier are ω -hydroxylated fatty acids with several CYP86 and CYP94 enzymes mediating hydroxylations on these fatty acids at the ω position (Wellesen et al. 2001; Xiao et al. 2004; Duan and Schuler 2005). It is notable that CYP96, a fourth well known family in the CYP86 clan, is absent in moss but present in monocots and dicots. CYP96 seems to be a younger CYP family.

CYP727 was first identified in rice and has since been sequenced in barley, wheat and poplar. No CYP727 family is evident in moss, but there is a related CYP751A1 sequence that is a probable ortholog of this family. CYP727A1 is represented

by a single gene in rice, two exist in poplar, as the result of a recent genome duplication, while none are found in Arabidopsis. These are probably solo-function genes as seen with CYP51G.

More recent P450-containing pathways appearing in gymnosperms or angiosperms

Present evidence concerning P450s in ferns and gymnosperms is incomplete. EST projects in these organisms do provide some information, but the absence of a specific CYP gene in these species cannot yet be confirmed because complete gene sets are not defined. Rice, Arabidopsis and poplar do provide complete CYP gene sets from one monocot and two dicots. The predicted origin of a CYP family in angiosperms may be pushed farther back as more sequence data accumulates for gymnosperms, ferns and the gemmiferous spike moss (*Selaginella moellendorffii*).

Searches of coniferales in the nr and ESTdb sections of GenBank with CYP96 sequences show the best BLAST hits are to CYP86 or CYP94, but not CYP96. Additional searches in filicales (ferns) found best hits that matched the CYP86 or CYP704B sequences, but not CYP96. This suggests that CYP96 may be absent from ferns and conifers because it is an angiosperm-specific family. This family is quite abundant in rice, Arabidopsis and poplar.

Abscisic acid is a growth regulator/stress signal in plants that is largely associated with the prevention of water loss (“The abscisic acid site” 2006). The catabolism of abscisic acid is a P450-dependent 8'-hydroxylation catalyzed by members of the CYP707A subfamily (Nambara and Marion-Poll 2005; Saito et al. 2004; Kushiro et al. 2004). The CYP707 family is not seen in moss and BLAST searches of the nr or ESTdb sections at GenBank do not show any strong hits for coniferales. The best matches in conifers are in the CYP716 family, but these are seen in Arabidopsis, poplar and soybeans that also have a CYP707. Therefore, one is forced to conclude that CYP707 is an angiosperm-specific P450 family present in both monocots and dicots. An EST (CV005308.1) having about 70% identity to rice

CYP707A6 is found in *Persea americana* (avocado) that is in the Laurales group which predates the divergence of monocots and dicots.

Flavonoids are made in very complex pathways that utilize several P450s. Over 9000 flavonoid structures are known (Martens and Mithofer 2005). CYP75A is a flavonoid 3', 5'-hydroxylase and CYP75B is a flavonoid 3'-hydroxylase. Because the flavonoid 3', 5'-hydroxylase is missing in Rosaceae roses and their relatives cannot make blue pigments (de Vetten et al. 1999). Both of these P450s use dihydroflavonol as substrate which is made from flavanone by flavanone 3 β -hydroxylase. Flavanone is a substrate for two P450 proteins CYP93B (flavone synthase II, FSII) and CYP93C (isoflavone synthase, IFS). CYP93C produces isoflavone that can be modified by isoflavone-*O*-methyl transferase to make formononetin. Isoflavones made by IFS are almost exclusively found in legumes (Jung et al. 2000). Formononetin is then a substrate for CYP81E1 (isoflavone 2'-hydroxylase) (Akashi et al. 1997) and CYP81E9 (isoflavone 3'-hydroxylase) (Liu et al. 2003). Both CYP81E3 and CYP81E7 act later in this pathway on the way to maackiain and pisatin ("MetaCyc Pathway" 2006). None of these CYP75, CYP81 or CYP93 families are found in moss. However, CYP75A14 and CYP75B13 are found in pine. It is possible that some of these enzymes may have been lost in *Physcomitrella* but are still present in other mosses since some mosses do have flavonoids, but "more than 50% of bryophyte species examined do not contain detectable flavonoids." (Stafford 1991).

CYP93B and CYP93C are missing in rice, although there are some related sequences named CYP93F and CYP93G. It is not clear what their function is. The fact that the best BLAST hits in conifers to CYP93B are CYP75A and CYP75B sequences suggests that the CYP75 family is older and the CYP93 genes arose from CYP75 genes by duplication and divergence. It is likely that the CYP93B (FSII) and CYP93C (IFS) genes are dicot-specific genes since they do not appear to be in rice. In contrast to the limited distribution of isoflavones and CYP93C to the legumes, the CYP93B sequences are found in wider distribution in both rosids and asterids. CYP93B (FSII)

appears to be an older subfamily and CYP93C may have derived from it.

Ah, but the strawberries!

Some plant P450s (and probably the majority) are unique to the specific requirements and properties of individual plant families or possibly even a species. I have written about P450s and the individuality of species before, referring to polymorphisms in animals (Nelson 1999), but plants have three to five times as many P450s as animals, with the potential for some acting as taxon-specific enzymes. There are certainly P450s such as members of the CYP725 family involved in the taxol biosynthesis pathway of yew trees that make rare chemicals in a limited taxonomic range. There are at least 8 monooxygenation steps in the taxol pathway that are all probably encoded by CYP725 enzymes (Schoendorf et al. 2001). A BLAST search in GenBank with CYP725A1 showed 14 hits to *Taxus* species with expect values of 1e-146 or better. The next best hit is to *Picea sitchensis* AY779542 CYP716B1 at 1e-113. Another case of a unique biochemical pathway involving a P450 is vernolic acid biosynthesis in Euphorbiaceae species which is catalyzed by the CYP726A1 enzyme. Vernolic acid has also been found in Asteraceae species, but in these species it is made by a different $\Delta(12)$ -oleic acid desaturase-like enzyme that is not a P450 (Cahoon et al. 2002), so the CYP726 family is apparently unique to Euphorbia.

Finally, the flavor and aroma of strawberry fruits are dependent on more than 300 compounds, many of which are volatile chemicals. A recent review on the biochemistry of plant volatiles states that "more than 1000 low M_r organic compounds have been reported to be emitted from plants" (Dudareva et al. 2004). The major difference between the inedible wild strawberry (a diploid) and cultivated varieties (octoploid) is the presence of different terpene compounds. In the wild strawberry *Fragaria vesca*, pinene synthase (FvPINS) produces pinene that is hydroxylated to myrtenol by the CYP71AR1 P450 and acetylated to make myrtenyl acetate. In cultivated strawberries (*Fragaria* \times *ananassa*), the

pinene synthase gene FaPINS is defective, eliminating the P450 substrate pinene and production of myrtenol and myrtenyl acetate. Instead, a different terpene synthase (FaNES1) produces nerolidol and linalool (Aharoni et al. 2004). CYP71AR1 represents only one of 303 P450s presently named in the CYP71 family. Although it is not known what most of these enzymes do, it is likely that many of them are like the strawberry CYP71AR1, dedicated to unique functions in complex processes such as the production of fruit flavors and aromas. Interestingly, the very first cloned plant P450 was CYP71A1, a fruit ripening P450 from avocado (Bozak et al. 1990).

Conclusions

Plant cytochrome P450s can be divided into ancient genes that predate the emergence of land plants (CYP51, CYP97, CYP710, CYP746), and moderately old genes that were early innovations in evolution (CYP73, CYP78, CYP98, CYP701 and CYP703). Genes in all of these families are easily recognized in moss. There are also clade-specific genes for each level of plant evolution. Some are found only in gymnosperms and angiosperms (CYP75), or in the older Laurales (CYP707), a distant angiosperm group, but not further back. Some are limited to dicots and are missing in rice (CYP93B), while others are in more limited phylogenetic clades like yews (CYP725), legumes (CYP93C) and strawberries (CYP71AR). Following the phylogenetic distribution of these enzymes, it is possible to determine P450 families that mediate the primary core biochemistry of plants. The recent identification of functions for CYP97A3 (Kim and DellaPenna 2006), CYP97C1 (Tian et al. 2004), CYP710A1 (Morikawa et al. 2006) and CYP711A1 (Booker et al. 2005) continues the process of defining P450 roles in plants. Only the CYP727 and CYP746 clans remain without any known function. Considering the nature of evolution, only a few P450 genes will be in the conserved central pathways. The majority can be expected to be in specialized roles in secondary metabolism such as vinca alkaloid synthesis as in tabersonine 16-hydroxylase CYP71D12 (Schroder et al. 1999), secologanin synthase

CYP72A1 (Irmiler et al. 2000), and geraniol 10-hydroxylase CYP76B6 (Collu et al. 2001). The majority of members in the CYP71 family are probably engaged in secondary metabolism.

By definition, the eleven plant P450 clans have ancient beginnings because they are recognized as the deepest branching gene clades in plants. Each of these 11 must harbor at least one pathway that is ancient and conserved in plant biology. Some of these clans contain highly conserved solo-function genes like CYP51, the three subfamilies of CYP97, CYP710, CYP711, and probably CYP727 and CYP746, even if we do not yet know what those functions are. The CYP74 clan, like the CYP97 clan, has only one family, but more than one function, with the production of jasmonate in the oxylipin pathway being one major CYP74 contribution and production of hexenal and other C-6 volatiles being another. The CYP86 clan is heavily biased toward fatty acid ω -hydroxylases and is key to cuticle synthesis. The CYP85 clan catalyzes the synthesis of brassinosteroids, while some in the CYP72 clan destroy these important signaling molecules. However, the CYP72 clan is present in *Chlamydomonas* so the original function cannot be breakdown of brassinosteroids, which came later. The earlier role of the ancient CYP72 clan is not yet identified. The CYP71 clan catalyzes many reactions in the phenylpropanoid pathway. Because it is so large it is perhaps very old with five family members seen in moss. With members such as CYP701 in the gibberellin pathway, it is probable that the CYP71 clan has other basic roles to play. The goal of studying P450 evolution in plants will be to reconstruct the “tree of life” for the whole plant clade and assign approximate or at least relative dates of appearance and functions to each P450 family branch and subfamily branch down to the tips of the tree. This has been just the outline of a much larger program with much left to discover.
