matched precisely between the two abstracting researchers (100 % agreement, Cohen's $\kappa=1.00$). Of 542 potentially relevant published articles, 272 represented unique studies. Of these, we eliminated 151 (56 %) that did not measure a single cigarette or WTS session, 88 (32 %) that were not laboratory experiments, and 16 (6 %) that did not assess one of the substances of interest. The 17 remaining studies were eligible for meta-analysis. The 9 WTS studies quantified inhalation of smoke volume ($n=4$), nicotine ($n=6$), tar ($n=5$), and CO ($n=5$). The 8 cigarette studies quantified inhalation of smoke ($n=5$), nicotine ($n=7$), tar ($n=7$), and CO ($n=5$). Based upon summary estimates obtained, one WTS session exposed users to 125.6 times the smoke volume of a single cigarette (95 % Confidence Interval [CI]=64.1, 190.7). Compared with a single cigarette, one WTS session also exposed users to 2.25 (95 % CI=1.39, 3.51) times the nicotine, 25.3 (95 % CI=9.5, 49.0) times the tar, and 10.9 (95 % CI=4.2, 17.9) times the CO. There were no significant differences between studies utilizing data from human subjects compared with studies utilizing machine smoking protocols.

CONCLUSIONS: This meta-analysis demonstrates consistently higher exposures in a WTS session compared to smoking a single cigarette, with large variation in the relative exposures by toxicant type. Compared with one cigarette, one WTS session exposed users to about 125 times the smoke volume, 25 times the tar, 2 times the nicotine, and 11 times the CO. These results suggest that there are potential health concerns posed by WTS and that it should be monitored. The estimates provided here may be valuable for clinical education and media-based interventions to reduce WTS. An important limitation of this work is the fact that we examined *inhaled* toxicant as opposed to *in vivo* toxicant. Because studies examining *in vivo* toxicants are currently highly varied in their methodologies, it was not feasible to combine them with meta-analysis at this time. Another important caveat is that a single WTS session generally requires one hour, while smoking a cigarette generally requires about 11 min. Despite these limitations, however, these findings suggest that waterpipe tobacco users are exposed to high toxicant loads of which they may be unaware.

TAKING INITIATIVE: INTEGRATING DATA FROM A LIFESTYLE MODIFICATION PROGRAM INTO AN ELECTRONIC HEALTH RECORD, A USABILITY STUDY Jordan Yoder; Rebecca G. Mishuris; Devin Mann. Boston University Medical Center, Boston, MA. (*Tracking ID #2199308*)

BACKGROUND: The Goal-focused Online Access to Lifestyle Support (GOALS) program is an online adaptation of the markedly successful Diabetes Prevention Program that aims to curb the burden of diabetes through education, coaching, and lifestyle modification. The program incorporates physical activity tracking, diet reporting, and educational modules with personalized lifestyle coaching. The program has been adopted broadly, and has been shown to help patients lose weight and improve blood pressure control. Despite their successes, there is limited meaningful interface between providers and behavior modification programs such as GOALS. There is a particular void in the ability of electronic health records (EHRs) to integrate lifestyle modification data. To date, little is known about the preferences of providers concerning the type, amount, and location of behavior change data or regarding its optimal workflow interface with the EHR. We designed a qualitative study to characterize the preferences of providers concerning the integration of lifestyle modification data from patients in the GOALS program into a primary care EHR workflow.

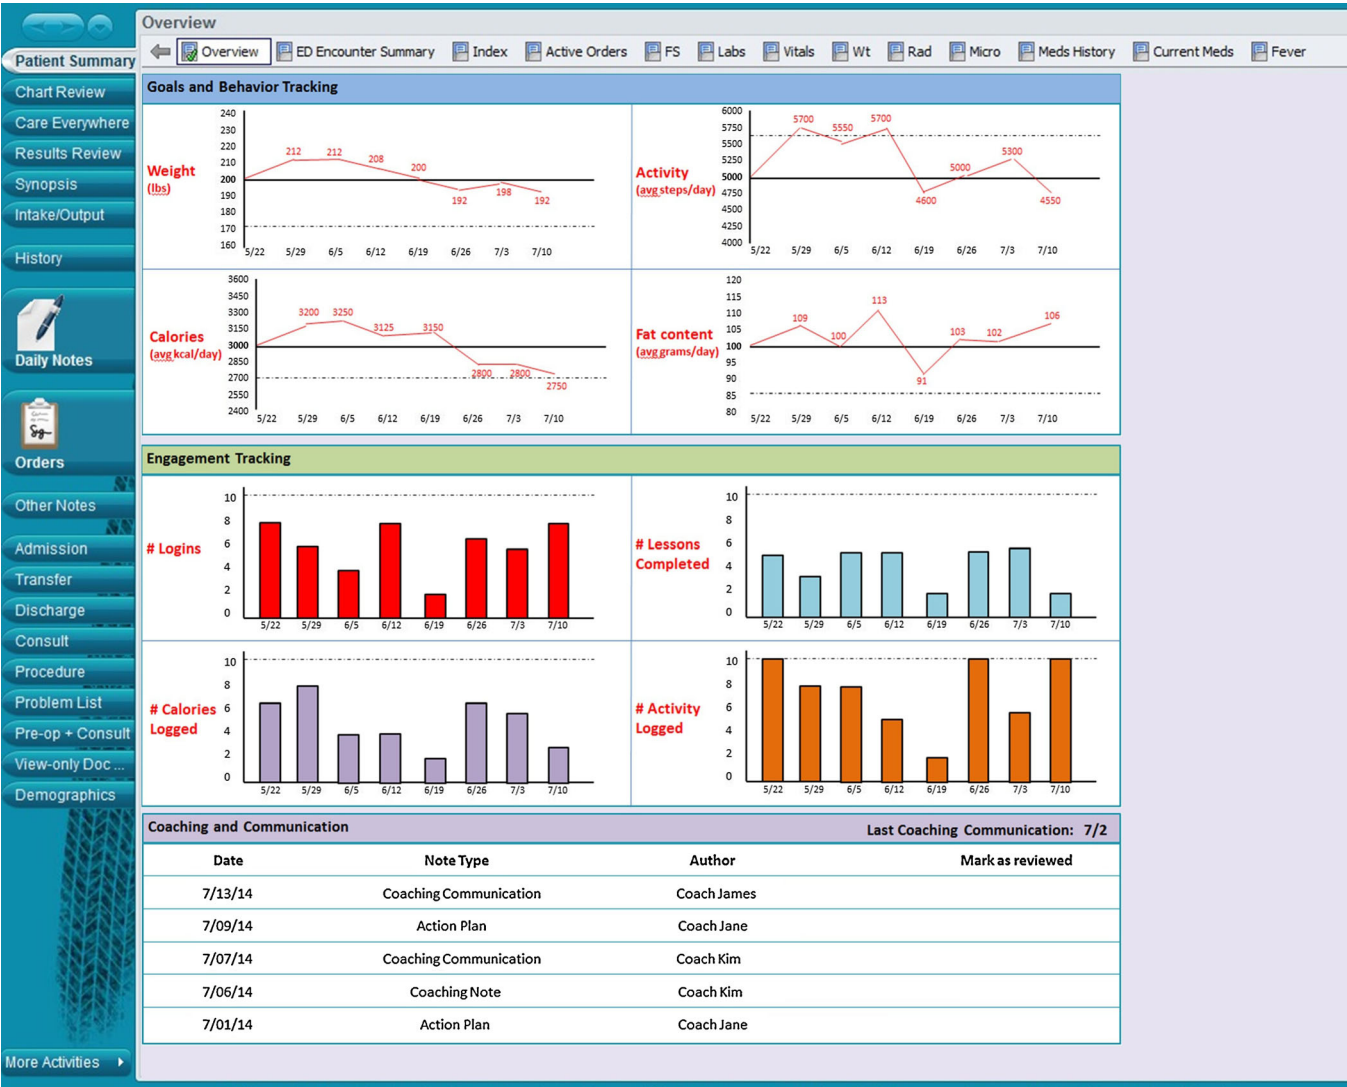

METHODS: Using a literature-based, semi-structured interview guide, we conducted in-depth interviews with primary care providers to inform the development of an EHR interface for the GOALS collaborative behavior change effort. Areas discussed included behavior change models, clinic workflow, and a draft of the potential EHR interface was displayed for providers to provide feedback. Interviews will be analyzed to identify workflow preferences which will then be used to develop a design document for prototype development.

RESULTS: To date, we have completed 9 of 10 planned provider interviews. All interviewees are faculty primary care providers in a large, academic medical center which uses a single electronic health record. Providers were recruited by email solicitation, with an effort to reach a cross-section of the providers in the General Internal Medicine and Family Medicine departments. All the providers to date are comfortable using the EHR with the patient in the room and counseling their patients on behavior change, however have limited ability to accomplish this during a clinic visit. The information most important to providers were patient engagement with the system and progress toward their goals. Providers preferred to receive reporting via the EHR only at the time of a clinic visit. When shown the EHR interface mockup, providers felt it met their needs in counseling patients in lifestyle modification programs, and provided suggestions for improvements such as the ability to overlay results graphs and print handouts to further reinforce goals with patients. They envisioned the data from the GOALS program being integrated into the clinician portion of the patient visit to review a patient's progress. The remainder of the interviews will be similarly analyzed to develop a consensus approach to

the design of the interface. We will employ an iterative design and rapid prototyping approach to develop the final interface design.

CONCLUSIONS: Lifestyle modification programs such as GOALS and the Diabetes Prevention Program have become an invaluable part of preventative medicine. Yet, they are limited by their relative inability to interface with the primary care providers. Similarly, with the rise of fitness trackers, mobile apps, and other digital health innovations, lifestyle modification data is becoming increasingly ubiquitous. However, there is no clear con-

sensus on how providers and EHRs could most effectively utilize these tools. We found that providers prefer high level data about patient engagement and progress toward goals which could be used to reinforce ideas presented by online coaches. With these findings, we intend to launch a pilot EHR interface in a large, academic primary care practice. If successful, such a program could provide a pathway to broad integration of behavior change information into primary care clinics' workflow, thereby more effectively promoting health and wellness and preventive care.

Mockup of EHR Interface to display lifestyle modification data from GOALS Program

TARGETED NEWSLETTERS TO PROMOTE CANCER CONTROL IN AFRICAN AMERICANS Monica Ferguson; Marilyn M. Schapira; E. P. Wileyto. University of Pennsylvania, Philadelphia, PA. (Tracking ID #2200659)

BACKGROUND: African Americans experience excess morbidity and mortality from breast and colon cancers. Decreased intake of fruits and vegetables and reduced rates of exercise have been associated with higher rates of these two cancers. In addition to having lower rates of cancer screening, African Americans are less likely than whites to adhere to national guidelines for fruit and vegetable intake and physical activity. Print materials have been used successfully to increase cancer screening, fruit and vegetable intake, and physical activity. Interventions using materials targeted towards African Americans to change these behaviors have had mixed results, perhaps because few of these interventions

have been developed using a theoretical framework that encompasses specific community social and ecological constructs. The purpose of this study was to evaluate a series of newsletters developed using the social ecological model of behavior change and designed to motivate African American patients to adopt healthy behaviors to decrease cancer risk.

METHODS: Content areas for the newsletters were informed by theoretically based communication strategies to promote cancer control. The development phase included evaluation of a broad range of potential newsletter content and formats in focus groups consisting of our target population (African-American patients from one urban medical practice, age 40–70, residents of 5 zip codes). Finalized newsletters were mailed to 500 patients once a month for 6 months. A prospective cohort study design was used to compare our intervention group ($n=500$) to a control group ($n=51$) from our target population who were not mailed the newsletters. Outcomes were evaluated by telephone survey and included reach, uptake, daily fruit and vegetable intake, and weekly exercise. We also developed and administered a 12-item knowledge survey and assessed behavioral intentions related to cancer screening and healthy behaviors. Chi square was used to

compare outcomes of interest. Continuous and count outcomes were tested using generalized linear models, with Gaussian family models for continuous outcomes and binomial or negative binomial family models for count outcomes. Hypotheses were then tested in regression models.

RESULTS: Out of 500 patients, one newsletter was undeliverable and one patient opted not receive the newsletters. We successfully contacted 310 of the remaining 498 patients who were mailed the newsletters (62 %). Of these, 60 % recalled receiving the newsletters, 53 % read the newsletters, and 24 % shared one or more newsletters with family or friends. The intervention group reported a higher intake of fruit per day than controls (1.77 servings vs 1.29), a finding that remained statistically significant after controlling for a higher proportion of women in the intervention group in negative binomial regression analysis ($p=0.03$, Table 1). However, no difference was found in vegetable intake, exercise, behavioral intentions regarding diet, exercise, and cancer screening or in knowledge scores.

CONCLUSIONS: We demonstrate high uptake of targeted newsletters that were designed using the social ecological model of behavioral change to address cancer disparities among an African American primary care population. Further, the intervention was associated with a higher reported intake of fruit, a lifestyle change that increases cancer control. Mailing a series of targeted newsletters is a feasible strategy to communicate important health information which may result in behavior change.

Impact of Targeted Newsletters on Reported Health Behaviors

	Mean (SD)		IRR or	95 %	p-value
	Intervention	Control	OR	CI	
Daily Servings of Fruit	1.77 (1.52)	1.29 (1.00)	1.35	1.03, 1.77	0.03
Daily Servings of Vegetables	1.83 (1.54)	1.73 (1.25)	1.06	0.84, 1.34	0.62
Weekly Exercise (Days per week)	3.23 (2.42)	3.01 (2.65)	1.13	0.90, 1.41	0.28

TEACHING WOMEN'S HEALTH TO ATTENDING PRIMARY CARE PROVIDERS—CURRICULUM IMPROVES CONFIDENCE OF FACULTY AND THEIR TRAINEES Ann R. Garmen⁴; Valerie Perel²; Lynn Bui³; Anne Dembitzer^{1,3}. ¹NY Harbor VA, New York, NY; ²NYU Department of Internal Medicine, New York, NY; ³New York University, New York, NY; ⁴New York University School of Medicine, New York, NY. (Tracking ID #2198062)

BACKGROUND: Access to and quality of routine women's healthcare is greatly increased when clinical educators are able and confident to deliver such care. However, many primary care providers feel uncomfortable both offering basic women's healthcare to their patients and teaching residents this material. Toward the end of improving patient care, we designed a curriculum to strengthen attendings' ability to offer women's healthcare to their own patients. We also measured the impact of this on their confidence teaching such topics to internal medicine residents as well as the impact on trainee comfort with managing women's health-related issues.

METHODS: We developed a women's health curriculum consisting of a series of 3 1-hour workshops (the breast exam and management of common breast complaints; the pelvic exam and management of vaginitis; and preconception counseling), simulations sessions (practice of breast and pelvic exams on models), and online resources. The curriculum was offered to all faculty who both practice and teach at our hospital's Adult Primary Care Clinic. Following each workshop participants were asked to provide Commitment to Change (CTC) statements through which they set personal behavior change goals regarding their practice and teaching. Participants also completed retrospective assessments to evaluate changes in their practice and teaching confidence and were surveyed several months later regarding their ability to incorporate the behavior changes they had previously listed on their CTCs. Residents were asked about their satisfaction with attendings' teaching of women's health-related topics and their own ability to manage women's health issues before and after the attendings received the curriculum.

RESULTS: Twenty-five attendings enrolled in our study (76 % female), and 100 % of the participants completed the retrospective survey. Following completion of the workshops, faculty reported improvements in both their ability to manage and their confidence teaching about all domains covered in the curriculum. For example, on a scale of 1 (not confident at all) to 4 (very confident), participants improved from 2.72 to 3.24 regarding their ability to perform a breast exam ($p=0.0002$, $d=0.654$) and from 2.56 to 3.2 regarding their ability to supervise residents performing a breast exam ($p=0.001$, $d=0.777$);

participants improved from 2.44 to 3.12 regarding their ability to perform a pelvic exam ($p=0.001$, $d=0.834$) and from 2.32 to 3 regarding their ability to supervise residents performing a pelvic exam ($p=0.0009$, $d=0.802$); and participants improved from 2.4 to 2.76 regarding both their own ability to begin preconception counseling as well as supervise residents about preconception counseling with female patients ($p=0.006$, $d=0.591$ and $p=0.001$, $d=0.591$ respectively). Sixty-seven percent of respondents reported that they had either fully or partially incorporated their CTC goals into their clinical practice and 67 % into their teaching practice. Ninety-eight percent of the residents ($n=128$) completed pre- and post-curriculum surveys; 33 % were PGY1, 34 % PGY2, and 34 % PGY3; 46 % were female. Residents reported a statistically significant improvement in management of their patients' pelvic complaints ($p=0.05$); there were trends toward improvement in satisfaction with attendings' ability to precept cases regarding breast complaints, pelvic complaints and contraception; and there were trends toward improvement in management of patients' breast complaints and contraception. Residents' confidence in managing their patients' breast health correlated with their satisfaction with attendings' ability to precept such cases ($r^2=0.442$, $p=0.003$).

CONCLUSIONS: Our women's health curriculum for attending physicians - which incorporated workshops, simulation-based skills practice, online resources and goal-setting—improved their confidence in both their own patient-care practice and teaching trainees. In addition, resident satisfaction with attending supervision as well as resident confidence providing women's healthcare trended toward improvement in multiple domains. This type of attending-focused intervention has the potential to improve access to high-quality care for women.

TECHNOLOGY ACCESS AND COMPUTER SKILLS IN ONLINE SELF-MANAGEMENT SUPPORT Reem M. Hanna²; Gary Fischer¹; Molly B. Conroy¹; Laurey R. Simkin-Silverman¹; Rachel Hess¹; Kathleen M. McTigue². ¹University of Pittsburgh, Pittsburgh, PA; ²University of Pittsburgh Medical Center, Pittsburgh, PA. (Tracking ID #2199696)

BACKGROUND: The USPSTF recommends screening all adults for obesity and offering or referring obese patients to a behavioral intervention. Primary care providers are aware of the importance of addressing obesity, but there are numerous barriers to providing intensive counseling during clinic appointments. Health information technology and online tools are promising avenues for providing convenient self-management support. For such approaches to be effective, patients must have access to a computer and the internet, and possess basic computer skills. Little is known about computer use patterns among primary care patients who could benefit from online lifestyle support, or how patterns of technology access influence outcomes of an online weight loss intervention.

METHODS: We conducted a randomized controlled clinical trial to test an online behavioral lifestyle treatment in six primary care practices. Patients who felt that they could access the Internet at least weekly were enrolled in a year-long online weight loss program with a lifestyle coach or automated coaching, or an education control via a referral from their PCPs. Participants were surveyed at baseline regarding their computer use patterns, internet access, and computer skills. We used descriptive statistics including means and standard deviations to examine baseline computer access and skill level among all participants. In the subset in one of the two arms that received the comprehensive intervention, student T-tests determined whether patients' computer skills and internet access were associated with their measured 12-month weight loss.

RESULTS: Three hundred seventy-three obese adults were enrolled and 255 received one of the two comprehensive lifestyle interventions. On average, participants were age 49.4 (SD 12.6), and weighed 106.1 kg (SD 20.7). Of the sample, 76 % were female and 20 % were African American. Among all study participants, 7 % self-reported beginner-level computer skills, 39 % intermediate, 41 % advanced, and 13 % expert. Of the 373 patients, 351 (96 %) reported having a computer at home, 69 % used a computer at work, and 22 % used public computers. Forty-one percent of participants reported that the main purpose of using their home computer was online activities while 42 % reported that it was primarily used for work. Many participants reported using the internet to obtain health information (38 %) or to obtain nutritional information (38 %). Only 0.3 % of participants reported that they did not use the internet prior to enrollment. Patients with lower levels of computer skills (beginner/intermediate) showed similar mean weight loss to those with higher levels (advanced/expert); (-3.1 vs. -3.7 kg; $p>0.05$). No significant difference was noted in the magnitude of weight loss between patients who used a computer daily and those that did not ($p>0.05$). There was no significant difference in weight change between patients who reported the presence of home computer and those who did not ($p>0.05$). Similarly, there was no difference between patients who used computer at work and those who did not. However, patients

who reported using public computers experienced significantly less weight loss at the end of the one year intervention compared to those who did not use a public computer (-1.4 ± 6.8 kg vs. -4.0 ± 7.0 kg; $p=0.047$).

CONCLUSIONS: Primary care patients recruited for an online lifestyle intervention had a broad range of self-reported computer skills. Most had computer access at home or at work, and nearly a quarter accessed public computers. While perceived computer skills or access to a computer at home or at work were not associated with 12-month weight loss, patients who accessed public computers had significantly less weight loss at the completion of the 1-year intervention. Interventions aiming to bolster self-management support via the internet should accommodate a range of patient computer skills. Public computer access may be less effective for delivering an online intervention than access at home or work locales.

TEST CHARACTERISTICS OF PROPOSED STRATEGIES TO SELECT ASYMPTOMATIC OLDER MEN FOR INITIAL BONE MINERAL DENSITY TESTING: RESULTS FROM THE OSTEOPOROTIC FRACTURES IN MEN (MROS) STUDY Susan Diem¹; Katherine Peters²; Margaret L. Gourlay³; John Schousboe^{1, 4}; Brent C. Taylor^{1, 5}; Eric Orwoll⁶; Jane Cauley⁷; Carolyn J. Crandall⁸; Kristine E. Ensrud¹. ¹University of Minnesota, Minneapolis, MN; ²University of California, San Francisco, CA; ³University of Carolina, Chapel Hill, NC; ⁴Park Nicollet Health Services, Minneapolis, MN; ⁵VA Healthcare System, Minneapolis, MN; ⁶Oregon Health Sciences University, Portland, OR; ⁷University of Pittsburgh, Pittsburgh, PA; ⁸University of California, Los Angeles, CA. (Tracking ID #2180509)

BACKGROUND: The best strategy to select older asymptomatic men for osteoporosis screening is uncertain. We evaluated the operating characteristics of currently proposed strategies for selecting men for initial BMD testing for the detection of osteoporosis.

METHODS: We measured bone mineral density (BMD) using DXA at the femoral neck, total hip, and lumbar spine in 4057 community dwelling men age ≥ 70 years without bisphosphonate use or a history of previous clinical vertebral or hip fracture. Information regarding demographic characteristics, anthropomorphic measures, and medical history, including history of previous fractures, was collected. Ten year risk of a major osteoporotic fracture (clinical spine, hip, forearm, or shoulder fracture) was calculated using the FRAX model without BMD. Our primary outcome was osteoporosis as defined by a femoral neck T-score of ≤ -2.5 or below calculated using a young female normal referent base. Our secondary outcome was osteoporosis as defined by a T-score of ≤ -2.5 or below at the femoral neck, total hip or lumbar spine. We calculated the sensitivity, specificity, positive predictive value (PPV), and negative predictive value (NPV) for the identification of men with osteoporosis using the following screening strategies: 1) Screen all men aged 70 years and older; 2) screen men with a 10-year predicted major osteoporotic fracture at or above that of an average 65 year old Caucasian woman (i.e. ≥ 9.3 %); 3) screen men at varying cutoff points (ranging from -1 to 2) of the Osteoporosis Self-Assessment Tool (OST) score [(WEIGHT (KG)—AGE (YR)) X 0.2].

RESULTS: The mean age of men in the cohort was 76.3 (± 4.8 years). One hundred five (2.6 %) had a femoral neck T score of ≤ -2.5 and 220 (5.4 %) had a femoral neck, total hip, or lumbar spine T score of ≤ -2.5 . The proportion of men referred for testing ranged from 23.5 % for an OST cutoff of ≤ -1 to 100 % for the strategy of screening all men 70 years and older. Test characteristics of the screening strategies for the detection of men with a femoral neck T-score ≤ -2.5 appear in Table 1. Use of an OST cutoff of 1-2 had a sensitivity of 85-90 % for identifying men with a femoral neck T-score ≤ -2.5 , with a specificity ranging from 0.36-0.51. Use of a FRAX estimated risk of a major osteoporotic fracture of 9.3 % had a sensitivity of 0.77 and specificity of 0.58. All strategies had a low PPV due to the low prevalence of osteoporosis among men. For the secondary outcome of femoral neck, total hip, or lumbar spine T score ≤ -2.5 , the strategy of screening men with a FRAX estimated 10-year risk of a major osteoporotic fracture of ≥ 9.3 % had a sensitivity of 0.60 and specificity of 0.59; an OST score of ≤ 2 had a sensitivity of 0.83 and specificity of 0.36.

CONCLUSIONS: The prevalence of osteoporosis in this cohort of asymptomatic community dwelling men was similar to that reported for a population based sample of older men enrolled in NHANES 2005-2010. We found that recommended strategies for selecting older men for initial BMD testing varied widely in the proportion of men who were chosen for testing. Use of the OST with a cutoff of ≤ 1 or 2 identified 85-90 % of men with femoral neck osteoporosis, while substantially reducing the number of men referred for testing compared with the strategy of testing all men 70 years and older. In contrast, use of the more complex FRAX based strategy identified 71 % of men with femoral neck osteoporosis. These findings suggest that a simple strategy based on age and weight performs better than a more complex FRAX based strategy in selecting older asymptomatic men for BMD testing to detect osteoporosis.

Operating characteristics of proposed screening strategies for the detection of men with femoral neck T-score ≤ -2.5

Screening strategies	% of men referred for BMD testing	Sensitivity	Specificity	PPV	NPV
Age ≥ 70 years	100 %	1.00	0.00	0.03	0.00
FRAX ≥ 9.3 %	42.4 %	0.71 (0.62, 0.8)	0.58 (0.57, 0.60)	0.04 (0.03, 0.05)	0.99 (0.98, 0.99)
OST ≤ -1	23.5 %	0.52 (0.42, 0.62)	0.77 (0.76, 0.79)	0.06 (0.04, 0.07)	0.98 (0.98, 0.99)
OST ≤ 0	36.6 %	0.71 (0.62, 0.80)	0.64 (0.63, 0.66)	0.05 (0.04, 0.06)	0.99 (0.98, 0.99)
OST ≤ 1	50.3 %	0.85 (0.76, 0.91)	0.51 (0.49, 0.52)	0.04 (0.04, 0.05)	0.99 (0.99, 1.0)
OST ≤ 2	64.6 %	0.90 (0.82, 0.95)	0.36 (0.35, 0.38)	0.04 (0.03, 0.04)	0.99 (0.99, 1.0)

TEXT MESSAGING VERSUS USUAL CARE FOR WEIGHT LOSS IN PATIENTS WITH PRE-DIABETES Ilana P. Fischer¹; Henry H. Fischer¹; Rocio I. Pereira^{1, 2}; Jeanne M. Rozwadowski^{1, 3}; Silvia Gutierrez-Raghuath¹; Anna L. Furniss³; Michael J. Durfee¹; Susan L. Moore¹; Adam G. Tsai^{4, 3}; Karen Albright^{2, 3}; Edward P. Havranek^{1, 3}. ¹Denver Health and Hospital Authority, Denver, CO; ²University of Colorado, Anschutz Medical Campus, Aurora, CO; ³University of Colorado School of Medicine, Aurora, CO; ⁴Kaiser Permanente, Denver, CO. (Tracking ID #2191733)

BACKGROUND: Approximately one-third of Americans are considered to have pre-diabetes, with low-income and Latino patients representing a disproportionate share of those that go on to develop diabetes. Moderate weight loss has been shown to be effective in preventing diabetes, with long-lasting benefits that persist even with partial weight regain. Intensive behavioral interventions like the Diabetes Prevention Program (DPP) are effective for weight loss, but may be inaccessible for patients of low socioeconomic status and are expensive for safety-net providers to administer. This study tests the effectiveness of a 1-year text message-based program for weight loss compared to usual care.

METHODS: This randomized control trial was conducted at the Westside Clinic, one of Denver Health's federally qualified health centers, providing nearly 20,000 unique visits annually to a predominantly Latino patient population (80 %). Subjects were recruited from an eligible pool of 1116 English or Spanish-speaking patients without diabetes, ages 18 and older, with HbA1c greater than 5.6 % but less than 6.5 % and BMI between 25 kg/m² and 50 kg/m². Enrolled patients were randomized to the text-message based intervention or to usual care. Text message content was developed using the National DPP curriculum and refined with input from patient focus groups. Starting April 2014, intervention patients received six messages per week (in English or Spanish) relating to nutrition, physical activity, and motivation, as well as a once-weekly text message querying for most recent weight. Intervention patients were also eligible for individual motivational interviewing appointments with a health coach, generally by telephone. Control patients did not receive weekly messages or motivational interviewing, but like intervention patients were eligible for all standard-of-care weight loss resources at Denver Health including access to DPP classes and individual appointments with a nutritionist or nurse for diet support. The primary outcome was weight lost, by amount in pounds and by percent. Patients returned for an interim 6-month weigh-in. These data are presented below.

RESULTS: Of the 163 individuals enrolled, 3 were lost to follow-up due to pregnancy, leaving 160 individuals in this analysis. At 6 months, mean weight loss was 3.6 lb in the intervention group versus 1.7 lb in the control group ($p=0.12$). Thirty-one intervention patients versus 18 control patients ($p=.03$) achieved at least 3 % weight loss while 19 intervention versus 10 control patients achieved at least 5 % weight loss ($p=0.08$). A larger proportion of Spanish-speakers were randomly assigned to the intervention group; the intervention effect was observed among Spanish-speakers but not among English-speakers (see table).

CONCLUSIONS: The 6-month results of this study demonstrate that a text-message based intervention may be effective in helping low-income, Spanish-speaking individuals achieve modest weight loss. Effectiveness of the intervention among English-speakers is

unclear as uneven randomization by language may have affected our results. This will be examined further upon completion of the study in April 2015. Nevertheless, the interim

data show promise for a low-cost, wide-reaching text message approach to achieve moderate weight loss in patients with pre-diabetes.

Baseline to 6 Month Follow-up Weight Loss, by Intervention and Control groups and by Language

Measure	All (n = 160)			Protocol in English (n = 71)			Protocol in Spanish (n = 89)

THE ASSOCIATION BETWEEN DIFFERENT FORMS AND FUNCTIONS OF MENTORING AND CAREER OUTCOMES AMONG FEMALE FACULTY IN ACADEMIC MEDICINE Lyndonna M. Marrast¹; Rene caraphina²; Michael Wake²; Emorcia Hill²; Joan Reede². ¹Hofstra North Shore LIJ School of Medicine, Kew Gardens, NY; ²Harvard Medical School, Boston, MA. (Tracking ID #2198947)

BACKGROUND: Mentorship is recognized as valuable to success in academic medicine. Mentoring can take various forms (i.e. formal versus informal, single versus multiple mentors) and serve different functions (i.e. psychosocial and/or career-oriented support). Prior studies have been limited by sample size, involvement of one specialty and/or setting at a single institution. In this study, we add to the growing body of literature reporting on the impact that different forms and functions of mentoring have on career outcomes related to grants, publications and promotion of a diverse group of female faculty across multiple institutions and sub-specialties.

METHODS: Using online survey data from the Women in Academic Medicine (WIAM) study, we conducted a comparative investigation of the association between different forms and functions of mentoring and career outcomes, including: receipt and/or funding of a NIH K-award, NIH RO1-award, external grant, being aware of or having seen promotion criteria at one's institution, planning to seek promotion, and number of peer reviewed manuscripts published. We used Chi Square to assess differences between forms of mentoring. We then calculated adjusted odds ratios using multivariable logistic regression controlling for age, race/ethnicity, rank, time at the institution, department type, having an additional degree, fellowship training, and early exposure to academic medicine to assess the impact of mentoring type and function on these specific career outcomes.

RESULTS: Among the sample of 3, 127 women, the majority, 62 %, reported that they have received some form of mentoring at some time in their careers. Over one-third reported they *currently* have a mentor, 11.4 % reported having a single mentor and 25.9 % have several mentors. Participants with multiple mentors and those receiving formal mentorship during fellowship and as junior faculty were more likely to have applied for grants (K-award, external, and RO1, P-value<0.05). Having multiple mentors impacted one having seen the institution's promotion criteria but did not impact their intent to seek promotion. In multivariable analysis, those with multiple mentors had higher odds of receiving funding for a K-award (OR 3.64; CI 1.89–7.00) or an external grant (OR 1.63; CI 1.05–2.56). We did not find a strong association between receiving career support from mentors and outcomes in multivariable models. However, a disaggregation of mentor functions reveals a positive association between some functions with publications and promotion preparation but no relationship to grant-related outcomes.

CONCLUSIONS: Having multiple mentors and formal mentors is important for the promotion and publication processes within academic medicine. The art of successful grant writing may require mentoring functions that are not captured in the current scale. Future research is needed to identify the characteristics of mentoring that lead to positive results regarding applying and obtaining grants. Women in academic medicine have varying definitions of career success; therefore mentorship must be congruent to the needs of the women based on career goals.

THE ASSOCIATION BETWEEN INSURANCE TYPE AND COST-RELATED DELAY IN CARE: A SURVEY OF ACCESS TO CARE IN MASSACHUSETTS

Sora A Rowas^{3, 6}; Michael B. Rothberg⁵; Sarah L. Goff^{4, 2}; Benjamin Johnson^{3, 6}; Joel Miller⁴; Jennifer Friderici^{1, 2}; Tara Lagu^{2, 4}. ¹Baystate Health System, Springfield, MA; ²Baystate Medical Center, Florence, MA; ³Baystate Medical Center, Springfield, MA; ⁴Baystate Medical Center/Tufts University School of Medicine, Springfield, MA; ⁵Cleveland Clinic, Cleveland, OH; ⁶Tufts University, Boston, MA. (Tracking ID #2197465)

BACKGROUND: Massachusetts has had a health insurance mandate since 2006, resulting in insurance rates similar to those projected under the Affordable Care Act (ACA). As a result, many patients in Massachusetts have private insurance plans with low premiums but high out-of-pocket costs. In this survey study, we aimed to explore the relationship between insurance type (private or public) and self-reported access to health care as well as self-reported delays in care due to cost.

METHODS: Using previously validated instruments as a guide, we designed, pilot-tested and administered a questionnaire to English-speaking adult patients and their companions who presented to the waiting rooms of one adult emergency department and two outpatient clinics. The questionnaire was designed to enable us to examine the relationship between insurance type (Public: Medicaid, Medicare, Commonwealth Care; Private; or Uninsured) and validated measures of access to health care (e.g., cost-related delay in care, emergency department as usual source of care, having a PCP). Results were stratified by tertiles of per-person household income (PPHI). We generated descriptive statistics and tested an interaction term between income, insurance, and delay in care using the Likelihood Ratio (LR) test. We then created a multiple logistic regression model that included an insurance-by-income level interaction term with age, sex, and race/ethnicity as covariates.

RESULTS: Of 800 people approached, 619 (77 %) completed the survey. Respondents were 60.6 % female and 40.2 % white, 37.2 % Hispanic, 12.6 % Black and 9.1 % other. Out of those surveyed; 47.3 % were employed (including self-employed), 22.0 % were disabled and 12.0 % were unemployed. Most had public insurance (61.4 %); 34.1 % had private insurance and 4.5 % were uninsured. Overall, 30.5 % (95 % CI 27.0 %, 34.3 %) reported delay in health care for any reason. Cost was the most commonly cited reason for delay (22.0 %, 95 % CI 10.8 %, 16.2 %). Tertiles of the PPHI corresponded roughly with cutpoints from the 2014 Federal Poverty Guidelines: (tertile 1: <\$12,500; tertile 2: \$12,500 to <\$25,000; tertile 3: \geq \$25,000) Privately insured subjects were significantly more likely than publicly insured to delay care due to cost in the middle-income group (private insurance 18.5 %, public insurance 7.2 %, OR 3.18, 95 % CI 1.27, 7.98), but not in the lower income (4.6 % vs. 11.8 %, OR 0.34, 95 % CI 0.07, 1.64) or upper income (12.0 % vs. 12.2 %, OR 0.97, 95 % CI 0.31, 3.11) groups. Out-of-pocket costs significantly mediated the association between delay in care and insurance type in the middle income stratum (16 % reduction to private vs. public regression coefficient, $p=0.02$).

CONCLUSIONS: A substantial number of patients in a state with an insurance mandate report cost-related delays in care. Patients with private insurance and PPHIs above \$12,500 and under \$25,000 were more likely to report cost-related delays in care compared to similar respondents with public insurance; this difference appears to be mediated by out-of-pocket costs. These findings suggest that, compared to publicly-insured patients, some privately-insured patients may be more likely to experience cost-related delays in care after full implementation of the ACA.

THE ASSOCIATION OF NEIGHBORHOOD ENVIRONMENT AND MORTALITY: RESULTS FROM A NATIONAL STUDY OF VETERANS

Karin M. Nelson¹; Gregory J. Schwartz²; Susan Hernandez²; Joseph A. Simonetti^{2, 1}; Idamay Curtis³; Stephan D. Fihn^{3, 1}. ¹University of Washington, VA Puget Sound, Seattle, WA; ²VA, Seattle, WA; ³Veterans Health Administration, Seattle, WA. (Tracking ID #2198108)

BACKGROUND: The VHA is the largest integrated US health system and is increasing its focus on community strategies to improve health outcomes. Neighborhood environment is thought to influence health on a variety of levels and neighborhood factors may capture information not available at the individual level. However, there is limited evidence about the association of neighborhood environment and health outcomes among Veterans. We sought to determine the association of neighborhood factors with all-cause mortality rates among Veterans.

METHODS: We used data from the VA Corporate Data Warehouse (CDW) to obtain individual data on vital status, clinical and demographic characteristics. The Gagne comorbidity index was generated to estimate individual risk based on diagnoses occurring in 2011. Census Tract level socio-economic data was obtained from the US Census Bureau and linked to individuals by residence. Census tract level socio-economic status (SES) was characterized by a previously validated index based on 6 components: 1) percentage of adults >25 y old with less than a high school education; 2) percentage of unemployed males; 3) percentage of households with income below the poverty line; 4) percentage of households receiving public assistance; 5) percentage of households with children that are headed by a female; and 6) median household income. The SES index was calculated as the sum of component z-scores standardized to range from 0 to 1 with increasing SES. Logistic regression was used to model the association of the tract level SES index with all-cause mortality in 2012 while controlling for individual level co-morbidity and other demographic characteristics.

RESULTS: We analyzed data on all Veterans alive on January 1, 2011 for which vital status, demographic and SES data were available ($n=4,814,631$). The majority of Veterans were men (94 %), either white (75 %) or black (15 %), and resided in urban areas (62 %). Tract level SES had a large effect on the likelihood of mortality after controlling for individual co-morbidity and demographics. After categorizing the SES index into deciles, individuals living in tracts with an SES Index in the 1st decile (lowest SES) were 30 % (OR 1.3, 95 % Confidence Interval: 1.26, 1.34) more likely to die in 2012 than individuals living in tracts in the 10th decile (highest SES). The likelihood of mortality decreased with increasing decile of SES status. For example, mortality for individuals living in the 9th decile was 4 % more likely (95 % CI: 1.012, 1.066) compared to the highest decile.

CONCLUSIONS: Neighborhood socioeconomic environment is strongly associated with all-cause mortality among Veterans independent of individual-level comorbidities and socioeconomic characteristics. Strategies to improve health ultimately will need to incorporate information about neighborhood characteristics.

THE BUILT AND SOCIAL ENVIRONMENT: NEIGHBORHOOD OBESITY IN VULNERABLE POPULATIONS

Elizabeth L. Tung¹; Monica E. Peek¹; Jennifer A. Makelarski²; Stacy T. Lindau². ¹University of Chicago, Chicago, IL; ²University of Chicago, Chicago, IL. (Tracking ID #2199111)

BACKGROUND: People living in low-income, minority neighborhoods have disproportionately high rates of obesity and obesity-related disease (e.g. diabetes). Observational studies suggest, with mixed findings, that poor access to healthy food or recreational space, racial segregation, and psychosocial stress are all potential environmental mechanisms for behaviors that contribute to these conditions (e.g. poor diet, sedentary lifestyle). However, many of these larger studies rely on secondary data for measures of the built environment and health. This study draws on contemporaneous primary data collected on Chicago's South Side to gain a more robust understanding of the relationship between the neighborhood built and social environment with obesity in vulnerable populations.

METHODS: This study included an address-based probability sample of 267 residents, aged 35 and older, enrolled from Chicago's South Side from November 2012-July 2013. During hour-long, in-person interviews, participants were queried about the neighborhood built environment (awareness and use of grocers and primary care), social environment (validated measures of neighborhood satisfaction, safety, social cohesion, and social control), demographics, and health status. Biological measures (height, weight, and HbA1c) were obtained at the time of interview. Data from the 2012 MAPSCorps asset census, a comprehensive census of all operating, public-facing businesses and organizations, were paired with survey data to calculate distances to neighborhood resources that participants reported using (utilized resources, d_u) and distances to resources closest to home (nearest resources, d_n). Multiple linear regression was used to evaluate associations between the neighborhood built and social environment with body mass index (BMI). All analyses were adjusted for age, gender, income, and self-reported health status. Survey

weights were used to adjust for differential probability of selection and non-response in order to generate population estimates.

RESULTS: The overall cooperation rate was 62 %. People were primarily African American (53.6 %) and non-Black Hispanic (34.8 %), female (57.8 %), and between the ages of 35–70 (mean age 55.0 ± 1.0 years). Approximately half (52.8 %) were obese ($BMI \geq 30$). Overall, participants did not utilize the resources nearest to their homes. More than three quarters (80.7 %) utilized a grocer that was further than their nearest grocer ($d_n = 2.3$, $d_u = 1.1$; $P < 0.01$). BMI was not associated with distance to nearest grocer, but each additional mile traveled to utilized grocer was associated with a 0.8 kg/m^2 increase in BMI (95 % CI, 0.4–1.3; $P < 0.01$). Few participants reported having a regular primary care physician (PCP) (total 21.6 %; obese 19.9 %). However, the majority did have access to a PCP when necessary (total 93.3 %; obese 94.7 %). BMI was not associated with distance to nearest PCP, but each additional mile traveled to utilized PCP was associated with a 0.2 kg/m^2 increase in BMI (95 % CI, 0.1–0.4; $P < 0.01$). Neighborhood social environment, with the exception of neighborhood theft, was not significantly associated with obesity. Any prior experience of theft was associated with a 3.0 kg/m^2 increase in BMI (95 % CI, 1.0–5.0; $P < 0.01$).

CONCLUSIONS: Our findings suggest that distance to utilized grocer, distance to utilized PCP, and neighborhood theft may be several factors in the built and social environment that drive previously identified associations between neighborhoods and health. Notably, there is a discrepancy between the resources nearest to home and the resources actually utilized. These findings suggest that it is not sufficient for community resources to be ‘merely available’ nearby. Low-income communities may have lower quality resources, not just fewer resources, and this may be a more powerful predictor of health than quantity. Moreover, neighborhood theft is most strongly associated with obesity, further emphasizing the impact of social influences on health and presumptively, health-seeking behavior. Thus, it is necessary to examine the many factors mitigating patient preference (e.g. affordability, accessibility, safety, quality) in building a resource infrastructure with downstream health effects. In summary, developing holistic strategies that address neighborhood crime and local access to high-quality community resources may be critical to curbing the obesity epidemic in vulnerable populations.

THE COLORADO TRANSGENDER HEALTH SURVEY

Robin Christian; Rita Lee. University of Colorado, Aurora, CO. (Tracking ID #2196394)

BACKGROUND: Transgender people, those whose gender identity does not match their birth sex, face discrimination in many areas of life. Previous work has identified barriers to receiving appropriate health care, including discrimination, prohibitive cost, and difficulty finding a provider. The Colorado Transgender Health Survey sought to explore current disparities and their effects on the health of transgender people in Colorado.

METHODS: The Colorado Transgender Health Survey was developed through collaboration between the Colorado LGBT Health Coalition, the Colorado Department of Public Health and Environment, and transgender community members. The survey was based on the Behavioral Risk Factor Surveillance System (BRFSS). The survey was primarily web-based, using convenience and snowball sampling techniques. Outreach was performed at transgender-specific events, LGBT pride festivals, colleges and universities, LGBT support organizations, healthcare providers, churches, and their networks/social media. Participation was voluntary and anonymous. Results from participants who identified as transgender or gender-nonconforming, lived in Colorado, and were over the age of 18 were included in the analysis. Descriptive statistics were used.

RESULTS: There were a total of 507 respondents, 417 of whom met inclusion criteria. Forty-eight percent of our sample were assigned female at birth—43 % currently identify as a woman/transgender woman and 29 % identify as a man/transgender man. In all, 25 distinct gender identities were reported. Forty-two percent of had a household income under \$25,000, though 61 % hold a college degree. The most recent BRFSS reported that 24 % of Colorado households earn under \$25,000, and 33 % of Coloradans hold a college degree. Eighty-six percent of our sample has health insurance—59 % receive insurance through work or school, 13 % have individual insurance, and 19 % have Medicaid. Forty percent reported delaying necessary medical care due to cost (40 %), inadequate insurance coverage (23 %), as well as fear of discrimination (31 %). While the overall health of our sample appeared similar to the general population of Colorado, mental health outcomes were drastically different—53 % had been diagnosed with an anxiety disorder, 44 % were currently depressed, 36 % had contemplated suicide in the past year, and 10 % reported attempting suicide in the past year. Respondents with an inclusive provider were more likely to receive wellness exams (76 % vs 48 %), less likely to delay care due to discrimination (24 % vs 42 %), were more likely to report excellent, very good, or good health (84 % vs 75 %), and were less likely to be depressed (38 % vs 54 %) or attempt suicide (7 % vs 15 %).

CONCLUSIONS: This survey found that the transgender community in Colorado continues to face significant disparities. Mental health is highlighted as a critical element in addressing health disparities in this community. The impact of a transgender-friendly provider was found to be a major factor in improving health and health behavior. Limitations include convenience and snowball sampling design, Colorado only sample, and lack of inclusion of adolescents and youth that limit generalizability. Further research and education on transgender health and health care should be incorporated into national efforts to eliminate health disparities.

THE COURSE OF FUNCTIONAL IMPAIRMENT IN OLDER HOMELESS

ADULTS Theora Cimino¹; Michael A. Steinman²; Yinghui Miao²; Susan Mitchell³; Monica Bharel⁴; Rebecca Brown². ¹School of Medicine, University of California, San Francisco, San Francisco, CA; ²Division of Geriatrics, University of California, San Francisco, San Francisco, CA; ³Hebrew SeniorLife Institute for Aging Research, Boston, MA; ⁴Boston Health Care for the Homeless Program, Boston, MA. (Tracking ID #2196383)

BACKGROUND: Functional impairment is common in homeless adults in their fifties and sixties. Because these individuals are relatively young, it may be reasonable to assume that many of these impairments are transient. However, it is unknown if functional impairment among older homeless adults is transient or persistent, and thus whether long-term interventions are needed to address these deficits.

METHODS: We recruited 250 homeless adults age 50 and older from 8 homeless shelters in Boston, MA. At baseline and 12 months, participants reported if they had difficulty performing 5 Katz activities of daily living (ADLs) and 6 instrumental activities of daily living (IADLs). We assessed IADLs using a validated instrument developed for use in homeless persons. We defined persistent ADL impairment as difficulty performing the same number of ADLs at baseline and follow-up, and worsened ADL impairment as difficulty performing an increased number of ADLs from baseline to follow-up. We defined IADL impairment similarly. We used multivariable regression models to identify risk factors for persistent or worsened functional impairment.

RESULTS: Overall, 204 of 250 participants completed follow-up interviews. Mean age was 56 years, 18 % were women, and 40 % were black. At baseline, 65 participants reported impairment in 1 or more ADLs. Of these 65 participants, 21 (32 %) had persistent ADL impairment one year later and 11 (17 %) had worsened impairment. Among the 32 participants with persistent or worsened ADL impairment, the individual impairments often changed over time: one-third of participants had improvement in the original impairment but onset of 1 or more other impairments. Results were similar for IADLs. At baseline, 119 participants reported impairment in 1 or more IADLs, of whom 30 (25 %) had persistent impairment and 31 (26 %) had worsened impairment. In multivariable analyses, demographics, medical comorbidity, substance use, and health services use were not associated with persistent or worsened versus improved functional impairment.

CONCLUSIONS: Although functional impairment was transient in some older homeless adults, it persisted or worsened in many others. These findings suggest that housing solutions and services for older homeless adults must be tailored to benefit individuals with differing functional trajectories.

THE EFFECT OF ADVANCE DIRECTIVE COMPLETION ON HOSPITAL CARE AMONG HOMELESS PERSONS: A PROSPECTIVE COHORT STUDY

Alexander Leung¹; Matthew To¹; Linh D. Luong¹; Victor Goncalves¹; Zahra Syavash Vahabi¹; John Song²; Stephen Hwang¹. ¹St. Michael, Toronto, ON, Canada; ²University of Minnesota, Minneapolis, MN. (Tracking ID #2193667)

BACKGROUND: End-of-life care planning is important for homeless individuals because they experience high morbidity and mortality. A previous study has shown that many homeless persons are willing to complete an advance directive, but the impact of advance directives on subsequent hospital care has not been examined in this population. The objective of this study was to determine if chronically homeless individuals who completed an advance directive through a shelter-based intervention were more likely to have the information in this document (treatment preferences and/or identification of a substitute decision maker) documented during hospitalizations over a 1-year follow-up period, compared to homeless individuals who did not complete an advance directive through the intervention.

METHODS: This prospective cohort study recruited 205 chronically homeless persons at a large men's shelter in Toronto, Ontario from April to June 2013. Participants were offered the opportunity to complete an advance directive through a one-on-one counselor guided intervention; 103 (50.2 %) completed an advance directive and gave permission

for the document to be made available to health care providers during future hospitalizations, and 102 (49.8 %) chose to not complete an advance directive. Extensive efforts were undertaken to make advance directives available to health care providers, including giving copies of advance directives to participants' primary care providers, informing clinicians at nearby hospitals of the initiative, and making advance directives available within a hospital information system. Medical records at the hospital that provides the majority of inpatient care for shelter residents were searched to identify all participants who were admitted during a 1-year follow-up period. Charts were reviewed independently by two reviewers who were blinded as to whether participants had completed an advance directive. The pre-defined primary outcome was documentation in the hospital chart that explicitly referenced the contents of an advance directive (treatment preferences and/or identification of a substitute decision maker). If a participant was hospitalized multiple times, documentation during any single hospitalization was considered sufficient. Chi-square analysis was used to compare the proportion of participants with a primary outcome among those who completed an advance directive vs. those who did not complete an advance directive. To account for possible differences in hospitalization rates in the two groups, the analysis was also conducted including only participants who were hospitalized during the follow-up period.

RESULTS: Hospitalization during the follow-up period occurred in 32 participants who completed an advance directive vs. 27 participants who did not complete an advance directive (31.1 vs. 26.5 %, $p=0.47$). The primary outcome occurred in 8 of 103 participants who completed an advance directive vs. 2 of 102 participants who did not complete an advance directive (7.8 vs. 2.0 %, $p=0.054$). Considering only individuals who were hospitalized during the follow-up period, the primary outcome occurred in 8 of 32 participants who completed an advance directive vs. 2 of 27 participants who did not complete an advance directive (25.0 vs. 7.4 %, $p=0.073$).

CONCLUSIONS: Among chronically homeless individuals, completion of an advance directive through a shelter-based intervention was associated with a higher probability of having information from an advance directive (treatment preferences and/or identification of a substitute decision maker) documented during hospitalizations over a 1-year follow-up period, but this association did not achieve statistical significance. The observation that only 25 % of homeless participants who completed an advance directive and were subsequently hospitalized had information from their advance directive recorded in their hospital chart indicates the need for improved information systems to make this information available to hospital-based health care providers, especially for marginalized populations.

THE EFFECT OF ATTENDING PRACTICE STYLE ON GENERIC MEDICATION PRESCRIBING BY RESIDENTS IN THE CLINIC SETTING

Kira L. Ryskina¹; Constance J. Dine¹; Esther J. Kim¹; Tara F. Bishop²; Andrew Epstein¹. ¹University of Pennsylvania, Philadelphia, PA; ²Weill Cornell Medical College, New York, NY. (Tracking ID #2198475)

BACKGROUND: With an increased emphasis on value-based care from policy makers, educators have been tasked to evaluate and improve resident competency in cost-effective care. Bedside teaching and modeling is an effective mechanism of knowledge transfer between attendings and their trainees; however, there is little empiric evidence of the role of attending physician supervision on resident practice in the area of low value care. Our objective was to study whether attendings' prescribing practices influence residents' prescribing of generic medications in the ambulatory clinic setting (adopting brand name vs. generic statin prescribing as a model of value-based care).

METHODS: A retrospective study of initial statin prescriptions by residents and attendings at five internal medicine resident practices in the Northeast, using electronic medical record data from July 2007 through November 2011. All in-person resident encounters were precepted and co-signed by an attending, and the attending-resident pairs were captured for each resident-written prescription for a patient. To measure the brand name statin prescribing rate for an attending, all initial statin prescriptions written by the attending physicians for their patients seen without a resident were evaluated. We estimated multivariable hierarchical logistic regression models to assess the independent effect of the supervising attending's rate of brand name prescribing in the preceding quarter on the likelihood of a resident prescribing a brand name statin in a patient encounter supervised by that attending. We adjusted for practice characteristics (practice site), patient characteristics (age, gender, comorbidities, tobacco use, and insurance type), and resident characteristics (year in training (PGY level), cohort year, and whether the resident was the patients' designated primary care provider) in the model. Predictive marginal effects of attending brand name statin prescribing rate in the preceding quarter on the probability that a brand name statin was prescribed by the resident were estimated at each PGY level.

RESULTS: The sample included 342 resident and 58 attending participants, accounting for 10,151 initial statin prescriptions including 3942 written by residents. Resident and attending physicians had similar brand name prescribing rates; residents on average wrote 24.9 % (SD 24.2 %) of new statin prescriptions for brand name medications, while attendings wrote for brand name statins in 25.7 % (SD 23.3 %) of encounters. A larger proportion (60.3 %) of generic statin prescriptions was written under the supervision of attendings with <20 % brand name prescribing rate for the previous quarter, while residents supervised by attendings with ≥ 20 % brand name prescribing rate prescribed a larger proportion (78.0 %) of brand name statins ($p < 0.001$). After adjusting for institutional, provider, and patient characteristics, attending brand name prescribing rate in the quarter prior to the encounter was associated with the odds of a PGY1 resident prescribing a brand name statin (adjusted odds ratios [aOR] ranging from 2.26, 95 % CI 1.34–3.81, $p = 0.002$, for attendings who prescribed brand name statins 40–59 % of the time, to aOR 3.40, 95 % CI 1.10–10.50, $p = 0.034$, for attendings who prescribed brand name statins at least 80 % of the time, compared to attendings who prescribed brand name statins <20 % of the time). There was no relationship between attending and resident brand name prescribing for PGY2 or PGY3 residents. For PGY1 residents, the probability of a resident prescribing a brand name statin ranged from 22.6 % (95 % CI 17.3 %–28.0 %, $p < 0.001$) for residents supervised by an attending who prescribed <20 % brand name statins in previous quarter to 41.6 % (95 % CI 24.6 %–58.5 %, $p < 0.001$) for residents supervised by an attending who prescribed at least 80 % brand name statins in previous quarter.

CONCLUSIONS: Our findings provide evidence of attending effect on resident practice of one specific example of low-value care. The high variation in generic prescribing of statins in the academic setting points to room for improvement in generic prescribing by residents as well as their supervising attending physicians. These findings are important to medical educators as residency programs respond to the challenge of teaching cost-effective medicine and evaluating residents in this competency.

THE EFFECT OF HOSPITAL-ACQUIRED ANEMIA ON 30-DAY READMISSION AND MORTALITY Anil N. Makam¹; Oanh K. Nguyen¹; Christopher Clark²; Song Zhang¹; Bin Xie²; Ruben Amarasingham^{2, 1}; Ethan Halm¹. ¹UT Southwestern Medical Center, Dallas, TX; ²Parkland Center for Clinical Innovation, Dallas, TX. (Tracking ID #2196285)

BACKGROUND: Hospital-acquired anemia (HAA) is associated with increased inpatient mortality and resource utilization. However, little is known about the effect of HAA on adverse outcomes following hospital discharge. We sought to describe the prevalence and patterns of HAA and examine the association between HAA and 30-day readmission and mortality.

METHODS: This is an observational study using EHR data from 6 hospitals in the Dallas-Fort Worth metroplex, including safety net, community, teaching, and non-teaching sites. We included hospital discharges from all internal medicine inpatient services among adults (≥ 18 years) between Nov. 1, 2009 and Oct. 30, 2010. We excluded patients with anemia (Hct < 36 % for women and < 40 % for men) within the first 24 h of hospitalization, missing a Hct value within the first 24 h and/or at the time of discharge, inpatient deaths, transferred to an acute care facility, or those leaving against medical advice. For patients with multiple admits, we included only the first one. We classified severity of HAA as either none (nadir Hct at time of discharge ≥ 36 % for women and ≥ 40 % for men); mild (women: 33 % Hct < 36 %; men: 33 % Hct < 40 %), moderate (27 % $<$ Hct ≤ 33 %), or severe (Hct ≤ 27 %). The primary outcome was a composite of death and non-elective readmission to any of 75 acute care hospitals in north Texas within 30 days, ascertained using an all payer regional hospitalization database. We used logistic regression to adjust for demographic, clinical, and healthcare utilization characteristics, accounting for clustering at the hospital level.

RESULTS: Of 10,962 patients, one-third (32.4 %) developed HAA (mild 21.1 %, moderate 9.9 %, severe 1.4 %; **Figure**). Only 2.8 % of patients received a blood transfusion during hospitalization; 0.6 % had an admission diagnosis of either GI bleed, anemia of any type, coagulopathy or hemorrhagic disorder. Patients with HAA had a higher frequency of adverse outcomes compared to patients without (mild 11 %, moderate 12.8 %, severe 16.0 % vs. 8.9 %, $p < .001$). Compared to those without HAA, having mild HAA was associated with an AOR of 1.10 (95 % CI, 0.94–1.28), moderate HAA with an AOR of 1.11 (95 % CI, 0.90–1.36) and severe HAA with an AOR of 1.34 (95 % CI, 0.86–2.09) for a 30-day adverse outcome.

CONCLUSIONS: HAA occurred in one-third of all hospitalizations and is associated with a potential severity-dependent increase in 30-day readmission and mortality, though the association was not statistically significant. Our study may have been underpowered to

detect a difference among those with severe HAA given the small number of patients. Further research is needed to examine the influence of HAA on 30-day adverse events and the factors that may lead to its development.

THE EFFECT OF OPIATE SUBSTITUTION THERAPY ON HEALTHCARE UTILIZATION AND ENGAGEMENT AMONG HIV-INFECTED PEOPLE WHO INJECT DRUGS IN UKRAINE Chethan Bachireddy¹; Jacob Izenberg²; Michael Soule³; Sergey Dvoryak⁴; Frederick L. Altice⁵. ¹Brigham and Women's Hospital, Boston, MA; ²UCSF, San Francisco, CA; ³MGH/McLean Hospital, Boston, MA; ⁴Ukrainian Institute on Public Health Policy, Kyiv, Ukraine; ⁵Yale University School of Medicine, New Haven, CT. (Tracking ID #2199349)

BACKGROUND: Eastern Europe and Central Asia face a rapidly escalating HIV epidemic driven by injection drug use (IDU). Key to stemming the tide of this epidemic is engaging HIV-infected people who inject drugs (PWID) in regular care and reducing their HIV infection risk through the expansion of opiate substitution therapy (OST) and antiretroviral therapy (ART). However, governments have been reluctant to scale up lifesaving OST due to stigma and cost. We evaluate the role of OST in engaging HIV-infected PWID in care and the effect of OST on utilization of medical services.

METHODS: Cross-sectional study of 296 randomly sampled HIV-infected opioid-dependent PWID conducted in healthcare clinics in 2010 across Ukraine. Participants asked about their healthcare utilization in the past 6 months and categorized as therapeutic on OST if they had taken OST for at least three consecutive months prior to the past 6 months or as not taking OST if they had not taken any OST in the past 6 months. Of the 296, 24 individuals were excluded based on having taken OST fewer than three consecutive months prior to the past 6 months.

RESULTS: The 65 % therapeutic on OST (177/272) were less likely to have income below the poverty line and live alone and more likely to be married or have gone to prison ($p < 0.05$). The two groups did not differ significantly in terms of age, gender, or education. Those therapeutic on OST had more years of opioid injection but were less likely to have injected in the past 30 days, to have engaged in polysubstance abuse, or to have overdosed on drugs in the past ($p < 0.01$). In the past 6 months, those therapeutic on OST were less likely to seek emergency care (72 % v 84 %, $p < 0.05$) and had fewer mean emergency care visits (2.77 v 4.57, $p < 0.02$) but similar mean ambulatory visits (1.78 v 0.59, $p = 0.11$) and hospitalizations (0.53 v 0.34, $p = 0.36$). Those therapeutic on OST were more likely to be engaged in HIV care, as evidenced by higher rates of ART (37 % v 26 %, $p = 0.08$), recent CD4 testing (82 % v 60 %, $p < 0.01$), and recent TB testing (95 % v 71 %, $p < 0.01$). The number of self-reported symptoms was higher in the non-OST group compared to those therapeutic on OST (10.46 v 7.75, $p < 0.01$). Limitations include the cross-sectional design and the potential for recall and social desirability biases.

CONCLUSIONS: Despite higher rates of incarceration and more years of opioid injection, those therapeutic on OST were much less likely to seek emergency care than those not on OST and much more likely to be engaged in HIV care with fewer overall symptoms. These results suggest that OST may decrease HIV transmission not only by limiting IDU but also by increasing engagement in HIV care.

THE EFFECT OF POINT-OF-CARE PRICE INFORMATION ON OUTPATIENT PHYSICIAN ORDERING BEHAVIOR Alyna T. Chien^{2, 3}; Carter Petty²; Meredith Rosenthal⁴; Thomas D. Sequist¹. ¹Partners Healthcare System, Boston, MA; ²Boston Children's Hospital, Boston, MA; ³Harvard Medical School, Boston, MA; ⁴Harvard School of Public Health, Boston, MA. (Tracking ID #2200024)

BACKGROUND: Physicians are critical targets for price transparency initiatives because they lack knowledge of the price of the health care they provide and have the expertise needed to distinguish when medical spending is necessary versus wasteful. Prior studies find that short-term provision of price information to trainees in hospital settings lowers ordering rates, but little is known about how longer-term exposure to price information affects primary care and specialist physicians in outpatient practice. We study the effect of providing two different forms of price information to physicians for four types of commonly-ordered outpatient procedures: advanced imaging (e.g., CTs, MRIs), cardiac testing (e.g., ECHOs, stress tests), endoscopy (e.g., colon, nasal), and other specialty procedures (e.g., electromyography, sleep studies).

METHODS: In January 2014, we block randomized 1388 primary care and specialist physicians practicing in 36 locations within a large multi-specialty group in Massachusetts. Arm 1 (control) was given the median amount paid to the group for commonly-ordered procedures via a written memo once at the beginning of the year. Arms 2 and 3 (intervention arms) then received price information through the electronic health record system throughout 2014. For each procedure, Arm 2 was given a single median price while Arm 3 was provided a pair of median prices corresponding to whether the procedure was performed “inside” or “outside” the organization. We obtained patient encounter and ordering data for pre-intervention and intervention years 2013–2014 from the multi-specialty group. We calculated the odds of an order being placed per health care encounter across all procedures and for each of the four procedure types using logistic regression. We assessed the intervention effect using an interaction term between intervention arm and study year, clustering on physicians.

RESULTS: Across all procedures, changes in Arm 2 (single median price) and Arm 3 (paired “inside” and “outside” median prices) were not significantly different from Arm 1 (control). However, arm effect varied by procedure type. For physicians in Arm 2, the adjusted odds of ordering were significantly lower for advanced imaging and other specialty procedures (AOR 0.98 [0.96, 0.99], 0.94 [0.92, 0.96], respectively); they were significantly higher for cardiac testing (AOR 1.24 [1.19, 1.28]), but there was no significant change for endoscopy. For physicians in Arm 3, the adjusted odds of ordering were significantly lower for endoscopy and other specialty procedures (AOR 0.75 [0.72, 0.78], 0.97 [0.95, 0.99], respectively), but significantly higher for advanced imaging and cardiac testing (AOR 1.02 [1.01, 1.04], 1.04 [1.01, 1.08], respectively).

CONCLUSIONS: Price information can have a mixed effect on primary care and specialist physicians in outpatient practice. It could have a lowering effect, but also a heightening one suggesting that revealed prices could be higher or lower than physicians expect depending on the type of procedure being ordered. Response to single median price information appears different from that to a pair of “inside” and “outside” prices. When changes were significant, the magnitude of the effect tended to be small but could still translate into substantial differences in spending across thousands of commonly-ordered outpatient procedures.

THE EFFECT OF RECENT MALPRACTICE REFORMS ON THE SUPPLY OF PHYSICIANS Tara F. Bishop¹; Jayme Mendelsohn²; Michael Pesko¹. ¹Weill Cornell Medical College, New York, NY; ²Bryn Mawr College, Bryn Mawr, PA. (Tracking ID #2194798)

BACKGROUND: Physician labor supply affects access to and quality of healthcare. According to the Association of American Medical Colleges, there will be a shortage of 45,000 primary care physicians and 46,000 surgeons and medical specialists by 2020. Physicians may choose to practice in states with favorable malpractice laws. We studied the effect of the most recent wave of malpractice reforms on physician supply.

METHODS: We performed a difference-in-difference analysis of states that had implemented new malpractice damages between 2000 and 2008. For state malpractice law information, we used the Database of State Tort Law Reforms Version 4 (DSTLR4), which is the most comprehensive dataset of state-level malpractice reforms from 1980 to 2010. For physician supply, we used data from the Area Resource File (ARF), which is a county-level database maintained by the U.S. Department of Health and Human Services’ Health Resources and Services Administration. Our main outcome variables were the total number of physicians per 100,000 residents and physicians in the fields of primary care, obstetrics/gynecology, and general surgery. We controlled for state, year, and state-level population characteristics.

RESULTS: Between 2000 and 2008, ten states instituted new damage caps. The number of physicians per 100,000 residents increased from 2000 to 2008 in all the states categories but the percent increase was lowest in states with new caps (2.2 % increase) versus states with existing caps (5.6 % increase) and states with no caps (6.2 % increase). The number of surgeons per 100,000 residents decreased in all state categories—the decrease was lowest in states with existing caps (0.9 % decrease) and no caps (1.1 % decrease) than in states with new caps (5.2 % decrease). The number of obstetricians/gynecologists per 100,000 residents increased in states with existing caps (0.5 % increase) but decreased in states with no caps (0.1 % decrease) and states with new caps (3.2 % decrease). The number of primary care physicians per 100,000 residents increased in states with existing caps (3.1 % increase) and in states with no caps (3.3 % increase) but decreased in states with new caps (0.8 % decrease). In sum, states that implemented new damage caps had the lowest increases in physician supply and, for the fields of surgery and obstetrics/gynecology, the highest decreases in physician supply. In regression analysis, we found a statistically significant decrease of 6.1 physicians per 100,000 residents (95 % confidence interval [CI], −6.1 to −3.6, $p < 0.001$) and 1.7 primary care physicians per 100,000 residents (95 % CI, −2.7 to −0.6, $p = 0.002$) in states that implemented damage caps. There were no significant effects of malpractice caps on the number of surgeons or obstetricians/gynecologists in regression analysis.

CONCLUSIONS: We found that physician supply did not increase in states after they implemented damage caps. Our findings suggest that damage caps are not an effective solution for states seeking to reverse declining physician labor supply.

THE EFFECTIVENESS OF SYMPTOM CHECKERS FOR SELF-DIAGNOSIS AND TRIAGE: BEYOND “GOOGLING” SYMPTOMS Hannah Semigran²; Jeffrey A. Linder^{1,2}; Courtney Gidengil^{3,4}; Ateeq Mehrotra^{2,5}. ¹Brigham and Women's Hospital, Boston, MA; ²Harvard Medical School, Boston, MA; ³RAND Corporation, Boston, MA; ⁴Children's Hospital, Boston, MA; ⁵Beth Israel Deaconess Medical Center, Boston, MA. (Tracking ID #2197500)

BACKGROUND: Over one-third of US adults use the internet for self-diagnosis. Symptom checkers are online tools which use computer algorithms to help patients with self-diagnosis and/or self-triage. Symptom checkers have been introduced by a range of organizations including insurers, physician specialty societies, and private companies. The performance of popular symptom checkers has not been previously assessed. Our objective was to determine the effectiveness of symptom checkers in diagnostic and triage advice.

METHODS: We performed an audit study of 20 symptom checkers using 45 standardized patient (SP) vignettes divided equally into three categories based on the urgency of the problem: emergent care required (e.g., pulmonary embolism), non-emergent care required (e.g., otitis media), and self-care reasonable (e.g., viral upper respiratory illness). The symptoms for each of the 45 SP vignettes were entered into each symptom checker. For symptom checkers that provided a diagnosis, the main outcome was whether the symptom checker listed the correct diagnosis first or in list of potential diagnoses ($n=650$ SP evaluations). For symptom checkers that provided a triage recommendation, the main outcome was whether the symptom checker properly recommended emergent care, non-emergent care, or self-care ($n=516$ SP evaluations).

RESULTS: The symptom checkers provided the correct diagnosis first in 33 % (95 % confidence interval [CI], 30-37 %) of SP evaluations, listed the correct diagnosis at all in 60 % (95 % CI, 56-63 %) of SP evaluations, and provided the appropriate triage advice in 56 % (95 % CI, 51-61 %) of SP evaluations. Triage performance varied by condition urgency, with appropriate triage advice provided in 80 % (95 % CI, 74-86 %) of emergent cases, 55 % (95 % CI, 47-62 %) of non-emergent cases, and 34 % (95 % CI, 27-41 %) of self-care cases ($P<0.001$). The range of appropriate triage advice provided by individual symptom checkers was 33 % (95 % CI, 19-48 %) to 78 % (95 % CI, 64-91 %) of SP evaluations.

CONCLUSIONS: Symptom checkers had deficits in both diagnosis and triage. Triage advice was generally risk-averse; symptom checkers encouraged users to seek care for conditions where self-care was reasonable.

THE EFFECTS OF A MULTI-FACETED MEDICATION RECONCILIATION QUALITY IMPROVEMENT INTERVENTION ON PATIENT SAFETY: FINAL RESULTS OF THE MARQUIS STUDY Jeffrey L. Schnipper^{6, 2}; Jason Stein⁷; Tosha B. Wettemeck^{4, 8}; Peter Kaboli^{3, 9}; Stephanie Mueller^{6, 2}; Amanda S. Mixon³; Stephanie Labonville⁶; Jacquelyn A. Minahan⁶; Elisabeth Burdick^{1, 6}; Endel John Orav⁶; Jenna Goldstein¹⁰; Nyryan V. Nolido⁶; Sunil Kripalani¹¹. ¹Brigham & Women, Boston, MA; ²Harvard Medical School, Boston, MA; ³Iowa City VAMC, Iowa City, IA; ⁴University of Wisconsin School of Medicine and Public Health, Madison, WI; ⁵VA Tennessee Valley Healthcare System and Vanderbilt University, Nashville, TN; ⁶Brigham and Women's Hospital, Boston, MA; ⁷Emory University School of Medicine, Atlanta, GA; ⁸University of Wisconsin Madison, Madison, WI; ⁹University of Iowa Hospitals and Clinics, Iowa City, IA; ¹⁰Society of Hospital Medicine, Philadelphia, PA; ¹¹Vanderbilt University Medical Center, Nashville, TN. (Tracking ID #2194915)

BACKGROUND: Unintentional medication discrepancies during hospitalization can contribute to patient harm. Discrepancies can be reduced by performing medication reconciliation; however, effective implementation is challenging. The goals of the Multi-Center Medication Reconciliation Quality Improvement Study (MARQUIS) were to operationalize best practices for inpatient medication reconciliation and test their effect on potentially harmful medication discrepancies.

METHODS: Five U.S. hospitals participated in a 2-year quality improvement (QI) study between September 2011 and July 2014. With the guidance of trained mentors and using standard QI principles, each site implemented at least one of 11 intervention components on some or all medical-surgical inpatient units. A toolkit and supplementary materials such as instructional videos and slide presentations described the design and implementation of these intervention components in detail. Mentors conducted monthly phone calls and two site visits during the intervention period. The primary outcome was the number of

potentially harmful unintentional medication discrepancies per patient. This was determined in approximately 22 randomly selected patients per month at each site during a 6-month baseline period and throughout the intervention. Trained on-site pharmacists took “gold standard” medication histories on these patients, compared these histories to admission and discharge medication orders, and identified and categorized all discrepancies. Trained physician adjudicators at each site determined the potential for harm of all unintentional discrepancies. To analyze the effect of the entire intervention on the primary outcome, we conducted an interrupted time series analysis using multivariable Poisson regression to detect both sudden improvement with initiation of the intervention and change in the temporal trend after initiation, adjusted for baseline temporal trends and baseline differences between intervention and any control units.

RESULTS: Across the five participating sites, 1479 patients were enrolled, including 548 patients during the baseline period and 931 patients during the intervention period. Implementation of the intervention as a whole was associated with a reduction in the number of potentially harmful discrepancies over time, beyond any baseline temporal trends: incidence rate ratio 0.89 per month (95 % CI 0.80 to 0.99), $p=0.03$. Of the 4 sites that implemented anywhere from 4 to 7 different intervention components during the study period, 3 sites saw reductions in their potentially harmful discrepancy rate. The site that saw an increase in their discrepancy rate implemented a new electronic medical record shortly after beginning the intervention.

CONCLUSIONS: Adoption of a multi-faceted medication reconciliation quality improvement initiative using a mentored implementation model was associated with a reduction in potentially harmful medication discrepancies over time.

THE EFFECTS OF IMPLEMENTING A PATIENT-CENTERED MEDICAL HOME MODEL ON EMERGENCY UTILIZATION IN A VA HEALTH CARE SETTING Ana Quinones¹; Sandra Joos²; Kyle D. Hart¹; Ana Rosales³; Nancy Perrin³; Devan Kansagara^{3, 4}. ¹OHSU, Portland, OR; ²Portland VA Medical Center, Portland, OR; ³VA Portland Health Care System, Portland, OR; ⁴Oregon Health and Science University, Portland, OR; ⁵Kaiser Permanente Center for Health Research, Portland, OR. (Tracking ID #2201320)

BACKGROUND: The patient-centered medical home (PCMH) model has garnered widespread interest, in part as a way to reduce unnecessary emergency room and hospital use by providing more patient-centered, coordinated and comprehensive care. During the 1990's, the Veterans Health Administration (VHA) instituted major healthcare transformations that touch on aspects of the PCMH model including the establishment of an electronic medical record, quality measurement, and a limited use of team-based care. In 2010, given remaining gaps in care, the VHA began a nationwide implementation of its version of PCMH called the Patient-Aligned Care Team (PACT) initiative. Five evaluation centers, called Demonstration Labs, were concurrently established to proactively examine PACT implementation. We report data from clinics in our Demonstration Lab comparing trends in emergency utilization outcomes before and after PACT implementation.

METHODS: The VA Portland Health Care System encompasses 11 clinics which treat approximately 80,000 outpatients. We used administrative data from the VHA Corporate Data Warehouse to create a longitudinal database from 2005 to 2014, organized in month-long snapshot periods. For each snapshot, we calculated the proportion of patients assigned to a given clinic that experienced one or more utilization events of interest (emergency room visits, hospital admissions, 30-day hospital readmissions). We conducted a time-series analysis to compare trends in utilization before and after PACT implementation. We excluded data during a six month implementation window following the official PACT start date in April 2010.

RESULTS: We had adequate data to establish stable baseline trends in utilization for 8 of the 11 clinics (3 of the clinics were too small to contribute reliable data). Over the first four years of PACT implementation, all clinics improved staffing ratios and 4 of 8 clinics reached recommended staffing ratios. However, 6 of 8 clinics had low levels of staffing stability (<0.5 on a staffing stability scale from 0 to 1). PACT implementation was not associated with reductions in emergency room (ER) visit or hospital admission rates in any clinic. The rates of ER visits were declining slightly (-0.01 to -0.02 % monthly) in 6 of 8 clinics over the 5 years prior to PACT implementation. One of the 8 clinics experienced reductions in readmission rates after PACT implementation (pre-PACT 0.2 %/month increase; post-PACT .5 %/month decrease; $p<0.001$).

CONCLUSIONS: We found that ER visit rates declined slightly in most clinics in the years prior to PACT implementation. However, we found no consistent evidence that PACT implementation was associated with further reductions in ER or hospital utilization. It is unclear whether these results reflect limits in the ability of PACT to impact utilization outcomes, or the relative immaturity of PACT implementation at this stage. It will be important to track utilization outcomes as important elements such as staffing stability improve. We are currently conducting qualitative analyses as well to better understand facilitators and barriers to PACT implementation that may help further explain our findings.

THE FAMILY NAVIGATOR: PILOT STUDY OF A NEW ROLE TO SUPPORT FAMILY COMMUNICATION IN THE ICU Alexia M. Torke^{3,4}; Lucia D. Wocia⁴; Shelley A. Johns^{3,1}; Christopher M. Callahan^{3,1}; Greg A. Sachs^{3,1}; Susan M. Perkins^{1,2}; Mary Austrom¹; Richard M. Frankel^{1,5}; Babar Khan³; James E. Slaven²; Kianna Montz³; Emily Burke³. ¹Indiana University, Indianapolis, IN; ²Indiana University School of Medicine, Indianapolis, IN; ³Regenstrief, Indianapolis, IN; ⁴Fairbanks Center for Medical Ethics, Indianapolis, IN; ⁵Richard L. Roudebush VA Medical Center, Indianapolis, IN. (Tracking ID #2197536)

BACKGROUND: In the intensive care unit (ICU), family members suffer from high levels of psychological distress. Inadequate communication with clinicians and challenges in decision making are two important sources of distress that are amenable to intervention. New interventions are needed that support family surrogate decision makers with communication and decision making. We developed and pilot tested the Family Navigator (FN), a new nursing role to address surrogates' unmet communication and support needs in order to improve decision making and surrogate outcomes.

METHODS: The setting was the medical ICU of a tertiary referral center. The intervention was developed based on prior research and an interdisciplinary team model involving close collaboration with ICU nurses, physicians and social workers who met weekly to develop the intervention. The team considered interventions that met 6 communication needed identified by family surrogates in our prior research (Table). The intervention included a semi-structured initial interview with the FN to establish rapport and daily contact to provide information and assess needs. The FN was fully integrated into the ICU team and rounded with them daily. She collected specific information during rounds, including changes in condition, overall goals of care and daily goals. The FN used this information to provide a daily update to the family regarding the patient's clinical condition. The FN also selected educational/emotional support modules that she delivered to the family member(s) based on needs identified during the initial interview and the daily contacts. The FN was a registered nurse with extensive ICU experience who underwent a 2 week training program. We conducted a single-site, randomized pilot study to test feasibility and acceptability. Patient/Surrogate dyads were eligible if the patient had severe cognitive impairment based on coma, sedation or the Short Portable Mental Status Questionnaire and the surrogate could be enrolled within 3 days of ICU admission.

RESULTS: We identified 69 eligible patient/surrogate dyads and enrolled 26 (13 in each group). Patients were 58 % female, 27 % African American and 73 % white. Surrogates were spouses (54 %) and children (31 %). All intervention surrogates completed the introductory interview, and all were contacted by the FN on greater than 90 % of eligible study days. The most frequently used educational modules were: code status (delivered to 92 % of surrogates); making a medical decision (77 %), and withdrawal of life sustaining therapy (69 %). In follow-up interviews, all subjects agreed or strongly agreed that they would recommend the FN to other families. One participant said, "The support and the overall counseling was comforting and gave optimism and relief. She talked to my kids, which helped them relax." Clinicians were also highly positive. One physician said, "For family members, it helped them understand better what was going on with the (patient). It helped us to establish the goals of care much faster. For staff, it decreased our frustration." Clinicians did not believe they communicated any less with families because of the intervention. As one said, "On the contrary, I think it was better communication. More than usual because of her presence."

CONCLUSIONS: A nurse-led intervention to support surrogates is feasible and well received by surrogates. This intervention was integrated fully into the system of care and met needs previously identified by ICU family members. Future research will test the impact of the intervention on family well-being and decision making in a larger randomized controlled trial.

Elements of Communication

Element of Communication	Problem	FN Intervention
Communication Timing	Lack of timely updates, delays in communication, sporadic and random timing of contact with clinicians, based on rounds, schedules and family availability	Planned daily contact with the surrogate, individualized time and mode (phone, in-person) based on individual surrogate needs Coordinate family meetings with clinical team
Information Disclosure	Inadequate provision of information about the patient's condition, treatment and prognosis	Provide or facilitate regular clinical updates about the diagnosis and medical care Protocols about key decisions and options (goals of care, resuscitation status, hospice) Provide written resource documents Use teach back strategies to reinforce information
Emotional/spiritual support	Strong or overwhelming emotions and unmet spiritual needs that interfere with coping and decision making	Provide emotional and spiritual support, involves other resources as needed (chaplain)
Treated with Respect	Surrogates sometimes feel their role is as a family member is not understood or respected	Active listening, use of the VALUE framework
Surrogate Engagement/advocacy	Lack of knowledge of how to navigate a complex environment; varying skill levels at advocating for patient or family needs	Educates the family on hospital resources and how to navigate the hospital and health care system Coordinates inpatient care and discharge transitions Post-discharge phone calls to manage care and facilitate follow-up
Strength of Relationships	Fragmented relationships with clinicians	Form an ongoing relationship with the surrogate

THE FREQUENCY OF ATTENDING-LED DISCUSSION OF TEST ORDERING PRINCIPLES DURING INTERNAL MEDICINE WARDS ROUNDS Cason Pierce^{1,4}; Daniel Ozzello⁴; Angela Keniston²; Chad Stickrath³. ¹Denver Health, Denver, CO; ²Denver Health and Hospital Authority, Denver, CO; ³Denver VA Medical Center, Denver, CO; ⁴University of Colorado, Denver, CO. (Tracking ID #2197468)

BACKGROUND: Teaching rounds play a central role in the education of medical trainees. Beyond transmitting medical knowledge, they allow attending physicians to inculcate important behaviors through role modeling. In the last few years, policymakers and medical educators have stressed the importance of educating future practitioners about cost consciousness and the provision of high value care. Recognizing that the topic of high value care is relatively new in medical education, we sought to quantify the frequency with which attending physicians lead team discussion about test ordering principles.

METHODS: As part of a larger study examining the effects of a faculty seminar on the teaching behaviors of attending physicians during team rounds, we collected data on the frequency with which faculty discussed test ordering principles with their teaching teams. All observations occurred at either Denver Health, a safety-net teaching hospital in Denver, Colorado, or the University of Colorado, a tertiary academic center in Aurora, Colorado. Both hospitals are University of Colorado affiliates. Teaching teams always consisted of one attending, one resident, and one intern. Teams usually included one third and one fourth year medical student. Separate, paid fourth year medical students were trained to be non-participant observers of faculty-led team rounds on the internal medicine wards at these two sites. The student observers used a standardized instrument to classify for each patient discussed whether or not the attending asked any member of the team: 1) If a diagnostic test other than a complete blood count, basic metabolic panel, hepatic panel, or coagulation panel had previously been performed on the same patient 2) Whether the results of any ordered diagnostic test would affect patient care 3) Whether a discussed test result represented a false positive or whether a diagnostic study under consideration might result in a false positive 4) Whether the patient would suffer any short-term harm if a test

was not ordered 5) Whether the team considered the patient's preferences in ordering a diagnostic study. In addition, we recorded for each patient encounter the total time discussing the care plan, the total time spent at the patient's bedside, and whether a patient was on the day of observation "new" or "already known" to the team. Observations about the discussion of test ordering were scored as "0" (did not occur) or "1" (did occur). We aggregated data from all encounters separately for each of the five questions above. We then performed secondary analysis to see whether there were frequency differences between new and known patients and whether the percentage of time at the bedside correlated with frequency of discussion about test ordering principles.

RESULTS: Observations occurred between December 2013 and December 2014. A total of 16 rounding days led by 15 different attending physicians were observed for a total of 159 unique patient encounters. Eleven rounding day observations occurred at Denver Health and five at the University of Colorado. Results are shown in table 1 below. Overall, rates at which attending physicians discussed test ordering were very low. Across all 159 observed patient encounters, the frequency ranged from 1.89 % for discussion about short-term harm to 13.84 % for whether a test affected care. For patients who were "new" to the team, there was a trend toward more frequent discussion of whether tests affected care, but this trend was not statistically significant ($p=.066$). There was no clear relationship between time spent at the bedside and the likelihood of discussion about test ordering practices in any of the five defined categories.

CONCLUSIONS: In our study that involved direct observation of attending teaching for 159 patient encounters at two hospitals within the same academic training center, the frequency with which test ordering principles were discussed was very low. In the vast majority of cases—greater than 75 %—the attending physician did not engage the team in any discussion about test ordering principles or the implications on patient care. Although our study was limited by a relatively small sample size, we did not find a correlation between time spent at the bedside and greater frequency of discussion about test ordering. We also did not detect that these discussions happened more frequently for patients who were "new" to the team. While our study results need validation at more centers, they suggest the principles of high value care are not being widely taught during team rounds in internal medicine. Efforts to increase trainee exposure to the principles of high value care during team rounds may require targeted faculty development.

Frequency of Occurrence of Discussion About Test Ordering Principles

	Previously done?	Affect care?	False Positive?	Short-term harm?	Patient preference?
All patients	6.33 %	13.84 %	3.14 %	1.89 %	3.14 %
New patients	9.09 %	23.53 %	2.94 %	2.94 %	5.88 %
Old patients	5.93 %	11.86 %	3.39 %	1.69 %	2.54 %

THE HEPATITIS C VIRUS CASCADE AT AN URBAN POST-INCARCERATION TRANSITIONS CLINIC Laura C. Hawks¹; Brianna L. Norton³; Chinazo Cunningham²; Aaron D. Fox³. ¹Albert Einstein College of Medicine, Bronx, NY; ²Albert Einstein College of Medicine & Montefiore Medical Center, Bronx, NY; ³Montefiore Medical Center, Bronx, NY. (Tracking ID #2196502)

BACKGROUND: In the United States, Hepatitis C Virus (HCV) infection is a public health crisis that causes more annual deaths than HIV (15,106 vs. 12,704 in 2007). HCV

infection mostly affects marginalized groups such as injection drug users and criminal justice populations. Among prison inmates, HCV infection rates can be 23-fold that of the general population. Transitions clinics, which provide care to individuals following release from jail or prison, target this population, but it is unknown whether these clinics facilitate treatment of chronic HCV. New medications with higher cure rates and fewer side effects than previous regimens create an opportunity to address the HCV crisis, but it is estimated that only 9 % of Americans with chronic HCV will ever achieve cure. The HCV treatment cascade is a model that describes the steps necessary to identify and treat HCV infection. We used the HCV cascade to identify gaps in care for patients at an urban transitions clinic, which could inform future interventions to improve HCV treatment and cure rates.

METHODS: We conducted a retrospective cohort study reviewing electronic health records for formerly incarcerated individuals who received medical care at the Bronx Transitions Clinic (BTC) between July 2009 and October 2014. Subjects were all patients of the BTC, which is located in a federally qualified health center (FQHC) and receives referrals from a community-based criminal justice organization. Clinical and sociodemographic data was extracted from electronic health records using a standardized data collection tool. Steps of the HCV treatment cascade were based on prior published data. These measures included the proportion of patients who were screened (assessment of anti-HCV antibodies, yes/no), chronically infected (presence of HCV RNA > 75 IU/mL, yes/no), referred to a specialist (referral made, yes/no), completed referral (specialist evaluation, yes/no), initiated treatment (documented prescription, yes/no), and completed treatment with cure (post-treatment HCV RNA < 75 IU/mL, yes/no). The reason for discontinuation of care was determined by consensus among authors based on documented clinical data and review of an online New York State Department of Corrections database.

RESULTS: Of 451 BTC patients, 317 (70 %) were screened for HCV, and 108 (34 %) tested positive for HCV. Median age was 50, and the majority were male (93 %), Hispanic non-Black (62 %), and had Medicaid (97 %). Of the 108 patients with serologic evidence of HCV infection, 99 (92 %) were evaluated for HCV viremia and 90 (83 %) had chronic HCV infection. Of these 90 with chronic HCV, 45 (50 %) were referred to an HCV specialist, 28 (31 %) completed the referral, 6 (7 %) initiated treatment, and 3 (3 %) were cured. Reasons for discontinuation of care were established for all participants. Of the 45 who were referred to a HCV specialist, 17 (38 %) did not complete the referral; the most common reasons were re-incarceration (6) and loss to follow-up (6). Of the 28 participants who completed specialist referral, 22 (79 %) failed to initiate treatment; this was most commonly due to: waiting for availability of new medications (10) or undergoing additional evaluation (7).

CONCLUSIONS: Among patients of an urban post-incarceration transitions clinic, chronic HCV infection was common but few completed treatment and achieved cure. The majority of patients lost contact with the treatment cascade before they could be considered for antiviral therapy. Referral to a specialist was a major gap in care with approximately one-third lost to follow-up and one-third re-incarcerated before specialist evaluation. With the availability of new highly-effective medications, cure of HCV is a realistic goal, but first barriers to care must be addressed. Broader interventions to help individuals achieve stability following release from jail or prison are necessary to encourage continuity of medical care. Integrating HCV specialists within FQHCs or training primary care physicians to provide HCV care could obviate the need for specialist referral. However, the high rates of loss to follow-up and re-incarceration also suggest that some barriers to care for criminal justice populations may be outside of the realm of the health care system.

THE HIDDEN CURRICULUM IN HIGH-VALUE CARE EDUCATION: RESIDENT-PERCEIVED BARRIERS TO PRACTICING HIGH VALUE CARE IN A TRAINING ENVIRONMENT Maggie K. Benson¹; Anna K. Donovan²; Megan Hamm²; Susan Zickmund²; Melissa McNeil¹. ¹University of Pittsburgh Medical Center, Pittsburgh, PA; ²University of Pittsburgh School of Medicine, Pittsburgh, PA. (Tracking ID #2196705)

BACKGROUND: Healthcare professionals have embraced the concept of high-value care (HVC) to eliminate the medical and financial harms of unnecessary care. Formal curricular interventions for physicians in training have been developed, but there has been limited investigation into residents' barriers to practicing HVC. In this qualitative study we sought to elicit resident-perceived barriers to HVC in academic and community training environments.

METHODS: Six focus groups with internal medicine, transitional and preliminary interns and internal medicine residents were held in the spring of 2014. Four groups were held at a tertiary academic medical center, and two at a community affiliate site. Groups were stratified by training level. The study team created a question script that was used by an experienced facilitator to lead all groups. The focus groups ranged in size from 7 to 13 participants. The 60-min discussions were audio-recorded and transcribed verbatim. Using the Editing approach to qualitative analysis developed by Crabtree and Miller, a codebook was developed by a qualitative expert and the principle investigator. Two coders independently applied the codes to the focus group transcripts using ATLAS.ti (Scientific Software, Berlin Germany) software. After coding, discrepancies between coders were adjudicated until agreement was achieved. The original coding files prior to adjudication were used to calculate intercoder reliability. The mean Kappa statistics was 0.85.

RESULTS: Fifty-three trainees (26 interns and 27 upper level residents) participated. Thirty-six residents were in training at the tertiary academic center, and seventeen at the community affiliate site. The majority of trainees at the academic medical center had completed at least one rotation with the Veterans Affairs Hospital System. The most common barriers to emerge were: (1) patient expectations, (2) the influence of subspecialist and attending physicians, (3) the lack of cost transparency, (4) pressures for efficiency, and (5) fear of missing a diagnosis. First, residents were concerned that not meeting patient expectations for resource-intensive healthcare would negatively impact the doctor-patient relationship and physician performance measures. One resident stated, "I think, unfortunately, patients associate more tests with better doctors. If you reassure them, even if you have a great relationship, they'll think 'Oh, my doctor didn't care.'" Second, residents felt generalists were more cognizant of HVC than subspecialists, and this difference in practice created a conflict for trainees. One resident described "hostility and tension" as a result of not following subspecialist recommendations that were perceived as low-value. Others acknowledged difficulty in communicating differing physician recommendations to patients. The impact of the medical hierarchy also extended to supervising generalist physicians. "I think we are empowered to state our points, but ultimately we just end up doing what someone superior wants us to do." Third, residents had difficulty identifying costs of care and were most concerned with how cost might impact patients, in contrast to society in general. Simply stated, one said, "The biggest obstacle to talking about cost is that we don't know the cost." Another explained, "It's Monopoly money. This \$90,000 bill? That was the charge, but that's not what [the patient] is going to pay." Fourth, pressures for efficiency were cited as limited time to: research evidence-based practice, investigate cost, and engage in shared-decision making. "Getting people to understand that in medicine the tried and true stuff that's old and cheap is actually the best stuff...takes convincing and energy and the ability to communicate well. Sometimes we're overwhelmed and the time just isn't there." Finally, residents expressed fear of missing a diagnosis by showing restraint. Residents' past experiences in over-ordering created a cognitive bias that encouraged future over-ordering. "You are going to miss things when you practice high value care. A couple times I've actually had a result come back positive that I wasn't expecting and probably wouldn't have ordered it had I really been focused on high value care."

CONCLUSIONS: While the medical community has promoted HVC in the formal curriculum, trainees identify barriers in the hidden curriculum that hinder the practice of HVC. Residents are apprehensive about communicating with patients about avoidance of unnecessary care. Their discomfort with resolving differences with attendings and subspecialists indicates the hierarchical structure of medicine may undermine the academic mission, especially with regards to HVC. Future efforts to promote HVC in training environments should address the hidden curriculum by providing residents with easily-accessible, individualized cost information and cultivating an academic learning

environment that fosters dialogue about value between residents and both patients and physicians.

THE IMPACT OF AN AWARENESS CAMPAIGN ON HOSPITAL COST REDUCTION AND REDUNDANT LABORATORY TESTING IN A COMMUNITY TEACHING HOSPITAL Kofi M. Osei¹; Virginia Cody¹; Heather G. Huribal¹; Forugh Homayounrooz¹; Catherine Apaloo². ¹ST VINCENTS MEDICAL CENTER, Bridgeport, CT; ²Athens Regional Hospital, Athens, GA. (Tracking ID #2168748)

BACKGROUND: Introduction: Health care waste, estimated at \$690 billion dollars annually (2012) contributes to the rising cost of healthcare in the U.S. Unnecessary testing or diagnostic procedures accounts for between \$158 billion and \$226 billion (2012), with physicians being one of the drivers of this rising cost in healthcare. The ACP and AAIM have found ways to incorporate high value care (HVC) curricula in residency training programs to raise awareness of this issue. As part of a quality improvement (QI) project we assessed the impact of a computer monitor post-it to heighten awareness of HVC on cost savings and the number of laboratory tests ordered per hospital admission days. **Objectives:** (1) To determine the absolute cost reduction (ACR) in the average cost per hospital admission days due to CBC and BMP ordering before and after intervention. (2) To determine and compare the total number of laboratory tests—complete blood count [CBC] and basic metabolic panel [BMP]—ordered per hospital admission days, before and after the intervention. (3) To compare (1) and (2) amongst three physician groups, residents, hospitalists and private physicians

METHODS: Study Design: Prospective interventional QI study, conducted over a 6 month period. The first 3 months were pre-interventional and the subsequent 3 months post-interventional. **Study Site:** St Vincent's Medical Center (SVMC) a Quinnipiac University affiliated community hospital located in Bridgeport, CT. **Participants:** Physicians in the Dept. of Medicine were categorized into 3 groups: residents, hospitalists and private physicians. **Intervention:** A 4.5×5.5" post-it about careful laboratory and diagnostic testing was attached to every SVMC computer monitor used access the CPOE system over the entire interventional period. HVC education was provided during physician meetings and at resident noon conferences. **Ethics:** IRB approval was obtained **Data and Statistics:** Data was extracted from the SVMC database. The cost of CBC and BMP were per hospital charges. Poisson regression was used for unadjusted and adjusted analysis. Student's t-test used to obtain ACR. *p*-value<0.05 was considered significant. Stata 11 was used for the analysis.

RESULTS: Results: There were 19,380 orders for CBC and BMP during the pre-intervention period compared to 17,848 during the post-interventional period. The ACR was 8.32 (2.95–13.70), *p* 0.002 with an estimated cost savings of \$139,000 over the 3-month period. ACR was largest amongst the residents [ACR 17.14(4.12–30.16), *p* 0.01], hospitalists [ACR 13.17 (3.76–22.57), *p* 0.01], private physicians [ACR 4.85(–2.15–11.84), *p* 0.174]. The incidence rate ratio (IRR) for total number of labs per hospital admission days was 0.98 (0.92–1.05), *p* 0.64 after adjusting for physician groups. Subgroup analysis showed favorable trend for residents though not significant; [IRR 0.99 (0.89–1.10), *p* 0.870], hospitalist [1.04 (0.93–1.17), *p* 0.490] and private physicians [1.00 (0.93–1.08), *p* 1.00]. After adjusting for physician group CBC ordering pattern was not different pre or post interventional [IRR 1.01 (0.944–1.08), *p* 0.78], there was a non-significant favorable trend toward reduction in BMP orders after adjusting for physician group [RR 0.96(0.90–1.02), *p* 0.27]

CONCLUSIONS: Discussion: Our study demonstrates that a simple intervention such as post-it on HVC coupled with HVC awareness education can help reduce the cost of care. The greatest effect was seen in the resident group attesting that introducing HVC during training is likely to alter future ordering habits and help reduce the cost of care. Though there was a non-significant trend toward reduction in lab ordering, it was financially significant (**\$139,000**). Thus minor reductions in wasteful tests are likely to produce huge healthcare cost savings. Future research should include radiologic testing. Such research in the future should adjust for disease burden in the pre-interventional and post-interventional period. **Conclusion:** Low cost interventions such as post-its on HVC along with heightened HVC awareness is effective in reducing health care costs.

THE IMPACT OF AND INTERACTION BETWEEN CHRONIC OPIOID THERAPY AND BEHAVIORAL HEALTH COMORBIDITIES ON HOSPITAL, EMERGENCY DEPARTMENT, AND PRIMARY CARE UTILIZATION IN A LARGE INTEGRATED HEALTH SYSTEM Edward Ewen; Jennifer LeComte; Bailey C. Ingraham Lopresto; Sarah Schenck. Christiana Care Health System, Newark, DE. (Tracking ID #2196060)

BACKGROUND: There is little known about health care resource utilization in patients receiving chronic opioid therapy (COT) for chronic non-cancer pain. In addition, many of these patients have comorbid behavioral health conditions (BHC) that are already well associated with increased resource utilization. This study examines the potential association between COT and the utilization of hospital, emergency department (ED), and office resources and explores the interaction between COT and behavioral health conditions with regards to utilization in a large primary care network within an integrated health system.

METHODS: We performed a retrospective cohort analysis of all patients age 18 and older seen in a 12 month period (3/27/2013 to 3/27/2014) in one of 19 primary care practices. All demographic information, clinical observations, hospitalizations, ED visits, and office visit activity were obtained from a shared electronic health record. Chronic opioid use was defined as current use and continuous prescribing by the primary care provider of any opioid (excluding tramadol and propoxyphene) for 6 or more months during the study year. COT patients managed outside of the primary care setting were excluded from this analysis. BHCs were identified using problem list entries. Outcomes measures included the number of primary care office visits, total office clinical interactions (defined as office visits+patient calls to the office for reasons other than scheduling and billing inquiries), ED visits, and hospitalizations. A propensity score (PS) for the population overall was generated based on the probability to receive COT using a logistic regression model including 30 variables other than those indicating COT or a BHC. Those receiving COT were matched by PS to controls in a 1:5 ratio using greedy, nearest neighbor matching without replacement and a caliper width of .12 standard deviations of the logit of the estimated PS. Outcomes and description variables were compared using Chi-square or Mann-Whitney U tests in the matched population as appropriate. Visit counts were compared with negative binomial regression to overcome over dispersion in the outcome distribution while controlling for presence of behavioral health conditions and its interaction with chronic opioid therapy.

RESULTS: We identified 56196 eligible patients with 815 (1.4 %) receiving COT from their primary care provider. A total of 814 COT patients were successfully matched to 4 or 5 control patients ($n=4020$) for a total of 4832 study patients. There were no significant differences between populations in any of the 30 variables used to generate the PS. Over one-half of the matched patients had a behavioral health diagnosis ($n=2452$). Patients receiving COT were significantly more likely to have a BHC (70.0 vs. 46.8 %, $p<0.001$). There were a total of 20719 office visits (mean 4.29, SD 3.17), 64535 office interactions (mean 13.35, SD 12.05), 2977 ED visits (mean 0.62, SD 1.84), and 1338 hospitalizations (mean 0.28, SD 0.85) in this matched population. Both COT and BHC were associated with a greater number of office visits (COT: IRR 1.82, 95%CI 1.58–2.10 BHC: IRR 1.34, 95%CI 1.25–1.43) and office interactions (COT: IRR 2.76, 95%CI 2.40–3.16 BHC: IRR 1.56, 95%CI 1.46–1.66). The interaction between COT and BHC was not significant for office visits ($p=0.057$). However, when examining office clinical interactions among those with COT, those with a BHC had nearly 20 % more interactions than those without a comorbid BHC (IRR 1.19, 95%CI 1.02–1.39). COT and BHC were also associated with increased risk of hospitalization (COT: IRR 2.06, 95%CI 1.57–2.71 BHC: IRR 2.01, 95%CI 1.74–2.32). Among those receiving COT, those with a BHC were over 40 % more likely to be hospitalized (IRR 1.42, 95%CI 1.06–1.90). When examining ED utilization both COT and BHC were again associated with increased rates of utilization (COT: IRR 1.79, 95%CI 1.44–2.22 BHC: IRR 2.30, 95%CI 2.07–2.56). Among those receiving COT, those with a BHC were nearly 40 % more likely to have an ED visit (IRR 1.37, 95%CI 1.09–1.73).

CONCLUSIONS: Overall, both COT and BHC were associated with significantly increased utilization rates in all settings. In addition, significant interactions between COT and comorbid BHC were apparent in all but office visits. The impact of COT alone was most apparent in office interactions, which were over 2 ½ times greater in the COT group. The appropriate management of COT requires frequent reassessment and month-to-month prescription generation, which likely explains at least a portion of the excess office activity seen in this population. In those receiving COT, a comorbid BHC increased the risk of both hospital and ED utilization by approximately 40 %. Given the significant observed interactions between COT and comorbid BHCs, future efforts to address resource utilization in this population will also likely need to address the frequent comorbid behavioral health conditions that are so prevalent in this population.

THE IMPACT OF CHRONIC OPIOID THERAPY FOR NON-CANCER RELATED PAIN ON THE DELIVERY OF PREVENTIVE SERVICES AND CHRONIC DISEASE MANAGEMENT IN PRIMARY CARE PRACTICES Edward Ewen; Jennifer LeComte; Bailey C. Ingraham Lopresto; Sarah Schenck. Christiana Care Health System, Newark, DE. (Tracking ID #2195604)

BACKGROUND: The appropriate management of chronic opioid therapy (COT) for chronic non-cancer pain requires considerable time and attention to both the effect of

therapy and the risk of opioid misuse, addiction, and diversion. Given the visit time constraints of a typical primary care practice there is concern that the complexity of COT management could distract providers from other important tasks related to the management of chronic diseases and preventive services. This study examines the potential association between COT and selected outcomes for diabetes, hypertension, and preventive services in a large primary care network.

METHODS: We performed a retrospective cohort analysis of all patients age 18 and older seen in a 12 month period (3/27/2013 to 3/27/2014) in one of 19 primary care practices. All demographic information, clinical observations, and office visit activity were obtained from the office electronic medical record. Chronic opioid use was defined as current use and continuous prescribing by the primary care provider of any opioid (excluding tramadol and propoxyphene) for 6 or more months during the study year. COT patients managed outside of the primary care setting were excluded from this analysis. Subpopulations of those with diabetes and hypertension were identified using problem list entries. Outcomes measures included the number of office visits, HgbA1c, proportion with HgbA1c<9 %, LDL, proportion LDL<100, annual foot exams in diabetics, proportion with blood pressure<140/90 mmHg, proportion of biannual mammography screening in women age 50 to 75 years and proportion of those age 65 and older with documented pneumococcal vaccination. A propensity score (PS) was generated using a logistic regression model for the population overall and for each disease and demographic subpopulation based on the probability to receive COT. Those receiving COT were matched by PS to controls in a 1:5 ratio using greedy nearest neighbor matching without replacement and a caliper width of .12 standard deviations of the logit of the estimated PS. Outcomes and description variables were compared using Chi-square or Mann-Whitney U tests in the matched population as appropriate. The number of office visits over the year of follow-up were compared with negative binomial regression to account for over-dispersion observed in the count data.

RESULTS: We identified 56196 eligible patients with 815 (1.4 %) receiving COT from their primary care provider. All 815 COT patients were successfully matched to 3 to 5 ($n=4007$) control patients for a total of 4822 study patients. Subpopulations were matched with similar success. For diabetics ($n=7735$), 185 of 187 COT patients were matched to 874 controls; 477 of 479 COT patients were matched to 2321 controls for hypertensives ($n=22533$). The mammogram eligible ($n=14490$) population matched 284 of 287 COT patients to 1331 controls; and of those with age≥65 ($n=12336$) 215 of 217 COT patients matched to 1037 controls. After matching there were no significant differences between populations in any of the variables used to generate the PS. COT patients had significantly higher office utilization (6.6 vs 4.0, IRR=1.66, $p<0.001$) compared to the controls. Among diabetics there were no significant differences in proportion between COT and non-COT in HbA1c<9 % (73.5 % vs. 72.7 %, $p=0.86$), LDL<100 mg/dL (22.7 % vs. 19.2 %, $p=0.31$), BP control (70.8 % vs. 67.4 %, $p=0.39$), or annual foot exams (48.1 % vs. 53.3 %, $p=0.22$). In the hypertensive population there was no difference in proportion achieving BP control (63.3 % vs. 66.1 %, $p=0.24$). There were also no significant differences in eligible women receiving mammograms (69.4 % vs. 70.1 %, $p=0.83$), or patients age≥65 years receiving pneumococcal vaccine (89.8 % vs. 85.8 %, $p=0.15$).

CONCLUSIONS: We found no difference in observed outcomes with respect to preventive care, diabetes or hypertension management between those patients receiving COT and those without in our primary care population. COT patients were seen 70 % more frequently in the office, providing more opportunities to address chronic disease and preventive care issues. It is possible the increased frequency of interactions overcame the difficulty seen with addressing multiple competing problems at any given visit.

THE IMPACT OF PHYSICIANS' ONLINE BEHAVIOR ON PATIENT TRUST: A MULTISITE SURVEY STUDY Katherine C. Chretien⁵; Javad J. Fatollahi⁵; James Colbert³; Joy L. Lee²; Priyanka Agarwal¹; Lisa S. Lehmann¹. ¹Brigham and Women's Hospital, Boston, MA; ²Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; ³Newton-Wellesley Hospital, Newton, MA; ⁴University of California, San Francisco, San Francisco, CA; ⁵Washington DC VAMC, Washington, DC. (Tracking ID #2200315)

BACKGROUND: Medical institutions and organizations have developed online professionalism policies and curricula to help guide physician behavior in the digital age. Prior research has gathered multiple stakeholders' perspectives on online professionalism including medical educators and administrators, practicing physicians, trainees, and to a much lesser extent, the public. These studies have shown differing opinions about how professionalism is defined online based on population studied, with medical educators having the most conservative views in general. Public views are poorly understood. Importantly, the impact of medical professionals' online behavior on patient trust—the foundation of the patient-physician relationship—is unknown.

METHODS: A cross-sectional survey study was conducted with patients at four academic primary care outpatient clinics in 3 US cities in 2014. Clinics were chosen for geographic and demographic diversity. The paper-based survey explored patients use of social media and technology for healthcare. One section asked respondents how their trust in their doctor might or might not change if they witnessed online scenarios involving their doctor. Scenarios were selected based on prior literature. Demographics including age, gender, education, race, ethnicity and health status were collected. Descriptive statistics were performed. Logistic regressions were performed with the dependent variable as change in trust and independent variables age, sex, race, education, and health status.

RESULTS: In total, 491 patients completed the survey. Response rate was 86 % for three sites; response rate could not be calculated for the fourth site (representing 21.2 % of total respondents). Respondents reported that they would have less trust if their doctor posted racist comments online (90 %), wrote a disrespectful patient narrative (84 %), appeared intoxicated in a photograph (73 %), or wrote profanity (55 %) (Table). The majority (85 %) reported no difference in trust if they saw a photograph of their doctor holding a glass of wine. Around a third (35 %) reported they would have more trust in their doctor if they saw a respectful patient narrative written by their doctor. Older respondents (≥ 65) were more likely to report less trust in their doctor after seeing a photograph of their doctor holding a glass of wine (OR 4.3, $p=0.03$), appearing intoxicated (OR 4.0, $p=0.003$), or posting profanity (OR 3.3, $p=0.004$) compared to those ages 18–34. More highly educated respondents were more likely to report less trust after seeing a racist post (OR 10–20 for those with college or graduate-level education versus high school education or less, $p<0.001$ for both) or after seeing a disrespectful patient narrative (OR 3.1–9.5, $p=0.03$ and $0<0.001$, respectively).

CONCLUSIONS: Physicians' online behavior may affect their patients' trust, at least as reported by patients responding to hypothetical situations. Whether this would change actual patient-physician relationships is unknown. Patient age and education may influence whether trust is influenced by physicians' online postings. Better understanding of how physicians' online presence impacts the patient-physician relationship, in both positive and negative directions, can help guide personal and institutional policy as well as inform educational efforts.

How would your trust in your doctor change if you saw the following online?

	Less trust N (%)	No difference in trust N (%)	More trust N (%)
A racist comment written by your doctor	416 (90)	43 (9)	3 (1)
A disrespectful story written by your doctor about a patient he/she saw in clinic (patient not identified by name)	390 (84)	67 (15)	6 (1)
A photo of your doctor appearing drunk.	338 (73)	120 (26)	5 (1)
A comment written by your doctor that included profanity.	249 (55)	201 (44)	7 (2)
A photo of your doctor holding a glass of wine.	61 (13)	389 (85)	10 (2)
A respectful story written by your doctor about a patient he/she saw in clinic (patient not identified by name)	57 (12)	245 (53)	149 (35)

THE IMPACT OF PRIMARY CARE REDESIGN ON RESIDENTS' EXPERIENCE IN CONTINUITY CLINIC Matthew Tobey³; Anthony H. Bu¹; Antoinette S. Peters²; Alyna T. Chien¹. ¹Harvard Medical School, Boston, MA; ²Harvard Medical School, Brookline, MA; ³Massachusetts General Hospital, Somerville, MA; ⁴Children's Hospital Boston, Boston, MA. (Tracking ID #2197828)

BACKGROUND: Continuity clinic (CC) serves as the cornerstone for generalist education during residency. The effect of primary care practice redesign—especially the establishment of team-based care—on residents' training experience remains largely unexplored. Exposure to enhanced teams and other aspects of redesign, such as population management, quality improvement and patient engagement, has the potential to improve resident training and to encourage more residents to pursue primary care careers, especially if CC becomes more enjoyable. Between 2012 and 2014, 19 Harvard Medical School-affiliated primary care training practices participated in the Academic Innovations Collaborative (AIC), a practice redesign initiative aimed at building highly effective teams, managing populations, and engaging patients. This study assessed the impact of the AIC on residents' educational experience of aspects of primary care redesign, as well as on CC enjoyment. Since the AIC devoted the most time to the improvement of team dynamics, the study also explored the relation of team dynamics to core outcomes.

METHODS: We conducted a pre/post intervention study treating each AIC year as an independent cross-section. We emailed an electronic survey link to all residents with CC at AIC practices (Year 1 $N=467$, Year 2 $N=451$). The survey inquired after exposure to population management (PM, 4 items), quality improvement (QI, 4 items), and patient engagement (PE, 2 items), as well as CC enjoyment (single item); these were taken to be the core outcomes. It also assessed team dynamics (TD, 29 items), resident supervision and workload (RSW, 6 items) and the existence of clinical protocols (CP, single item). All items were drawn from previously validated questionnaires; responses were gathered using 5-point Likerts (1=negative, 5=positive). Descriptive statistics examined rating levels and two-sided t-tests were employed to examine changes across years. The impacts of TD, RSW and CP on each of the four core variables were assessed using multivariate linear regression; the two years of the intervention were analyzed separately.

RESULTS: Response rates were 62 % ($N=289$) and 52 % ($N=235$) in Years 1 and 2, respectively; 119 individuals participated in both years. Residents' ratings of all domains related to redesign improved significantly over the two years: continuity clinic enjoyment (3.5 to 3.7, $p<0.02$); TD (3.4 to 3.6, $p<0.0001$); PM (3.5 to 3.7, $p<0.01$); QI (3.4 to 3.6, $p<0.01$); PE (3.5 to 3.7, $p<0.01$); CP (3.3 to 3.5, $p<0.02$). Ratings of resident supervision and workload in CC did not significantly change (3.3 to 3.4, $p=0.30$). In multivariate regression analysis, TD ratings were significantly associated with all four outcomes of interest (CC enjoyment, PM, QI and PE) during both years of the intervention (p values <0.001 except for PE, where $p<0.05$). Resident supervision and workload ratings were significantly associated with CC enjoyment and PM ratings in both years (p values <0.01). Residents' perception of the existence of clear clinical protocols was only significantly associated with QI ratings, and only in year 2.

CONCLUSIONS: Between the two years of a primary care practice redesign effort, resident ratings of team dynamics and exposure to population management, quality improvement, and patient engagement all improved, as did ratings of continuity clinic enjoyment. Enhanced team dynamics were associated with an improved resident training experience. These results suggest that practice redesign with a focus on establishing team-based care enhances resident learning and enjoyment of CC.

THE IMPACT OF SITTING OR STANDING AT THE BEDSIDE ON PATIENTS' RATING OF PHYSICIANS' COMMUNICATION SKILLS AND PERCEPTION OF TIME SPENT DURING MORNING ROUNDS: A CLUSTER RANDOMIZED TRIAL Alan C. Kwan²; Christy McKinney¹; Andrew A. White¹; Patrick Ufkes¹; Susan E. Merel¹. ¹University of Washington, Seattle, WA; ²Johns Hopkins Bayview Medical Center, Baltimore, MD. (Tracking ID #2153255)

BACKGROUND: Prior studies suggest that sitting at the bedside may improve patients' perceptions of physician's communication skills and increase the amount of time patients believe physicians spend with them, but this hypothesis has not been tested in the inpatient general medicine setting. We hypothesized that inpatients whose physician sat rather than stood would perceive the physician spent more time with them and would rate the physician's communication skills more highly as measured by questions modeled on the communication questions from the Hospital Consumer Assessment of Healthcare Providers and Systems (HCAHPS) survey.

METHODS: We conducted a cluster randomized clinical trial randomizing physicians to an alternating order of sitting and standing within a 7-day workweek. We enrolled patients being cared for by hospitalists on a general internal medicine service in an academic tertiary care hospital. Wall-mounted folding chairs were installed in all rooms on a 28-bed unit. Eligible subjects were English-speaking adults consenting to their own medical care and newly admitted or transferred from the ICU between June and December 2014. Physicians were randomly assigned to sit or stand during morning rounds in patients' rooms for the first 3 days of their workweek. The last 4 days they provided care using the other posture. Blocks of 4 weeks were used to randomize the sit/stand order to ensure an equal number of sit/stand days and to account for day of the week trends. Trained observers measured the length of the physician-patient interaction, asked both the physician and the patient to estimate the length of the interaction, and administered a written survey to the patient with questions about the physician's communication skills. We estimated descriptive statistics for physician and patient participants using means and proportions. We compared estimates of time spent between patients and providers and patients' satisfaction overall and according to whether the provider sat or stood. We used generalized estimating equations to generate p-values accounting for clustering of patients within provider. We will complete data collection in this ongoing project in June 2015.

RESULTS: Twelve physicians participated in the study; 88 % had been in practice less than 3 years and 67 % were female. Before entering the study, only 33 % of physicians reported usually sitting at bedside during morning rounds. Among 101 patients invited, 74 patients (73 %) participated; 77 % were Caucasian and 7 % Asian or Pacific Islander and

mean age was 51. An estimated 41 % of interactions were with sitting physicians. Overall, patients and providers estimated greater time spent (3 min 24 s more for patients and 52 s more for physicians) than was measured (both p -values < 0.001). When we stratified by the physician's posture, differences in time spent (Table 1) and on physician communication skills (Table 2) were in the direction hypothesized, but not statistically significant (all p -values > 0.05).

CONCLUSIONS: Physicians did not spend more time with the patient on rounds if they were seated. Consistent with prior studies, regardless of posture patients and physicians overestimated the amount of time spent on morning rounds, a finding that was statistically significant. Our findings that patients perceived providers spent more time with them, and patient perceptions of physicians communication were more favorable when providers sat rather than stood, were both consistent with our hypotheses and the supporting literature. That these findings were not statistically significant may be related to our sample size at this point in recruitment. Though our study is ongoing, these findings suggest sitting may be a simple potential strategy to improve patient satisfaction in an inpatient general medicine setting.

Table 1. Estimates of time spent and differences in time spent for interactions with a seated or standing provider.

* Time in minutes:seconds

	Seated (n=30) Mean*	Standing (n=44) Mean*	p-value
Recorded time spent in morning rounds	10:48	11:08	0.07
Patient's estimate of time spent	14:58	14:02	0.61
Physician's estimate of time spent	11:12	12:21	0.86
Difference between patient's estimate and recorded time	4:09	2:50	0.62
Difference between physician's estimate and recorded time	0:23	1:12	0.17

Table 2. Patients' responses to HCAHPS-adapted questions on physician communication skills.

	Seated (n=30) n (%)	Standing (n=44) n (%)	p-value
Today on rounds, did this doctor:			
Listen carefully to you?			
Never, sometimes or usually	2 (7)	11 (25)	0.06
Always	28 (93)	33 (75)	
Treat you with courtesy and respect?			
Never, sometimes or usually	0 (0)	5 (11)	**

THE INFLUENCE OF DO-NOT-ATTEMPT-RESUSCITATE ORDERS ON NURSES' WILLINGNESS TO AGREE WITH PHYSICIANS' DECISION-MAKING IN JAPAN Eiji Hiraoka; Yosuke Homma; Yasuhiro Norisue. Tokyo Bay Urayasu Ichikawa Medical Center, Urayasu, Japan. (Tracking ID #2179040)

BACKGROUND: A do-not attempt resuscitate (DNAR) order prohibits use of cardiopulmonary resuscitation (CPR) in the event of cardiopulmonary arrest. It should not be applied to any other interventions other than CPR. However, it has been reported that it affected physicians' decision making unrelated to CPR in the USA. We reported that patient DNAR status altered physician behavior pertaining to use of non-CPR procedures in Japan (reported in ACP Japan chapter 2014, unpublished data). We explored the influence of DNAR status on nurses' willingness to agree with physicians' medical decision-making in a variety of clinical contexts.

METHODS: The influence of DNAR status on nurses' willingness to agree with physicians' decision to pursue intervention was investigated at an urban community hospital in Chiba, Japan, and its two affiliating hospitals, using a case scenario-based questionnaire containing three scenarios: Case 1: advanced stage cancer; Case 2: advanced stage dementia; and Case 3: non-end stage heart failure. Each case was followed by questions assessing nurses' willingness to agree with physicians' decision making to pursue non-CPR interventions as well as CPR interventions. Examples of questions are "Would you agree with physicians' decision making to perform blood culture when sepsis

is suspected?" "Would you agree with physicians' decision making to transfer the patient to ICU?" Either of Case 1 and Case 2 has 13 questions. Case 3 has 11 questions. Rates of willingness to pursue interventions were calculated by number of nurses answering "Yes" for each procedure, divided by total number of nurses. The rate was statistically compared between the presence and absence of DNAR order by chi square analysis. For each scenario, relative rates (RR) were calculated based on the number of nurses willing to pursue a certain procedure in the presence of a DNAR order divided by those willing to in the absence of a DNAR order. Procedures were stratified by invasiveness (very invasive, moderately invasive, non-invasive), with RRs calculated in each to investigate the influence of invasiveness on decision-making. RRs were compared among 3 levels of invasiveness for each case scenario by using one way ANOVA.

RESULTS: Three hundred seventeen out of 423 nurses responded to the questionnaire. Thirty-one could not be analyzed because of incomplete answer. Therefore, 286 was analyzed (67 %). Pooling all procedures, fewer nurses were willing to agree with physicians' decision making to perform interventions in the presence of DNAR order than in its absence: Case 1, 89 % (absence of DNAR) vs. 46 % (presence of DNAR) ($p < 0.001$); Case 2, 83 % vs. 44 % ($p < 0.001$); and Case 3, 92 % vs 53 % ($p < 0.001$). The average RRs for non-invasive, moderately invasive, and very invasive interventions were 0.77, 0.34, and 0.09, respectively, in Case 1. Corresponding RRs for Case 2 were 0.77, 0.34, and 0.11; and 0.82, 0.47, and 0.15 in Case 3. The difference of the RRs between each groups were statistically significant ($p < 0.05$) for each case scenario. Discussion DNAR order is originally applied only to CPR in case of cardiopulmonary resuscitation. We demonstrated here that DNAR order affected nurses' willingness to agree with physicians' decision making of various procedures unrelated to CPR. We also showed that the influence increase linearly in the more invasive procedures. The reason may be that some nurses might believe that patients who want DNAR do not want to accept any procedure other than palliation as well. However, actually some patients would like to accept procedures unrelated CPR to prevent cardiopulmonary arrest and prolong advanced but stable stage of the disease and would like to accept DNAR at the time of cardiopulmonary arrest. Others would not like any invasive procedures and would like to accept only comfortable management. Therefore, we need to clarify whether they would like to undergo a certain procedure for each patient, especially when he or she requests for DNAR. Otherwise, some patients would receive a certain medical intervention adequately; some patients would not if DNAR is ordered.

CONCLUSIONS: DNAR status affects nurses' willingness to agree with physicians' decision making to perform a variety of non-CPR interventions. This association is linearly related to invasiveness. To ensure appropriate and equal care of patients with DNAR status, clear definitions of DNAR orders should be emphasized for nurses. Otherwise, DNAR order can be harmful.

THE LINK BETWEEN EDUCATION AND HEALTH: IT IS NOT WHAT YOU KNOW, BUT WHOM YOU KNOW Danielle Strom¹; Rebecca Dudovitz²; Lourdes R. Guerrero¹; Mitchell D. Wong². ¹David Geffen School of Medicine at UCLA, Los Angeles, CA; ²David Geffen School of Medicine at UCLA, Mitchell Wong, CA; ³University of California, Los Angeles, Los Angeles, CA; ⁴University of Michigan, Ann Arbor, MI. (Tracking ID #2199285)

BACKGROUND: Numerous observational studies have identified a strong link between education and health, suggesting that improving the quality of schools might be a way to improve population health and reduce health disparities. Almost all of these studies have examined years of schooling (attainment) and have consistently found substantially worse health behaviors and outcomes among high school drop-outs compared to high school graduates. In contrast, there have been almost no studies that have examined the association between health behaviors and outcomes with the quality of schooling (achievement). Further, association with risky peers likely reinforces both poor academic and health behaviors, potentially confounding this relationship. Thus, it is not known whether improving academic achievement will lead to improvements in health outcomes, particularly after accounting for peer influence.

METHODS: We analyzed data from the RISE Study, a natural experiment of students who had applied in 2007–2010 to attend one of the three high-performing charter public high schools in very low-income neighborhoods in Los Angeles and were selected for admission by random lottery. Students were excluded from the study if they went to other charter or private schools. The final sample of students in the study attended one of 3 study charter public schools or 69 traditional public high schools throughout Los Angeles. Subjects completed a 90-min face-to-face survey and reported their 30-day substance use and depression using the CES-D scale. Subjects answered sensitive questions about substance use using audio computer-assisted self-interviews (audio-CASI). We assessed the student's personal social network by having subjects name 20 of their closest network members (including friends and family members) and then answer follow-up questions

about the network member's age, relationship, and recent substance use. We grouped subjects into tertiles of peer group risk (low, medium, high) based on the proportion of the peer network who used alcohol and drugs in the last 30 days. We obtained student's California standard test scores from the California Department of Education as a measure of academic achievement.

RESULTS: Nine hundred twenty-nine students from grades 9–12 were included in the study. Most were Latino (84 %) or African American (12 %). Thirty-eight percent were native English speakers, and about half (50.7 %) of student's parents had graduated from high school. Almost all (90 %) of parents were employed. In multivariable analysis adjusting for grade, gender, race/ethnicity, language, parental education and employment, standard tests scores in math or English were not associated with 30-day alcohol use, 30-day marijuana use or depression. In contrast, peer network was strongly associated with substance use and depression. The adjusted OR was 15.0 ($p<0.001$) for 30-day alcohol use and 9.7 ($p<0.001$) for 30-day marijuana use if the subject had a high-risk peer group compared to having a low-risk peer group. There was almost no association between depression and the risk of the peer network.

CONCLUSIONS: Although previous studies have found much higher rates of depression and substance use among high school drop-outs compared to high school graduates, we did not find any association between these outcomes and academic achievement, measured by performance on standardized tests. It is possible that the effect of better education on health might occur later in life. Alternatively, improving academic achievement (through better schools) may not have a causal effect on health, but rather other factors, such as social networks and the risky behaviors of peers, are the root cause that leads to both poor educational and health outcomes. The present study suggests we do not fully understand how education contributes as a social determinant of health or how policies to improve school quality might influence population health.

THE MEDIATING AND EFFECT MODIFYING EFFECTS OF POSITIVE AFFECT IN THE RELATIONSHIP BETWEEN CHALLENGING CAREGIVING SITUATIONS AND PERCEIVED STRESS Albert Do¹; Allison Citro²; Jennifer Lyons²; Lisa Fredman². ¹Yale-New Haven Hospital, New Haven, CT; ²Boston University School of Public Health, Boston, MA. (Tracking ID #2196654)

BACKGROUND: Caring for a relative or close friend is often stressful, but the degree of stress has been found to vary with the care recipient's (CR) cognitive status and characteristics of the caregiving situation. Research on the disease-buffering effects of positive affect (PA) suggests that it may influence caregiver (CG) stress levels in these challenging situations. This study tested the hypothesis that PA is both a mediator and an effect modifier of the impact of three conditions on perceived stress in caregivers: caring for a person with dementia, living with the CR, and performing more instrumental and basic activities of daily living (I/ADLs) for the CR (i.e., high-intensity caregiving).

METHODS: The sample consisted of older women participants from the Caregiver-Study of Osteoporotic Fractures (CG-SOF). Participants had 5 interviews conducted over 9 years (1999–2009), with caregiver status assessment at each interview. These analyses pooled participants who were caregivers at each interview; thus, each participant could contribute from 1 to 5 data points over intervals from 1–3.8 years. High- versus low-intensity caregiving was determined by the median number of I/ADLs caregivers assisted the CR with at the first CG-SOF interview. A 3-category positive affect (PA) variable was created from the 20-item Center for Epidemiologic Studies-Depression Scale: participants who scored ≥ 16 were classified as depressed; those with lower scores were classified as low or high PA based on responses to four items on positive affect. Perceived stress was measured with the 14-item Perceived Stress Scale (PSS, possible range 0–56). Separate associations between each caregiving situation and perceived stress were evaluated using mixed effects regression models to account for multiple observations per subject. We performed the Sobel test for mediation of these associations by PA and used stratified analyses to assess effect modification.

RESULTS: There were 354 caregivers at the baseline interview, 272 at the 2nd, 206 at the 3rd, 67 at the 4th, and 42 at the 5th, resulting in 941 total observations. The mean age was 82.5 ± 3.7 years, 89 % were white, 54 % lived with the CR, 54 % were high-intensity caregivers, and 26 % cared for a person with dementia. The mean PSS score was 17.4 ± 7.7 . High-intensity caregivers, those who lived with the care recipient and who cared for a person with dementia reported significantly higher stress than their counterparts, adjusting for confounders ($\beta = 1.26, 3.26, 1.80$, respectively, $p < 0.01$). Inclusion of the PA variable in these models eliminated the association between caregiving intensity and perceived stress ($\beta = 0.58, p = 0.16$), and reduced associations with living with the CR and caring for a person with dementia ($\beta = 2.13$ and 1.38 , respectively, $p < 0.01$). Sobel tests indicated that PA mediated the association between caregiving intensity and perceived stress, but not other associations. In stratified analyses, living with the CR was associated with

significantly higher stress in caregivers with low PA or high PA, but not in those with depression (Table 1). Caring for a person with dementia was associated with higher stress in women with low PA, but not in the other affect groups, and high caregiving intensity was not significantly associated with perceived stress in any affect group.

CONCLUSIONS: Among older women caregivers, higher perceived stress associated with high intensity caregiving is mediated by PA. PA is also an effect modifier of the association between stressful caregiving situations and perceived stress. In practice, although such caregiving situations may not be preventable, interventions aiming to increase PA in caregivers may reduce psychological stress resulting from these caregiving situations. This, in turn, may serve to curtail fatigue and burnout in this rapidly growing and important population.

Table 1. Adjusted associations between caregiving situations and perceived stress, stratified by positive affect category in elderly caregivers of the Caregiver-Study of Osteoporotic Fractures study

Characteristic	Depressed (n=124) PSS Score ^{**} : β (SE)	Low PA (n=327)	High PA (n=490)
CG lives with CR ^a	1.27 (1.46)	2.10* (0.74)	2.09* (0.60)
CR with dementia ^a	2.10 [^] (1.17)	2.74* (0.82)	0.61 (0.67)
High-intensity caregiving ^b	1.19 (1.18)	1.32 (0.72)	0.09 (0.55)

CR=care recipient; PA=positive affect

a Associations adjusted for age, race, education status

b Associations adjusted for age, race, education status, living with CR and caring for person with dementia

^{**} Beta coefficients compare PSS among caregivers with characteristic to those without, i.e., adjusted PSS score was 2.10 points higher in caregivers with Low PA who lived with CR than in those who did not live with the CR.

THE MEDICAL ASSISTANT EXPERIENCE IN TEAM-BASED PRIMARY CARE: A QUALITATIVE STUDY Bethany S. Gerstein⁴; Alyna T. Chien²; Antoinette S. Peters³; Meredith Rosenthal¹; Sara Singer¹. ¹Harvard School of Public Health, Boston, MA; ²Boston Children's Hospital, Boston, MA; ³Harvard Medical School, Boston, MA; ⁴Harvard University, Cambridge, MA. (Tracking ID #2194023)

BACKGROUND: Medical Assistants (MAs) play a central role in team-based primary care. As more practices organize patient care around physician-led teams, MAs are taking on new responsibilities in an effort to maximize the time physicians spend on high-value clinical care. However, little research describes how the MA role is changing or how practices can most effectively manage the transition from support staff to team member. Between 2012 and 2014, as part of a learning collaborative called the Academic Innovations Collaborative (AIC), 19 Harvard-affiliated primary care practices transitioned from traditional practice to team-based care, empaneled all of their patients, expanded population management capacity, and reallocated tasks among their staff. The objective of this qualitative study is to understand, from the MA perspective: 1. how MA roles and experiences have changed during a transition to physician-led team-based care, and 2. what drives effective teamwork when care is team-based.

METHODS: In July 2014, we stratified practices according to levels of MA job satisfaction (available from a 2013 survey) and selected 3 practices within each of 3 levels (low, medium, high) for a total of 9 practices. Within each level, we selected practices for diversity in size and system affiliation, and included both community- and hospital-based offices. We then randomly selected 1 MA per clinical team ($n = 32$ total, ranging from 3 to 5 teams per practice) within each practice to participate in a 30-min semi-structured interview. If an MA did not respond or declined participation, we invited another MA from the same team. From August to November 2014, 1–2 interviewers audio-recorded interviews that asked MAs about their perspectives on changing tasks and responsibilities, facilitators and barriers to teamwork and communication, and the process of implementing team-based care. The interviewers also asked participants how their overall job satisfaction had changed over time using a 5-point response scale.

RESULTS: Data analysis is ongoing. Across 9 practices, 30 of 47 MAs recruited (64 %) agreed to participate; 27 of 30 participants were female. All but 3 interview participants had been at their practices for 2 years or more. A large majority of these participants (23 of

27) described being more satisfied with their jobs than before team-based care was implemented. MAs generally reported assuming additional responsibilities under team-based care; ill feelings about higher workloads were frequently offset by stronger relationships with patients and physicians, as well as a greater sense of efficacy and ownership of their work. MAs described the most positive experiences with teamwork and communication when they had consistent MA-physician dyads, adequate MA staffing, high physician commitment to team processes, and co-location with physicians and other team members. One barrier at several healthcare systems was a policy prohibiting MAs from performing some patient care tasks that they had been trained to perform.

CONCLUSIONS: MAs are often expected to play a larger role in delivering physician-led team-based care compared to traditional models of care delivery. Understanding what causes the MA experience to vary across practices may lead to broader insights about how best to implement primary care teams and to shift tasks to reduce the burden on physicians. Results suggest that the way practices structure and manage their teams matters; more research is needed to understand which factors matter most.

THE MODERATING EFFECT OF EMOTIONAL REGULATION ON THE ASSOCIATION BETWEEN CHRONIC STRESS AND CARDIOVASCULAR DISEASE RISK Brita Roy^{1, 2}; Carley Riley¹; Adam Hong¹; Rajita Sinha¹. ¹Yale University, New Haven, CT; ²Veterans Administration Health System, West Haven, CT. (Tracking ID #2198982)

BACKGROUND: Chronic stress is a risk factor for the development of cardiovascular disease, mediated via low-grade elevation of hormones and biomarkers of stress and inflammation, which are associated with higher incidence of myocardial infarction and stroke. Emotional regulation is the ability to modulate one's state or behavior in response to a given situation or stressor. We hypothesized that effective emotional regulation may mitigate the effect of chronic stress on cardiovascular risk.

METHODS: We used data from a cohort of 1032 community-dwelling adults followed by the Yale Stress Center Consortium. Chronic stress (CS) and cumulative adverse life events (CALE) were measured in all adult participants using the Cumulative Adversity Interview (CAI), a 140-item multifaceted assessment of life events and subjective stress. Additionally, perception of stress was measured using the Perceived Stress Scale (PSS), a widely used 10-item instrument. We created a composite stress score by summing the normalized scores of the PSS and the CS and ALE components of the CAI. Emotional regulation was measured in all participants using the Difficulties in Emotion Regulation Scale (DERS), with higher scores reflecting a greater degree of impairment in emotional regulation. We categorized participants as having high emotional regulation if their DERS score was less than the 50th percentile score. Our outcomes included blood pressure (BP), body mass index (BMI), and insulin resistance as measured by the Homeostasis Model Assessment (HOMA-IR). We created a composite outcome of cardiovascular risk (CV risk): 0 points for normal BP, BMI and HOMA-IR; 1 point each for BP 121-139/81-89, BMI 25-30, and HOMA-IR 2.6-3.8; and 2 points each for BP ≥ 140/90, BMI > 30, and HOMA-IR > 3.8. Covariates included age, sex, race, years of education, and smoking status. We used linear regression to evaluate unadjusted and adjusted associations between the chronic and perceived stress scales, as well as the composite stress score, and cardiovascular risk among participants with high and low emotional regulation, respectively.

RESULTS: Our sample was 57 % female, 71 % white, 25 % current smokers, and had a mean (SD) age of 31.5 (10.7) years, and obtained 15.1 (2.5) years of education. Our sample had mean (SD) systolic BP 123.1 (15.2), diastolic BP 75.8 (11.4), BMI 27.6 (5.7), and HOMA-IR 3.17 (2.06). In the full sample, CV risk was associated with chronic stress ($r=0.514$; $p<0.001$), cumulative adverse life events ($r=0.05$; $p<0.001$), perceived stress ($r=0.411$; $p=0.018$), and our composite stress score ($r=0.13$; $p<0.001$). All associations remained significant after adjusting for covariates, except the association with CALE. Among those with high emotional regulation, CV risk was associated with CS ($r=0.04$; $p=0.008$), CALE ($r=0.046$; $p<0.001$), and our composite stress score ($r=0.123$; $p=0.011$), but not with PSS alone ($r=0.008$; $p=0.597$). After adjustment for covariates, the association with the composite stress score was attenuated ($r=0.036$; $p=0.485$). Among participants with low emotional regulation, CV risk was associated with CS ($r=0.041$; $p=0.002$), CALE ($r=0.055$; $p<0.001$), PSS ($r=0.029$; $p=0.011$), and the composite stress score ($r=0.151$; $p<0.001$). The association between our composite stress score and CV risk remained significant after adjustment for all covariates ($r=0.096$; $p=0.041$).

CONCLUSIONS: Emotional regulation may mitigate the association between chronic stress and cardiovascular risk. Composite chronic and perceived stress and cumulative adverse life events was associated with cardiovascular risk only among participants with poor ability to regulate emotions. Emotional regulation is a teachable skill, and may play a role in prevention of cardiovascular disease. Furthermore, because racial/ethnic minorities and those with low socioeconomic status face greater chronic stress from ongoing

discrimination and financial insecurity, improving emotional regulation in these target populations may reduce disparities in cardiovascular risk.

THE PATIENT-CENTERED MEDICAL HOME AND ASSOCIATIONS WITH HEALTHCARE QUALITY, UTILIZATION AND COSTS: A FIVE-YEAR COHORT STUDY Lisa M. Kern; Alison M. Edwards; Rainu Kaushal. Weill Cornell Medical College, New York, NY. (Tracking ID #2196102)

BACKGROUND: Effects of the Patient-Centered Medical Home (PCMH) are unclear. Previous studies may have been limited by relatively short follow-up periods and may not have fully distinguished the effect of the PCMH (which involves electronic health records (EHRs) plus organizational changes) from EHRs alone. Our objective was to determine effects of the PCMH on quality, utilization and costs, compared to paper records and to EHRs alone, with extended follow-up.

METHODS: We conducted a prospective cohort study (2008–2012), including 3 years post-PCMH implementation. The study took place in the Hudson Valley, a 7-county, multi-payer, multi-provider region in New York State. We included a total of 438 primary care physicians in 226 practices, with 136,480 patients, across 5 health plans. The intervention group consisted of those primary care physicians who achieved Level III PCMH (as defined by the National Committee for Quality Assurance), all of whom used EHRs, and their attributed patients. We had two control groups: those primary care physicians who used paper medical records without PCMH transformation and those primary physicians who used EHRs without PCMH transformation. Outcomes were generated from administrative claims aggregated across the participating health plans, including 8 quality measures, 7 healthcare utilization measures, and total costs. We used generalized estimating equations to compare study groups for differences in the rate of change over time, adjusting for clustering and 13 potential confounders.

RESULTS: Of the primary care physicians, 125 (29 %) used EHRs and implemented the PCMH, 226 (52 %) used paper records without the PCMH, and 87 (20 %) used EHRs without the PCMH. The odds of quality improvement were 5 % greater in the PCMH group than in the paper group ($p<0.05$). The PCMH group used 7 % more primary care visits, 10 % fewer specialist visits, 4 % fewer laboratory tests, 4 % fewer radiology tests, 21 % fewer admissions and 57 % fewer readmissions, compared to the paper group over time ($p<0.05$), with no difference in emergency department visits. Total costs were lower in the PCMH group than in the paper group. Results were similar for comparisons between the PCMH and EHR group.

CONCLUSIONS: The PCMH model of primary care was associated with greater quality improvement, lower healthcare utilization and lower total costs, compared to either paper records or EHRs alone 3 years post-PCMH transformation. This study suggests that it is the combination of technology and practice culture that drives changes, rather than technology alone.

THE PROMISE OF SOCIAL MEDIA FOR HEALTH: A NATIONWIDE SURVEY OF PRIMARY CARE PATIENTS ON USAGE PATTERNS AND ATTITUDES James Colbert^{2, 6}; Neal Yuan⁴; Priyanka Agarwal³; Joy L. Lee¹; Katherine C. Chretien⁵; Lisa S. Lehmann⁶. ¹Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; ²Newton-Wellesley Hospital, Newton, MA; ³University of California, San Francisco, San Francisco, CA; ⁴University of California, San Francisco, Walnut Creek, CA; ⁵Washington DC VAMC, Washington, DC; ⁶Brigham and Women's Hospital, Boston, MA. (Tracking ID #2199096)

BACKGROUND: Online social networks such as Facebook, Twitter, and Instagram have seen explosive growth in usage over the past few years. Data from the Pew Research Center reveal that approximately 73 % of online adults use at least one social networking site. However, little is known about whether this degree of online engagement holds true for patients at academic primary care clinics. Furthermore, scant data exist regarding the extent to which patients are sharing information about their own health on social media sites.

METHODS: We conducted a paper-based cross-sectional survey of patients at four academic primary care centers in Boston, Washington DC, and San Francisco. Clinics were chosen for geographic and demographic diversity. As part of the survey, patients were asked about ownership of electronic devices, usage of social media, and whether they posted about their own health on social media. The surveys were administered in English, and non-English speakers were excluded from participation. Logistic regression analysis was performed to evaluate the effect of age, race, ethnicity, education, and health status on use of internet and posting about health on social media.

RESULTS: The survey was completed by 491 respondents with a response rate of 86 %, recorded at 3 of the 4 sites. Overall, 92 % of respondents have a device capable of accessing the internet, including desktop computers (49 %), laptop computers (61 %), tablet devices (44 %) and smartphones (69 %). Eight percent did not own any device with internet access. With regards to social media usage, 68 % used at least one social media site within the last month. Of those using social media, 85 % use Facebook, 33 % Instagram, 28 % Twitter, 26 % Pinterest, and 18 % use blogs. Among patients who use social media, 34 % posted about their health on a social media site within the past 6 months: 80 % doing so on Facebook, 20 % on Instagram, 9 % on Twitter, and 7 % on blogs. Patients posted most frequently about their wellness (64 %), but other topics included mood (40 %), acute conditions (34 %), chronic conditions (31 %), and women's health (24 %). Most popular reasons for posting on social media were to connect with similar patients (36 %) or to share information with others (35 %). Fifty-four percent of patients listed privacy as "very important" when selecting a social media site to post about their health. When asked whether "social media can help me obtain useful health information," 27 % of all respondents agreed. However, among those who post about their health on social media, 46 % agreed with the statement. When compared with 18 to 34 year olds, patients aged 35–49, 50–64 and 65+ all had progressively lower rates of social media usage (OR=0.17, OR=0.04, OR=0.02, $p<0.05$). Those with a college degree were more likely to use social media when compared with those having a high school education or less (OR 2.7, $p=0.018$). When compared with the youngest patients, those aged 35–49, 50–64 and 65+ had lower odds of posting about health on social media (OR=0.37, OR=0.20, OR=0.23, $p<0.05$). Patients with a college degree were also less likely to post about their health when compared to patients with high school degrees or less (OR 0.42, $p<0.05$). Race, ethnicity and gender did not significantly affect social media usage or the odds of posting about health.

CONCLUSIONS: Rates of social media use among a geographically diverse cohort of primary care patients is high and mirrors use in previously published surveys of the general public. In addition, more than one-third of patients who use social media are posting about their own health, most frequently on topics concerning wellness and mood. Patient age and education level were the only demographic factors that significantly affected social media usage. While a majority of patients prioritize privacy concerns when choosing where to post online, they continue to share personal health information on Facebook, Instagram and other non-HIPAA secure public sites. These data support an opportunity for primary care and public health interventions to utilize social media sites such as Facebook to better engage with patients. Healthcare providers and systems will, however, need to find a way to balance patients' seemingly conflicting desire for privacy and sharing of personal health information online.

Usage of social media by primary care patients

	Number of respondents using social media platform	Percent of survey respondents using social media platform	Number of respondents posting about health on given social media site	Percent of respondents using given social media site who post about health on that site
Facebook	283	58 %	91	32 %
Instagram	111	23 %	23	21 %
Twitter	92	19 %	10	11 %
Pinterest	86	18 %	2	2 %
Blogs	60	12 %	8	13 %

Total survey respondents: $N=491$

THE RELATIONSHIP BETWEEN MULTIMORBIDITY AND CONCORDANT AND DISCORDANT CAUSES OF HOSPITAL READMISSION AT 30-DAYS AND ONE YEAR Arlene S. Bierman¹; Jun Guan²; Therese Stukel². ¹University of Toronto, Toronto, ON, Canada; ²Institute for the Clinical Evaluative Sciences, Toronto, ON, Canada. (Tracking ID #2200233)

BACKGROUND: Rates of hospital readmission increase with the number of comorbid conditions and comorbidities are often responsible for potentially avoidable readmissions. Thirty day readmission rates reflect hospital care and care transitions, while one year readmission rates reflect chronic disease management in the community. A better understanding of the contribution of comorbid conditions to readmissions among patients with multimorbidity is needed to reduce readmission rates.

METHODS: Using linked population-based administrative data from Ontario Canada from FY 2011 and 2012, a longitudinal cohort study of acute myocardial infarction (AMI), congestive heart failure (HF), chronic obstructive pulmonary disease (COPD) and hip fracture patients discharged after an index hospitalization determined disease-specific,

concordant (readmission diagnosis related to index condition), and discordant (readmission diagnosis unrelated to index condition) causes of hospital readmissions in each cohort at 30-days and 1 year. Multivariable regression models were used to assess the contribution of markers of patient complexity including multimorbidity to readmissions for discordant comorbidities.

RESULTS: Cohorts included 29,607 admissions for AMI; 22809 for COPD; 20,095 for HF; and 12857 for hip fracture. Age, sex, and readmission rates varied across cohorts. There was a high burden of readmissions at one year. For example, 18.5 % of HF patients were readmitted at 30 days and 57.5 % at one year. Across all cohorts the proportion of readmissions attributable to discordant comorbidities was greater at one year than 30 days ranging from 44 % for AMI to 91 % for hip fracture. Geriatric conditions (i.e., dementia, decubiti) contributed to readmission rates. Patient complexity was associated increased rates of readmission at 30-days and one year as well as with an increased proportion of readmissions attributable to discordant comorbidities.

CONCLUSIONS: After hospital admission for common conditions (AMI, HF, COPD, and hip fracture), discordant comorbidities are responsible for a sizable proportion of hospital readmissions and the burden of discordant admissions increases over the course of a year. Attention to readmission rates beyond 30-days and patient-centered models of care to effectively manage multimorbidity will be needed to reduce rates of potentially avoidable hospitalizations among older patients with multimorbidity and complexity who comprise the majority of patients admitted for these conditions.

THE ROLE OF ORGANIZATIONAL FACTORS IN THE PROVISION OF COMPREHENSIVE WOMEN'S HEALTHCARE IN THE VETERANS HEALTH ADMINISTRATION Shivani Reddy^{1, 3}; Danielle Rose²; James Burgess⁴; Martin Charns⁴; Elizabeth M. Yano². ¹Boston University, Boston, MA; ²VA Greater Los Angeles HSR&D Center, Sepulveda, CA; ³VA Boston Healthcare, Boston, MA; ⁴Boston University School of Public Health, Boston, MA. (Tracking ID #2197702)

BACKGROUND: The increasing number of women veterans (WVs) using the Veterans Health Administration (VHA) presents an organizational challenge to a healthcare system that, historically, has served primarily men. Female users of the VHA tend to be younger, use more services, have complex health issues, and require reproductive services traditionally not provided by the VHA. We examined the association of organizational factors and adoption of comprehensive women's healthcare models in the VHA.

METHODS: We conducted a cross-sectional secondary analysis of the 2007 VHA Survey of Women's Veterans Health Programs and Practices, administered to senior women's health clinicians at all VA facilities serving ≥ 300 WV in 2006. We achieved a response rate of 86 % ($n=193$ facilities) representing all Veterans Integrated Service Networks, and both hospital-based and community based clinics). Our primary dependent measure was type of local adoption of model of women's health care; specifically, a separate women's health clinic (WHC), a designated women's health provider integrated within primary care (DWHP), both (WHC/DWHP), or neither. Our secondary dependent measure was availability of a bundle of basic women's health (WH) services considered within the scope of primary care: cervical cancer screening and evaluation and management of vaginitis, menstrual disorders, contraception and menopause. Exposure variables included organizational factors drawn from an adaptation of the Greenhalgh model of diffusion and implementation of innovations and include: facility type and size, centralization, and slack resources; measures of absorptive capacity for change including academic affiliation and WH representation on VHA committees; and system readiness for innovation including quality assurance activities and champions for gender specific care.

RESULTS: Thirty-nine percent of sites had adopted a WHC, 12 % had DWHPs, 29 % had both models, and 20 % had neither. There was a greater likelihood of WHC and WHC/DWHP models at: hospital-based clinics; sites with a gynecology clinic, academically affiliated facilities, and facilities with larger numbers of WVs, compared to sites with DWHP or neither ($p<0.05$ for all). Sites with WH representation on higher-impact VHA committees (medical executive committee, space/building committee, pharmacy committee) were more likely to have WHC or WHC/DWHP (46 and 32 %, respectively) as compared to DWHP (12 %) or neither (22 %) ($p=0.05$). All five basic WH services were more likely to be offered at sites with WHC (89 %) or both WHC/DWHP (89 %) as compared to sites with DWHP (71 %) or neither (66 %) ($p=0.003$).

CONCLUSIONS: Organizational factors associated with adoption of WHC and WHC/DWHP models of care include larger sites (hospital-based sites and larger volume of WV patients) and greater absorptive capacity (e.g., academic affiliation and WH representation on high-impact committees). Moreover, facilities that adopt a model of WH care that includes a separate WHC are more likely to deliver a bundle of basic WH services, realizing the goal of "one stop shopping" for WVs. Developing relationships between VA WH within the VA through committee leadership and outside of the VA with academic institutions may promote comprehensive models of WH care.

THE ROLE OF THE HOSPITAL PHYSICIAN IN LONG TERM OPIOID USE

Susan L. Calcaterra^{1, 2}, Traci E. Yamashita³, Angela Keniston¹, Joseph W. Frank^{2, 3}, Ingrid Binswanger^{2, 4}. ¹Denver Health Medical Center, Denver, CO; ²University of Colorado School of Medicine, Aurora, CO; ³VA Eastern Colorado Health Care System, Denver, CO; ⁴Institute for Health Research, Kaiser Permanente Colorado, Denver, CO; ⁵University of Colorado Denver, Aurora, CO. (Tracking ID #2199195)

BACKGROUND: The use of chronic opioid therapy (COT) to treat chronic, non-cancer pain has increased in spite of limited evidence for its efficacy. Patients on COT have increased risk of opioid use disorders. Most opioid prescribing has traditionally involved primary care physicians, orthopedists, and emergency physicians. Hospital physicians increasingly care for many hospitalized patients yet little is known about opioid prescribing at hospital discharge. We aimed to characterize the frequency of opioid initiation at hospital discharge and to quantify the risk of long-term opioid use in patients initiated on opioids at hospital discharge.

METHODS: This was a retrospective cohort study of all patients presenting to a single safety-net medical center in 2011. We electronically queried data from the medical record. The first hospital discharge per patient during 2011 was the 'index discharge'. Patients who received opioids within 12 months preceding their index discharge were excluded. Remaining patients were described as *opioid naïve* and were categorized into two groups, 'opioid receipt' if the patient filled an opioid within 72 h of hospital discharge or 'no opioid receipt' if the patient did not fill an opioid within 72 h of hospital discharge. We defined long-term opioid use as 'receipt of a 120+ day supply of opioids or 10+ opioid prescriptions dispensed 365 days following hospital discharge. Logistic regression modeled the risk of long-term opioid use while adjusting for chronic pain, malignancy, chronic disease, and hospital readmissions. Cumulative logistic regression modeling described the risk of greater opioid use while adjusting for gender, insurance, mental health disorder, chronic disease, chronic pain, surgery, and hospital readmissions.

RESULTS: In 2011, 16,053 index discharges were identified. Of these, 6689 discharges (42 %) were among opioid naïve patients. Twenty-five percent of opioid naïve patients ($n=1699$) were prescribed a new opioid within 72 h of their index discharge. Hydrocodone/acetaminophen ($n=910$, 50 %) was the most frequently prescribed opioid followed by oxycodone/acetaminophen ($n=342$, 19 %). Patients with 'opioid receipt' at discharge were more likely to have a 3-year history of neoplasm (6.3 % versus 3.5 %, $p<0.001$), a discharge diagnosis of acute pain (2.7 % versus 1.0 %, $p<0.001$), or underwent surgery during their index visit (65.1 % versus 18.4 %, $p<0.001$) compared to patients with 'no opioid receipt' at discharge. Patients with 'no opioid receipt' at discharge were more likely to have a 3-year history of alcohol use disorder (20.7 % versus 15.7 %, $p<0.001$) and a 3-year history of any mental health disorder (31.4 % versus 23.9 %, $p<0.001$) compared to patients with 'opioid receipt' at discharge. Opioid naïve patients with 'opioid receipt' at discharge were more likely to meet criteria for long-term opioid use 365 days following their index discharge compared to patients with 'no opioid receipt' at discharge (4.1 % versus 1.3 %, $p<0.0001$). The adjusted odds of long-term opioid use in patients with 'opioid receipt' at discharge was 5.80 (95 % CI 3.87–8.68; $p<0.001$). The adjusted odds of greater number of subsequent refills among patients with 'opioid receipt' at discharge was 2.84 (95 % CI 2.43–3.31; $p<0.0001$) over a 365 day period.

CONCLUSIONS: Among opioid naïve patients discharged from a safety-net medical center, 25 % filled an opioid prescription within 72 h of hospital discharge. Receipt of a new opioid at discharge increased long-term opioid use by nearly 6-fold. Limitations included the absence of information regarding opioid fills at non-affiliated pharmacies, which likely resulted in ascertainment bias. Hospital physicians should consider the risk of long-term opioid use when initiating opioids at hospital discharge. Involving the primary care physician before opioid initiation and ensuring reliable patient-provider follow-up may reduce long-term opioid use.

THE USE OF FICTIONAL MEDICAL TELEVISION IN MEDICAL EDUCATION: A SYSTEMATIC REVIEW

Brian A. Primack; Beth Hoffman; Ariel Shensa; Charles B. Wessel. University of Pittsburgh, Pittsburgh, PA. (Tracking ID #2198764)

BACKGROUND: Over the past 20 years, since the 1994 premiere of *ER* and *Chicago Hope*, the number of fictional medical television shows has increased substantially. The popularity of medical television shows among medical and other health professional students is well documented. For example, one study reported that more than 90 % of medical and nursing students watch these programs. Furthermore, fictional medical television may influence health professional students. For example, more than 50 % of students report that they discuss ethical issues from fictional medical television with friends, and the number of students pursuing an emergency medicine specialty doubled immediately after the premiere of *ER*. Some medical educators have taken advantage of the popularity of these programs by utilizing them as a mechanism to explore critical

issues in medical education, such as bioethics and professionalism. However, there has yet to be a systematic review of this literature to synthesize existing research and make recommendations for future study. This review aims to fill that gap.

METHODS: Systematic literature searches were conducted in three databases: Medline, Ovid CINAHL and Ovid PsychINFO. Search strategies were developed by a professional research librarian with specialized experience in systematic literature reviews. Reference lists of retrieved articles were searched to identify additional relevant articles. Selected studies were required (1) to be published in a peer-reviewed journal, (2) to be related to a fictionalized medical television program taking place primarily in a health-related setting, and (3) to assess health professional students' knowledge, perceptions and/or behaviors based on exposure to the program. In light of critical consensus supporting the 1994 premiere of *ER* and *Chicago Hope* as marking a distinct new era of fictional medical television, we also restricted selected studies to those published in the past 20 years. Studies were classified according to (1) participant factors such as student type and target student level, (2) exposure-related factors such as the specific program and its dose of exposure, (3) outcome-related factors such as whether knowledge, perceptions, and/or behavior were assessed, and (4) study quality.

RESULTS: Of 1422 unique studies identified, only eight met all selection criteria. Four studies (50 %) involved undergraduate medical students, one study (13 %) involved nursing students, one study (13 %) involved both medical and nursing students, and the remaining two studies (25 %) involved other graduate health professional students. The most commonly utilized programs were *ER* (50 %), *Grey's Anatomy* (38 %), and *House M.D.* (38 %). Four studies (50 %) examined the association of program exposure with student perceptions of health care, three studies (38 %) examined associations between program exposure and student behavior, and four studies (50 %) examined the effectiveness of using clips as educational tools. Of studies assessing the impact on student perceptions of health care, 100 % found that students identify with fictional characters and plot lines. The most common behaviors studied were viewing habits (100 %) and being asked about plot lines with friends or family (38 %). The majority (75 %) of studies utilizing clips in a classroom setting focused on issues of communication and professionalism. All studies reported that students found the seminars helpful and engaging. However, no studies described educational experiences extending beyond a single university, and no studies assessed the impact of the educational experience on intentions and/or behaviors related to clinical practice. Most studies were of fair to poor quality in terms of rigor of study design.

CONCLUSIONS: Students of the health professions commonly view fictional medical television dramas. There seems to be substantial promise in terms of leveraging these characteristics of fictional medical television programs to enhance current classroom instruction and facilitate discussions related to factors such as patient-provider communication, biomedical ethics, and professionalism. This is especially the case because viewers are generally able to recall storylines from fictional narratives and to identify with fictional characters. Some studies have explored the potential use of these programs to improve medical education, and these studies suggest that these types of educational experiences are highly acceptable to students, feasible to implement, and potentially valuable in terms of efficacy. However, only a few studies have been conducted in this area, and these studies have been limited in terms of scope and study quality. It would be particularly valuable for future work to utilize more rigorous study designs and to more directly assess the impact of these experiences on clinical practice instead of focusing on feasibility and acceptability.

THE USE OF TELE-MENTAL HEALTH TO ADDRESS WOMEN VETERANS' MENTAL HEALTH NEEDS IN VA

Jessica L. Zuchowski¹; Kristina M. Cordasco^{2, 1}; Sabine M. Oishi¹; Danielle Rose¹; Ismelda Canelo¹; Elizabeth M. Yano^{1, 3}; Alison Hamilton^{1, 3}. ¹US Dept of Veterans Affairs, North Hills, CA; ²VA Greater Los Angeles Healthcare System/ UCLA, Los Angeles, CA; ³UCLA, Los Angeles, CA. (Tracking ID #2196274)

BACKGROUND: Tele-mental health promises much for providing access to mental health care for patients in rural areas, and reducing geographic limitations on meeting the needs of patients in areas that lack experienced providers for specific conditions. Tele-mental health applications such as one-on-one and group video conferencing have been shown to have a high degree of acceptability with patients and providers. Women are a growing minority in VA with significant mental health needs that may differ from their male counterparts. Little is known about the availability and potential for tele-mental health to better address the mental health needs of women Veterans.

METHODS: We conducted semi-structured interviews with key stakeholders at four VA hospitals and associated community outpatient clinics in four metropolitan centers and their surrounding areas. Interviewees were recruited by email and included clinic directors, primary care and mental health leaders, women's health and mental health providers,

women's services directors, tele-health coordinators, and other VA staff members directly involved in the care of women patients. We asked about the main needs, including mental health needs, of women patients and the availability of tele-mental health services to meet these needs. Interviews were recorded, professionally transcribed, and summarized within a template of key domains. Transcripts were coded in ATLAS.ti (version 7) for content related to women's mental health needs and mental health applications for tele-health services. Thematic analysis was facilitated by the grouping of relevant coded sections of text.

RESULTS: Interviews were completed with 43 participants between July and September of 2012. Interviewees generally viewed mental health needs as highly prevalent among women Veterans, including Military Sexual Trauma (MST), Post-Traumatic Stress Disorder (PTSD), depression, anxiety, and eating disorders, as well as trauma in general. Across all four geographic areas, tele-mental health was the most established form of tele-health services, utilized to connect patients at outpatient clinics with distant mental health providers for one-on-one therapy via video conferencing; tele-mental health group therapy was less widely used. Interviewees frequently mentioned the advantage of tele-mental health to reduce the burden of travel on rural patients, and connect patients with providers who have specialized experience with particular mental health needs, such as MST. Due to the significant mental health needs of women Veterans, most interviewees expressed the desire to expand tele-mental health in order to better serve more women. Some hoped to expand tele-mental health to include gender-specific group therapy, offering women's-only groups in geographic areas having insufficient numbers of women Veterans for in-person groups. A minority of interviewees voiced concerns about using tele-mental health in women with significant trauma histories who may be prone to suicidal tendencies.

CONCLUSIONS: Tele-mental health is well established at the VA sites studied and, among key provider and leadership stakeholders, had a high degree of acceptability for addressing the mental health needs of women Veterans. Stakeholders also expressed enthusiasm at tele-mental health's potential to improve access to care. Both within and outside VA, there is opportunity for further growth to make tele-mental health services available to more women, especially those in rural areas. Tele-mental health group therapy may be one area for expansion. Future work in this area should incorporate the perspectives of women Veterans, as they were not included in this study. More research is also necessary to determine if some sub-groups of women patients, such as those with significant trauma, are more or less appropriate to be served by tele-mental health.

TIMING OF READMISSIONS FROM POST-ACUTE CARE: IMPLICATIONS FOR IMPROVING THE QUALITY OF TRANSITIONAL CARE

Robert E. Burke¹, Emily Whitfield², Eric A. Coleman³, Dr. Robert Schwartz³, Adit A. Ginde⁴, Dr. David Hittle³. ¹Denver VA Medical Center, Denver, CO; ²Veteran Affairs, Westminster, CO;

³University of Colorado School of Medicine, Aurora, CO; ⁴University of Colorado School of Medicine, Denver, CO. (Tracking ID #2199110)

BACKGROUND: The number of older adults discharged to post-acute care (PAC) facilities after hospitalization has increased by 50 % nationally between 1996 and 2010. However, outcomes of this care are far from optimal: readmission rates from these facilities exceed those of discharges home and are increasing rapidly as patients are discharged from the hospital "quicker and sicker." These readmissions are important because they are linked to progressive disability and early mortality in older adults. Best practices for reducing these readmissions are not known. Describing the timing of readmissions during the PAC stay may lend insight into the role hospital and transitional care processes (which more likely lead to early readmissions) and PAC facility care processes (which may be more associated with readmissions after this initial period) play in readmissions, guiding future interventions. We sought to describe the timing of readmissions from PAC facilities using the Medicare Current Beneficiary Survey (MCBS) from 2000–2009.

METHODS: The MCBS is a nationally representative cohort of approximately 16,000 Medicare beneficiaries surveyed at regular intervals over a 4-year period with matching Medicare claims data. We identified Medicare beneficiaries who had an acute hospitalization, were discharged to a PAC facility (defined as a skilled nursing or rehabilitation facility), and were readmitted to an acute care hospital during that stay. We recorded the post-hospital day their readmission occurred. We also examined trends from 2000 to 2009 in early (within 7 days), late (day 8 to day of PAC discharge), and post-PAC (within 30 days of PAC discharge) readmissions.

RESULTS: Overall, 1288 of 6502 patients discharged to PAC were readmitted during their PAC stay (19.8 %). Of all readmissions, 66.7 % occurred in the first 7 days after hospital discharge and more than 90 % within the first fifteen days (Figure 1). Each year, early readmissions were more common than late or post-PAC readmissions (Figure 2), though early readmissions increased throughout the time period without substantial increases in readmissions during either of the other two periods. The 7-day readmission rate increased from 10.6 % (2000–2004) to 12.8 % (2005–9) on average.

CONCLUSIONS: More than 2/3 of all readmissions from PAC facilities occur in the first 7 days after hospital discharge and early readmissions are becoming more common over time. This is a strikingly different distribution than for discharges home, for example, in which only one-third of readmissions occur during the first 7 days after hospital discharge. Our results suggest targeting hospital and transitional care processes may be most fruitful for reducing these readmissions. Our future work will seek to identify the cause of readmissions during early and late periods, identify modifiable risk factors for readmission in patients being discharged to PAC, and evaluate how these factors are changing over time.

TOBACCO USE AMONG FORMER INMATES: RELAPSE AND PREDICTORS OF A DESIRE TO QUIT Michael Frank²; Sung-joon Min²; Rachel Blumhagen⁴; David Weitzenkamp⁴; Shane Mueller^{3, 2}; Brenda Beaty⁵; Ingrid A. Binswanger¹. ¹University of Colorado School of Medicine, Denver, CO; ²University of Colorado School of Medicine, Aurora, CO; ³University of Colorado at Anschutz Medical Campus, Aurora, CO; ⁴Colorado School of Public Health, Aurora, CO; ⁵University of Colorado, Aurora, CO. (Tracking ID #2173116)

BACKGROUND: Inmates and former inmates have a high prevalence of tobacco use. Evidence suggests that the majority of inmates and former inmates, reflective of the general population, will die of tobacco-related illnesses rather than illicit substance abuse, alcohol use, or traumatic injuries. Despite widespread tobacco-free prison policies making it more difficult to smoke in prison, almost all inmates relapse on tobacco within days of release from prison. Social stressors and risky health behaviors are associated with tobacco use in the general population. However, the relationship between social stressors, risky health behaviors, and tobacco use in former inmates has not been studied. The aim of this study is to explore the relationship between the desire to quit smoking and seven distinct social stressors and risky health behaviors in a sample of former inmates.

METHODS: Former inmates were interviewed 7 to 21 days after release from prison. Social stressors and risky health behaviors were characterized by unemployment, unstable housing, problems with family, friends, and/or significant others, low educational achievement, hazardous drinking, recent drug use, and major symptoms of depression. Associations between social stressors and risky health behaviors and the desire to quit smoking were analyzed using Pearson chi-square test of association. The final multivariable logistic regression model was selected based on a comparison of AIC values.

RESULTS: Of those who had to quit smoking due to tobacco-free prison policies, 98 % reported that they relapsed on tobacco after being released, 74 % of them within 1 day and 26 % in 2 or more days. The desire to quit smoking was associated with the absence of hazardous drinking in the past 30 days (Adjusted OR 6.4, 95 % CI 2.0–20.5) and the absence of any drug use in the past 30 days (Adjusted OR 3.3, 95 % CI 1.1–10.6).

CONCLUSIONS: Tobacco-free policies in correctional facilities are not an effective strategy to promote long-term smoking cessation among former inmates. Targeting tobacco cessation interventions at former inmates who do not engage in hazardous drinking or illicit drug use may be more effective. Further research may determine whether interventions addressing risky health behaviors, namely hazardous alcohol use and drug use, can reduce smoking relapse among former inmates.

TOO OLD TO GET TESTED?: HIV TEST ACCEPTANCE AMONG PATIENTS 50 YEARS AND OLDER IN A ROUTINE HIV TESTING PROGRAM AT A PRIMARY CARE CENTER IN A HIGH HIV PREVALENCE AREA Enoch Kotei¹; Heather Freiman²; Natasha Travis². ¹Emory, Atlanta, GA; ²Emory University, Atlanta, GA. (Tracking ID #2198562)

BACKGROUND: UNAIDS and the WHO estimate that 2.8 million of the 40 million people worldwide infected with HIV are age 50 and older. In the United States, over 15 % of the 40,000 new cases diagnosed yearly are in persons age 50 years and older, and 2 % of these cases are in patients age 65 years and older (CDC 2006). Due to the increased life span for HIV-infected persons, it is estimated that this year, half of all adults living with HIV in the United States will be over the age of 50. Older adults are less frequently tested for HIV often when providers selectively initiate testing (Moore & Amburgey, 2000); thus, older adults, in particular, may benefit from routine testing as recommended by the CDC. Therefore, the acceptance rate of testing in the older adult population compared to younger patients merits further investigation.

METHODS: In this analysis, data from a routine HIV screening program in a primary care center (PCC) were compared for patients age 50 and older vs. patients age 18–49 years at time of visit. During triage, staff members were asked to complete an HIV test eligibility assessment for every patient. Patients who were not known to be HIV positive, over 18 years old, not incarcerated, clinically capable of consent, and not tested in the past 6 months were eligible for the HIV test offer. HIV testing was conducted via 3rd generation EIA testing with reflex Western Blots for EIA positive samples. Data were extracted from Electronic Medical Record reports for all PCC patients triaged during the 12 month period from October 1, 2013 to September 30, 2014. Frequencies of the following variables were compared for older vs. younger patients: HIV test eligibility assessment initiation, HIV test offer, HIV test acceptance, and HIV test completion. Data analyses were conducted using SAS 9.3 statistical software, and the Z-test for proportions was used to assess differences between comparator groups.

RESULTS: From October 1, 2013 to September 30, 2014, 42,420 patients were triaged in the PCC. Of these patients, 30,652 were at least 50 years old (72.2 % of patients triaged), with a mean age of 55.4 ± 12.9 years (patient age range of 18–106 years). Older patients less frequently had the HIV test eligibility assessment initiated at triage (69.4 % of patients 50 and older vs. 72.8 % of younger patients, $p=0$). Among patients with the eligibility assessment completed, older patients were more frequently offered an HIV test (69.6 vs. 63.7 % of younger patients, $p=0$). However, older patients declined the HIV test offer more frequently than younger patients (37.1 vs. 52.6 %, $p=0$). Additionally, older patients were less likely to complete an HIV test within one year of accepting the test, compared to younger patients (39.1 vs. 42.1 %, $p=0.01$). Frequencies of demographic characteristic (race and sex) were similar for comparator groups (50 years and older vs. 18–49 years old) in all analyses described here.

CONCLUSIONS: In this primary care population, older adults were less likely to accept and complete HIV testing when compared to younger adults, with multiple factors possibly contributing. First, as previously mentioned, the perceived risk by provider and patient could be relatively low, since the general public commonly associates HIV infection with younger individuals engaging in risky behaviors. In addition, concerns about HIV infection could be overshadowed by concerns about chronic disease management and addressing more common causes of death in this population, such as heart disease and cancer. These factors may cause a provider to be less insistent on testing and lead to patient refusal or procrastination. Missed opportunities for testing in older adults are consequential, as undiagnosed patients further contribute to high infection rates and fail to benefit from therapies which could extend their life expectancy. The data in this study highlights the need for providers to educate older adults on their risk of HIV acquisition and the importance of testing, using pre-existing statistics as rationale for screening.

TRAINING HOSPITALISTS TO USE MICROSKILLS AND SMALL GROUP TEACHING STRATEGIES CAN IMPROVE CONFIDENCE AND PERFORMANCE IN WARD ROUND TEACHING Verity Schay¹; Frank Volpicelli¹;

Lynn Bui³; Mark D. Schwartz^{2,3}; Anne Dembitzer^{1,3}. ¹NY Harbor VA, New York, NY; ²VA NY Harbor, New York, NY; ³New York University, New York, NY; ⁴NYU School of Medicine, New York, NY. (Tracking ID #2197902)

BACKGROUND: Inpatient ward rounds are an essential component of clinical training for residents and medical students. However, attendings are often challenged to engage and teach learners at various training levels. The effective use of the five-step microskills and small group teaching skills has been well studied in the outpatient setting but not the inpatient setting. We sought to improve teaching to all levels of learners by training hospitalists in the use of these educational methods.

METHODS: Internal medicine hospitalists were recruited from 3 institutions to participate in a three-hour workshop focused on the use of microskills and small group teaching skills during ward rounds. The workshop paired clinical content (case based discussion of pain management) with these teaching skills. Participants were divided into small groups (3–4) that first reviewed the five-step microskills and small group teaching skills, and then engaged in role play exercises with feedback from medical education experts and peers. Participants teaching skills were assessed 7 months apart using a pre and post-intervention Observed Standardized Teaching Exercise (OSTE) where participants were tasked with leading ward rounds for a team that consisted of 3, standardized learners—intern, resident and student. Each of these learners independently completed a checklist that rated the participants teaching skills as not done, partially done, or well done. Teaching skills were assessed in three domains: general teaching skills, use of microskills, and use of small group teaching skills. At the conclusion of the workshop, participants completed retrospective pre/post assessments that assessed change in teaching confidence and likelihood of using microskills or small group teaching skills.

RESULTS: Eighteen hospitalists participated in the workshop. At the baseline OSTE, general teaching skills were rated highest by the standardized intern (45 % well done) compared to the resident (39 %) and the student (27 %) (difference between the intern and student, $P=0.003$). At the post-intervention OSTE, the resident and student ratings of general teaching skills increased (resident 62 % well done, $P=0.03$, and student 53 % well done, $P=0.005$). There was no longer a difference between the intern and student ratings ($P=0.29$). Rating of participant small group teaching skills improved for the resident (40 to 67 % well done, $P=0.04$) and student (39 to 62 % well done, $P=0.05$) but decreased for the intern (55 to 33 % well done, $P=0.07$). Use of microskills ratings were high at baseline OSTE assessment and did not significantly change post-intervention. In retrospective pre/post assessments, program participants reported increased confidence in their ability to teach on the ward from baseline to post-intervention (7 to 40 % very confident, $p=0.02$) and teach learners at different levels during ward rounds (0 to 42 % very confident, $p=0.02$). Participants reported they were more likely to develop a teaching strategy before beginning ward rounds (0 to 58 % very likely).

CONCLUSIONS: A three-hour workshop with peer and medical education faculty feedback was able to improve hospitalists' ability to teach a range of learners rather than focus on one. Hospitalists' confidence in their ability to conduct ward rounds, teach a range of learners and to develop a teaching strategy prior to rounds increased. Hospitalists trained to use small group

teaching skills and microskills may be able to positively change the dynamic of the inpatient learning environment.

TRAINING THE NEXT GENERATION OF PHYSICIANS: HOW EFFECTIVE ARE RESIDENTS AT DIAGNOSING AND TREATING DEPRESSION? Sondra

Zabar²; Kathleen Hanley²; Lisa Althuler²; Amara Shaker-Brown²; Irina Nudelman²; Ellen Wagner²; Barbara Porter²; Andrew B. Wallach¹; Adina Kalet²; Mrudula Naidu²; Colleen Gillespie². ¹Bellevue Hospital, New York, NY; ²NYU School of Medicine, New York, NY. (Tracking ID #2198869)

BACKGROUND: The high prevalence of depression in primary care clinics, depressed patients' low quality of life, and extensive use of health care services underscores the need for all internal medicine residents to be skilled at diagnosing, treating, and managing depression. We designed an unannounced standard patient (USP) case to assess residents' clinical skills and help tailor future curriculum on depression.

METHODS: The USP was a 22-year-old male presenting as a new patient to an urban public clinic complaining of fatigue. He reported problems sleeping and stress at work. Goals of the case were for the resident to diagnose a common presentation of depression and engage the patient in a treatment and follow-up plan. The USP was trained to have a positive PHQ 2, meet depression criteria on a PHQ 9 if symptoms elicited, have family history of depression, and be willing to engage in treatment (medication and/or therapy) if offered and explained. The USPs trained for six hours in character portrayal and checklist completion. Tablets were used post-visit to collect data. A checklist was created to assess general communication and case specific skills. Domains included: depression and substance use screen, current life situation assessment, and follow-up. Item response options were: not done, partly done, and well done, each with descriptive behavioral anchors to enhance rating reliability. Domain scores were calculated as percent items rated well done. Case fidelity was checked by audiotape review of encounters to ensure presentation matched core case details and appropriate emotional tone. One hundred two medicine residents saw the USP case from 2009 to 2014.

RESULTS: Mean USP visit length=44 min, SD=18 min (range:15 to 155 min). Overall communication skills in the fatigue case were not significantly different than those of the other USP cases. Specifically, a little over 50 % acknowledged emotions appropriately and 60 % used effected non-verbal behaviors to enrich communication. Though 62 % provided clear explanation and information in manageable chunks, only 50 % checked back to confirm patient understanding. Sixty-nine percent screened for depression with PHQ2, and 68 % further explored criteria for depression. Only 42 % asked about family history for depression and 34 % about social or family support. Over 70 % completely assessed smoking, drug use, and past medical problems. Only 48 % drew a connection between depression and the presenting symptoms, 44 % discussed medication and therapy as treatment options, and 29 % did not discuss either. A third assessed the patient understanding of depression while a third did not ask at all. Over 68 % reviewed the final plan with the patient. Though most of the patients were satisfied with the time spent (76 %), only 50 % reported they got enough information and had all their concerns addressed. Only 25 % of the USPs reported that they were activated to deal with their depression after the visit. Residents' patient activation skills were lower in this case compared to other USP visits (25 % vs 32 %, $p<.003$).

CONCLUSIONS: Most residents are able to diagnosis depression in a new patient, but there is large variation in patient education and counseling skills. More attention needs to be paid to these skills in order to improve patient activation, which leads to improved patient outcomes.

TRAIT, STATE, AND PLACE: THE ROLE OF PERSONALITY AND ENVIRONMENT IN DRUG USE Karan A. Phillips¹; Dexter Louie²; Melody Fumari¹; William

Kowalczyk¹; David H. Epstein¹; Kenzie L. Preston¹. ¹National Institute on Drug Abuse, National Institutes of Health, Baltimore, MD; ²University of California, San Francisco School of Medicine, San Francisco, CA. (Tracking ID #2199122)

BACKGROUND: Addiction is complex with many attributed causative factors. Personality traits have long been linked to vulnerability to SUD as have state variables such as family history. Environmental factors such as neighborhood of residence have also been found to contribute to vulnerability to addiction. We sought to compare the personality traits and neighborhood of residence of drug users and non-drug users to better understand the relative contributions of trait/personality vs. place/environment to vulnerability to addiction.

METHODS: Participants were administered the NEO Five Factor Inventory to assess 5 personality or trait factors—neuroticism, extraversion, openness, agreeableness, and

conscientiousness, and the Addiction Severity Index to assess state variables such as personal and family drug use history. Place of residence was assessed with the Neighborhood Inventory for Environmental Typology (NIEtY), a standardized inventory assessing the incidence and prevalence of environmental indicators of physical, social, and drug-related disorder (1 lowest to 8 highest disorder). Analysis was done with Stata 10 and included *t* tests, Pearson χ^2 , Fisher's exact and multivariate logistic regression.

RESULTS: Participants included 104 current opioid/stimulant users (CDUs) and 88 non drug users (NDUs). The average age (SD) was greater in the CDUs (46(9) vs. 35(11) years, $p<0.001$) and more CDUs were male (76 % vs. 39 %, $p<0.001$). There was no difference in race ($p=0.109$). Neuroticism percentiles were higher in the CDUs ($p<0.001$); and extraversion, openness, agreeableness, and conscientiousness percentiles were lower (all $p<0.001$). NIEtY scores were higher for CDUs (mean (SD) 5.1(1.5) vs. 3.9(1.8), $p<0.001$). In the multivariate model predicting drug use status, age (OR 1.10, CI(1.05,1.17), $p<0.001$), female gender (OR 0.22, CI(0.07,0.66), $p=0.007$), years of cannabis use (OR 1.26, CI(1.12,1.42), $p<0.001$), nuclear family history of addiction (OR 4.34, CI(1.49,12.6), $p=0.007$), openness (OR 0.97, CI(0.95, 0.99), $p=0.007$), agreeableness (OR 0.98, CI(0.96, 1.00), $p=0.03$), and NIEtY scores (OR 1.53, CI(1.08, 2.16), $p=0.017$) were significant.

CONCLUSIONS: While trait, state, and place variables all determined drug use status, a nuclear family history of addiction (state variable) and neighborhood physical, social, and drug-related disorder (place variable) were stronger predictors of drug use status than personality (trait variable).

TRANSFORMING TEAM DYNAMICS IN PRIMARY CARE PRACTICES: CHANGES BETWEEN YEAR 1 AND YEAR 2 OF THE ACADEMIC INNOVATIONS COLLABORATIVE Hummy Song³, Alyna T. Chien^{4, 1}, Antoinette S. Peters¹, Meredith Rosenthal², Sara Singer². ¹Harvard Medical School, Boston, MA; ²Harvard School of Public Health, Boston, MA; ³Harvard University, Boston, MA; ⁴Boston Children's Hospital, Boston, MA. (Tracking ID #2196136)

BACKGROUND: Team-based medical practice has been promoted as critical for improving health care quality and patient outcomes. Better team dynamics among primary care providers (PCPs) may also improve clinical work satisfaction and enhance patient care coordination between PCPs. The Academic Innovations Collaborative (AIC) was a 2-year learning collaborative of 19 hospital- and community-based, academically-affiliated primary care practices committed to building highly functional teams, managing populations, and engaging patients. In AIC Year 1 (FY 2012/13), participating practices reorganized all personnel into teams; in AIC Year 2 (FY 2013/14), practices finished empaneling their patients to physicians and their respective teams. In this paper, we assess the changes in primary care team dynamics, clinical work satisfaction, and patient care coordination between PCPs between AIC Years 1 and 2.

METHODS: We employed a pre-post design using survey data collected in AIC Years 1 and 2. We used a previously validated 29-item Primary Care Team Dynamics survey instrument to assess levels of team dynamics across 7 domains, 1 item to measure clinical work satisfaction, and 8 items to measure perceived quality of patient care coordination between PCPs. All responses were assessed using a 5-point Likert response scale, from 1 = strongly disagree to 5 = strongly agree. In the fall and winter months of each year, we administered this survey to all attending and trainee PCPs (primary care physicians, nurse practitioners, physician assistants, residents), and non-PCPs directly involved in patient care (nurses, allied health professionals, administrative staff). We examined the change in primary care team dynamics and clinical work satisfaction, respectively, using individual-level, linear regression models adjusting for age, gender, race/ethnicity, and professional discipline. To examine the change in patient care coordination between PCPs, we used the same model specification but limited our population to attending and trainee PCPs, because patient care coordination between PCPs is not applicable to non-PCPs. For all models, we used practice-level fixed effects to account for unobservable differences across practices and estimated heteroskedasticity-robust standard errors clustered by primary care practice. To control for practices' Year 1 levels of team dynamics, clinical work satisfaction, and patient care coordination between PCPs in examining changes between intervention Years 1 and 2, we repeated these analyses while holding constant the Year 1 quartile of the practice's average responses.

RESULTS: We received 1034 responses (66 %) for the Year 1 survey and 1001 responses (64 %) for the Year 2 survey. Year 1 levels of team dynamics, clinical work satisfaction, and patient care coordination between PCPs were 3.4, 3.7, and 3.9 respectively out of 5. By Year 2, ratings for each measure had increased. The overall team dynamics score increased by 7 % (.38 of 1 SD), clinical work satisfaction increased by 3 % (.09 of 1 SD), and PCP ratings of patient care coordination between PCPs increased by 5 % (.38 of 1 SD). After adjusting for respondent characteristics and practice-level fixed effects and

clustering standard errors, we found statistically significant improvements for the overall team dynamics score, each of the 7 domains of team dynamics, and patient care coordination between PCPs ($p<0.01$ for each). However, we found no statistically significant difference in clinical work satisfaction between intervention Years 1 and 2 ($p=0.08$). When also adjusting for the Year 1 quartile of the practice's average responses, we obtained results of similar magnitude and significance, which indicates that results improved without regard to practice's performance level in Year 1.

CONCLUSIONS: The first year of AIC activity has yielded statistically significant improvements in primary care team dynamics and patient care coordination between PCPs. However, we do not find statistically significant improvements in clinical work satisfaction. Across all of these dimensions, the changes between intervention Years 1 and 2 represent moderate increases, and opportunities remain to improve team dynamics, coordination, and satisfaction. Nevertheless, the identification of some progress after just the first year of collaborative effort suggests that focusing a primary care transformation initiative on building highly functional teams has potential to yield a range of positive repercussions for academically-affiliated primary care practices.

TRANSLATING CHANGES IN CHOLESTEROL TREATMENT GUIDELINES INTO CLINICAL PRACTICE- A HEAVY LIFT FOR SAFETY-NET INSTITUTIONS Valy Fontil^{2, 3}, Courtney Lyles^{2, 3}, Dean Schilling^{2, 3}, Sara Ackerman^{1, 2}, Margaret A. Handley^{2, 3}, Kirsten Bibbins-Domingo^{2, 3}, Gato I. Gourley^{2, 3}, Urmimala Sarkar^{2, 3}. ¹UCSF, San Francisco, CA; ²University of California San Francisco, San Francisco, CA; ³Center for Vulnerable Populations, San Francisco, CA. (Tracking ID #2198800)

BACKGROUND: Use of clinical performance measures based on practice guidelines increasingly plays an integral role in the provision of medical care. However, it is unclear how healthcare institutions and clinicians respond to evolving practice guidelines which necessitate changing measures of performance. Changes in practice guidelines may be especially challenging to resource- limited healthcare institutions which lack infrastructure, in terms of personnel and technology, needed for quality measurement. The recent 2013 American College of Cardiology/American Heart Association (ACC/AHA) cholesterol treatment guideline changed current standards for both clinical practice and performance measurement, moving away from a numeric low-density-lipoprotein (LDL) target towards a risk-calculation approach. Within California's public hospital systems, these new guidelines came in the middle of an ongoing statewide focused quality improvement (QI) effort aimed at reaching the existing LDL target. This offers a unique opportunity to examine how healthcare leaders, QI professionals, and clinicians at these safety net systems respond to changing guidelines.

METHODS: Through the Public Healthcare system Evidence Network and Innovation eXchange (PHoENIX) initiative we performed six focus group interviews with representatives of California's 21 public hospital systems to explore reactions to the recent, 2013 ACC/AHA cholesterol treatment guideline and understand the impact on performance reporting and QI. Purposive sampling was used to recruit frontline staff, managers, administrators, and clinicians working on data management and reporting from these organizations' membership for the focus groups. The interview process and subsequent qualitative analysis was informed by grounded theory without specified a priori hypotheses.

RESULTS: The new cholesterol guidelines were seen as controversial and inconsistent by some participants but generally accepted as evidence-based. We identified three common reactions to the guideline: lost momentum for current cholesterol QI efforts; confusion leading to disparate views and clinician behaviors with regards to cholesterol management and performance measurement; and calls for more flexibility with latitude for institutions to set their own quality goals. Reported challenges to implementing the new guideline included: inadequate data infrastructure to move from LDL targets to medication prescription as a performance measure, lack of organizational infrastructure for disseminating and implementing new guidelines, and limited funding and staffing for simultaneously implementing a new performance measure and undertake quality improvement efforts based on the new guideline.

CONCLUSIONS: The combination of cholesterol performance reporting requirements and changing guidelines led to quality improvement inertia and increased practice variations in healthcare safety-net settings. Implementing a new performance measure in response to changing guideline can be a resource-intensive process that could limit a system's capacity to undertake quality improvement efforts for better patient care. A new approach that shifts focus away from reporting quality measures to participation in quality improvement efforts to optimize management of cholesterol may be warranted.

Exhibit 1. Attitudes and reactions to the 2013 AHA/ACC cholesterol guidelines in the California healthcare safety net

Exhibit 1. Attitudes and reactions to the 2013 AHA/ACC cholesterol guidelines in the California healthcare safety net

Reaction	Representative quote(s)
Guidelines recommendations seen as controversial and inconsistent by some participants but generally accepted as authoritative	<p>“Well, these are the “guidelines.” Following the guidelines is less resource intensive than not following them, the latest guidelines, right? So we were in favor of, well, we’re going to move our system forward with whatever we can.”</p> <p>“The risk factor calculator guidelines and what percentage you start putting patients on moderate to high-dose statins is debatable... Britain guidelines are different than American guidelines and blah, blah....ACC guideline and the risk calculator starts at 40 years old. So anyone between 19 and 39 you get a nice little message from the calculator that says, “By the way, it’s invalid but thanks for trying.”</p>
Current performance measurements and QI goals now seen as invalid and unenforceable	<p>“When the guidelines came out last year, the medical director of our patient care and medical home called me and said ‘what am I supposed to do with this?’ Was being held to this particular metric for DSRIP and this new evidence came out, and I can tell you up front our physicians really care about the evidence and we’re probably not going to get much support for the LDL metric.”</p>
Sense of confusion and lack of direction for cholesterol management and performance measurement	<p>“So I think when the guidelines aren’t very clear, then you have the physicians practicing all over the map. So I think that’s part of the problem with the new lipid guidelines.”</p> <p>“Even in the same clinic, we have clinicians that don’t agree about how they want to do this now.”</p> <p>“So as far as the number goes, it’s pseudo proxy kind of but I feel like we need guidance as far as, okay, look, if we’re going to go with statins, yes or no, then we need to go ahead and say something so that people could evaluate. “Okay, what does this mean to us? What’s our risk? Is it doable or not?” This is doable, this is buildable. This is not buildable”</p> <p>“So I think it just made it, without commenting on the guidelines, it just made it a challenge...having a moving standard in terms of focusing every body’s attention on the same goal... I think that’s really where we are—is probably not having clarity of focus I think that we would like to have because of the change.”</p>
Performance measuring and QI based on the new guidelines for cholesterol management will be challenging	<p>“We talked about—and we actually measure percent reduction, it’s that one way of looking at it, that’s much more complicated to do. Then looking at statin usage and looking at high intensity versus moderate intensity dosaging to see whether or not that’s a good measure for this particular new guideline or not. If that is the case, how do we actually get that data because do you look at prescribing data? Did the patient actually pick up the medication? I mean that gets really complicated I think.”</p>
calls for more flexible performance measures and institutional partnerships to produce their own standards and performance metrics	<p>“One thing I would like to see in the future is maybe a little bit more flexibility in terms of how the metrics are defined so that the metric can accommodate changes in guidelines over time...”</p> <p>“What I’m trying to say, even as an institution or an organization or neighboring facilities, let’s at least, for our geographical, with 200 miles of each other, what are we going to do with our neighbors or something like that? What are going to report or something to try to develop some unity?”</p>

TREATING OLDER MEN WITH LOCALLY ADVANCED PROSTATE CANCER—IS IT UNDERUSE OR CLINICAL JUDGEMENT? Stephen Supoyo⁴; Simon Hall⁴; Richard Stock⁴; Gerald P. Hoke¹; William Oh⁴; Kezhen Fei²; Rebeca Franco³; Nina A. Bickell³. ¹Columbia University Medical College, New York, NY; ²Mount Sinai School of Medical, New York, NY; ³Mount Sinai School of Medicine, New York, NY; ⁴Ichan School of Medicine at Mount Sinai, New York, NY. (Tracking ID #2198643)

BACKGROUND: Prostate cancer (PCa) predominantly affects older men ≥ age 65y, yet they are less likely to receive appropriate treatment than younger men <65y. Definitive treatment is recommended for all patients with locally advanced intermediate and high D’Amico risk PCa. We aimed to identify reasons older men may not receive definitive PCa treatment.

METHODS: We reviewed medical records of 649 men diagnosed and treated for a new, locally advanced PCa (Gleason ≥ 7, stage ≥ IIA) from 2007–2012 at an inner-city tertiary referral and a municipal hospital. We compared demographics, PCa characteristics, comorbidities at time of diagnosis, and low or high 9 year overall mortality risk (≤ 16 % or > 16 %), as predicted by the Schenberg ePrognostic Index, for men ≥ 65y (n=431) vs <65y (n=218). Evidence-based quality measures for PCa treatment defined underuse of definitive treatment as ADT monotherapy or no surgery, radiation or cryotherapy.

RESULTS: Men’s average age was 61y (±8.8), 56 % were black, 44 % white, 8 % had Medicaid. Of older men, 57 % had surgery and 26 % radiation therapy, compared to 88 and 8 %, respectively, of the younger men (p<.0001). Median overall 9y mortality risk was 16 % in younger vs. 26 % in older men (p<.0001). Older men were more likely than younger men to have intermediate D’Amico PCa risk, 24 % vs 12 % (p<.0001). Fifteen percent of older men compared to 4 % of younger men experienced underuse (p<.0001). However, among older men, 6 % of those with low 9y mortality risk experienced underuse compared to 18 % of those with high mortality risk (p=.03). A greater proportion of men with high mortality risk had intermediate vs high D’Amico PCa risk (61 % v 45 %; p=.004). Multivariate modeling (c=.89; p<.0001) found that age was not associated with underuse; Intermediate D’Amico risk PCa (OR=9.81 among men with low mortality risk) and black race (OR=7.27; 95%CI: 2.2–24.5) was associated with greater underuse, while having commercial insurance was protective (OR=0.14; .07–0.3).

CONCLUSIONS: Age is not a risk factor for underuse. Rather, PCa risk affects treatment rate and life expectancy modifies this effect, suggesting that physicians utilize these factors in their treatment decisions regardless of patient age. Nonclinical factors such as patient access to treatment and race also affect underuse.

TREATMENT PATTERNS FOR OLDER VETERANS WITH LOCALIZED PROSTATE CANCER Richard Hoffman^{3, 4}; Ying Shi¹; Stephen Freedland⁵; Nancy L. Keating⁶; Louise Walter^{1, 2}. ¹San Francisco VA Medical Center, San Francisco, CA; ²University of California, San Francisco, San Francisco, CA; ³Albuquerque VA Medical Center, Albuquerque, NM; ⁴University of New Mexico School of Medicine, Albuquerque, NM; ⁵Duke University, Durham, NC; ⁶Harvard Medical School, Boston, MA. (Tracking ID #2190732)

BACKGROUND: Practice guidelines have discouraged actively treating prostate cancers diagnosed in men with limited life expectancies and/or low-risk tumors. However, population-based SEER-Medicare data indicate that substantial proportions of older men with prostate cancer, regardless of comorbidity or tumor characteristics, undergo surgery or radiotherapy. We evaluated VA treatment patterns for older veterans with localized prostate cancers, including those with low-risk tumors.

METHODS: We used national VA Cancer Registry data to identify men aged 65+ diagnosed with clinically localized prostate cancer between 1/1/03 and 12/31/08. We obtained baseline data on demographics, tumor characteristics, comorbidities, and initial treatment within 6 months of diagnosis (radical prostatectomy, radiotherapy, primary androgen deprivation therapy [PADT], no active treatment). National VA surveys provided facility data, including academic affiliation, availability of oncologic specialists, and distance to radiotherapy facilities. We used multinomial regression analyses to determine associations between patient and facility characteristics with treatment selection for men with localized and low-risk (stage ≤ 2a, PSA < 10 ng/mL, Gleason ≤ 6) cancers, respectively.

RESULTS: Seventeen thousand two hundred six veterans had localized prostate cancer; 32 % age 75+, 76 % white, 59 % married, 12 % comorbidity scores ≥ 3. Overall, 39 % received radiotherapy, 6 % surgery, 20 % PADT, and 35 % no active treatment. Older and

sicker men were less likely to receive surgery or radiotherapy vs. no active treatment, but more likely to receive PADT. Higher clinical stage, PSA levels, and Gleason scores predicted receiving active treatment. Over time, use of PADT decreased from 22 to 16 % while the proportion receiving no active treatment increased from 33 to 40 %, $P<0.001$. Facility characteristics, including availability of specialists and academic affiliations, were not significantly associated with treatment selection. About 1/3 of the cohort ($n=5616$) had low-risk prostate cancer; no active treatment (48 %) was the most common option, followed by radiotherapy (37 %). Older and sicker men were less likely to receive surgery or radiotherapy than no active treatment; older men were more likely to receive PADT. Over time, significantly more men with low-risk prostate cancer received no active treatment (41 to 57 %) and fewer received PADT (11 to 4 %), $P<0.001$.

CONCLUSIONS: VA treatment patterns followed evidence-based guidelines against treating older and sicker men with surgery or radiotherapy, for decreasing use of PADT, and for increasingly withholding active treatment, particularly for men with low-risk prostate cancer. Our findings suggest the potential value of an integrated health care system in reducing unnecessary utilization, though there is still considerable room for improvement.

TRENDS IN ECHOCARDIOGRAPHY UTILIZATION IN AN INTEGRATED DELIVERY SYSTEM Dipesh Amin³; Arthur Davidson¹; Susan Shetterly⁴; Elizabeth A. Bayliss². ¹Denver Health, Denver, CO; ²Kaiser Permanente and University of Colorado, Denver, CO; ³University of Colorado School of Medicine, Aurora, CO; ⁴Kaiser Permanente, Denver, CO. (Tracking ID #2198429)

BACKGROUND: Echocardiography is indispensable for evaluating cardiovascular function. Inappropriate and repeat testing contributes to healthcare costs and may not improve patient outcomes. Previously published reports show frequent repeat testing in Medicare fee-for-service beneficiaries. The Choosing Wisely campaign of the American Board of Internal Medicine recommends against routine follow up imaging in patients who have mild disease without symptoms. Fee-for-service reimbursement, patient demand, geographic variation and provider uncertainty may all drive increased utilization. Despite the economic and clinical importance of echocardiography, little is known about testing trends in an integrated healthcare system. We examined the trends in utilization and repeat testing in an integrated health system with salaried providers and a shared electronic health record.

METHODS: We examined patterns of repeat echocardiography in a retrospective cohort of adults 18 years and older receiving an initial index echocardiogram from January 1, 2007 to December 31st, 2010. The sample was divided into 4 annual inception cohorts and repeat echocardiograms defined as those completed within 3 years of index echocardiogram. We required a full year of enrollment without an echocardiogram prior to index. Those with diagnoses of congenital heart disease were excluded. Using Kaplan Meier survival analyses censoring for repeat testing and health plan disenrollment, trends of repeat testing over time were examined. Cox regression proportional hazard analysis was used to assess repeat echocardiogram as a function of cohort year adjusting for age, gender, specific diagnoses for which echocardiograms are indicated, and insurance type.

RESULTS: Twenty-four thousand five hundred thirty-nine patients received an index echocardiogram between 2007 and 2010. The average age was 64 years and 53.8 % were female. Repeat echocardiograms were performed in 25.1 % ($N=6156$) of patients. The average age of those with repeat was 68 years and 50 % were female. The unadjusted likelihood of having a repeat echocardiogram was lower in the 2009 and 2010 cohorts compared to the 2007 cohort (Hazard Ratio 0.82; 95 % CI: 0.74 to 0.91 and HR 0.80; 95 % CI: 0.72 to 0.89 respectively). Of those ordered in the outpatient setting ($N=10,196$), patients of cardiologists and other specialties were more likely to obtain repeat echocardiograms compared to internal medicine (Adjusted HR 1.66; 95 % CI: 1.51 to 1.82 and HR 1.50; 95 % CI: 1.34 to 1.68 respectively). After adjusting for age, gender and common cardiac conditions, those with high and standard deductible plans had decreased hazard of repeat echocardiogram (HR 0.68; 95 % CI: 0.53 to 0.88 and HR 0.64; 95 % CI: 0.58 to 0.72 respectively) relative to those with Health Maintenance Organization (HMO)/Medicare Advantage plans (Table 1).

CONCLUSIONS: The odds of obtaining a repeat echocardiogram do not appear to be increasing over time in this integrated healthcare delivery system. Patients enrolled in this system are more likely to have a repeat echocardiogram if older and have an HMO insurance plan. Deductible and high deductible plans decrease repeat testing over time. Outpatients seen by cardiologists and other specialists are more likely to undergo repeat testing, possibly due to higher disease severity.

TRENDS IN MEDICAID REIMBURSEMENT AND REFERENCE PRICES FOR INSULIN: 1991–2014 Jing Luo²; Jerry Avorn³; Aaron Kesselheim¹. ¹Brigham and Women, Boston, MA; ²Division of Pharmacoepidemiology and Pharmacoeconomics, Brigham and Women's Hospital / HMS, Boston, MA; ³Harvard Medical School, Boston, MA. (Tracking ID #2200691)

BACKGROUND: Insulin has been used to treat diabetics for over 90 years, yet no generic insulin product is available in the United States today. Lack of generic competition may keep drug prices high, so we sought to assess recent trends in Medicaid reimbursements and reference prices for insulin products.

METHODS: We first identified all insulin products continuously available to US patients since 2006, excluding discontinued products and those sold by repackagers (and Humulin R U-500). The 16 insulin products were then grouped by duration of action according to American Diabetes Association Guidelines and by patent status as of January 2013. Finally, we obtained annual Average Wholesale Prices for these products using Redbook from 1991 to 2014 and tracked quarterly Medicaid reimbursement for each product during the same period using the Centers for Medicare and Medicaid's aggregated drug spending data, adjusting for inflation using annual Consumer Price Indexes. We used linear regression to compare trends in reimbursements for patented and non-patent-protected insulins.

RESULTS: Medicaid reimbursement for currently-available insulin products has risen steadily per unit dispensed since 1991 (Figure 1). In the early 1990s, Medicaid reimbursed pharmacies approximately \$3/100u. By 2014, reimbursement rose to under \$8/100u for short-acting and intermediate insulins, \$15/100u for pre-mixed insulins and approximately \$20/100u for long-acting and rapid-acting analogues. The rate of increase in reimbursement was higher for patented than non-patent-protected insulins ($p<0.001$). Listed average wholesale prices increased in a manner almost identical to Medicaid reimbursements.

CONCLUSIONS: There was a nearly exponential upward trend in Medicaid payments and reference prices for a wide variety of insulin products over the past decade. This trend was consistent across all patent statuses, formulations, or durations of action of insulin products. These results suggest a lack of robust price competition in the insulin market in the United States, likely attributable to the lack of generic competition. These data indicate that the usual expectations of marketplace pressure and price competition after patent expiration are not functioning as some would predict, rendering this essential medication class less affordable for millions of patients.

Figure 1: Trends in Medicaid reimbursements by type of insulin from 1991 to 2014 (adjusted for inflation).

TROPICAL MEDICINE—RE-EMERGENCE OF HOOKWORM IN RURAL UNITED STATES Megan L. McKenna; Dr. Rojelio Mejia. Baylor College of Medicine, Houston, TX. (Tracking ID #2200065)

BACKGROUND: Parasitic gastrointestinal infections cause devastating effects on populations worldwide, including significant stunting in children repeatedly exposed to diarrheal diseases, as well as significant iron deficiency anemia (most commonly caused by hookworm), leading to impaired cognitive development in children. According to a study in the 1950s, rural Alabama suffered from a high prevalence of hookworm infection in schoolchildren, with counties as high as 60 % infection. However, due to improved sanitation methods and waste disposal, the incidence has decreased significantly. According to the Alabama Center for Rural Enterprise (ACRE) work plan, there are still environmental conditions with concerns for poor or no sanitation systems with open sewage close to dwellings. Due to these conditions, a more current investigation using modern molecular diagnostics is warranted to determine possible recurrence of gastrointestinal parasitic infections.

METHODS: Areas with poor sanitation were selected. The team visited these areas of residence to conduct a survey and collect data, and then follow up to collect samples (stool and environmental samples). Stool samples from 56 patients (ages 8 to 60 years old) and 34 soil samples were collected, with the following exclusion criteria: those who have traveled to endemic areas, children under 2 years of age, and no HIV or immunocompromised status patients were evaluated. Multi-parallel qualitative real-time PCR were run in duplicate for all patients, including positive, negative, and internal controls, as well as standards to determine parasite burden in each sample. The threshold for positivity was set at 38 cycle thresholds (Ct) and this value was the limit of detection for our dynamic range of positive standard curves.

RESULTS: Stool samples showed 20 (35.7 %) positive results were found for *Necator americanus*, 4 (7.7 %) positives for *Strongyloides stercoralis*, and 1 (1.7 %) for *Entamoeba histolytica* (Figure 1). Soil samples were positive for 1 (2.9 %) *Cryptosporidium* species. Subsequent stool studies using microscopy ova and parasite techniques were negative for 20 of the infected patients.

CONCLUSIONS: By using multi-parallel qualitative real-time PCR, several gastrointestinal parasites known to be endemic to developing countries have now been identified in a resource poor county in Alabama, among people who have never traveled abroad previously. This was a small preliminary study using a proven and field-tested novel assay. The burden of parasitic infection was low and may explain the microscopic lack of parasitic evidence. As shown in the 1950's Alabama study, Hookworm infection rates were as high as 60 % in some of the more poverty-stricken communities. After treatment

of those infected and improvement of sanitation, these pockets of infection were thought to have resolved. However, given continued poor sanitation and advancement of detection methods (improved sensitivity with PCR compared to microscopy), low burdens of infection have been discovered in the United States among populations who have never left the country. This begins to shift the idea behind global health. One concept is the Blue Marble Health Collection (Peter Hotez), which finds that many of the world's neglected tropical diseases are paradoxically found in some of the wealthiest countries, especially in these small regions of extreme poverty. As world travel becomes more widely available, opening access to poverty stricken communities both abroad and at home, and with the introduction of more advanced diagnostic techniques, emergence of rare, endemic infections may eventually become less defined by geographic location, but more by economic status of visited areas.

Figure 1. Parasite DNA fg/μL in stool samples from rural Alabama

TRUST AND FUNCTIONAL STATUS PREDICT PATIENTS' ADHERENCE TO PHYSICIANS' RECOMMENDATIONS IN A PROSPECTIVE COHORT OF VETERANS WITH HEART FAILURE Howard Gordon^{2, 1}; Oksana Pugach¹; Marvella E. Ford³. ¹University of Illinois at Chicago, Chicago, IL; ²Veterans Affairs Medical Center, Chicago, IL; ³Medical University of South Carolina, Charleston, SC. (Tracking ID #2197769)

BACKGROUND: Heart failure outcomes may improve when patients are more adherent to physicians' recommendations for medications and lifestyle modifications. Patients who

have more trust in physicians may be more adherent to physicians' recommendations, yet the relationship between patients' trust in physician and adherence is not well studied.

METHODS: Participants ($N=149$) were from a prospective cohort study in which patients with heart failure (HF) were followed at two visits within 6 months after hospital discharge at two Veterans Affairs medical centers. Patients with dementia, discharged to a nursing home, or whose HF was secondary to another condition were excluded. Patients completed self-report questionnaires on demographics, functional status, ratings of the doctors' informativeness and supportiveness, ratings of their own communication self-efficacy, trust in physician and adherence to physicians' recommendations regarding treatment for heart failure. Trust in physician was measured with a five item scale administered in clinic before and after each visit ($\alpha=0.82$). Adherence was measured with a five-item scale administered by telephone 4 weeks after each visit. All self-report measures were normalized to a 100-point scale. Visits were audiorecorded and later transcribed. Transcriptions were coded and the number of utterances for elements of physicians' patient centered and informed decision making communication and patients' participatory communication behaviors were quantified. In our analysis, we examined the bivariate relationship of several factors with adherence using mixed-effects regression models with random intercept. The independent predictors of adherence were examined with three steps of data modeling using backward elimination for variables with $P>0.20$ at each step. Significant demographic and clinical predictors of adherence were identified in the first step. Next, significant self-reported communication variables were identified. Last, significant communication behaviors were added to the model.

RESULTS: Adherence was higher in older patients for each additional year of age (0.34 %, $P=0.04$) and was higher for patients reporting higher functional status (0.19 %, $P=0.0004$). Adherence was not significantly different for Blacks or Hispanics, was not significantly different according to education, income, or marital status, and was not significantly different in patients who had the same doctor at both visits, or according to study site ($P>0.40$). Higher ratings of self-reported self-efficacy to communicate and post-visit doctor trust were significantly associated with higher self-reported adherence (0.18 %, $P=0.045$; and 0.20 %, $P=0.03$, respectively). Patients' question-asking and physicians' partnership-building communication behaviors were inversely associated with adherence (-0.39 utterances, $P=0.03$; and -0.42 utterances, $P=0.048$, respectively). In multiple regression analysis using backward elimination, functional status, age, education, trust in physician, and physician communication behaviors (partnership-building and recommendations) were retained in the final model, but only functional status and post-visit trust in physician were significant predictors of adherence to physicians recommendations 4 weeks after the visit (0.20 %, $P=0.0003$; and 0.25 %, $P=0.009$).

CONCLUSIONS: In this sample of Veterans with heart failure, age, functional status, patients' ratings (self-efficacy and post-visit trust in physician) and communication behaviors (patients' questions and physicians' partnership-building) were significantly associated with self-reported adherence. Specific communication behaviors were inversely associated with adherence suggesting that physicians and patients may have had higher rates of these communication behaviors when anticipating lower adherence. Nonetheless, in regression analysis communication behaviors were not independently associated with adherence, whereas functional status and patients' ratings of trust in physician measured after medical visits were independently associated with self-reported adherence measured 4 weeks later. Although the study was observational and the findings are primarily correlational, these findings are strengthened by the longitudinal study design in which independent variables such as the trust measure were measured at two time points.

TUBERCULOSIS SCREENING FOR DIABETIC PATIENTS IN COMMUNITY CLINICS IN KUNMING, CHINA Alanna Stone⁵; Li Ling^{1, 4}; Anh Innes^{1, 3}; Xu Lin². ¹CAP-TB, USAID Regional Development Mission Asia, Bangkok, Thailand; ²Yunnan Center for Disease Control and Prevention, Kunming, China; ³Family Health International, Bangkok, Thailand; ⁴Family Health International, Kunming, China; ⁵University of California, San Francisco, San Francisco, CA. (Tracking ID #2194674)

BACKGROUND: China has a rising epidemic of diabetes mellitus (DM) with a prevalence of 11.6 %, representing up to 113.9 million people. China also has an estimated 12 million cases of tuberculosis (TB). Diabetic patients have up to a 3-fold increased risk of developing active TB in addition to higher risk of TB treatment failure and even death. The present intervention was developed through the USAID Control and Prevention of TB (CAP-TB) project from FHI 360 in conjunction with partners the International Union Against Lung Disease and Tuberculosis and the Yunnan Anti-TB Association as a method to increase detection of TB in high-risk groups. This study aims to determine whether a simple screening tool for TB can be implemented by primary care providers in community clinics in Kunming, China to increase TB case detection in diabetic patients. Primary Objective: To build health workforce capacity of primary care providers in the region to improve diagnosis and treatment of TB among high-risk groups. Secondary Objective: To

determine whether TB screening in diabetic patients by primary care providers should be recommended in China.

METHODS: Primary care physicians and nurses at 5 designated district health centers and 5 sub-centers in the Xishan District of Kunming, Yunnan Province, China were trained to screen diabetic patients for TB. A symptom questionnaire was used at each clinic visit for each diabetic patient: cough for >2 weeks, night sweats for ≥ 4 weeks, fever for ≥ 4 weeks, weight loss over the previous 4 weeks, and symptoms of extra-pulmonary TB. A "yes" answer to any of these questions generated a referral for evaluation in the district TB clinic. Data were collected monthly on number of diabetic patients screened, number of positive screens, patients referred to and seen at the district TB clinic, and the number of patients diagnosed with TB. From this data, the case notification rate was determined. In addition to quantitative data collection, quarterly site visits were conducted to elicit initial success with enacting the screening protocol as well as to discuss barriers to screening with the trained providers.

RESULTS: From June 2013 to April 2014, 2942 diabetic patients were screened for TB in the designated clinics. Of these, 278 patients had TB symptoms and 209 patients arrived at TB clinic for diagnostic testing resulting in 3 confirmed cases of TB. Six patients had positive symptom screens but had chest x-rays that were read as inactive or old TB. The case notification rate was 102 per 100,000 screened as compared to a baseline notification rate in the general population of Yunnan province of 55 per 100,000.

CONCLUSIONS: Providers at health centers in Kunming, China are able to implement a simple protocol integrating TB screening into diabetes care. However, while many diabetic patients were screened, few screened positive resulting in a relatively low case notification rate. Success of implementation (measured by number of patients screened) also varied between sites. Poor provider understanding of reasons for screening, including risk factors for and symptoms of TB, was a barrier to successful detection. Other barriers included poor integration of screening into provider workflow and patient resistance to referral for diagnosis. Ongoing provider and patient education is needed on early case detection of TB and the importance of active screening for timely diagnosis and treatment of TB among diabetic patients. Screening for TB in diabetic patients in areas of high prevalence of both diseases is likely important to decrease the incidence of TB. However, even among those referred for TB diagnosis, relatively few had active TB. More information is needed to determine the most cost-effective and efficient means to screen these high-risk patients for TB. In the future, a new intervention aimed at focusing on patients at the hospital level in diabetic outpatient clinics (as opposed to community primary care settings) in Kunming will be piloted. Other interventions may also prove to be more effective, such as targeting a certain hemoglobin A1C to stratify for those with poorly controlled diabetes. Data on screening thus far has not been sufficient to recommend wider implementation, but it is necessary to continue to pursue new strategies as diabetes becomes a greater issue in areas of high TB prevalence.

TWICE THE IMPACT—A FDP THAT COMBINES CLINICAL AND EDUCATIONAL SKILL LEARNIN Lynn Bui³; Anne Dembitzer¹; Verity Schae²; Frank Volpicelli³; Binhuan Wang³; Audrey Grask²; Mark D. Schwartz¹. ¹NY Harbor VA, New York, NY; ²NYU School of Medicine, New York, NY; ³New York University, New York, NY. (Tracking ID #2198000)

BACKGROUND: Clinician educators (CE) are the primary teachers of medical students and residents on the wards, yet most have not had formal training in education. CE are interested in improving their teaching skills but often choose to attend clinical rather than educational CME programs. We sought to determine the impact of including teaching skill learning in a clinically focused longitudinal faculty development program (FDP) on participants teaching skill confidence and performance, and self-reported behavior change.

METHODS: We recruited hospitalists from 3 institutions to participate in an 8 month-long FDP. The FDP consisted of five 3-h sessions; a pre and post 3-station OSTE, and three workshops. Clinical content was selected based on a faculty's needs assessment. The educational component was based on learner's feedback. We created 3 workshops: 1. Performing Lumbar Puncture/how to teach procedures; 2. Dermatologic examination/observation and feedback; and 3. Inpatient pain management/using Microskills on ward rounds. Teaching skill performance was assessed using pre and post OSTEs. Standardized learners rated teaching performance using a checklist. Domains included general teaching skills (learning climate, control of session, assessment, instructional skills, and feedback), and workshop specific teaching and clinical skills; items were rated as "not done", "partly done" or "well done". Change in teaching and clinical skill confidence was assessed after each workshop using a retrospective pre post survey using a 4 point scale from "not

confident" to "very confident". Participants completed commitment to change (CTC) statements after each workshop.

RESULTS: Eighteen hospitalists completed the program, 65 % male with an average of 4 years in practice (range 1 to 8 years). Participant confidence, as measured by the retrospective pre-post assessments, improved in all areas: confidence in clinical skills improved for lumbar puncture from 11 to 53 % very confident ($p=0.0006$); the dermatologic exam 12 to 38 % very confident ($p=0.002$); and managing pain 37 to 60 % very confident ($p=0.007$). Confidence in teaching skills improved for teaching procedures 2 to 56 % very confident ($p=0.00007$), observation and feedback 26 to 46 % very confident ($p=0.01$) and using Microskills on ward rounds 4 to 48 % very confident ($p=0.005$). OSTE teaching skill performance improved for clinical skills; teaching the dermatologic examination 40 to 67 % well done ($p=0.002$) and teaching pain management 37 to 60 % well done ($p=0.007$). Educational skill performance also improved for observation and feedback 42 to 85 % well done ($p=0.00003$), and general teaching skills improved in learning climate (62 to 73 % well done, $p=0.03$), control of session (56 to 73 % well done, $p=0.008$) and instructional skills (50 to 69 % well done, $p=0.001$). At the end of the FDP, participants implemented 56 % and partially implemented 44 % of their goals focused on changing clinical practice and implemented 16 % and partially implemented 58 % of their goals focused on teaching behaviors.

CONCLUSIONS: Combining education skills with clinical skill learning for CE FDP can meet the clinical needs of busy CE and the educational needs of residency and medical schools. Combined programs may increase CE interest in participation and can improve teaching confidence, teaching performance and self reported teaching behavior. Pragmatic designed faculty development in medical education has the potential to change the clinical and teaching culture at an institution.

TWO YEAR FOLLOW-UP OF THE EFFECTIVENESS OF A MULTIFACETED INTERVENTION TO IMPROVE ADHERENCE TO ANNUAL COLORECTAL CANCER SCREENING IN COMMUNITY HEALTH CENTERS David W. Baker^{1,1}; Tiffany Brown^{1,1}; Shira N. Goldman^{1,1}; David T. Liss^{1,1}; Stephanie Kollar²; Kate Balsley²; Ji Young Lee^{1,1}; David R. Buchanan². ¹Northwestern University, Chicago, IL; ²Erie Family Health Center, Chicago, IL. (Tracking ID #2198292)

BACKGROUND: Colorectal cancer (CRC) screening is recommended for adults age 50–75. One recommended screening modality is annual fecal occult blood testing (FOBT). A previous study, conducted within a network of community health centers (CHC) found that a multifaceted outreach intervention achieved 82 % adherence to annual FOBT. However, it is unclear whether that high adherence rate can be maintained over time. The main objectives of this study were to determine adherence to annual FOBT during a second round of outreach and to determine the overall adherence to CRC screening by any modality over the entire study period.

METHODS: This was a cohort study conducted within a network of CHCs following all 225 patients assigned to intervention group in the original randomized controlled trial (RCT). The RCT was stopped after one year because of the far greater adherence rate in the intervention group, but we continued to follow the intervention group and conduct outreach as originally planned. Of the 124 patients who completed FOBT within 6 months of their due date during the first wave of outreach; 90 % were Latino, 87 % preferred to speak in Spanish, and 77 % were uninsured. Outreach consisted of 1) a mailed reminder letter, a free fecal immunochemical test (FIT) with a postage-paid return envelope, 2) an automated phone and text message, 3) automated phone and text reminders 2 weeks later for those who did not return the FIT, and 4) outreach by a CRC screening navigator after 3 months. Outreach was delivered on a rolling basis based on a patient's due date for FIT. The main outcome measure was completion of FIT within 6 months of the due date for annual screening as collected via electronic health record query. A secondary measure was a composite outcome of adherence to CRC screening over the entire 2 year follow up period.

RESULTS: A total of 88.7 % of patients completed a second annual FIT within 6 months of their due date. Of the 110 who completed the FIT, 90 (81.8 %) completed this within the first 3 months without the need for calls from the CRC screening navigator. When these results were combined with the results of the first year of follow-up, 71.6 % of the original 225 intervention patients were fully up to date on CRC screening, and another 11.1 % had been screened, although the timing or number of FITs completed was suboptimal; 17.3 % had no screening or inadequate screening. Of the 24 subjects with a positive FIT

over the course of the study, 13 (54.1 %) had documentation of a completed diagnostic colonoscopy.

CONCLUSIONS: It is possible to achieve high rates of CRC screening over a 2-year period for vulnerable populations using outreach with FIT as a primary strategy. Although it is possible that adherence rates will wane over time, the available evidence suggests that FOBT (i.e., FIT) is a viable strategy to improve CRC screening rates for vulnerable population if outreach strategies such as the ones in this study are used. However, to reduce mortality, studies are needed to identify strategies to achieve much higher rates of colonoscopy for patients whose FITs are positive.

TYPOLOGIES OF VA AND MEDICARE UTILIZATION AMONG DUALY ENROLLED VETERANS WITH TYPE 2 DIABETES: A LATENT CLASS ANALYSIS Thomas R. Radomski^{4,2}; Xinhua Zhao²; Carolyn T. Thorpe^{1,2}; Chester Good^{2,4}; Maria Mor^{2,5}; Michael J. Fine^{2,4}; Walid F. Gellad³. ¹University of Pittsburgh, Pittsburgh, PA; ²VA Pittsburgh Healthcare System, Pittsburgh, PA; ³VA Pittsburgh/University of Pittsburgh, Pittsburgh, PA; ⁴University of Pittsburgh School of Medicine, Pittsburgh, PA; ⁵University of Pittsburgh, Pittsburgh, PA. (Tracking ID #2196785)

BACKGROUND: Many elderly Veterans treated within the VA Healthcare System (VA) are also enrolled in Medicare and receive treatment outside VA (i.e. dual use). Dual use will likely increase as the Veterans Choice Act and Affordable Care Act enhance access for Veterans to outside care; however, such enhanced access also potentially fragments medical care. Little is known about the specific types of care dually enrolled Veterans receive in each system. Our goal was to determine the degree to which Veterans were dual users for specific types of diabetes care and to identify typologies of dual use using latent class analysis.

METHODS: We performed a cross-sectional retrospective cohort study using linked VA and Medicare Parts A, B, and D data from fiscal year 2009. We identified a cohort of community-dwelling Veterans age 65 or older who had type 2 diabetes, were continuously enrolled in VA and fee-for-service Medicare, and had at least one outpatient visit within VA in fiscal year 2009. We generated dichotomous indicators to represent any utilization of the following diabetes-specific healthcare services through VA and Medicare: outpatient visits, laboratory tests (hemoglobin A1C and urine microalbumin), glucose testing supplies, medications, inpatient admissions, and emergency department (ED) visits. We determined the number and percent of Veterans who were dual users for each service. Using latent class analysis (LCA), we established distinct classes of Veterans based upon their probability of utilizing VA or Medicare for their diabetes care. We tested models with increasing numbers of latent classes and used Bayesian Information Criterion and Entropy statistics to determine the model that best accounted for the observed patterns of dual use. In the final model, we removed ED and inpatient care due to low probabilities of dual use and minimal distinction between classes.

RESULTS: There were 405,286 Veterans in the overall cohort. The median age was 75.0 years, 98.7 % were male, 83.4 % were non-Hispanic white, and 71.8 % had one or more comorbidities in addition to diabetes. Of the sample, 16.9 % were enrolled in the Medicare Part D drug benefit. Overall, 202,305 (49.9 %) Veterans used both VA and Medicare benefits for at least one diabetes-specific service (dual use). Specifically, 153,110 (37.8 %) were dual users for outpatient visits, 61,141 (15.1 %) for laboratory testing, 19,230 (4.7 %) for testing supplies, and 16,517 (4.1 %) for medications. Only 1608 (0.4 %) and 162 (0.04 %) Veterans were dual users for ED and inpatient care, respectively. Latent class analyses identified 7 distinct classes of VA and Medicare utilization (Table 1). Veterans in classes 1, 2, and 3 were defined by their high probabilities of VA use and low probabilities of Medicare use. Veterans in class 1 ($n=206,691$; 51.0 %) were likely to use VA and not Medicare for all facets of their diabetes care. Veterans in class 2 ($n=37,704$; 9.3 %) were likely to use only VA outpatient and laboratory services and Veterans in class 3 ($n=16,798$; 4.1 %) were likely to use only VA outpatient care. Veterans in classes 4, 5, and 6 were defined by their high probability of utilizing both VA and Medicare services, although they differed in the specific services used. For example, Veterans in classes 4 ($n=76,128$; 18.8 %) and 5 ($n=42,909$; 10.6 %) were similarly likely to have VA outpatient visits and laboratory tests, but class 4 received their testing supplies exclusively through Medicare while class 5 received them primarily through VA. Veterans in class 7 ($n=9777$; 2.4 %) were defined by their Medicare reliance, having high probabilities of receiving their outpatient visits, laboratory tests, and supplies through Medicare.

CONCLUSIONS: We identified 7 overarching latent classes that account for the diverse ways in which dually enrolled veterans receive diabetes care. The differing patterns of dual use make it challenging to study this population as a single entity, as has typically been done. Each of these typologies may represent differing risks of care fragmentation that may impact cost, safety, and clinical outcomes.

Table 1: Probability of VA and Medicare Healthcare Use by Latent Class Among Elderly Dually Enrolled Veterans with Diabetes*

Latent Class:	1	2	3	4	5	6	7
N (%):	206,691 (51.0)	37,704 (9.3)	16,798 (4.1)	76,128 (18.8)	42,909 (10.6)	15,279 (3.8)	9777 (2.4)
Probability of VA use:							
Outpatient visits	0.98	0.88	0.63	0.97	0.97	0.97	0.67
Laboratory tests	0.96	1.00	0.00	0.81	0.84	0.93	0.12

UNDERSTANDING BARRIERS TO INTERPROFESSIONAL COMMUNICATION BETWEEN INTERNAL MEDICINE PROVIDERS DURING A PATIENT'S DISCHARGE PROCESS: A QUALITATIVE STUDY OF PATIENTS AND PROVIDERS Vincent A. Pinelli; Heather L. Stuckey; Jed Gonzalo. Penn State College of Medicine, Hershey, PA. (Tracking ID #2195970)

BACKGROUND: Patient transitions from the inpatient to outpatient setting are a vulnerable point in a patient's care. As a result, transitions of care are becoming an increasing focus of quality improvement initiatives. Limited work has investigated the perception of provider roles and the barriers to interprofessional communication during the discharge process. In this study, we sought to advance our understanding of frontline providers' attitudes and perceptions regarding: (1) providers roles, (2) barriers, and, (3) potential solutions in relation to interprofessional communication during the discharge process on internal medicine units.

METHODS: We performed an inductive content analysis of data obtained from focus group interviews ($n=9$) with frontline providers about the discharge process. From February-June 2014, focus group interviews were performed with house staff and attending physicians, nurses, consult service physicians, care coordinators and social workers, and other health professionals (physical and occupational therapists, pharmacists, and nutritionists). The semi-structured interviews consisted of open-ended questions and related to participants' perceived roles in the discharge process, perceptions of others' roles, identification of barriers to interprofessional communication, and suggested strategies to improve communication and collaboration during the discharge process. During data collection, investigators took field notes, and using open coding, identified categories and generated a preliminary codebook to facilitate analysis. Two investigators analyzed two transcripts together to modify and agree upon the codebook, followed by independent analysis of the remaining transcripts with regular adjudication sessions.

RESULTS: Our preliminary analysis revealed four major categories related to barriers, including: (1) communication and collaboration, (2) systems issues, (3) provider roles, and (4) medication reconciliation. For communication and collaboration, participants identified several key themes including lack of keeping other providers informed about discharge plans, lack of specific instructions for discharge needs, failure to keep updated progress notes, inability to find contact information for other providers, and provider absences from interdisciplinary rounds. For systems issues, participants reported limitations in time frames for patient transport, lack of bed availability for patient placement, challenges in navigating the electronic discharge instructions, and lack of continuity secondary to provider assignments/schedules. For provider roles, participants identified a poor understanding in other providers' roles and the perception that roles were poorly defined, including who is responsible for performing discharge-relevant tasks. For medication reconciliation, participants reported poor functionality of the electronic discharge form, as well as patient-specific education regarding medications. Potential solutions included increasing frequency and quality of interdisciplinary rounding, optimizing synchronous communication between providers, improving understanding about the defined roles for providers, primary team education of the patients and families regarding discharge planning, maintaining up-to-date progress notes regarding patient status (eliminating 'copy and paste' culture), and utilizing patient-specific discharge instructions.

CONCLUSIONS: Frontline medicine providers identified a number of issues related to interprofessional communication during a patient's discharge that limit ideal discharges, including a general lack of understanding others' roles, several systems issues preventing ideal patient education and timeliness of the discharge process, and ineffective communication patterns between providers during the discharge process. Although research has

investigated the perspectives of the discharging physician and recipient primary care providers, little research has focused on the interprofessional collaboration processes at the time of discharge, the understanding of which is critical for safe and efficient patient discharges. Although the focus of research and quality improvement initiatives is on medication reconciliation, primary care follow up, and patient education, the processes and coordination involved with completing these tasks are critical for success—these results from medicine units elucidate the challenges at the communication and collaboration interface that may contribute to discharge failures. This work identifies a wide variety of potentially remediable systems issues and educational opportunities to optimize the interprofessional collaboration during patient discharges to improve this transition period. Clarification of roles and responsibilities and promoting a mutual understanding amongst providers about the treatment and discharge plan on the day of discharge may improve this process.

UNDERSTANDING OUT-OF-ACO CARE IN THE MEDICARE SHARED SAVINGS PROGRAM Maria Han²; Carol Mangione¹; Robin Clarke³; Susan Ettner²; Neil Steers²; Mei Leng². ¹David Geffen School of Medicine at UCLA, Los Angeles, CA; ²UCLA, Los Angeles, CA; ³UCLA, Santa Monica, CA. (Tracking ID #2191333)

BACKGROUND: Designed by the Centers for Medicare and Medicaid Services (CMS), the Medicare Shared Savings Program (MSSP) encourages the formation of accountable care organizations (ACOs) as a mechanism for improving the quality of and reducing the cost of care provided to Medicare fee-for-service (FFS) beneficiaries. The MSSP emphasizes care coordination and provider accountability as keys to success in improving value in care. However, providers and pundits have voiced concern that the open-network design of the MSSP and resulting out-of-ACO care would preclude ACOs from successfully managing the health of their patients. To date, out-of-ACO care has not been well described, and this study characterizes out-of-ACO care and identifies patient-level predictors for receiving out-of-ACO care.

METHODS: We obtained Medicare claims data from Medicare FFS beneficiaries who were both prospectively assigned to the UCLA MSSP at the beginning of 2013 and retrospectively confirmed to be in the ACO at the end of 2013. Beneficiaries agreed to share data with the ACO. The UCLA IRB reviewed and approved this study. All Medicare Parts A and B services delivered inside and outside of the ACO in 2013 were included in the study. We allowed a 9-month claim runoff period to account for lag in claims processing. Health care expenditures were quantified for each patient using Medicare paid amounts, as this is the basis for determining shared savings. Expenditures for services with start and through dates in 2013 were included in their entirety. Expenditures for services that were partially provided in 2013 (e.g., hospitalizations beginning in 2012 and ending in 2013) were pro-rated. In-ACO services were defined as services attributed to a billing provider with an NPI number registered with the UCLA MSSP in 2013. All other services were considered out-of-ACO. We used two-part models of out-of-ACO expenditures consisting of a logit model of the probability of any out-of-ACO expenditures and a zero-truncated negative binomial model of the level of out-of-ACO expenditures among the conditional subsample of those with any out-of-ACO care.

RESULTS: On average, the 12,480 beneficiaries in the study population are 74.4 (SD=12.17) years of age and suffer from 3.61 (SD=2.45) medical conditions. The population is predominantly Caucasian (72.7 %), female (59.2 %), and lives 32.9 miles (SD=179.2) from the main ACO campus. Overall, 32.8 % of total expenditures were paid to providers outside of the ACO. Specifically, 25.6 % of inpatient expenditures and 36.9 % of

outpatient and ED expenditures were out-of-ACO payments. Out-of-ACO care was associated with having a greater number of medical comorbidities and being younger in age.

CONCLUSIONS: Out-of-ACO expenditures represent a significant portion of total expenditures for the UCLA MSSP population. Patients obtaining a greater proportion of their care outside of the ACO tend to be younger in age and suffering from a greater number of medical comorbidities. Future studies should examine how higher rates of out-of-ACO care affect total cost of care and health outcomes to determine whether the MSSP's open-network structure impedes its ability to improve value in care.

UNDERSTANDING SUBSTANCE USE NEEDS AMONG HOSPITALIZED

ADULTS Honora Englander^{1, 3}; Christine Velez Klug²; Sarann Bielavitz¹; Benjamin Chan¹; Melissa B. Weimer^{1, 4}; Philip T. Korthuis¹. ¹Oregon Health & Science University, Portland, OR; ²Portland State University, Portland, OR; ³Central City Concern, Portland, OR; ⁴CODA, Portland, OR. (Tracking ID #2197943)

BACKGROUND: People with substance use disorders (SUD) have high rates of hospitalization, readmission, and complex chronic illness. Despite frequent contact with healthcare, many are not engaged in addiction treatment. Hospitalization may be a 'reachable moment' to initiate and coordinate addiction care. We aimed to determine the prevalence of substance use, readiness for change, and treatment preferences to understand patient perspectives to tailor an intervention to improve health outcomes.

METHODS: We surveyed hospitalized adults identified by nursing staff as having substance use disorder at a large academic medical center as part of a mixed-methods needs assessment. We included patients reporting high-risk alcohol or any drug use with the AUDIT-C and a single item drug screener, and enrolled consecutive adults screening positive. We assessed social and demographic factors, healthcare utilization, prevalence and severity of substance use, and experience and interest in treatment for those with moderate to high risk use on the ASSIST.

RESULTS: We enrolled 102 participants from September to December 2014 (Table 1). Participants reported high prevalence of moderate to severe substance use including alcohol (43.1 %), methamphetamine (31.4 %), and opioids (35.3 %). Medical conditions associated with SUD were common, including osteomyelitis (12.5 %), endocarditis (6.25 %), cirrhosis (19.6 %), and chronic pain (32.4 %). 55.6% of alcohol users and 61.6 % of illicit drug users reported interest in cutting back or quitting. Participants not already engaged in addiction treatment expressed high interest in medication-assisted treatment (18.9 % of alcohol users; among opioid users, 22.7 % interest in methadone, 29 % in buprenorphine). Many reported interest in initiating medications during hospitalization (Table 2).

CONCLUSIONS: Our findings support that hospitalization may be a reachable moment and suggest patient interest in integrated addiction care in the inpatient environment. Interventions to improve care might include initiation of medication-assisted therapies during hospitalization and improved linkages to residential and office-based addiction care upon discharge.

Readiness to change and treatment preferences

		% (n)
Interest in Cutting Back or Quitting	Among Alcohol Users	
	Do not want to quit	44.4 (28/63)
	Want to cut back	23.8 (15/63)
Among Drug Users	Want to quit	31.7 (20/63)
	Do not want to quit	38.4 (28/73)
	Want to cut back	21.9 (16/73)
Medication-Assisted Treatment (MAT) preferences	Want to quit	39.7 (29/73)
	Interested in receiving medication	18.9 (7/37)
	Interest in starting medication treatment while in the hospital	18.9 (7/37)
Moderate-severe alcohol users not on MAT	Interested in receiving methadone	18.1 (4/22)
	Interest in starting while in the hospital	22.7 (5/22)
Moderate-severe opioid users not on methadone	Interested in receiving buprenorphine	32.3 (10/31)
	Interest in starting while in the hospital	29.0 (9/31)

UNMATCHED MEDICAL GRADUATES AND PRIMARY CARE WORK-

FORCE Padmini Ranasinghe¹; Brandyn D. Lau². ¹Johns Hopkins School of Medicine, Baltimore, MD; ²The Johns Hopkins University School of Medicine, Baltimore, MD. (Tracking ID #2193196)

BACKGROUND: According to 2014 NRMP 13255 eligible medical graduates didn't match in to a residency program. Physicians who trained in medical schools outside of US and Canada represent 71 % of this group, defined as international medical graduates (IMGs). Nearly 40 % of IMG physicians are US citizens. IMGs play a vital role in the US health care system. they represent 26 % (or 263,473) of all practicing physicians in the US. IMGs are more likely to practice in primary care specialties facing physician shortages in underserved areas add to the diversity in workforce. According to ambulatory care survey they tend to cater for medicare and medicaid beneficiaries than US graduates. Approximately 50 % of all eligible IMGs match in to residency programs each year. Currently, the limiting factor in residency availability is the GME slot availability. With the implementation of new health care reforms, demand for physicians increase dramatically, including

a need for more than 40000 physicians in primary care. It is timely to understand the characteristics of medical graduates waiting for residency. Recent COGME report suggests exploring new ways to create outpatient residency positions.

METHODS: In August 2014 we conducted an exploratory cross sectional survey to examine the level of interest among ECFMG certified IMGs. Survey invitations (1468) were emailed to IMGs on AMA Masterfile using Qualtrics Survey Software. Individuals who are ECFMG certified medical graduates from medical schools outside of the US or Canada who were not accepted to a residency program in 2014 were eligible to respond to the survey. This study was approved by the Johns Hopkins Medicine Institutional Review Board.

RESULTS: Out of 1468 sample, 219 (15 %) responded representing 57 countries. Forty-nine percent were females. The majority was 31–40 years old (49 %) and married (72 %). The majority was either US citizens or permanent residents (78 %), and 17 % were visa holders. Most of them were graduated within last 6 years. Seventy-three percent had some US experience, including 42 % externship, 19 % electives, and 16 % core rotations. Thirty-one percent of respondents are employed in some medical profession, 47 % are either unemployed or working in a non-medical field. Reported current occupation varies from physicians in other countries, nurses, clinical assistants, etc. The majority support family of 1 or more financially (>64 %). Most respondents are interested in primary care disciplines (general practice [33 %] and Internal medicine [22 %] psychiatry [10 %] and pediatrics [8 %]). Sixty-four percent reported that they are interested in hospital-based practice and 30 % are interested in outpatient practice. Most respondents are interested in practicing in underserved inner city (88 %) and rural areas (87 %). Majority reported that they are determined to get in to residency. Eighty-six and 74 % reported scores between 180 to 220 for USMLE Step 1 and Step 2 respectively. Sixty-five percent reported passing Step 2 CS in the first attempt.

CONCLUSIONS: The majority of IMGs who are waiting to match in to a residency indicated interest in primary care discipline. This group is otherwise qualified but lacks required residency experience to practice as physicians. Our survey results confirm that the unmatched residency candidates are available to contribute their skills to primary care when given the opportunity. General Internal Medicine community has an opportunity to explore ways to integrate this group of skilled and motivated medical graduates in their workforce planning.

USE OF A BLOOD PRESSURE TRACKING TOOL IN AN ELECTRONIC MEDICAL RECORD Molly B. Conroy¹; Manisha Jhamb¹; Jonathan Yabes¹; Glenn M. Updike²; Gary Fischer¹. ¹University of Pittsburgh, Pittsburgh, PA; ²University of Pittsburgh Medical Center, Pittsburgh, PA. (Tracking ID #2198285)

BACKGROUND: Outpatient (ambulatory) blood pressure (BP) measures have been shown to be highly predictive of cardiovascular mortality. Despite this, ambulatory BP data is often not available to providers making decisions about hypertension management. Electronic medical records (EMRs) offer a potential avenue for patients to enter ambulatory BP data into a location where it could be readily viewed by providers.

METHODS: The University of Pittsburgh Medical Center (UPMC) uses the Epic EMR and has a patient portal of the EMR (MyUPMC) that offers a flowsheet for tracking ambulatory BP measurements (BP flowsheet). The BP flowsheet has been available since 2003 and can be ordered by a provider or requested by a patient. Patients enter systolic and diastolic BP (SBP, DBP) and heart rate data into the BP flowsheet, and new data is routed to their provider. We abstracted data from the EMR to determine how many current MyUPMC users with a diagnosis of hypertension (ICD-9 code 401.XX) had entered any BP flowsheet data in from 9/1/2013-9/30/2014. In addition, we abstracted data about patient demographic characteristics, comorbidities, most recent BP measured in clinic, number of BP medications, and number of provider visits in past year. We classified most recent SBP as poorly controlled if it was >140 mmHg. We examined descriptive statistics and used t-tests and Chi-squared tests to determine if there was a difference in demographic or clinical characteristics between MyUPMC patients without and with BP flowsheet data in the past calendar year. For those patients with BP flowsheet data, we further examined whether number of flowsheet entries was associated with most recent BP measured in clinic using Spearman correlation.

RESULTS: We analyzed data from 65,661 patients with an active MyUPMC account and a diagnosis of hypertension. Of these, only 588 (0.9 %) had BP flowsheet data in the past calendar year. MyUPMC users with flowsheet data were more likely to be younger (54.2 vs. 58.7 years; $p<0.001$) and male (48.5 vs. 42.5 %; $p=0.004$), with no difference seen in race, when compared to MyUPMC users without flowsheet data. Users with flowsheet data were also

more likely to never have smoked (59.2 vs. 53.8 %; $p=0.03$), have a lower BMI (31.5 vs. 32.9; $p=0.001$), and be free of diabetes and coronary heart disease (insert numbers). However, users with flowsheet data had higher mean SBP at last clinic visit (133 vs 130; $p<0.001$), higher frequency of poorly controlled SBP (24.7 vs. 20.1 %; $p=0.006$), a higher number of BP medications (1.6 vs. 1.3; $p<0.001$), and higher number of provider visits in past year (3.4 vs. 2.9; $p<0.001$) when compared to users without flowsheet data. Among users with flowsheet data, the median number of flowsheet entries in the past year was 7 (IQR 2, 17), with a range from 1 to 292. Number of flowsheet entries was not associated with SBP measured at most recent clinic visit ($r=0.05$; $p=0.24$).

CONCLUSIONS: Only a very small number of patients who were eligible to use the BP flowsheet did so, and users tended to be younger and have fewer comorbidities. Despite that, office SBP was higher in users, which may reflect the type of patient whose provider selected this type of monitoring (i.e., patients with higher BP), a lack of feedback given to those entering flowsheet data, or a poor association between ambulatory and clinic readings. Further work should be done to study uptake of BP flowsheet use and feedback provided to patients who do enter data.

USE OF COLORECTAL CANCER SCREENING SERVICES IN THE ERA OF THE AFFORDABLE CARE ACT Ilana B. Richman^{2, 1}; Steven Asch^{2, 3}; Douglas K. Owens^{2, 1}. ¹Stanford University, Stanford, CA; ²Palo Alto Veterans Affairs Hospital, Stanford, CA; ³Stanford Medical School, Stanford, CA. (Tracking ID #2194708)

BACKGROUND: Despite the established benefits of colorectal cancer screening, only about 65 % of the eligible population in the United States is adherent to current screening recommendations. In 2010, the Patient Protection and Affordable Care Act (ACA) eliminated out-of-pocket costs for evidence based preventive care including colorectal cancer screening. Whether this change in policy has increased uptake of these preventive services is not known.

METHODS: We used the 2008–2012 Medical Expenditure Panel Survey (MEPS) to ascertain rates of self-reported colorectal cancer screening using colonoscopy, sigmoidoscopy, and fecal occult blood testing (FOBT). Our study population included adults ages 50–64 with private insurance and adults 65–75 with Medicare, populations covered by the cost-sharing provision of the ACA and for whom screening is recommended by the United States Preventive Services Task Force. The main analytic variable indicated time pre- and post-ACA mandate. Logistic regression covariates included age, sex, income, and sampling weights. To account for non-age specific secular trends, we also performed a difference-in-difference analysis, comparing a group unaffected by the ACA and for whom these services are not recommended—privately insured adults ages 40–49—to older privately insured patients for whom the procedures are recommended.

RESULTS: Our study included 11,545 privately insured adults ages 50–64 and 6696 adults ages 65–75 with Medicare. Annual rates of colonoscopy and sigmoidoscopy ranged from 13–16 % per year among privately insured individuals and 15–19 % among Medicare beneficiaries. FOBT rates ranged from 13–20 % per year among those with Medicare and 9–13 % per year among the privately insured (Figure). Among adults ages 50–64, those in the post-ACA period were not more likely to have received a colonoscopy or sigmoidoscopy compared to those in the pre-ACA period (OR 0.90, 95 % CI 0.79–1.20, $p=0.10$). Use of FOBT was slightly lower post ACA (OR 0.83, 95 % CI 0.69–0.99, $p=0.044$). Among adults with Medicare, those in the post-ACA period were not more likely to have received a colonoscopy or sigmoidoscopy (OR 0.92, 95 % CI 0.78–1.09, $p=0.34$) and were less likely to have received FOBT (OR 0.72, 95 % CI 0.58–0.88, $p=0.002$). Our difference-in-differences analysis compared rates of colonoscopy or sigmoidoscopy for privately insured adults ages 40–49 ($n=8176$) to privately insured adults ages 50–64. The interaction term, representing the difference-in-differences estimator, was not significant (coefficient for interaction term -0.01 , 95 % CI -0.32 – 0.30 , $p=0.95$).

CONCLUSIONS: Elimination of cost-sharing for colorectal cancer screening has not resulted in increased use of these preventive services in the post-ACA period. There are a number of possible reasons for this: cost sharing may not be a substantial barrier to receipt of services, insurers may not be fully compliant with the law, patients may be unaware of this new benefit, and hidden costs for biopsies and follow up studies may still discourage use. Further analysis over the next several years will reveal whether rates of utilization remain flat or whether the elimination of cost sharing eventually promotes use of clinical preventive services.

Annual Frequency of Colorectal Cancer Screening by Age Group

USE OF HISTORICAL DATA TO VALIDATE SIMULATION MODELING IN THE CREATION OF A GEOGRAPHICALLY-FOCUSED ADMITTING SYSTEM Heather Masters¹; Vimal Mishra¹; Joseph Heim²; Richard Storch²; Shin-Ping Tu¹. ¹Virginia Commonwealth University, Richmond, VA; ²University of Washington, Seattle, WA. (Tracking ID #2189137)

BACKGROUND: It has been nearly a decade since the joint paper between the National Academy of Engineering and the Institute of Medicine recommended the application of systems engineering approaches in order to deliver health care that is efficient, effective, and patient-centered, yet large academic medical centers remain highly complex systems that are rife with inefficiencies. One area that has been shown to contribute to inefficient, ineffective patient care and poor patient and provider satisfaction is the geographic dispersion of traditional inpatient care teams. Simulation modeling has been used successfully to identify flow issues in the emergency department setting and has the potential to improve geographic assignment of admitted patients in the setting of variables such as high occupancy and the need for appropriate workload balance. In order to do this, the simulation technique must first be validated using historical distribution data.

METHODS: Admissions data for the Internal Medicine housestaff teams for calendar year 2013, including time/date of admission, initial bed assignment and discharge time/date, was extracted from the Electronic Health Records (EHR). Length of stay was calculated by the differential between admission and discharge times. Utilization of team patient load capacity for EHR data was calculated using Markovian queuing theory. Applying systems engineering techniques with SIMIO (simulation software), a current state model was developed to represent housestaff team admission rate and volume, bed location distribution and any queuing processes. For validation purposes, 50 iterations of the current state model were performed to decrease the variance of: 1) the mean of the number of patients in each unit, 2) the mean team census; and 3) the percentage utilization of each team's patient load capacity. The validated estimate was compared with the 12 month EHR data from 2013. A linear regression model and goodness of fit test was performed between the validated simulation data and EHR data.

RESULTS: A total of 3953 patients were admitted to the Internal Medicine housestaff teams. These patients were distributed across 17 nursing units throughout the hospital. The mean number of patients admitted to different nursing units was estimated from the simulation model then compared to the EHR data from 2013 respectively: #1 (29.88, 30.00), #2 (19.58, 19.00), #3 (128.10, 129.00), #4 (167.22, 172.00), #5 (91.88, 91.00), #6 (122.58, 121.00), #7 (244.06, 246.00), #8 (414.78, 417.00), #9 (2.10, 2.00), #10 (144.70, 149.00), #11 (56.10, 54.00), #12 (1176.52, 1172.00), #13 (1.20, 1.00), #14 (84.44, 86.00), #15 (116.54, 117.00), #16 (485.7, 486.00), #17 (667.62, 661.00). None were statistically significant ($p > 0.05$). Average team census based on EHR data was noted to be 12.00 compared to the validated simulation model of 11.55. EHR derived percentage utilization

of each team's patient load capacity was 72.00 % compared to the validated simulation model of 72.20 %. Goodness of fit for the validated model as compared to the EHR data resulted in a coefficient of determination of $r^2 = 0.99$, signifying the validated simulation model is similar to the EHR data from 2013 and therefore reliable.

CONCLUSIONS: Systems engineering principles such as simulation provide scientific and data driven methods to model highly complex processes, an example of which is the assignment of patients to hospital beds and care teams in a large academic medical center. Once validated by historical data to accurately reflect a particular health system's constraints, simulated distribution models can be developed and modified based on current state variables such as hospital occupancy or changes in provider-specific characteristics such as workload, allowing for targeted interventions that decrease waste both in time and effort over traditional methods of operational improvement.

USE OF PHYSICIAN ORDERS FOR LIFE SUSTAINING TREATMENT AMONG CALIFORNIA NURSING HOME RESIDENTS: SUCCESSFUL BROAD DISSEMINATION BUT MISSING SOME WHO NEED IT MOST Lee A. Jennings³; David Zingmond²; Rachel Louie²; Judy Thomas⁴; Kate O'Malley¹; Neil Wenger². ¹California HealthCare Foundation, Oakland, CA; ²UCLA, Los Angeles, CA; ³Division of Geriatrics, UCLA, Los Angeles, CA; ⁴Coalition for Compassionate Care of California, Sacramento, CA. (Tracking ID #2195735)

BACKGROUND: Physician Orders for Life-Sustaining Treatment (POLST) is a tool that facilitates elicitation and continuity of life-sustaining care preferences across care settings. POLST was implemented in California in 2009 using a novel dissemination strategy, which included the addition of a section on POLST use (Section S) to the California Minimum Data Set (MDS) in 2011. This allowed the first statewide evaluation of the use of POLST among nursing home residents. How well POLST was disseminated across a large, racially diverse population of nursing home residents is not known and has implications for end of life care for this vulnerable population. We examined the uptake of POLST across California nursing homes in 2011; variation and problematic use at the nursing home level; and the relationship of POLST completion with patient characteristics.

METHODS: We evaluated all California nursing home residents in 2011 using the MDS. We computed the proportion of residents with a valid POLST (containing an order concerning resuscitation status and both resident/proxy and physician signatures); change in POLST completion during 2011; the proportion of residents with unsigned POLST forms; and valid POLST completion and unsigned forms at the nursing home level. We also examined the relationship of POLST completion and resident length of stay, age, gender, race/ethnicity, and cognitive and functional status using multivariate logistic regression adjusting for nursing home as a random effect. The model was repeated on the sample stratified by long and short length of stay.

RESULTS: Of 296,276 people with a California nursing home stay in 2011, 98 % completed the MDS section concerning POLST use (Section S). Over the course of 2011, valid POLST completion increased from 33 to 49 % of nursing home residents. Resident mean age was 78 years, 61 % were female, and 33 % were racial or ethnic minorities. One third of residents were long-stay (≥ 100 days in nursing home), 30 % had extensive or total dependence in activities of daily living, and 34 % were severely cognitively impaired. In adjusted multivariate models, long stay residents were more likely than short stay residents to have a valid POLST [OR=2.36 (95 % CI 2.30, 2.42)]. Severely cognitive impaired residents were less likely than unimpaired to have a valid POLST, and this difference was more pronounced for long-stay residents [OR=0.76 (95 % CI 0.72, 0.80) vs. OR=0.95 (95 % CI 0.92, 0.98)]. However, among long-stay residents greater functional impairment was associated with an increased odds of POLST completion [OR=1.10 (95 % CI 1.19, 1.27)], while among short stay residents severe functional impairment decreased odds of POLST completion [OR=0.94 (95 % CI 0.89, 0.99)]. There was no difference in POLST completion among White non-Hispanic, Black, and Hispanic residents. Among nursing homes in California with greater than 20 residents, 40 % of facilities had ≥ 80 % of long-stay residents with a valid POLST, while in 20 % of facilities ($N=221$) ≤ 10 % of long-stay residents completed a valid POLST. Twenty-one percent of all POLSTs containing a resuscitation preference lacked a signature, and in 10 nursing homes ≥ 50 % of POLSTs containing resuscitation orders had at least one signature missing. One percent of all residents had a blank POLST containing a physician or resident/proxy signature.

CONCLUSIONS: Statewide nursing home data show wide and appropriate use of POLST in California 3 years into implementation of a novel dissemination strategy. The similarity in POLST use across race/ethnicity demonstrates uptake within racially diverse communities. The inverse relationship between severe cognitive impairment and POLST use conflicts with clinical expectations and suggests deficits in end of life care planning for the most vulnerable nursing home residents. This merits further investigation and intervention. Use of POLST rapidly increased during 2011, although a significant minority of nursing homes were slow to adopt POLST. MDS data identify nursing homes that may benefit from POLST quality improvement interventions. Lastly, POLSTs lacking signatures suggest a need for a POLST registry that would perform quality assessment on collected documents to ensure POLST forms are valid.

USE OF SAFETY NET CLINICS FOR PRIMARY CARE AMONG INSURED INDIVIDUALS IN THE UNITED STATES: NAMCS 2006–2010 Oanh K. Nguyen; Anil N. Makam; Ethan Halm. UT Southwestern Medical Center, Dallas, TX. (Tracking ID #2196419)

BACKGROUND: Individuals with health insurance coverage are thought to be less reliant on safety net settings for care. However, it is unknown the extent to which individuals with insurance coverage nonetheless use safety net settings for regular primary care. Thus, we sought to describe the prevalence and predictors of safety net use for primary care among insured adults, and clinical characteristics of this population.

METHODS: Cross-sectional analysis of all primary care visits by adults (≥ 18 years) in the National Ambulatory Medical Care Survey (NAMCS) from 2006–2010, a probability sample of outpatient visits in the U.S. Our primary outcome was use of a safety net clinic, defined as community health centers and non-federal government clinics. Individuals were considered insured if they had private insurance or Medicare. Analyses were weighted to reflect national estimates. Predictors of safety net use were estimated from logistic regression models adjusted for demographic characteristics.

RESULTS: Of a total of 37,155 primary care visits among insured adults, 4156 visits (2.0 % of weighted visits) occurred in safety net clinics. These constituted over 1 in 3 (35.0 %) of all primary care safety net clinic visits, representing an estimated 6,642,000 visits per year. The strongest predictors of safety net use among insured individuals were being from a high-poverty neighborhood (AOR 8.42, 95 % CI 4.09–17.31), being dually eligible for Medicare and Medicaid (AOR 4.59, 95 % CI 2.74–7.70), and being black (AOR 2.28, 95 % CI 1.28–4.07) or Hispanic (AOR 2.28, 95 % CI 1.38–3.79). Compared to non-safety net counterparts, insured adults in the safety net had a higher prevalence of diabetes (23.5 % vs 15.0 %, $p<0.001$), hypertension (49.4 % vs 36.0 %, $p<0.001$), multimorbidity (≥ 2 chronic conditions; 53.5 % vs 40.9 %, $p<0.001$) and polypharmacy (≥ 4 medications; 48.8 % vs 34.0 %, $p<0.001$). Nearly one-third (28.9 %) of Medicare beneficiaries in the safety net were dually eligible,

compared to only 6.8 % of Medicare beneficiaries in non-safety net clinics ($p<0.001$).

CONCLUSIONS: Safety net clinics are important primary care delivery sites for insured minority and low-income populations with a high burden of chronic illness. The critical role of safety net clinics in care delivery is likely to persist despite expanded Medicaid and insurance coverage under the Affordable Care Act.

USING ELECTRONIC HEALTH SYSTEMS DATA TO INVESTIGATE THE GEOGRAPHIC VARIATION IN DEPRESSION PREVALENCE ACROSS DENVER, COLORADO Carlos Irwin Oronce¹; Arne L. Beck²; Glenn K. Goodrich³; Michael J. Durfee¹; Sarah Madrid³; Suzanne Dirksen¹; Susan L. Moore¹; Arthur Davidson¹; John F. Steiner³; Edward P. Havranek^{2,4}. ¹Denver Health, Denver, CO; ²Denver Health Medical Center, Denver, CO; ³Kaiser Permanente Colorado, Denver, CO; ⁴University of Colorado School of Medicine, Denver, CO. (Tracking ID #2196003)

BACKGROUND: The growth and availability of data from electronic medical records (EMR) has made it easier to conduct public health surveillance, build disease registries, and integrate community-level data for the purposes of population health management. Furthermore, geographic information systems (GIS) software has facilitated nuanced population health assessment by allowing health systems or public health agencies to identify “hot-spots” of common diseases, behaviors or outcomes in communities served and to examine their relationships with social determinants of health. We provide a case example that draws on data from two health systems in Denver, Colorado to identify neighborhoods where depression is highly prevalent and to examine the socioeconomic characteristics of these communities.

METHODS: De-identified data of patients 18 years and older were extracted from the EMR of an integrated health maintenance organization (Kaiser Permanente—Colorado) and an integrated safety net health care system (Denver Health). Patient addresses were geocoded to Denver census tracts and cases of depression identified by ICD-9 code (296.2x, 296.3x, 296.82, 298.0, 300.4, 301.12, 309.0, 309.1, 309.28, 311). Crude prevalence rates were calculated for each census tract (CT). Demographics, total population, poverty rates, and unemployment rates at the census tract-level were derived from the 2010 American Community Survey (ACS) and crime rates came from publicly available data from Denver County. To identify “hot spots”, three GeoDa software techniques were implemented: Empirical Bayes (EB) smoothed rates, Local Moran’s I test, and Getis-Ord Gi* test. Those CT with EB-smoothed prevalence rates above the 90th percentile were identified as potential “hot spots” for depression. The Local Moran’s I and Gi* are spatial association tests that convert rates to z-scores and determine if significant differences exist on the basis of geography and neighboring rates. For these methods, significance was established at $p<0.01$. CT identified by all three methods were considered true “hot spots” where depression was highly prevalent and clustered.

RESULTS: One hundred seventy-four thousand seven hundred thirty patients, representing 35.4 % of the Denver population, were geocoded to 144 census tracts. Using the ACS population as the denominator, the rate of individuals represented for each CT ranged from 10.9 to 58.9 %. The mean crude prevalence of depression by CT was 103.1 cases per 1000 residents. Neighborhood rates varied from 0 to 169.9 cases per 1000 residents. EB-smoothing did not alter which 14 CT were identified as potential “hot spots” (Fig. 1). Local Moran’s I analysis revealed a depression cluster of 6 CT. Gi* analysis revealed 7 high-risk CT in the same area. Four CT were identified as “hot spots” by all three methods. Crude prevalence rates for these tracts were: 143.3, 131.3, 129.9, and 127.4 cases per 1000 residents. All four neighborhoods were in the top quartile for poverty rate and percent of residents identifying as Hispanic. Two neighborhoods were in both the top quartile for unemployment rate as well as top quartile for percent of residents identifying as black. All neighborhoods were above the median for crime rate, with two in the top quartile.

CONCLUSIONS: Three separate methods for geographic analysis of depression epidemiology revealed four neighborhoods where depression cases were concentrated. All neighborhoods identified as “hot-spots” were notably characterized as high poverty with large Hispanic populations. Identifying “hot-spots” can help public health officials and urban planners determine where resources should be invested. These results should be presented to community members to understand their perceptions and help identify ways to inform future interventions.

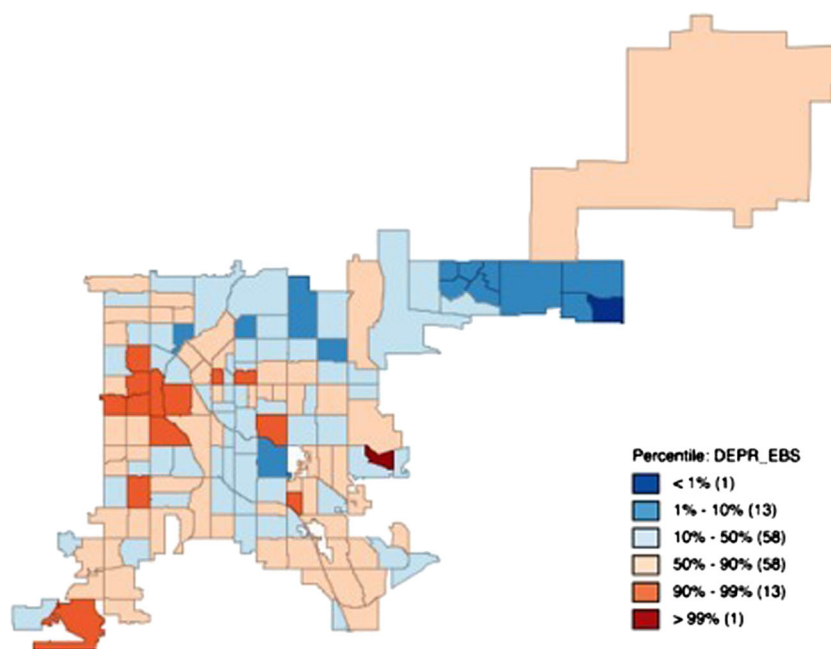

Fig. 1. Percentiles of EB-smoothed depression prevalence rates in Denver, CO

USING GEOCODING TO DEVELOP AN INTERVENTION TO IMPROVE DIABETES OUTCOMES AT AN URBAN SAFETY-NET HOSPITAL

Karen E. Lasser¹; Lisa Quintiliani¹; Ve Truong¹; Pamela D. Waterman²; Julia Matthews¹; Julianne McNamara¹; Nancy Krieger². ¹Boston Medical Center, Boston, MA; ²Harvard School of Public Health, Boston, MA. (Tracking ID #2187042)

BACKGROUND: Effectively addressing diabetes-related health disparities requires better understanding of both the spatial and social distribution of the disease. Geographic information systems methodology can assist primary care practices, providing guidance for disease management programs. Approximately 20 % of 7470 diabetics in the general internal medicine practice at Boston Medical Center, an urban safety-net hospital, have poorly controlled diabetes, with a hemoglobin A1C >9. In order to inform a possible community-based intervention that integrates social and environmental contexts, we sought to identify geographic areas with a high number of patients with poorly controlled diabetes.

METHODS: Using the geographic information systems software ArcGIS, we geocoded (to street address) records on general internal medicine patients with poorly controlled diabetes (hemoglobin A1C >9) who had a primary care provider visit in the past 24 months. We identified and mapped the census tracts containing at least 20 patients with poorly controlled diabetes, and identified both community assets (green space) and deficits (indirect bus lines to reach the hospital, and crime using www.spotcrime.com). We used chi square tests to compare groups.

RESULTS: Among the 1494 patients with poorly controlled diabetes, 97 % ($n=1454$) had an address that could be geocoded. Of these 1454 patients, 23 % resided within 13 Boston-area census tracts that each contained at least 20 patients with poorly controlled diabetes. Sociodemographic characteristics of the geocoded patients were as follows: mean age 56 (standard deviation 12.8); 53.2 % women; 61.1 % black, 9.5 % white, 18.5 % Hispanic, and 10.9 % of other race. 67.1 % of patients spoke English, 14.4 % Haitian Creole, 11.8 % Spanish, and 6.7 % other languages. Relative to the 1114 patients who lived in the 348 census tracts with <20 patients with uncontrolled diabetes, the 340 who lived in the 13 census tracts with 20 or more such patients were of similar age and gender, but were more likely to speak English (71.5 % vs. 65.7 %; $p=0.05$) and less likely to speak Haitian Creole (11.2 % vs. 15.4 %; $p=0.05$). Patients in the 13 census tracts were more likely to be black (70.6 vs. 58.3 %; $p<0.0001$) or Hispanic (22.3 % vs. 17.3 %; $p=0.04$) and less likely to be white (2.1 vs. 11.8 %, $p<0.0001$). With regard to census tract characteristics, among the 13 with 20 or more patients with uncontrolled diabetes, the percent of persons below the federal poverty line ranged from 15 to 45.0 %. All 13 census tracts contained green space or abutted areas of green space. Twelve of the 13 census tracts had no direct bus line to the safety-net hospital-based primary care practice, and the

number of crimes in each census tract ranged from 4 to 16 in the past week (mean 9.9; standard deviation 3.9).

CONCLUSIONS: Nearly one-fourth of patients with poorly controlled diabetes who receive primary care at a large safety-net hospital reside in census tracts with a high number of other patients with poorly controlled diabetes. In order to reduce racial disparities in diabetes control, the health system might engage and target these census tracts for community-based outreach. Further qualitative research with patients residing in the 13 census tracts with the most poorly controlled diabetics is planned, to explore community-level barriers to better diabetes control.

USING SIMULATION TO IMPROVE HOUSE STAFF ACLS SKILLS Michael Lindeke³; Jennifer Camahan¹; Kathlyn Fletcher². ¹Indiana University Center for Aging Research/Regenstrief Institute, Indianapolis, IN; ²Medical College of Wisconsin/Milwaukee VAMC, Tbd, AL; ³Medical College of Wisconsin, Milwaukee, WI. (Tracking ID #2200254)

BACKGROUND: House staff leading code teams are often observed to lack leadership skills, confidence, and Advanced Cardiac Life Support (ACLS) knowledge. Our objective was to determine the efficacy of a simulation-based ACLS curriculum to improve the preparation of house staff to lead teams while managing cardiac arrest.

METHODS: This quality improvement project occurred at a VA affiliated with an academic internal medicine residency program. The participants were internal medicine house staff who rotated at the VA during the intervention period (March-December 2014). We performed a longitudinal pre/post analysis to assess the ACLS knowledge, confidence, and leadership skills of residents who have completed a simulation-based ACLS curriculum. The intervention consisted of a didactic lecture focused on ACLS knowledge and practical aspects of running a code (such as how to use the defibrillator). We also conducted an hour-long simulation exercise that included two simulated code scenarios. These simulation exercises were conducted in small groups of house staff (4-5 at a time). The chief resident also led a debriefing after each simulation. We evaluated the effectiveness of the curriculum in a few different ways. First, we distributed a quiz to all house staff in the program that assessed their initial experience, knowledge, and confidence related to code situations. Second, during each of the two simulations, the performance of the house staff as a team was graded by a chief resident, based on a rubric of pre-determined ACLS and Crisis Resource Management (CRM) tasks. Third, the house staff assessed their confidence before and after participating in the simulation (this assessment was added later). Lastly, a post-simulation questionnaire was completed by all participating residents assessing the value of the simulation training.

RESULTS: To date, 51 house staff have participated in the simulation exercise. House staff who had not participated in any simulation based training rated their comfort leading a code an average of 2.44/5, with 5 being most comfortable (STD=.95, $N=77$). In a pre/post simulation comparison, house staff who completed the training showed a higher level of confidence leading codes after completing the simulation session (3.33/5 vs. 4.00/5; $P=0.15$, $N=16$). House staff who completed simulation based ACLS training also showed a significantly higher confidence in their knowledge of ACLS algorithms (4.33/5 vs. 3.96/5; $P=.034$). Improvement in resident ACLS and CRM performance, as graded by a chief resident, improved from the first to second simulations (7.5/18 vs. 11.4/18; $P=.084$). In the post simulation survey, 100 % of house staff agreed or strongly agreed that their leadership skills and level of ACLS knowledge improved by completing the training ($N=51$). Lastly, 100 % of residents who completed the training agreed it was worth taking time out of their work day to complete ($N=51$).

CONCLUSIONS: Our results suggest that a simulation based ACLS intervention may increase house staff confidence, knowledge, and leadership when leading a code team. This may improve outcomes as well as team dynamics in code situations. Further investigation into the translation of simulation training into the actual patient care setting should be investigated.

UTILIZATION OF A MENTAL HEALTH COLLABORATIVE CARE MODEL BY PATIENTS WITH LIMITED ENGLISH PROFICIENCY IN A PRIMARY CARE SETTING Jane Njeru; Ramona S. DeJesus; Jennifer St. Sauver; Debra Jacobson; Patrick Wilson; lila rutten; Mark L. Wieland. Mayo Clinic, Rochester, MN. (Tracking ID #2199243)

BACKGROUND: Immigrants to the United States with limited English proficiency have a higher prevalence of depression compared to the general population. They are also less likely to receive necessary mental health services and treatment, and even when received, these services often do not meet the accepted standards of care. Collaborative care management (CCM) for depression has been shown to be an effective model in achieving treatment goals among a wide range of patient populations, including patients with limited English proficiency. The Depression Improvement across Minnesota, Offering a New Direction (DIAMOND) a statewide program, is one such CCM that has been effective in improving outcomes in depression treatment in primary care. CCM utilization among patients with limited English proficiency has not been previously studied. Therefore, the purpose of this study was to assess utilization of a mental health CCM among patients with limited English proficiency within a patient centered medical home.

METHODS: Within a large primary care network in Minnesota, we compared the enrollment rates of adult patients into the DIAMOND program by interpreter status. We included all 7561 patients who had a provider generated diagnosis of major depression or dysthymia and a Patient Health Questionnaire-9 (PHQ-9) score of 10 or greater. We used need for interpreter services as a proxy for limited English proficiency.

RESULTS: Patients who required interpreters were older (median age in years 47.4 vs 40.2; $p=0.001$) and had a higher mean PHQ-9 score at baseline (median score 16 vs 15 $p=0.0347$) when compared to patients who did not require interpreters. Only 18.2 % of eligible patients who required interpreters were enrolled into the DIAMOND program, compared to 47.2 % of patients who did not require interpreters ($p<0.0001$). Even after adjustment for the differences in age, gender and PHQ-9 scores, patients who required interpreters were significantly less likely to be enrolled in the DIAMOND program, with adjusted OR (95 % CI) of 0.31 (0.17, 0.57).

CONCLUSIONS: Patients with limited English proficiency were less likely to be enrolled into an effective CCM for the treatment of depression. Additional research is needed within primary care practices to better understand the mechanisms of this disparity, and to implement sociolinguistically tailored interventions that improve the utilization of this effective model among patients with limited English proficiency.

VACS-TLFB FOR ALCOHOL USE: A WEB BASED TIMELINE FOLLOWBACK APPLICATION - A HEALTH TECHNOLOGY ASSESSMENT FARAH KIDWAI-KHAN^{2, 5}; Kathleen A. McGinnis¹; Janet P. Tate⁴; Kendall Bryan⁵; Amy C. Justice³. ¹VA Pittsburgh Healthcare System, Pittsburgh, PA; ²YALE UNIVERSITY, Sleepy Hollow, NY; ³Yale University, West Haven, CT; ⁴Yale University SOM, West Haven, CT; ⁵VA Connecticut Healthcare Systems, West Haven, CT. (Tracking ID #2198915)

BACKGROUND: The Timeline Followback (TLFB) is a highly detailed calendar based method for collecting self-reported behaviors and is considered the gold standard for collecting data on alcohol consumption. Whether administered by an interviewer or done

directly by study participants, paper based calendar entry is cumbersome and requires subsequent data entry. We have developed a computerized tool to collect TLFB alcohol use information that can be self-completed at home or in a clinical setting.

METHODS: The Veterans Aging Cohort study (VACS) enrolls patients at nine geographic locations in the United States and uses a web-based survey to collect health and health-related information. Based on responses to lead-in questions on the survey, the application directs participants to the VACS-TLFB, a web based tool that collects daily use of alcohol. Visual controls allow users to drag and drop specific types of drinks onto the calendar and to specify date ranges for days on which the same types of drinks were consumed (on consecutive days or daily). The interface communicates directly with a relational database which stores respondent's data. First introduced in 2013, Phase 1 resulted in lower than expected completion rates, and user-interface inconsistencies were identified. In Phase 2, we improved the interface, usability, and data integrity of the web-based VACS-TLFB. We calculated the Phase 2 completion rate, and total number of drinks reported on the VACS-TLFB over a 28-day period. We also compared the total number of drinks reported on the VACS-TLFB to the total number of drinks over a 28-day period estimated from the first two questions of the Alcohol Use Disorders Identification Test-Consumption (AUDIT-C) using Spearman's correlation coefficient and corresponding p-value. Lastly we compared total number of drinks estimated from the AUDIT-C between those who did and did not complete the VACS-TLFB. The first two AUDIT-C questions are "How often do you have a drink containing alcohol?" (With choices of never, monthly or less, 2 to 4 times a month, 2 times a week or 4 or more times a week) and "How many drinks containing alcohol do you have on a typical day when you are drinking?" (With choices of 1 or 2, 3 or 4, 5 or 6, 7 to 9, 10 or more). Using these items, total number of drinks over a 28-day period was estimated using the median of each item's category options.

RESULTS: Of 237 subjects reporting drinking in the past 30 days on the web-based survey, 78 % (185) completed the alcohol portion of the VACS-TLFB. Median (IQR) total number of drinks reported over 28 days on the VACS-TLFB and web-based survey is 9.0 (3.6–20.8) and 10.5 (3.5–30), respectively. The correlation between VACS-TLFB and first two items of AUDIT-C total number of drinks was 0.67 ($p<.001$) which represents a strong association. Those who did not complete the VACS-TLFB reported a lower median (IQR) total number of drinks (4.5 (1.5–22.5)), based on the first two items of the AUDIT-C, than those who completed the VACS-TLFB, although the difference is not statistically significant ($p=.14$).

CONCLUSIONS: Phase 2 VACS-TLFB data are highly correlated with AUDIT-C responses on the web-based survey, providing validity to the self-administered VACS-TLFB. Using the web-based version of the VACS-TLFB is both a more efficient and more detailed method for data collection. This application may be useful to other clinicians and researchers looking for a more efficient mode for TLFB data collection.

VASCULAR SURGERY-HOSPITALIST COMANAGEMENT PROGRAM REDUCES EARLY READMISSIONS Matthew Shaines²; Calie Santana²; Peter Shamamian²; William Southern¹. ¹Montefiore, Bronx, NY; ²Montefiore Medical Center, Bronx, NY. (Tracking ID #2199215)

BACKGROUND: Hospitalist comanagement is a model of care in which a hospitalist and surgeon have shared responsibility and accountability for the care of hospitalized patients. The model has become increasingly popular and 85 % of hospitalist groups report having engaged in some form of comanagement. Although the comanagement model was created to improve throughput and quality of care on the surgical services, there are few empirical data to support its effectiveness in improving patient outcomes. It has been suggested, though, that the comanagement model will be most effective when medically complex patients are cared for. The effect of a hospitalist-surgical comanagement model of care on a vascular surgery service, which cares for a high volume of highly complex medical patients, is unknown. Additionally, hospitalists often do not rate their experience working on a comanagement service very highly. Our objective was to evaluate a vascular surgery-hospitalist comanagement service with respect to rate of readmissions, length of stay, and hospitalist satisfaction.

METHODS: We examined all patients admitted to the vascular surgery service at an urban academic medical center in the year before (10/12-9/13) vs. year after (11/13-10/14) the implementation of a comanagement model. During the comanagement period a full-time hospitalist was integrated into the vascular service and rounded 7 days a week. All patients admitted to the vascular service were eligible for comanagement. Admissions were considered for analysis if they were both admitted to and discharged from the vascular surgery service. The main outcome measured were both 3-day and 30-day readmission rates and length of stay (LOS). For each admission demographic, laboratory, and diagnosis data were extracted from our clinical information system. A Laboratory-based Acute Physiology Score (LAPS), a validated measure of acuity of illness, and a

Charlson co-morbidity score was calculated for each patient encounter. Patients cared for before and after the comanagement initiative was implemented were compared with respect to 3 and 30-day readmission rates and LOS using t-tests and Wilcoxon rank-sum tests as appropriate. In addition, survey data was collected from the participating hospitalists, assessing their satisfaction with various aspects of the program.

RESULTS: The study included 532 patients in the before comanagement period and 551 patients in the after comanagement period. Comanagement was associated with a significant reduction in the 3 day readmission rate (3.95 % before vs 1.27 % after; OR=0.31; $p=0.008$). This association remained strong and significant after adjustment for age, gender, race/ethnicity, insurance status, Charlson score and LAPS. However, comanagement was not associated with a significant difference in 30 day readmission rate, (22.93 % before vs 21.78 % after; $p=0.65$) or length of stay (6.50 days before vs 6.53 days after; $p=0.53$). The overall satisfaction score of the hospitalist providers was 4.14 (on a 5 point Likert scale), where all respondents either “agreed (4)” or “strongly agreed (5)” that they were satisfied with the service. More specifically, hospitalists felt valued and appreciated by the surgical team, were empowered to make independent decisions, and were satisfied with the level of communication and collegiality with the surgical team

CONCLUSIONS: A hospitalist-vascular surgery comanagement program was associated with a reduced 3-day readmission rate, but without change in the 30-day readmission rate or length of stay. The reduction in 3-day readmissions may reflect a hospitalist's expertise in transitions of care and medication management and thus an ability to improve patients' preparedness for discharge. A further analysis of the quality of care delivered in the pre- vs. post- co-management periods is planned.

VETERANS HEALTH ADMINISTRATION ELECTRONIC CONSULTATIONS: WOMEN'S HEALTH PRIMARY CARE PROVIDERS' PERCEPTIONS Kristina M. Cordasco^{1,2}; Jessica L. Zuchowski¹; Alison Hamilton^{1,2}; Canning Mark¹; LaShawnta Bell-Lewis¹; Joya G. Chrystal¹; Susan Kirsh^{4,3}; Donna L. Washington^{1,2}; ¹VA Greater Los Angeles Healthcare System, Los Angeles, CA; ²UCLA School of Medicine, Los Angeles, CA; ³Cleveland VA Medical Center, Cleveland, OH; ⁴VA Central Office, Washington, DC. (Tracking ID #2195043)

BACKGROUND: Primary care providers (PCPs) and specialists are increasingly using electronic consultations (e-consults) as a communication modality. We sought to capture Veterans Health Administration (VHA) PCP perceptions of the benefits, barriers and limitations of e-consults as implemented within VHA.

METHODS: Using a mixed-methods approach, we surveyed and interviewed VHA PCPs designated as women's health PCPs (WH-PCPs). WH-PCPs who utilized a gynecology e-consult were sent, within 7 business days of the completed consult, an e-mail invitation to complete a survey assessing their experience with that e-consult. Since PCPs could request multiple e-consults over time, we sent invitations to WH-PCPs no more frequently than every 21 days. Interim e-consults within the 21 data window were ineligible for prompting a survey request. Separately, as part of semi-structured interviews assessing for needs and perceptions of virtual care consultations and education, we asked WH-PCPs about their use of and experiences with e-consults across all specialties. All interviews were professionally transcribed and then summarized. Summaries were reviewed by two team members to identify themes related to e-consult benefits, barriers and limitations.

RESULTS: Between June and December 2014, 66 of 147 completed gynecology e-consults were eligible and prompted survey invitations to the WH-PCP requesting them. Twenty-five surveys were completed (38 % response rate) by 16 WH-PCPs. Twenty-three (92 %) of the surveys indicated that implementing all recommendations contained in the e-consult would be “very” or “somewhat” easy. The remaining two surveys (8 %) indicated that it would be “neither easy nor difficult” to implement the recommended treatment plan. Twenty (80 %) surveys indicated that the e-consult “definitely” provided the WH-PCPs with information that they could apply to the care of other patients. Between October 2012 and October 2014, we interviewed 32 WH-PCPs. All interviewees reported overall having a very positive experience with e-consults. All interviewees identified one or more benefits of e-consults, including increasing clinical efficiency, with both improving care timeliness and replacing/facilitating in-person specialty visits; being more convenient for patients; facilitating primary-care specialty communication; and enhancing WH-PCPs' knowledge and care quality. Nine WH-PCPs identified one or more barriers or limitations to e-consults including increased workload for primary care practices and providers implementing the specialist recommendations; specialists providing unclear or incomplete responses, and an in-person specialist visit being needed, rather than an e-consult, for some patients or aspects of care.

CONCLUSIONS: VHA WH-PCPs have an overall positive assessment of the role of e-consults in patient care, with a majority specifically benefitting from use of gynecology e-consults. However, some barriers and limitations were reported that should be addressed

when pursuing expansion or modification within VHA, or implementation in other care settings. As settings outside of VA expand use of electronic health records and consider uptake of e-consults, research should be directed toward quantifying e-consult benefits and cost-effectiveness.

VETERANS' PREFERENCES FOR SMOKING CESSATION TREATMENT David A. Katz; Kenda R. Stewart; Monica Paez; John Holman; Mark Vander Weg; Gary Gaeth. University of Iowa, Iowa City, IA. (Tracking ID #2199268)

BACKGROUND: Despite the evidence that counseling and pharmacotherapy significantly improve cessation rates, most veterans are reluctant to talk to a cessation counselor and many do not adhere to prescribed pharmacotherapy for smoking cessation (or prefer to quit “cold turkey”). Incorporation of patients' preferences into treatment decisions may improve patient satisfaction and adherence, but little is known about veterans' preferences for tobacco treatment. The goal of this study is to assess the importance of specific treatment attributes in driving the choice of smoking cessation counseling and pharmacotherapy using discrete choice experiment (DCE) methods.

METHODS: We conducted a semi-structured interview and cross-sectional survey of 30 current smokers who planned to quit smoking within the next 6 months and were active primary care patients (pts) in a single VA medical center and two affiliated community based outpatient clinics. Key attributes of tobacco treatment were initially based on literature review and were confirmed in semi-structured interviews. We selected an efficient subset of all possible treatment scenarios in order to develop separate DCE questionnaires for cessation counseling and pharmacotherapy. Pts were randomly assigned to counseling or pharmacotherapy versions of the questionnaire (15 choice sets each). We used multinomial probit models to estimate the marginal effect of changing a particular treatment attribute on the likelihood of treatment selection, accounting for clustering of choice data within subject.

RESULTS: Pts were predominantly middle-aged (mean 57.5 years) and smoked 18 cigarettes per day on average; 23 and 72 % had previously tried to quit with cessation counseling and medication, respectively. In the DCE analysis, pts were significantly more likely to choose a particular counseling option with the following treatment attributes: 1) excellent communication skills (“always listens and explains things”): +22 % [95%CI=11-32 %], 2) familiarity of the counseling (“someone whom you usually see”): +18 % [95%CI=12-25 %], and 3) group counseling format: +7 % [95%CI=2-13 %]. Minimal effects were observed for counselor's thoroughness, number of counseling sessions, or quit rate. Pts were significantly more likely to choose a particular pharmacotherapy option with the following attributes: 1) Higher quit rate: +10 % [95%CI=3-17 %], and 2) lower risk of medication-related side effects: +6 % [95%CI=0-11 %]. Minimal effects were observed for amount of weight gain during quit attempt and copayment.

CONCLUSIONS: To increase veterans' participation in smoking cessation counseling, cessation programs should focus on improving counselors' communication skills and building the capacity of clinic teams to provide cessation counseling (including group format). With regard to drug therapy, clinicians should emphasize the relative advantage of drug therapy in improving quit rates and should be particularly attentive to concerns regarding side effects. Future research should consider how to tailor tobacco treatment based on veterans' preferences.

VITAL SIGNS ARE STILL VITAL—ASSOCIATION BETWEEN INSTABILITY ON HOSPITAL DISCHARGE AND 30-DAY READMISSIONS AND MORTALITY Oanh K. Nguyen^{1,1}; Anil N. Makam^{1,1}; Christopher Clark²; Song Zhang¹; Bin Xie²; Ruben Amarasingham^{2,1}; Ethan Halm^{1,1}; ¹UT Southwestern Medical Center, Dallas, TX; ²Parkland Center for Clinical Innovation, Dallas, TX. (Tracking ID #2196001)

BACKGROUND: Instability on discharge has been previously shown to be associated with adverse clinical outcomes among hospitalized patients with pneumonia. However, little is known about the association between instability and outcomes among all hospitalized individuals. Thus, we sought to describe rates of instability on discharge among hospital patients and examine associations between instability on discharge on 30-day readmissions and mortality.

METHODS: This was an observational cohort study using EHR data from 6 hospitals in the Dallas-Fort Worth metroplex, including safety net, community, teaching, and non-teaching sites. We included hospital discharges from all internal medicine inpatient services among adults (≥18 years) between November 1, 2009 and October 30, 2010. We excluded inpatient deaths, transfers to an acute care facility, those who left against medical advice, and those discharged to hospice. Instability was defined as temperature ≥37.8 °C, heart rate >100 beats/min, respiratory rate >24 breaths/min, systolic blood pressure ≤90 mmHg, or oxygen saturation <90 %. The primary outcome was a composite

of death and any non-elective readmission to any of 75 acute care hospitals in North Texas within 30 days of discharge, both ascertained using an all-payer regional hospitalization database. We used logistic regression to adjust for demographic, clinical, and healthcare utilization characteristics, accounting for clustering at the hospital level.

RESULTS: Among 32,835 individuals, 18.7 % had ≥ 1 instability on discharge. Overall, 12.8 % of individuals with no instabilities on discharge died or were readmitted, compared to 16.9 % with 1 instability, 21.2 % with 2 instabilities, and 26.0 % with ≥ 3 instabilities ($p < 0.001$, Figure). The presence of any (≥ 1) instability on discharge was associated with higher risk-adjusted odds of either death or readmission (AOR 1.36, 95 % CI 1.26–1.48,

Table); this association was primarily driven by the increased odds of death. Individuals with ≥ 3 instabilities had a nearly 4-fold increase in the odds of death (AOR 3.91, 95 % CI 1.69–9.06), and an increased odds of 30-day readmission (AOR 1.36, 95 % CI 0.81–2.30) compared to individuals with no instabilities.

CONCLUSIONS: Instability on discharge is associated with increased risk of 30-day readmission and mortality. Discharge guidelines should include vital sign criteria for judging stability on discharge to improve disposition planning, post-discharge patient safety and to reduce 30-day mortality and readmission.

Table. Effects of Vital Sign Instability on Discharge on 30-Day Mortality and Readmission^a (N=32,835)

WAM! WEEK OF ADDICTION MEDICINE: AN INTENSIVE CURRICULUM FOR INTERNAL MEDICINE-PRIMARY CARE INTERNS Elenore P. Bhatraju⁶; Sienna Kurland⁴; Laura Van Metre Baum⁷; Andrew A. Chang³; Jessica Taff⁴; Jaclyn Fox¹; Mack Lipkin⁵; Kathleen Hanley². ¹Manhattan VA & NYU SoM, New York, NY; ²NYU, New York, NY; ³NYU/Gouverneur, New York, NY; ⁴New York University, New York, NY; ⁵New York University School of Medicine, New York, NY; ⁶Virginia Mason, Seattle, WA; ⁷Montefiore Medical Center, New York, NY. (Tracking ID #2198070)

BACKGROUND: Medical residencies inadequately address substance use (SU) disorders despite their significant contribution to disability, death, and healthcare costs. Physicians avoid counseling and treating patients with SU disorders because of discomfort discussing SU with patients, poor baseline knowledge and clinical skills, and negative attitudes towards SU. We undertook to improve SU education in a primary care residency by designing and implementing an intensive weeklong addiction medicine curriculum for interns and assessed its impact on knowledge, skills, and attitudes.

METHODS: The curriculum utilized a learner-centered, experiential education model. Sessions included lectures, guided discussions, patient interviews, journal club, and

treatment site visits. Content included neurobiology of addiction, opiates, alcohol, motivational interviewing (MI), brief interventions, harm reduction, and policy. MI training included theory, skills based practice, and coaching sessions. Knowledge and attitudes were assessed by pre- and post-test: 18 questions tested clinical knowledge; eight assessed confidence and attitudes using a Likert scale from (1) strongly disagree to (5) strongly agree. For the four questions pertaining to confidence, a composite “confidence score” was computed (Cronbach’s alphas > 0.85 for both pre- and post-tests). The intern cohorts were similar and analyzed together.

RESULTS: The curriculum was implemented in March 2013 ($n=9$) and March 2014 ($n=8$). Fifteen pre-tests and 17 post-tests were completed. The clinical knowledge mean test score improved from 50 to 70 % ($p < 0.0005$). The mean confidence score increased from 2.7 to 4.2 ($p < 0.0005$). Post-test, 94 % of participants somewhat or strongly agreed that treating SU is rewarding, vs. 69 % baseline. Eighty-eight percent somewhat or strongly believed they could make a difference in their addicted patients, compared to 57 % baseline. Participant feedback was strongly positive.

CONCLUSIONS: Baseline knowledge and confidence were poor. Knowledge, confidence, and attitudes towards SU improved after WAM. Further assessment is needed to determine if the effects are durable and translate into improved provider satisfaction, patient counseling and treatment, and health outcomes.

WATERPIPE TOBACCO SMOKING AMONG US YOUNG ADULTS BOTH IN AND NOT IN SCHOOL: A NATIONALLY-REPRESENTATIVE STUDY Brian A. Primack¹; Ariel Shensa¹; Jaime Sidani¹; Jason Colditz²; Judith Brook³; Michael J. Fine². ¹University of Pittsburgh, Pittsburgh, PA; ²VA Pittsburgh Healthcare System, Pittsburgh, PA; ³New York University, New York, NY. (Tracking ID #2197948)

BACKGROUND: A global resurgence of waterpipe (“hookah”) tobacco smoking (WTS) has resulted in a spread into Western nations, especially within the past decade. Many factors contribute to this trend, including misperceptions about the safety of WTS and its harm reduction capabilities, addition of sweeteners and flavorings, the belief that WTS is not addictive, and its social acceptability. However, WTS exposes users to tar, carbon monoxide, nicotine, polyaromatic hydrocarbons, and other toxicants, often in levels that are higher than that of smoking a single cigarette. WTS has been most commonly studied among adolescents and college students, and it is clearly increasing substantially among these populations. For example, nationally-representative data from 2014 showed that over 20 % of high school seniors engaged in the practice in the past year. However, to our knowledge, there has not yet been a large-scale, nationally representative study examining WTS behaviors and related factors that focuses on young adults, especially those who are not necessarily in college. Therefore, we aimed to fill this gap.

METHODS: Research participants were members of a nationally-representative probability-based online non-volunteer access panel recruited and maintained by an established organization called GfK (“Growth from Knowledge”). The panel was created

with a combination of random-digit-dialing and address-based sampling, creating a sampling frame including an estimated 97 % of US households. For this study, we commissioned GfK to recruit and survey approximately 3000 adults ages 18–30. The online survey was sent to a randomly selected sample of panel members in March of 2013 and was active for a 1-month period. For our outcome variable, respondents were asked to report on their ever and current (within the past 30 days) WTS behavior. In addition to WTS, we assessed many relevant socio-demographic factors potentially related to WTS, including age, sex, sexual orientation, race and ethnicity, relationship/marital status, living situation, and household income. We used survey weights to estimate national rates of ever WTS and current WTS by each of the key socio-demographic characteristics. Finally, we used multivariable logistic regression to examine independent associations between the socio-demographic independent variables and each of two key dependent variables: ever WTS and past-30-day WTS. Because prior national data have focused on school (i.e. university) populations but not community-based populations, we stratified both bivariable and multivariable analyses by status in school (e.g., college, university) vs. not in school.

RESULTS: Our sample consisted of 3131 young adults ages 18–30 of whom 1360 (43 %) were in school and 1771 (57 %) were not. Based on all participants, weighted data showed that 31 % were ever users of WTS while 5 % had used WTS in the past 30 days. When data were stratified, ever use was 36 % among participants in school and 30 % among participants not in school, and current use was 7 % among participants in school and 4 % among participants not in school. However, in some subgroups non-school participants had similar or higher usage rates. For example, among the youngest participants (ages 18–20), ever use was 26 % among participants in school and 30 % among participants not in school, and current use was 8 % for both school and non-school populations. Multivariable models demonstrated that a distinct set of socio-demographic factors was independently associated with WTS in the different (school vs. non-school) groups. Among participants in school, only bisexuality was significantly associated with increased current WTS (vs. heterosexual, AOR=3.36, 95 % CI=1.32, 8.53). Among participants not in school, however, lower current WTS was associated with being 27–30 (vs. 18–20, AOR=0.12, 95 % CI=0.04, 0.34), being married (vs. single, AOR=0.17, 95 % CI=0.07, 0.43), living with a significant other (vs. living alone, AOR=0.36, 95 % CI=0.13, 0.97), and having a household income of \$60,000 or above (vs. under \$25,000, AOR=0.26, 95 % CI=0.10, 0.68).

CONCLUSIONS: Among young adults, WTS is common not only in school-based populations (e.g., colleges and universities) but also in community-based populations. In fact, in certain subgroups, such as those 18–20, WTS may be higher among community-based populations. For this reason, surveillance and clinical counseling should extend to all young adults and not only those in school-based settings. When providing counseling and/or considering educational and policy intervention, it may be valuable to keep in mind that different socio-demographic factors are associated with WTS use among school and non-school populations. In particular, while among school-based populations only bisexuality is strongly associated with use, in non-school populations use seems to be highest among young, single, less affluent individuals living alone.

WATERPIPE TOBACCO SMOKING DEPENDENCE AMONG US YOUNG ADULTS Jaime Sidani¹; Saul Shiffman²; Ariel Shensa¹; Galen E. Switzer¹; Brian A. Primack¹. ¹University of Pittsburgh, Pittsburgh, PA; ²Pinney Associates, Pittsburgh, PA. (Tracking ID #2198152)

BACKGROUND: Waterpipe tobacco smoking (WTS) is the practice of smoking tobacco heated by lit charcoal through a small hose connected to a liquid-filled bowl. Traditionally associated with the Eastern Mediterranean Region, WTS has been increasing in popularity among US young adults despite evidence of its toxicant content and potential negative health effects. Many waterpipe smokers in the US believe WTS to be safer than traditional cigarette smoking, a misconception likely perpetuated by the belief that WTS exposes users to little or no nicotine, therefore leading to a reduced potential for dependence. While preliminary evidence from the Eastern Mediterranean Region suggests the potential for WTS to produce dependence in its users, there has been little research into WTS dependence among US users. To address this gap in the literature, we conducted a nationally-representative study of WTS dependence among US young adults.

METHODS: We assessed 436 past-year waterpipe tobacco users ages 18–30, who were part of a national probability-based online non-volunteer access panel randomly selected to participate in a study of WTS behaviors. These participants were presented with 6 dichotomous WTS dependence items adapted for the US young adult population from two existing scales: the Lebanon Waterpipe Dependence Scale (LWDS) and the Fagerstrom Test for Cigarette Dependence (FTCD). To examine the underlying structure of the dependence items, we created a pairwise correlation matrix and performed exploratory factor analysis with Varimax rotation. Participants were also asked about 5 behavioral dependence indicators that we expected to be associated with WTS dependence, such as

age of initiation and frequency of use. Individual regression analyses were performed to assess associations between the WTS dependence scale and the 5 behavioral dependence indicators, adjusting for all socio-demographic variables. Additionally, we calculated continuous and categorical summary scores of the dependence items to further assess associations with the behavioral dependence indicators.

RESULTS: Our sample was 55 % male, 58 % Caucasian non-Hispanic, 11 % African-American non-Hispanic, 24 % Hispanic, and 6 % of mixed or other race. Factor analysis suggested that the 6 dependence items represented one internally consistent factor (Cronbach's alpha=0.75). The range of endorsement for the WTS dependence items varied from 3.2 to 14.9 %, with the highest endorsement for engaging in WTS when the participant was so sick that he or she stayed home from work or school (14.9 %). In fully adjusted regression models, dependence items were strongly and consistently associated with each of the 5 behavioral dependence indicators. When the WTS dependence items were analyzed as a categorical summary score, 15.5 % of participants endorsed 2 or more dependence items. Compared with those who did not endorse any of the 6 dichotomous dependence items, the participants who endorsed 2 or more items had an adjusted odds ratio of 4.08 for waterpipe ownership, 3.03 for smoking more bowls per session, 23.42 for participating in more sessions per day, 5.23 for initiating use at a younger age, and 3.28 for WTS in the past 30 days.

CONCLUSIONS: Six WTS dependence items adapted from traditional tobacco dependence measures appear to be valuable for assessing WTS dependence among US young adults. Use of these items as a categorical scale may be useful for clinicians or other healthcare workers as a brief assessment tool to screen for WTS dependence. Although future work is needed to further extend validity by determining associations between these 6 items and other indications of dependence, such as increases in WTS over time, this work represents useful groundwork toward assessment of WTS dependence among US young adults.

WE NEED MORE: ADDING PEER SUPPORT AND GROUP COUNSELING TO BUPRENORPHINE MAINTENANCE TREATMENT IN PRIMARY CARE THROUGH GROUP MEDICAL VISITS Aaron D. Fox^{1, 2}; Mariya Masyukova². ¹Montefiore Medical Center, Bronx, NY; ²Albert Einstein College of Medicine, Bronx, NY. (Tracking ID #2198955)

BACKGROUND: Opioid addiction and overdose deaths have reached epidemic proportions in the United States, but most Americans with opioid use disorder remain out of treatment. Stigma associated with addiction may be reduced by offering opioid addiction treatment in primary care with buprenorphine maintenance treatment (BMT). Office-based BMT is safe and effective, but the inability to provide intensive behavioral counseling has prevented many primary care physicians from adopting BMT. Group medical visits (or shared medical appointments) utilize a multi-disciplinary team of providers to deliver health education, behavioral counseling, and medical management to multiple patients with chronic conditions. BMT group medical visits may be a good option for intensifying behavioral counseling in office-based BMT, but they have not been studied. In preparation for development of a model of BMT group medical visits, we investigated the perceptions of BMT patients toward offering BMT as a group.

METHODS: For this qualitative study we conducted five focus groups with past or present BMT patients in New York City who had previously indicated interest in participating in clinical research. We developed a semi-structured interview guide with questions relating to past experiences with BMT and therapeutic group counseling. We described group medical visits as a hypothetical option for BMT. Focus groups lasted an hour and were audio-recorded. Participants were compensated with \$20 and transit passes. Analysis was conducted with a grounded theory approach. Transcriptions of recordings were read, coded, and discussed in an iterative process. We created a list of “repeating ideas” by consensus based on the first two transcripts and then used these as codes for all transcripts. We then organized data into categories of increasing complexity, identifying common “themes” from the repeating ideas, and developing “theoretical constructs” based on these themes and our initial research question. We continued to conduct focus groups until reaching thematic saturation, which occurred when no new repeating ideas were identified from transcripts.

RESULTS: Of the 33 participants in the 5 focus groups (range: 3–11 participants), median age was 50 and most were male (N=28), Hispanic (20), and had experiences with therapeutic groups (21). Participants unanimously reported that therapeutic groups could potentially complement BMT, addressing the mental component of addiction while the medication addressed the physical component; however, there was disagreement about whether groups were necessary for most BMT patients. Some participants were highly satisfied with BMT provided by their primary care physician and did not think additional group counseling was necessary. Other participants desired more intensive treatment (e.g., “If we just had to see one doctor, that works all right for a little while, but we need more.

So the group comes in"). For participants in favor of combining groups with BMT, the perceived added benefits of groups were peer support, diverse sources of psychoeducation (e.g., "Different people have different information. And it's not even the counseling. We get it all from each other"), validation (e.g., "Being in groups with people that I know were going through the same thing that I was going through just validates it even more that I'm doing the right thing and the [buprenorphine] is working"), and being held accountable to the group. Concerns about combining groups with BMT were confidentiality, time commitment and decreased individual attention from the physician.

CONCLUSIONS: Focus groups with BMT patients demonstrated enthusiasm for the potential of BMT group medical visit; however, there was some concern about confidentiality, increased time commitment, and inadequate individual attention. Because some participants preferred the privacy and ease of receiving BMT at standard primary care visits, BMT group medical visits will not be acceptable to all BMT patients. Therefore, it may be best to target BMT patients who are unable to achieve abstinence with medical management alone for BMT group medical visits. Because participants highly valued their interactions with peers (e.g., validation), while developing BMT group medical visits, we will investigate the precise mechanisms supporting behavior change (behavioral counseling vs. peer support). BMT group medical visits are a promising model to deliver behavioral counseling and medical management of opioid addiction, while also capitalizing upon peer support. We are currently conducting a pilot study to test the feasibility of BMT group medical visits.

WHAT ARE THE BEST WAYS TO IMPROVE MEDICATION RECONCILIATION PRACTICES? AN ON-TREATMENT ANALYSIS OF THE MARQUIS STUDY Jeffrey L. Schnipper^{5, 10}; Jason Stein^{6, 7}; Tosha B. Wetterneck^{3, 8}; Peter Kaboli^{1, 9}; Stephanie Mueller^{5, 10}; Amanda S. Mixon⁴; Stephanie Labonville⁵; Jacquelyn A. Minahan⁵; Elisabeth Burdick⁵; Endel John Orav⁵; Jenna Goldstein¹¹; Nyryan V. Nolido²; Sunil Kripalani¹². ¹Iowa City VAMC, Iowa City, IA; ²Northwestern University, Boston, MA; ³University of Wisconsin School of Medicine and Public Health, Madison, WI; ⁴VA Tennessee Valley Healthcare System and Vanderbilt University, Nashville, TN; ⁵Brigham and Women's Hospital, Boston, MA; ⁶Emory University Hospital, Atlanta, GA; ⁷Emory University School of Medicine, Atlanta, GA; ⁸University of Wisconsin Madison, Madison, WI; ⁹University of Iowa Hospitals and Clinics, Iowa City, IA; ¹⁰Harvard Medical School, Boston, MA; ¹¹Society of Hospital Medicine, Philadelphia, PA; ¹²Vanderbilt University Medical Center, Nashville, TN. (Tracking ID #2199237)

BACKGROUND: Many hospitals have tried to improve their medication reconciliation processes, with mixed results. Currently, there are insufficient data to guide hospitals in the best ways to improve their practices. In the Multi-Centered Medication Quality Improvement Study (MARQUIS), sites chose to implement one or more components from a multifaceted toolkit. The goal of this analysis was to determine which components were associated with the greatest improvements in medication safety.

METHODS: Five U.S. hospitals participated in this quality improvement (QI) study between September 2011 and July 2014. With the guidance of trained mentors and using standard QI principles, each site implemented one or more of 11 intervention components. Sites were provided with an implementation manual and toolkit. Mentors conducted monthly phone calls and two site visits during the intervention period. The primary outcome was the number of potentially harmful unintentional medication discrepancies per patient, measured in approximately 22 randomly selected patients per month during a 6-month baseline period and throughout the intervention. To determine the most effective components of the intervention, we categorized all QI activities conducted by any site by component, including date(s) of implementation. We analyzed the data using Poisson regression to detect sudden reductions in potentially harmful discrepancy rates temporally associated with each implementation of each intervention component across all sites.

RESULTS: We identified 668 patients on intervention units during the post-implementation period. In on-treatment analyses, one intervention component was associated with significant reductions in potentially harmful discrepancies: hiring new staff (usually pharmacists) to assist with both medication reconciliation and patient counseling at discharge (incidence rate ratio 0.16 (95% CI 0.08 to 0.33)). Two components were associated with increases in discrepancy rates: training existing staff to take medication histories (IRR 1.27 (1.01 to 1.59)), and implementing a new electronic medical record (IRR 3.38 (1.65 to 6.93); Table 1).

CONCLUSIONS: We found that hiring additional pharmacy staff to assist with discharge reconciliation and patient counseling was the most effective component of a medication reconciliation QI program. Conversely, training existing staff to take medication histories was shown to increase potentially harmful discrepancies, perhaps because it leads to diffusion of responsibility or delays in hiring new staff, which could consolidate this role in a few well-trained personnel. Lastly, external factors, such as EMRs that are not designed and/or implemented optimally, were also shown to adversely affect discrepancy rates.

Table 1. Effects of Individual Intervention Components on Potentially Harmful Medication Discrepancies

Intervention Component	Incidence Rate Ratio (95% CI)	P value
Hiring additional staff to perform discharge medication reconciliation and patient counseling	0.16 (0.08 to 0.33)	<0.001
Training existing staff to perform discharge medication reconciliation and patient counseling	0.76 (0.45 to 1.26)	0.28
Hiring additional staff to take preadmission medication histories	1.17 (0.54 to 2.53)	0.68
Training existing staff to take preadmission medication histories	1.27 (1.01 to 1.59)	0.04
Making improvements to existing medication reconciliation health information technology	0.70 (0.08 to 5.84)	0.74
Performing high-intensity interventions on high-risk patients	0.92 (0.74 to 1.14)	0.45
Clearly defining roles and responsibilities and communicating this with clinical staff	0.62 (0.34 to 1.15)	0.13
Improving access to pre-admission medication sources	1.07 (0.65 to 1.75)	0.80
Implementing a new electronic medical record	3.38 (1.65 to 6.93)	<0.001

WHAT ARE THE CONTRIBUTING FACTORS TOWARDS OVERLY AGGRESSIVE CARE AT THE END OF LIFE? Elizabeth Dzung^{2, 4}; Thomas J. Smith¹; David M. Levine³. ¹Johns Hopkins, Baltimore, MD; ²Johns Hopkins School of Medicine, Baltimore, MD; ³Johns Hopkins U., Balt., Md., MD; ⁴University of Cambridge, Cambridge, United Kingdom. (Tracking ID #2193113)

BACKGROUND: Conversations surrounding the medical profession and society's understanding of death and dying have been in the spotlight in both the United States and United Kingdom. The Institute of Medicine's recent report on "Dying in America" highlights the many challenges that occur in end of life care, especially that most patients want to die at home comfortably, but the system is geared towards a default of aggressive care. The aim of this study was to understand factors that contribute to overly aggressive care at the end of life in the American health care system.

METHODS: Semi-structured in-depth interviews were conducted with 58 internal medicine doctors across four sites (New York, Baltimore, Seattle and Cambridge, England), who were routinely involved in DNR conversations with end of life patients. Participants were purposively sampled by stage of training and subspecialty to provide a wide range of perspectives and contribute to understanding emerging patterns and themes. Interviews lasted on average 60 min and were audio-taped and transcribed. Transcripts were analyzed and double coded using thematic analysis with an interpretive approach.

RESULTS: The interviews revealed many factors that contributed towards overly aggressive care at the end of life in the United States. These factors can be broadly categorized as patient, surrogate, physician, or systemic factors. Systemic or cultural factors included frequent mentions of cultural norms that fear death and defaults within the health system that result in an inadvertent drive towards overly aggressive care. Technological advances and legal concerns also contributed. Physician factors included delays in discussing death and delays regarding treatment decisions and overall prognosis. In contrast to experienced physicians, less experienced physicians (i.e. residents and fellows) sometimes felt compelled to offer a menu of choices including those unlikely to work such as futile resuscitation. In addition, they more frequently discussed patients who "wanted everything" or that they "did everything." Patient and surrogate factors frequently include a denial of death, unrealistic expectations, and surrogates' feelings of guilt over "killing their loved one." Comparisons are made to the UK where differing policies and philosophies regarding distribution of resources engendered a system that encouraged care that was less aggressive than their American counterparts. Medical trainees often remarked that there were few formal and informal opportunities to discuss issues surrounding death and dying during residency, which contributed to discomfort in discussing death. The notable exception was the Seattle hospital site, whose fortnightly "Death Rounds" discussions sharing experiences about dying patients, seemed to foster greater comfort in communicating issues of death and dying amongst house staff.

CONCLUSIONS: There are myriad factors at a societal, physician, surrogate, and patient level that drive the culture of overly aggressive care in American hospitals. The majority of these factors stem from challenges in discussing and accepting death at a societal and individual level. Targeted interventions to improve physician and institutions' ability to communicate with patients and accept death as a natural part of the life course rather than something to be defied, might decrease overly aggressive care at the end of life.

WHAT DO INTERNAL MEDICINE RESIDENTS SAY ABOUT INTERNSHIP PREPARATION? FINDINGS FROM AN INTERNAL MEDICINE IN-TRAINING EXAMINATION SURVEY Heather Harrell²; Anne Pereira³; T. R. Vu¹; Greg Kane⁴. ¹Indiana University, Carmel, IN; ²University of Florida, Gainesville, FL; ³University of Minnesota, Duluth, MN; ⁴Jefferson, Philadelphia, PA. (Tracking ID #2145569)

BACKGROUND: Medical educators have identified important skills to prepare students for internship.¹⁻³ One small survey of PGY1 residents in 2002 addressed the question of internship preparation but the results may be dated, for in the interim there has been widespread adoption of EMRs and duty hour changes that have highlighted skills such as handoffs.³ Recently, a small qualitative study of PGY2 residents addressed the value of the 4th year of medical school to internship preparation in several specialties.⁴ The purpose of this study was to obtain feedback from a large stakeholder group regarding what they found most valuable from the 4th year of medical school for internal medicine (IM) internship preparation to help educators better advise and prepare medical students pursuing careers in IM.

METHODS: All IM residents taking the 2013 In-Training Exam were asked to use a drop down menu of 11 common 4th year courses to rank which three were most helpful for internship preparation and to rank the importance of learning ten pre-defined skills prior to residency. The ten skills were chosen based on prior literature, a national subinternship curriculum, and expert consensus.^{1-3, 5-6} Results were analyzed with descriptive statistics and t-tests.

RESULTS: Table 1 demonstrates the ranking responses for 4th year courses in descending order of helpfulness to internship preparation. Comparing rankings by training level revealed that PGY1 residents selected subinternship, EM rotation, and subspecialty electives significantly more often and critical care and ward rotations significantly less often than PGY2 and 3 residents ($p < 0.01$). Table 2 shows all residents' ratings of the importance of 10 skills for internship. While there were statistically significant differences between the ratings by PGY1, 2, and 3 residents of skill importance, the absolute differences between years were small.

CONCLUSIONS: This is the largest study describing which medical school rotations and skills a key stakeholder group, current IM residents, found most helpful for internship preparation. The results confirm prior studies highlighting the perceived value of a subinternship and clinical rotations for internship preparation. Also, there is strong agreement between IM residents and medical educators about which skills are important to learn prior to internship.^{2, 4, 7} Capstone courses, often developed specifically for internship preparation, were rarely ranked as most helpful for internship preparation. Allowing residents to rank only their top three courses may under recognize the absolute perceived value of a course. This information should help inform curriculum development and student advisement to improve IM internship preparation. References 1. Langdale LA, et al. Obtaining informed consent	60	33	8

WHAT IS SPECIALTY CARE COORDINATION? PERSPECTIVES OF THE "TRIAD"—PATIENT, PCP AND SPECIALIST Varsha Vimalananda^{1, 3}; Kelly Dvorin¹; Dan Berlowitz^{1, 4}; Graeme Fincke^{1, 4}; Mark Meterko^{2, 4}; Barbara G. Bokhour^{1, 4}. ¹ENRM Veterans Affairs Medical Center, Bedford, MA; ²VA Boston Healthcare System, Boston, MA; ³Boston University School of Medicine, Boston, MA; ⁴Boston University School of Public Health, Boston, MA. (Tracking ID #2195820)

BACKGROUND: Specialty care coordination is critical to success of the patient-centered medical home. However, each participant in the "specialty care triad"—patient, PCP, and specialist—brings a different perspective to the specialty care referral process. We have little understanding of the common and unique elements of well-coordinated specialty care from each perspective. We sought to understand the meaning of successful specialty care coordination for each triad member, using diabetes as a case study.

METHODS: We conducted semi-structured telephone interviews with 12 primary care providers and 13 endocrinologists at 25 US Veterans Affairs Medical Centers and Community-based Outpatient Clinics across the country in 2014. We conducted two focus groups with Veterans with diabetes (N=9) at one urban and one rural VAMC. Interviews and focus groups were audiorecorded and transcribed. We analyzed the data using grounded thematic analysis, a systematic approach to deriving qualitative themes from textual data. We used constant comparative methods to compare findings from different triad member types. We sought to identify overlapping as well as distinctive themes from each group of participants.

RESULTS: Results: We identified six interrelated domains; each was important for all three types of triad members: 1) *Interpersonal communication*; 2) *Relationships*; 3) *Roles and responsibilities*; 4) *Information transfer*; 5) *Access to services*; and 6) *Avoiding unnecessary visits*. Within the domains, certain themes were common to all triad member types; others were unique to one or two. 1) *Interpersonal communication* and 2) *Relationships*: For patients, it was important to feel that either someone in the healthcare system understood and could manage all aspects of their care, or that they were provided tools enabling them to manage their own care in the absence of a perfectly-functioning system. Easy access to timely communication with a specific provider was important in this regard. Most often, patients named a particular nurse rather than a PCP or endocrinologist who helped them navigate their diabetes in a complex healthcare system over time. Both PCPs and endocrinologists described many system-level barriers to coordination, and in this setting, having personal relationships was critical to accomplishing needed tasks. When providers knew each other personally, they were more likely to call or email directly with questions and to receive a helpful response. 3) *Roles and responsibilities*: Patients described coordination of specialty care as either their job or that of the PCP, viewing the endocrinologist's role as limited to clinical care, explaining things clearly, and honoring appointment times. PCPs and endocrinologists wished for greater clarity in provider roles and responsibilities and an increased sense of shared goals. Frustration over shortcomings in these areas was compounded by poor relationships and limited communication. 4) *Information transfer*: Patients discussed the patient-accessible online health record and secure messaging as effective ways to track and manage their health care needs; this was an important piece of feeling that they were in control. Providers described the need for organized and meaningful information transfer with each other and the importance of making special efforts to communicate when information needed follow up. 5) *Access to services*: Timeliness in access to services was important to all three triad member types. All three discussed access to endocrinology appointments, PCPs discussed

access to specialty expertise through e-consults, and endocrinologists' concerns included obtaining insulin pumps and continuous glucose monitors. 6) *Avoiding unnecessary visits*: Patients wanted phone or secure messaging to replace clinic visits when possible. Endocrinologists saw triage of consults as a critical strategy to manage limited clinic availability. However, triage mechanisms such as service agreements and e-consults were sometimes seen by PCPs as methods of "blocking" access to specialty care.

CONCLUSIONS: Success in specialty care coordination is perceived in overlapping, but not identical, ways by patients, PCPs, and endocrinologists. These findings have implications for how we understand specialty care coordination and for the development of interventions to improve it. For all three triad member types, *Relationships* and *Interpersonal communication* emerged as particularly important domains of coordinated care in a complex and sometimes difficult-to-navigate system. However, interventions should account for differing perspectives within the domains. For example, for patients, it is important to ensure that a specific person is the "hub" of coordination, which could be the patient or a non-MD provider. For PCPs and endocrinologists, interventions that foster personal relationships between providers are needed, and may positively impact multiple aspects of specialty care coordination.

WHO IS RESPONSIBLE FOR WHAT TASKS WITHIN PRIMARY CARE: PERCEIVED TASK ALLOCATION AMONG PRIMARY CARE PROVIDERS AND INTERDISCIPLINARY TEAM MEMBERS

Samuel T. Edwards^{5, 6}; Lisa V. Rubenstein¹; Lisa S. Meredith²; Nicole Schmidt²; Susan E. Stockdale¹; Kristina M. Cordasco³; Andrew Lanto¹; Philip Roos⁴; Elizabeth M. Yano¹. ¹Greater Los Angeles VA Healthcare System, Sepulveda, CA; ²RAND Corporation, Santa Monica, CA; ³VA Greater Los Angeles Healthcare System/ UCLA, Los Angeles, CA; ⁴VA Loma Linda Healthcare System, Loma Linda, CA; ⁵VA Portland Health Care System, Portland, OR; ⁶Oregon Health and Sciences University, Portland, OR. (Tracking ID #2185177)

BACKGROUND: Unclear roles in interdisciplinary primary care teams are an impediment to achieving optimal team-based patient centered primary care. We assessed perceived allocation of a set of commonly performed clinical tasks among primary care providers (PCPs) and staff during early implementation of Patient Aligned Care Teams (PACT), a new patient-centered care model in Veterans Health Administration (VHA) primary care practices.

METHODS: We performed a cross sectional survey of all PCPs and primary care staff in 21 primary care practices within one VHA administrative region covering Southern California and Nevada. We asked PCPs (Physicians, Nurse Practitioners and Physician Assistants) which of 14 common primary care tasks they carried out on their own versus relied on help from staff. We also asked three categories of primary care staff members (registered nurses (RNs), licensed practical nurses (LPNs), and medical assistants/clerical staff) for which of the same 14 tasks they were relied upon by PCPs. We also performed multivariable regression to determine what provider characteristics and elements of PACT implementation were associated with perceived sharing of a given task.

RESULTS: One hundred sixty-two PCPs and 257 staff members responded, a 57 % response rate. Survey results are presented in the table. A minority of PCPs reported relying on staff for 12 of 14 tasks. Very few PCPs reported relying on staff for evaluating patients and making treatment decisions (2 % reported relying on staff), tracking diagnostic data (8 %), and handling forms for patients (14 %), while a slight majority reported relying on staff for receiving messages from patients (63 %), and screening patients for diseases (62 %). Conversely, over 85 % of registered nurses reported they were relied upon for all 14 tasks. All RNs reported being relied upon for receiving and resolving messages, and 98 % reported being relied upon for educating patients about diseases, responding to prescription refill requests, and tracking patient diagnostic study data. A majority of LPNs reported they were relied upon for 13 of 14 of tasks, with the exception of responding to requests for home health care orders where 44 % of LPNs reported being relied upon. A majority of medical assistants/clerical staff reported being relied upon for only 5 of 14 tasks, specifically receiving messages from patients (95 %), resolving messages from patients (88 %), and responding to prescription refill requests (77 %). Multivariable regression demonstrated no association between task sharing and years working in the clinic, or number of clinical sessions per week. Nurse Practitioners/Physician Assistants were less likely than physicians to report relying on staff for screening patients for diseases (OR 0.36, 95 % CI 0.15–0.85), educating patients about disease specific self care activities (OR 0.18, 95 % CI 0.05–0.63), and receiving messages from patients (OR 0.36, 95 % CI 0.15–0.87). For PCPs, increased PACT training was associated with increased sharing of the tasks gathering patient preventive services history (For each 10 h interval of PACT training, OR 1.19, 95 % CI 1.03–1.37), screening patients for diseases (OR 1.25, 95 % CI 1.05–1.47), and evaluating patients and making treatment decisions (OR 1.59, 95 % CI 1.18–2.13).

CONCLUSIONS: Early in implementation of a team-based primary care model, most PCPs perceived they were solely responsible for most clinical tasks. Registered nurses,

and licensed practical nurses felt they were relied upon for most of the same tasks, suggesting suboptimal understanding between nurses and PCPs regarding task allocation. Medical assistants/clerical staff reported being relied on for fewer tasks, suggesting their roles could be expanded. Better understanding of optimal inter-professional team task allocation in primary care is needed.

Proportion of PCPs, RNs, LPNs and clerical staff reporting that PCPs rely on staff for a given task

Task	PCP* (162)	RN** (103)	LPN** (110)	Clerical Staff** (43)
Gathering patient preventive services utilization history (e.g., immunization history)	41 %	87 %	97 %	30 %
Screening patients for diseases (e.g., doing a depression screen)	62 %	93 %	98 %	19 %
Evaluating patients and making treatment decisions	2 %	98 %	62 %	14 %
Intervening on patient lifestyle factors (e.g., diet, smoking cessation)	19 %	100 %	96 %	14 %
Educating patients about disease-specific self-care activities (e.g., foot care in diabetes)	29 %	98 %	92 %	16 %
Educating patients about medications	30 %	99 %	94 %	23 %
Responding to prescription refill requests	31 %	98 %	96 %	77 %
Receiving messages from patients (other than requests for prescriptions)	63 %	100 %	97 %	95 %
Resolving messages from patients (other than requests for prescriptions)	48 %	100 %	96 %	88 %
Handling forms for patients (e.g., disability documentation)	14 %	89 %	52 %	67 %
Tracking patient diagnostic data (e.g. labs, radiology studies)	8 %	98 %	74 %	49 %
Responding to patient diagnostic and treatment data (e.g. labs, radiology studies)	8 %	95 %	65 %	30 %
Following-up on referrals (e.g., to specialists)	17 %	97 %	76 %	65 %
Responding to requests for Home Health Care orders	20 %	92 %	44 %	28 %

*Percent of PCPs indicating they rely upon staff (vs. perform alone without help)

**Percent of staff indicating they are relied upon

WHO SHOWS UP AND LOSES? PREDICTORS OF ATTENDANCE AND WEIGHT LOSS IN URBAN AFRICAN AMERICAN WOMEN IN THE STRIDES BEHAVIORAL WEIGHT LOSS PROGRAM

Eileen Seeholzer^{1, 2}; James Yokley^{3, 2}; Martha Golubski¹; Keegan Conry²; Kelly Manger²; Charles Thomas^{1, 2}. ¹MetroHealth System, Cleveland, OH; ²Case Western Reserve University School of Medicine, Cleveland, OH; ³MetroHealth Medical Center, Cleveland, OH. (Tracking ID #2200342)

BACKGROUND: Behavioral weight loss program participants less likely to lose weight include persons who are an ethnic minority, have lower income, or lower-literacy skills. Other than demographic factors, reliable predictors of response to behavioral weight loss interventions are not well understood. Our team developed the STRIDES weight loss program: a free 12-week group weight loss program with materials at a 4th grade reading level. STRIDES stands for Steps to Reach Individual Diet and Exercise Solutions. STRIDES includes interactive group learning and individual counseling. STRIDES participants are obese African America (AA) women recruited from an urban primary care practice. Not compensated for attendance, 35 % of participants complete the 12-week program on average. Prior STRIDES program analysis showed disease burden, and insurance type were not predictive of attendance or weight loss among these AA women. The primary purpose of this evaluation was to assess among this demographically similar group, other predictors of attendance and weight loss (behavioral, motivational, physical and mood symptom).

METHODS: This program outcome evaluation analyzed participant survey data collected from STRIDES participants from 2011 to 2013 at program entry. The paper survey data

were entered in a secure Research Electronic Data Capture (REDCap) database. Survey measures include: readiness to change, current behaviors, mood and physical symptoms, fatigue, sleepiness, anger, Self-regulation competency (SRC), and environmental factors. These data were compared to STRIDES program participant data from program records (weight and attendance), and demographics and disease burden (electronic medical record). Data analyses. For two-category independent variables the Cochran-Armitage Trend Test was used to assess the trend in binomial proportions across levels of weight change (gain or loss categories). Similarly, this test was used to assess the trend across levels of attendance. Where the independent variables are more than two categories such as multi-categorical survey items with no inherent the Kruskal-Wallis test was used.

RESULTS: The surveys of 92 participants were analyzed. These participants represent a 70 % subset of 130 individuals attending an initial class from 2011 to 2013. (similar data from other participants collected electronically was unusable) This subset did not differ from the overall group in demographics, medical burden, attendance patterns and weight loss. Participants were AA women with an average age of 53 years and body mass index (BMI) of 43. Hypertension was present in 65 % and diabetes in 35 %. **Participant attendance:** 33 % dropped-out, 33 % partial completion, 34 % completion. **Participant Weight loss:** for completers ($n=34$) was 78 %, and 52 % lost 5 % or more. **Predictors of Attendance and Weight Loss.** Measures of Baseline diet or exercise habits, home environment, lifestyle and readiness to change eating and activity did not predict program completion or weight loss. Overall sleepiness and fatigue scale scores were not predictive, but those reporting headache with exercise were less likely to complete STRIDES ($p=0.004$) and trended to decreased weight loss ($p=0.0642$). Using the binomial PRIME MD utility, participants reporting ≥ 3 symptoms had less attendance and weight loss. ($p=0.0372$ and 0.0067 , respectively). Higher self-rating on SRC items to take initiative to solve a problem and to stick to a decision were significantly associated with weight loss ($p=0.0475$ and 0.0347 , respectively).

CONCLUSIONS: The STRIDES behavioral weight loss program is variably effective in obese African American urban women from a low income area. This variation is typical among behavioral weight loss programs. Poorer attendance and weight loss were correlated with pre-enrollment exercise-related headache and higher levels of overall physical and mood symptoms. Increased weight loss and program completion were associated with increased self-rated competency for problem solving and persistence. This suggests two areas of study to optimize weight loss results for participants in behavioral weight loss programs. First is assessing whether pre-program assessment and optimization of physical and mood symptoms may improve outcomes. Second, is the testing whether STRIDES program participation changes self-regulation competency skills like for initiating and persisting in personal change efforts. Broader assessments of factors predictive of success among persons with varied characteristics is also needed to optimize resource use and of success rates for participants of behavioral weight loss programs like STRIDES to achieve and maintain clinically meaningful weight loss.

WHY AREN'T MORE PRIMARY CARE RESIDENTS GOING INTO PRIMARY CARE? STUDYING PROGRAM FACTORS THROUGH QUALITATIVE INTERVIEWS WITH PRIMARY CARE RESIDENTS Theodore Long³; Krisda H. Chaiyachati¹; Olatunde Bosu¹; Sohini Sircar⁴; Bradley G. Richards²; Leslie Curry⁴; John P. Moriarty³; Stephen J. Huot³. ¹Yale School of Medicine, New Haven, CT; ²Yale University, New Haven, CT; ³Yale University School of Medicine, New Haven, CT; ⁴Yale School of Public Health, New Haven, CT. (Tracking ID #2192800)

BACKGROUND: Workforce projections indicate a potential shortage of up to 44,000 adult primary care providers by the year 2025. Nearly two-thirds of primary care internal medicine residents do not plan to have a career in primary care or general internal medicine. Previous studies have examined individual level factors such as debt burden as reasons for not choosing primary care careers. However, it remains largely unknown whether residency training environments influence such decisions. We explore contextual and programmatic factors within primary care residency training environments that may influence career choices.

METHODS: Qualitative study based on in-depth, in-person interviews. Three primary care internal medicine residency programs were purposefully selected to achieve diversity on key features in the training environments: exposure to academic general internal medicine faculty and fellowship opportunities, ambulatory training structures, and percentage of graduates retained in primary care. Second and third year residents were interviewed. We used an instrument developed from pilot interviews and existing literature. Three members of the research team independently coded the transcripts and then met to resolve differences. The code structure was developed in stages based on the constant comparative method, using a systematic and inductive approach to generate insights from the comments of the study participants. The research team identified emerging themes and refined codes. We used ATLAS.ti to facilitate data organization and retrieval.

RESULTS: We completed twenty-four interviews (twelve second year residents, and twelve third year residents). The age range was 27–39. Fifteen residents expressed

intentions to pursue a career in primary care. Four recurrent themes characterize contextual and programmatic factors as facilitators and barriers to a decision to continue in primary care. First, residents described cultural features of their training program, including strong mentorship as a key support and lack of prestige in primary care as a negative influence. Second, structural features of the training program included protected time as a supportive mechanism and lack of diversity in outpatient experiences as a constraint. Third, residents described challenges with navigating the health and social care boundary for primary care patients. Fourth, residents reflected on lack of alignment between their pre-residency expectations and the actual practice of primary care.

CONCLUSIONS: Residents enrolled in primary care programs identify experiences in training that may act as facilitators or barriers impacting their decision to enter into a career in primary care. Addressing aspects of training that are potential barriers (such as a lack of diversity in outpatient experiences and resident frustration with their inability to address social needs of patients) and strengthening those aspects of training that may act as facilitators (such as mentorship and protected time away from inpatient responsibilities during primary care rotations) may increase the proportion of residents enrolled in primary care training programs who pursue a career in primary care.

WHY DO EMPLOYERS OFFER WELLNESS PROGRAMS AND HOW DO THEY MEASURE SUCCESS? Joyce W. Tang¹; Margaret R. Moran¹; Pamela Allweiss²; Ronald T. Ackermann¹. ¹Northwestern University, Chicago, IL; ²Centers for Disease Control and Prevention, Atlanta, GA. (Tracking ID #2196109)

BACKGROUND: Workplace wellness programs are an important, but underutilized resource for primary care providers to consider when counseling patients for behavior change. Workplace wellness is a 6 billion dollar industry, with more than half of employers with 50 or more employees offering wellness programs. While cost savings has often been cited as an important reason for offering wellness programs, recent studies have raised questions about the ability of these programs to demonstrate significant cost savings. We sought to conduct an in-depth exploration of employers at the leading edge of the wellness movement to understand their motivations for offering wellness programs and metrics for evaluating success.

METHODS: We used several approaches to identify a diverse array of employers and vendors who are recognized by their peers as leaders in the wellness arena: 1) reviewed lists of recipients of national awards for wellness; and 2) solicited referrals from occupational medicine professional societies, wellness industry organization leaders, and interview participants. We conducted semi-structured interviews with senior leaders from each firm or their vendor partner who were knowledgeable about the firm's wellness strategy and activities. Participants completed a 1 h phone interview. Open-ended questions were used to elicit motivations for offering wellness programs and metrics for success. All interviews were digitally recorded and transcribed. We applied template analysis to code and organize themes. Two investigators reviewed all transcripts and agreed on an initial template. Subsequently, two investigators independently applied the hierarchical template to a set of eight interviews, using NVivo 9 to organize the data. After coding consensus was achieved, a single investigator coded the remaining 16 interviews. The study team worked together to finalize the thematic template.

RESULTS: Our sample included 20 employers and 3 vendors, with representation across 7 industries (mainly manufacturing, education, and healthcare) and all 4 geographic regions of the U.S. The employers ranged in size from 600 to 170,000 employees, with a median size of 17,000. Interviewees included Chief Medical Officers and Wellness Program Directors from employer sites; and Medical Directors at vendor sites. Virtually all participants described wellness under the larger umbrella of health management strategy, which encompasses both disease management and health promotion. Manufacturing companies often described an alignment between their wellness and safety initiatives. Health management programs were viewed as integral to the business strategy due to ability to increase productivity, decrease indirect costs (disability), and contain medical expenditures. Main metrics for success included high employee participation rates, improvement in clinical outcomes (i.e., shift toward a lower employee health risk profile, as measured via health risk assessment and biometric data), and a bend in the overall cost trend. While many employers measured return on investment (ROI) and felt it to be important in demonstrating value to senior leadership, virtually all agreed that it was both challenging to accurately assess and inherently limited in its ability to capture the true benefits of wellness programs (e.g., engagement, productivity).

CONCLUSIONS: Employers approach wellness and disease management under the umbrella entity of health management strategy. Main metrics used to evaluate success (cost trend, shift in employee health risk profile) are aligned with primary motivations for offering wellness programs (decrease cost, improve health). Given that healthcare providers and employers share the goal of improving population health, efforts to better coordinate these efforts should be encouraged.

WHY MEN GET OR DON'T GET TREATED FOR LOCALLY ADVANCED PROSTATE CANCER: PHYSICIANS' PERSPECTIVES Sarah R. Abramson⁵, Jenny J. Lin¹, Ann S. McAlearney⁴, Kezhen Fei², Rebecca Franco³, Nina A. Bickell³. ¹Mount Sinai, New York, NY; ²Mount Sinai School of Medical, New York, NY; ³Mount Sinai School of Medicine, New York, NY; ⁴The Ohio State University, Columbus, OH; ⁵Icahn School of Medicine at Mount Sinai, New York, NY. (Tracking ID #2196281)

BACKGROUND: Locally advanced prostate cancer treatment can improve survival. Yet, black are more likely than white prostate cancer patients to go untreated. We found that 13 % of black and 1 % of white men (25 of 641 men with Gleason Scores ≥ 7 diagnosed at an academic or a municipal inner-city hospital between 2006 and 2013) did not get definitive treatment. We undertook this study to describe physician reasons for treatment recommendation or underuse of definitive surgical, radiation or cryotherapy treatment.

METHODS: We interviewed 15 physicians treating 23/25 underuse patients; 2 physicians were unreachable. Interview summaries were reviewed and analyzed using a grounded theory approach.

RESULTS: Physician and patient factors influencing treatment recommendation and decision-making include: patient biological (age, life expectancy, comorbidities, tumor histology) and social characteristics (treatment logistics, patient lifestyle); physician specialty and financial incentives - 36 % of physicians described reimbursement incentivizing radiation. Among underuse patients, treatment was recommended but not received in 95 % (20/21) of men and was not recommended due to small tumor size in 5 % (1/21). Among men for whom treatment was recommended, 1 went untreated due to inability to afford ADT, 4 patients refused treatment, and the majority (71 %) (15/21) were system failures. Eighty-seven percent of system failures were lost to Urology follow up, yet a quarter of these men had subsequent visits at the hospital. Thirteen percent of system failures were lost "within" treatment- ADT was begun but planned primary treatment never ensued as medical workups proceeded.

CONCLUSIONS: For the vast majority of underuse, treatment is recommended but does not ensue due to loss to follow-up. As significant numbers of men continue to receive care at the treating hospital, there is ample missed opportunity to redress underuse and reduce racial disparities in cancer care. Financial incentives that influence treatment decisions have the potential to increase costs of care.

WILL YOU BE MY FRIEND?: A NATIONWIDE SURVEY OF PRIMARY CARE PATIENTS' ATTITUDES TOWARDS USE OF SOCIAL MEDIA FOR CONNECTING WITH PROVIDERS Priyanka Agarwal⁴, James Colbert³, Joy L. Lee², Katherine C. Chretien⁵, Lisa S. Lehmann¹. ¹Brigham and Women's Hospital, Boston, MA; ²Johns Hopkins Bloomberg School of Public Health, Baltimore, MD; ³Newton-Wellesley Hospital, Newton, MA; ⁴University of California, San Francisco, San Francisco, CA; ⁵Washington DC VAMC, Washington, DC. (Tracking ID #2196286)

BACKGROUND: Although many individuals communicate electronically with text messaging and social media sites such as Facebook, little is known about how they would like to use these tools to interact with physicians. Physicians themselves have little guidance about how to appropriately engage patients on these electronic platforms. This study is the first multi-site survey of primary care patients to assess how patients would like to interact with providers on social media sites, and more broadly assess their preferences for electronic provider communication.

METHODS: A cross-sectional survey study was conducted with patients at four academic primary care outpatient clinics in three US cities. Paper surveys were distributed in waiting rooms to English-speaking patients, and patients were asked about modes and preferences for communication with their primary care physician (PCP). Demographics including age, gender, education, race, and health status were collected. We analyzed the relationship between demographics and electronic communication preferences using descriptive statistics and multivariate logistic regression.

RESULTS: The survey was completed by 491 patients with a response rate of 86 %, recorded at three of the four sites. A response rate could not be calculated for the fourth site (representing 21.2 % of all respondents). Amongst all respondents, 69 % reported using at least one social media site with Facebook being the most popular site (85 % of social media users). Regarding current methods of communicating with their PCP, 64 % of patients use telephone, 47 % mail, 28 % email, 26 % a web portal, 3 % text messaging, and 0.5 % use social media sites. When asked how they would like to communicate with their PCP, 37 % of patients reported interest in using text messaging, 27 % in using an interactive website (e.g. web portal), and 11.1 % reported interest in using Facebook. Respondents who use social media were four times more likely to want to communicate with their PCP using an interactive website to communicate with their PCP (OR 3.9, $p < 0.001$) and were twice as likely to want to use texting to communicate with their PCP (OR 1.9, $P = 0.02$). Multivariate regression analysis found those who were more frequent users of Facebook would like to use Facebook to communicate with their PCP (OR 3.4 $p =$

0.01). In regards to how social media users engage with providers, among Facebook users, only 3 % are currently friends with their primary care physician (PCP), though 26 % of Facebook users reported interest in wanting to be Facebook friends with their PCP (Table 1). Multivariate regression analysis found that gender, education, race, ethnicity and health status did not significantly affect the desire to be Facebook friends with one's PCP. Age, however, did significantly impact the desire to be Facebook friends with one's PCP: Compared with patients aged 18–34, those aged 35–49 were about half as likely to want to be friends with their PCP (OR 0.45, $p = 0.04$), while those aged 65 and over were five times less likely (OR 0.19, $p < 0.001$). Patients using Facebook most days, relative to those using Facebook a few times a month, were three times as likely to want to be friends with their PCP (OR 3, $p = 0.006$).

CONCLUSIONS: While phone and mail are currently the most commonly used means for PCP communication, large percentages of patients would like to use an interactive website or text messaging to communicate with their PCP, and a smaller percentage would like to use Facebook. A majority of primary care patients in our sample use social media, and more engaged social media users were more likely to want to use an interactive web site, text messaging, or Facebook to communicate with their PCPs. If current trends of increased social media use continue, these data suggest that providers and healthcare systems should consider additional electronic means of communicating with their patients and develop unique ways of leveraging web portals, text messaging, and social media. Challenges with privacy and HIPAA will need particular attention on the part of providers. Although few individuals currently are connected through a social media site to their PCP, over a quarter of primary care patients in our sample who use Facebook were interested in establishing a connection to their PCP over social media, and those who were younger and use social media more frequently were more likely to desire such a connection with their PCP. PCPs may want to consider an increased presence on social media sites as a means of communicating information to their patients.

Current & desired 'Friending' of Providers by Primary Care Patients who use Facebook

	Number of patients who would like to be Facebook friends w/the following (%)	Number of patients who would like to be Facebook friends w/the following (%)
PCP	7 (3 %)	74 (26 %)
Other Physician	8 (3 %)	0 (0 %)
Nurse	5 (2 %)	43 (15 %)
Social Worker	5 (2 %)	23 (8 %)
Clinic Staff	5 (2 %)	29 (10 %)

WOMEN VETERANS WITH CO-OCCURRING MENTAL HEALTH CONDITIONS IN VA PRIMARY CARE CLINICS: A MIXED METHODS STUDY Alison B. Hamilton^{2,6}, Natalya Maisel⁵, Elizabeth M. Yano¹, Ruth Klap², Sabine Oishi², Vidhya Balasubramanian³, Fay Saechao⁴, Susan M. Frayne³. ¹VA Greater Los Angeles HSR&D Center, Sepulveda, CA; ²VA Greater Los Angeles Healthcare System, Los Angeles, CA; ³VA Palo Alto Health Care System/Stanford, Menlo Park, CA; ⁴VAPAHCs, Menlo Park, CA; ⁵Veterans Affairs Palo Alto Health Care System, Menlo Park, CA; ⁶University of California Los Angeles, Los Angeles, CA. (Tracking ID #2197845)

BACKGROUND: Co-occurring mental health (MH) conditions are prevalent in the US population and among Veterans. Little is known, however, about providers' perceptions of and experiences with primary care patients who have co-occurring MH conditions. To address this gap in knowledge, we focused on frontline providers' qualitative experiences of caring for women Veterans (WVs) in VHA women's health primary care clinics. Then, to substantiate providers' perceptions of WV MH needs, we analyzed administrative data to ascertain the prevalence of co-occurring MH conditions among these patients, and to examine their MH service utilization.

METHODS: Qualitative component: We conducted semi-structured interviews in fiscal years (FY) 2011 and 2012 with frontline women's health (WH) primary care and MH providers and staff ($n = 96$) from six VA healthcare systems, who described the main MH needs of WVs in their clinics. Quantitative component: We analyzed VHA administrative data for 313,029 FY12 WV VHA primary care patients nationwide, to ascertain the frequency of co-occurring MH diagnoses by mapping ICD-9 diagnosis codes to 16 MH conditions, and to examine MH utilization patterns by number of MH conditions.

RESULTS: Interview respondents pervasively observed that WVs' health, and particularly MH needs were typically "complex," with co-occurring MH conditions alongside psychosocial stressors that complicated the ways in which WVs utilized healthcare services. Participants perceived strong connections between women's trauma histories and eating and sleep disorders, family and relationship difficulties, unemployment, and

housing instability. Providers emphasized the challenges of meeting the needs and coordinating the care of WVs with physical health conditions as well as co-occurring MH conditions, psychosocial stressors, and trauma histories. In particular, providers were challenged by women's inconsistent use of health care (often due to their life stressors), which made it difficult to develop and maintain comprehensive, integrated care and innovative programming. Among 313,029 FY12 WV VHA primary care patients, 48 % had at least one MH condition. Twenty-seven percent of WVs had two or more conditions. The top five MH conditions were Depression (34 %), Anxiety Disorder (17 %), PTSD (16 %), Bipolar Disorder (6 %), and Alcohol Use Disorder (5 %). The most common MH co-occurrences among these patients were PTSD/Depression (11 %) and Anxiety Disorder/Depression (11 %). Among those with two or more MH conditions, 82 % had Depression, and 51 % had PTSD. Among those with one MH condition, 47 % had no MH encounters and 38 % had two or more encounters in FY12; among those with two or more MH conditions, 9 % had no MH encounters and 82 % had two or more encounters in FY12.

CONCLUSIONS: More than one-quarter of WV VHA primary care patients had two or more MH conditions, a finding that is consistent with providers' perceptions that many WVs in VA women's health primary care are "complex" in their healthcare needs. Depression was a prominent MH condition among these primary care patients, as was PTSD particularly among those with two or more MH conditions. Women with two or more MH conditions were utilizing MH services, but almost half of women with one MH condition were not utilizing MH services. WV primary care providers may be especially challenged with prioritizing and coordinating the diverse services needed to address women's physical, MH, and psychosocial needs. With the population of WV VHA users increasing, the system will need to generate innovative ways to address service needs of WVs and their varying degrees of engagement in care.

WOMEN'S AWARENESS OF THEIR CONTRACEPTIVE BENEFITS AFTER THE AFFORDABLE CARE ACT Cynthia H. Chuang¹; Julie Mitchell¹; Diana Velott³; Christopher Sciamanna²; Richard Legro¹; Erik B. Lehman⁴; Lindsay Confer⁴; Carol S. Weisman¹. ¹Penn State College of Medicine, Hershey, PA; ²Penn State Hershey, Hershey, PA; ³Penn State Hershey College of Medicine, Hershey, PA; ⁴Pennsylvania State University, Hershey, PA. (Tracking ID #2199328)

BACKGROUND: The Affordable Care Act (ACA) of 2010 eliminates the cost barrier to contraception for most women with private health insurance by mandating no out-of-pocket cost for FDA-approved contraceptive methods, including long-acting reversible contraceptives (LARCs)—intrauterine devices (IUDs) and contraceptive implants—which are the most expensive and effective reversible methods. However, whether privately insured women are aware of their newly expanded contraceptive benefits is unknown.

METHODS: We report baseline data from the MyNewOptions study, an ongoing randomized controlled trial of an online intervention to assist adult women make informed contraceptive decisions. The sample includes 989 female Highmark Blue Shield members in Pennsylvania between the ages of 18–40. After confirming eligibility (sexually active, not intending pregnancy in the next 12 months, not surgically sterile or having a partner with vasectomy, having Internet access and a valid email address), participants completed a baseline survey including assessment of pregnancy history, contraceptive history, and awareness of contraceptive coverage benefits [To the best of your knowledge, does your health insurance policy CURRENTLY cover these birth control methods at no cost to you (no copay or deductible payment)?—tubal sterilization ("tubes tied"), birth control pills, IUD].

RESULTS: Less than 5 % of women were aware that their insurance covers tubal sterilization, and less than 12 % were aware that they have full coverage for the IUD. Most women (58 %) were aware they have full coverage for birth control pills. Nearly one in five women reported they would change methods if they did not have to worry about cost, of whom 30 % would switch to an IUD and 9 % would switch to the contraceptive implant. Nearly half of the sample (48 %) were possible candidates for LARCs because they were either not intending any future pregnancy or not intending a pregnancy for at least 5 years, but less than 9 % were currently using a LARC.

CONCLUSIONS: We report that privately-insured women in the MyNewOptions study are largely unaware of their expanded contraceptive benefits under the ACA, including coverage for LARCs. For the ACA contraceptive coverage mandate to impact use of effective contraception, raising women's awareness of the expanded benefit is an essential first step. Private insurers, health care providers, and policymakers will need to better communicate the benefit or this could be a missed opportunity to reduce unintended pregnancy among U.S. women.

WORKING AT HOME: RESULTS FROM A NATIONAL, MULTI-CENTER SURVEY OF INTERNAL MEDICINE AND GENERAL SURGERY RESIDENTS

Lisa S. Lehmann^{1,3}; Frances Javier²; Matthew Erlendson²; Laura Skirp²; Mark Mercurio²; Kimberly Davis²; Carrie Thiessen². ¹Brigham and Women's Hospital, Boston, MA; ²Yale School of Medicine, New Haven, CT; ³Harvard Medical School, Boston, MA. (Tracking ID #2198976)

BACKGROUND: With the spread of electronic medical records, residents have increasing opportunities to do patient care work at home. ACGME guidance specifies that patient work at home should count toward the resident hour limits. This study evaluated the amount and type of patient care work residents report performing at home, and why they do so.

METHODS: Residents at 26 internal medicine and general surgery residency programs were invited to take an anonymous online survey about work at home and duty hours. Programs were selected to represent a range of geographic location, size, and academic status. The survey was administered in May and June 2014. When answering questions about work at home, residents were instructed to think only about patient care and to exclude time spent "studying, preparing for presentations, or doing research." Our results were analyzed with standard descriptive statistics in SAS 9.3. We used multivariate logistic regression to determine if demographic variables including specialty and training level were associated with reporting working at home.

RESULTS: Of 1591 contacted residents, 535 completed the survey (response rate 34 %). Sixty percent of all respondents were men, 60 % were Caucasian, 56 % were <30 years old, and 42 % were general surgery residents. Respondent level included PGY1 (38 %), PGY2 (28 %), PGY3 (22 %), and PGY4-5 and research years (12 %). Most residents reported performing patient care work at home, but did not count this toward their duty hours (88 %). Residents worked at home an average of 1–2 h (35 %), 2–5 h (36 %), 5–10 h (14 %), or >10 h (4 %) per week. Work at home included: checking lab and results (92 %), reading charts to prepare for a new rotation (87 %), reviewing patient vitals (75 %), and talking to other residents or attendings (72 %). Surgery residents also frequently reviewed charts for upcoming cases (94 %) and completed operative reports (65 %). Curiosity about patient outcomes (78 %), desire to leave the hospital (74 %), comfort (66 %), and increased time with family (61 %) were the most important reasons for working at home. Thirty percent of residents explicitly did work at home to avoid counting it as duty hours. On univariate and multivariate analysis there was no significant relationship between gender, age, race, specialty, or level and likelihood of reporting working at home.

CONCLUSIONS: Electronic medical records allow the majority of residents to shift some patient care work from the hospital to home. Most residents in our study reported not recording this time as duty hours despite ACGME guidance to the contrary. Our results indicate that residents' sense of responsibility for their patients continues after they leave the hospital, perhaps mitigating concerns about a "shift-work mentality." Given the prevalence of work at home, further research should assess its impact on patient care, resident education, and quality of life.

WORKPLACE WELLNESS INCENTIVES FOR WEIGHT LOSS—A RANDOMIZED, CONTROLLED TRIAL Mitesh Patel^{1,2}; David A. Asch^{1,2}; Andrea B. Troxel¹; Lisa Wesby¹; Victoria Ulrich¹; Jingsan Zhu¹; Wenli Wang¹; Kevin G. Volpp^{1,2}. ¹University of Pennsylvania, Philadelphia, PA; ²Philadelphia VA Medical Center, Philadelphia, PA. (Tracking ID #2196639)

BACKGROUND: More than one-third of adults in the United States are obese. The Affordable Care Act significantly increased the proportion of health benefit premiums available for outcome-based wellness incentives. However, there is little evidence about the effectiveness of longer term wellness incentives to guide the design of health benefit incentive plans for weight loss. The objective of this study was to evaluate the effectiveness of a commonly used approach to employee benefit design (premium adjustment next year) with two alternatives that utilize concepts from behavioral economics.

METHODS: Two hundred employees of a large health system in Philadelphia with a body mass index of 30 or greater were given the goal of losing 5 % of their body weight within 12 months and randomized to control or one of 3 intervention arms: a "standard" arm in which the employee would get \$550 off next year's benefit premiums if goal was met, an "immediate gratification" arm in which the employee would receive \$550 in reductions in their benefit premiums starting as soon as their goal was met, or a daily lottery arm in which each employee had an 18 % chance of winning \$10 and a 1 % chance of winning \$100 each day at work that their weight was below a gradual decline to 5 % weight loss by 6 months and that they maintained their weight goal in the subsequent 6 months. The intervention was designed to simulate a real-world workplace wellness incentive. Scales were placed within the workplace. Participants were allowed to use the scales at any time but only required to weigh in at 6 and 12 months. No other resources or feedback was provided other than informing participants of financial incentives. The

primary outcome measure was mean weight loss by arm at 12 months. The secondary outcome measure was the proportion of employees that met the 5 % weight loss target by 12 months and mean weight loss at 6 months.

RESULTS: Employees in the study sample had a mean body mass index of 36.9 (standard deviation [SD]: 5.3), mean weight of 227.1 lb (SD: 37.6), mean age of 44.9 (standard deviation: 9.8), and were 81.7 % female. At 12 months the mean weight loss for the control arm was -1.53 lbs. (95 % Confidence Interval [CI]: -5.34-2.27) and there were no significant differences compared to the standard incentive arm (Mean: -1.25, 95 % CI: -4.89-2.39, $P=0.92$), the immediate gratification incentive arm (Mean: -0.91, 95 % CI: -5.30-3.48, $P=0.82$), or the daily lottery incentive arm (Mean: -1.39, 95 % CI: -5.12-2.34, $P=0.96$). Mean weight loss at 6 months was similar among the arms. There were no significant differences in probability of achieving the 5 % weight loss goal during the 12 month period for the control arm (20.0 %, 95 % CI: 11.1 %-33.3 %), the standard incentive arm (22.5 %, 95 % CI: 12.9 %-36.2 %, $P=0.77$), the immediate gratification incentive arm (12.5 %, 95 % CI: 5.7 %-25.2 %, $P=0.32$), or the daily lottery incentive arm (20 %, 95 % CI: 11.1 %-33.3 %, $P=1.00$)

CONCLUSIONS: Workplace wellness programs designed to simulate real-world incentives through discounts in health premiums were not effective for promoting weight loss over an extended one year period. A daily lottery incentive unbundled from health premiums was also not effective for promoting weight loss over a one year period. Wellness programs using financial incentives for weight loss need further evaluation and may need to be launched in combination with other engagement strategies.

YOU CAN'T IMPROVE WHAT YOU DON'T MEASURE: A SYSTEMS ENGINEERING APPROACH TO DEVELOPING GEOGRAPHICALLY-MATCHED PATIENT-PROVIDER TEAMS Vimal Mishra¹; Heather Masters¹; Allison E. Phillips¹; Richard Storch²; Shin-Ping Tu¹. ¹Virginia Commonwealth University, Richmond, VA; ²University of Washington, Seattle, VA. (Tracking ID #2196164)

BACKGROUND: Effective health care requires a delivery system that is fully coordinated and interconnected, with teams that share a mental model regarding the plan and goals of care. To achieve this requires structured communication between the physicians and nurses who are on the front line of patient care, yet an increasingly recognized barrier to efficient, patient-centered care is the geographic dispersion of these primary team members. A joint report by the Institute of Medicine and the National Academy of Engineering recommends applying systems engineering methodology to the challenges of health care. This utilization of systems engineering and simulation modeling can provide a relatively inexpensive, data-driven alternative to evaluate complex health care issues leading to improved patient care. The purpose of our analysis was to explore the application of systems engineering techniques to more geographically match patients with their Internal Medicine (IM) teams at an urban medical center with a consistent capacity of over 90 %.

METHODS: Using electronic health records (EHR) we retrospectively extracted admission, bed assignment, and discharge data for IM patients from January 1, 2013 to December 31, 2013. Length of stay data was calculated based on the date and time of both admission and discharge. We developed a current state model using SIMIO simulation software, which was then validated for reliability and accuracy. Building on the validated current state model, we constructed our first experimental model to analyze IM patient volume, including those admitted to housestaff teams, in order to evaluate whether the average IM patient volume could be accommodated by a smaller number of nursing units. The housestaff service currently has five teams each with a capacity of 16 patients, resulting in a total capacity of 80. Three nursing units of interest were identified; each specializing in the care of IM patients with a total bed capacity of 81. The first experimental model was executed for one year and associated metrics were analyzed. Subsequently, 50 iterations of this experimental model were then performed in an effort to decrease variance and error. Building on the first experimental model, a second experimental model was constructed with the inclusion of the following variables: 1) level of patient acuity and 2) bed type. These were of particular interest due to patients' differential utilization of beds and resources depending on the severity of their illness. A node algorithm was created to admit patients to the units with the lowest census, as well as randomly selecting IM housestaff teams to ensure patients were distributed equally. Methods and analyses utilized for the first experimental model were then replicated for the second experimental model.

RESULTS: The first experimental model generated 3953 admissions (the same as original EHR admissions) and these patients were distributed to each of the three units. This model resulted in an average house staff team census of 11.57 (raw EHR data=12.00) with an average of 71 % utilization of patient load capacity for the unit (EHR derived est=72 %) and 72 % housestaff team utilization of patient load capacity. Additionally, the average number of patients across all three units was reported to be 62 with an average of 19 patients per unit. For the second experimental model, analysis of the dataset revealed two different types of patients - those requiring step-down beds and those requiring general

medicine beds. The three units used in our first experimental model had a total of 46 general beds and 35 step-down beds. The proportion of patients admitted to these two types of beds was derived from the EHR and was determined to be 76.5 to 23.5 %, respectively. The second experimental model was then simulated with the inclusion of these parameters. The results showed a general bed utilization of 96 % compared to the step-down bed utilization of 39 %. This bed mismatch increased the average length of stay for general medicine patients to 171 h as compared to 127 h for step-down patients. It also led to increased numbers of patients in the system to 71.

CONCLUSIONS: As exemplified by our analyses and results, simulation and the principles of systems engineering can provide us with a scientific and data-driven method with which to evaluate complex hospital operations processes, which may aid critical decision-making affecting system performance ultimately influencing the ability to provide equitable and quality care. For instance, based on the 2013 admissions data and our first model, we were able to successfully establish the feasibility of admitting all housestaff patients to only 3 units instead of the current practice of 17 units. Additionally through the second experimental model we were able to highlight a resource and demand misalignment that exists on those three units.

*CLINICAL VIGNETTES

A CASE OF POST-CHIKUNGUNYA INFLAMMATORY ARTHRITIS Michael J. Lau; Isabel Preeshagul; Sudha Dubey. Mount Sinai Beth Israel, New York, NY. (Tracking ID #2198967)

LEARNING OBJECTIVE #1: Recognize the presentation and complications associated with chikungunya virus infection

LEARNING OBJECTIVE #2: Manage post-chikungunya inflammatory arthritis

CASE: A 51 year-old woman presented for 3 weeks of hand and foot pain and swelling after returning from a trip to Puerto Rico 3 weeks prior. For the same duration she also noted a rash on her face and arms with subjective fevers, both of which had begun to improve. On exam, she had minimal cervical lymphadenopathy, a faint reticular erythematous rash on both arms including the palms, and mild swelling and tenderness of the proximal and distal interphalangeal joints of her hands and feet. She had normal conjunctivae, her lungs were clear to auscultation, her cardiac exam was normal, and her abdominal exam revealed no hepatosplenomegaly. Labs revealed a normal hemoglobin, white cell count and differential, platelet count, as well as normal transaminase levels and a creatinine of 0.6 mg/dL. Serology revealed positive IgM and IgG for chikungunya virus and negative antibodies for dengue. She was started on a 5-day course of oral prednisone and standing doses of NSAIDs. Her rash and fevers resolved completely, however joint pains recurred after discontinuation of prednisone causing significant disability and inability to sleep. She presented for follow-up 7 weeks after the initiation of symptoms with persistent pain. She was started on a twelve-day course with a slow taper of steroids and was referred to a rheumatologist. Labs on steroids revealed no elevation in sedimentation rate or C-reactive protein, and hand and foot x-rays revealed normal joint spaces. Based on her clinical presentation she was diagnosed with post-chikungunya inflammatory arthritis. She was started on sulfasalazine in addition to the steroid taper. Recurrence of symptoms after she completed steroids required re-addition of a smaller dose of prednisone (2.5 mg daily) in addition to sulfasalazine. On this combination she has had significant improvement of her joint pains.

DISCUSSION: Chikungunya is an arbovirus endemic to west Africa and south and southeast Asia and is transmitted by mosquitoes belonging to the *Aedes* genus. In the late 1990's, the virus' range began to extend to islands in the Indian Ocean, Europe, and more recently to parts of North, Central and South America. The name is derived from a Swahili term meaning "to be bent over," a reference to the debilitating arthralgias associated with the disease. Initial presentation is associated with high fevers, rash, and severe arthralgias most commonly involving the hands, wrists, and ankles. Lab findings commonly include lymphopenia or thrombocytopenia, and increased creatinine and transaminases. While the symptoms are typically self-limited and resolve within 7-10 days, some patients suffer from persistent or worsening arthralgias for months to years after initial presentation. This can be associated with an elevation in serum sedimentation rate or C-reactive protein. It is currently unclear what percentage of patients have symptoms that persist for a longer time. There is no specific treatment for chikungunya virus, and therapy consists mainly of supportive care and anti-inflammatory medication including NSAIDs and corticosteroids. There are currently no anti-viral medications or vaccinations that have proven to be effective. Management also involves ruling out other diseases with a similar presentation, particularly dengue hemorrhagic fever, which can sometimes present as a co-infection and lead to serious complications. Patients with a prolonged duration of arthralgias after chikungunya infection, particularly those with elevated serum inflammatory markers suggesting an inflammatory arthritis, may benefit from treatment with disease modifying anti-rheumatic drugs (DMARDs) including methotrexate or sulfasalazine. Use of DMARDs in this situation is based on expert opinion and several small trials which have

suggested a benefit. In the particular case described here, sulfasalazine and corticosteroids have led to an improvement in the patient's symptoms. In 2014, 3833 cases of chikungunya infection were reported in Puerto Rico and 2021 in the U.S. Of the U.S. cases over 98 % occurred in travelers returning from Central or South America or the Caribbean, while 11 cases in Florida were thought to be due to local transmission. As the number of infected patients in the U.S. returning from travel to Puerto Rico, the Caribbean, or South America is expected to increase, it is imperative for clinicians to be aware of the clinical presentation and management considerations for chikungunya infection and its complications.

A CASE OF ELUSIVE PORTAL VEIN THROMBUS: THE DEVIL IS IN THE DETAIL. Jason M. Duran¹; Yevgeniy Brailovsky²; Jihoon Baang¹. ¹Temple University School of Medicine, Philadelphia, PA; ²Temple University Hospital, Philadelphia, PA. (Tracking ID #2180728)

LEARNING OBJECTIVE #1: Recognize idiopathic portal vein thrombosis and know the clinical and radiological findings that may mimic a gastrointestinal malignancy.

LEARNING OBJECTIVE #2: Recognize the importance of discussing radiologic studies with a radiologist, especially when confronted with a diagnostic dilemma.

CASE: A 57-year-old Caucasian woman presented with abdominal pain, and 1 week of diarrhea. The patient was found to have a fever of 102, mild abdominal distention and tenderness but an otherwise normal exam. She was mildly anemic with significant leukocytosis. She had a recent history of recurrent *Clostridium difficile* colitis after taking ciprofloxacin for a urinary tract infection. Upon admission she was found to have a urinary tract infection and a relapse of her *clostridium difficile* colitis. She was treated with appropriate antibiotics but her abdominal pain persisted. A CT abdomen with contrast was performed which revealed a mass-like lesion in the colon "concerning for metastatic colon cancer", hepatic lesions, moderate amount of ascites, thrombus in the portal and intrahepatic vein and a "heterogenous mass" in the pancreatic head. Suspicion for malignancy was high and the thrombus was thought to be secondary to this malignancy. An aggressive GI work up including a colonoscopy, diagnostic paracentesis, upper GI endoscopy with biopsy of a nodular lesion in the duodenum and endoscopic ultrasound were performed, and all were negative for any significant findings. The pathology of the biopsied tissue was benign in nature. The patient's confusing picture prompted the primary team to discuss the CT findings with a hepatobiliary-imaging specialist that was not involved in the original radiologic readings. It was noted that the pancreatic duct was still intact, making malignancy very unlikely since this would cause destruction of the pancreatic duct. It was concluded that the stranding and "heterogenous mass" noted on the CT scan were secondary changes originating from the portal vein thrombosis. The patient was started on anticoagulation and was discharged with significant resolution of her symptoms.

DISCUSSION: Acute portal vein thrombosis is a condition not infrequently encountered in the hospital. It is being diagnosed more frequently mainly due to the wide availability of ultrasound doppler devices. The clinical presentation of acute portal vein thrombosis is broad and can be easily confused with other conditions that may have similar presentations. Radiologic findings can mimic cholangiocarcinoma or a pancreatic head mass. In our case there were many "red herrings" that guided the team and consultants towards a diagnosis of a GI malignancy. The key element in coming up with the diagnosis was an additional review of our imaging study with a radiologist, also known as radiology rounds. Concerns have been raised regarding the disappearance of traditional radiology rounds, mainly driven by wide spread implementation of PACS and teleradiology, and the impact it may have on diagnostic errors. Our case exemplifies the importance of recognizing the signs and symptoms of portal vein thrombosis, which can mimic GI malignancies, and the significance of traditional radiology rounds, especially when confronted with a diagnostic dilemma.

A CRYPTIC PNEUMONIA IN AN IMMUNOCOMPETENT PATIENT James Higgs; Amanda Fernandes. Baystate Medical Center, Enfield, CT. (Tracking ID #2200179)

LEARNING OBJECTIVE #1: Recognize *Cryptococcus* as a potential source of pneumonia in immunocompetent patients

LEARNING OBJECTIVE #2: Recognize indications for lumbar puncture and treatment of pulmonary *Cryptococcus* in immunocompetent patients

CASE: A 34 year-old Hispanic male with history only significant for juvenile cryptorchidism with prior surgical repair presented with a 1 month history of pleuritic chest pain, fevers, and dyspnea on exertion. On initial presentation, patient was hemodynamically stable and afebrile with exam notable for left lower lung crepitations. Lab work was notable for a WBC of 16,200/mm³ with a differential of 62 % neutrophils, and 7.4 % eosinophils. Chest x-ray showed multiple irregular opacities in the left lung base. The

patient was discharged home that same day with a course of azithromycin for community acquired pneumonia. Given persistent symptoms he returned the following day where CT imaging of his chest showed multiple cavitory and noncavitory lung nodules in the left lower lobe along with left hilar lymphadenopathy. Further workup was negative for urine streptococcus antigen, histoplasmosis antigen and serum *Aspergillus* antibodies. Serum *Cryptococcal* antigen titer was positive at 1:64. Expecterated sputum cultures further revealed *Cryptococcus neoformans* though direct visualization was not possible. Testing for immunocompromised states including HIV and PPD/AFB came back negative. It was decided that a lumbar puncture (LP) would not be performed given lack of neurological symptoms. Patient was discharged on a prolonged course of fluconazole 400 mg daily. Two weeks later, he represented with continued pleuritic chest pain and drenching sweats. He reported only taking 200 mg of fluconazole daily. Patient was afebrile, with a WBC of 11,200/mm³. Repeat CXR demonstrated worsening left lower lobe opacities and he was briefly commenced on vancomycin and piperacillin-tazobactam for concern of potential hospital acquired pneumonia. He also underwent an LP given worsening lung disease which was negative for *Cryptococcal* antigen. It was felt that his chest x-ray finding were consistent with progression of his *Cryptococcal* pneumonia in setting of potentially subtherapeutic fluconazole. Patient was started on 400 mg of fluconazole and after 1 week of improvement was discharged home to complete the remaining course of his treatment.

DISCUSSION: Classically labelled as an opportunistic organism in those with weakened immune systems, *Cryptococcus* can also be associated with lung disease in immunocompetent patients. Most often, patients are asymptomatic and lesions are picked up on radiologic imaging or discovered on lung biopsies for cancer workup. Given the fungus' tropism for the CNS, there is often concern for potential dissemination. Though there is no clear consensus in immunocompetent patients, routine LP is not often indicated given relatively low risk of dissemination to the CNS. However, cases of dissemination have been reported and carry significant mortality. Risks associated with dissemination that may warrant an LP include: weight loss, headache, altered mental status, skin lesions, and serum *Cryptococcal* antigen titer $\geq 1:64$. With mild-moderate respiratory symptoms, isolated *Cryptococcal* pneumonia in immunocompetent patients can be treated with 400 mg per day orally for 6 to 12 months; severe infections should be treated similar to CNS disease with induction therapy with amphotericin B plus flucytosine followed by 12 month consolidation therapy with fluconazole.

A FORTUITOUS FIND IN THE WORK-UP OF A CHRONIC COUGH Irina Kryzhanovskaya. UCSF, San Francisco, CA. (Tracking ID #2199739)

LEARNING OBJECTIVE #1: Review common and an uncommon cause of chronic cough

LEARNING OBJECTIVE #2: Familiarize the internist with a non-tuberculous form of mycobacterium: *M. Fortuitum*.

CASE: A 62 year old Chinese-born woman with history of neurofibromatosis 2 with remote resection of a meningioma reported 1 month of dry cough to her primary care physician. She denied fevers, chills, night sweats, weight loss, difficulty breathing, rhinorrhea, reflux, nausea, vomiting, or chest pain. Additionally, she was planning to volunteer at her grandson's school and needed a PPD checked. As her ROS was unremarkable and physical exam revealed a benign heart, lung, skin, lymph node, head and neck exam with normal vital signs, she was treated symptomatically for a post-tussive syndrome and had the PPD placed. Her PPD was positive and with the continuing cough, a chest x-ray, blood count, and three sputum cultures for AFB were obtained. The chest x-ray and blood count were normal but within a week, one out of three sputum cultures grew a species of mycobacterium. The patient followed up shortly to the primary care clinic noting her cough had significantly improved without any treatment just as the final report for one of three sputum cultures returned with *Mycobacterium fortuitum*. As her imaging was normal, her symptoms resolving, and only one of three AFB cultures positive, she was not prescribed any treatment and recommended to have a non-contrast Chest CT and repeat sputum cultures should her symptoms return.

DISCUSSION: Chronic cough is one of the most common presenting complaints to internists, and awareness of the initial differential diagnosis is imperative. This list includes such causes as medication effect, reflux, post-nasal drip, reactive airway disease, and post-tussive syndrome. Though less common, nontuberculous mycobacterium can also produce a chronic cough. In this case, we present a patient who grew *Mycobacterium Fortuitum* on one of three sputum cultures. *M. Fortuitum* is found in natural and processed water, sewage, and dirt. Most often, this rapidly growing mycobacterium manifests in cutaneous, bone, joint, or ocular infections, with cardiothoracic surgical site skin complications being the most frequent. While immunocompetent hosts rarely develop symptoms (aside from recent reports of cutaneous infections after use of contaminated nail salon footbaths), severe and disseminated disease occurs in severely immunocompromised hosts. With invasive disease, *M. fortuitum* tends to respond favorably to oral antimicrobials such as macrolides and quinolones in combination with IV therapy for a multiple month course. In summary, if initial treatment for some of the more common causes of

chronic cough is not successful, other etiologies such as nontuberculous mycobacterial infection should be considered in the right clinical setting.

A KILLER IN THE CONSERVATORY Patrick A. Proctor²; Thomas Montgomery¹; Robert Sautter¹; James Horton¹. ¹Carolinas Healthcare System, Charlotte, NC; ²Carolinas Medical Center, Charlotte, NC. (Tracking ID #2179932)

LEARNING OBJECTIVE #1: *Scedosporium prolificans* is an emerging and highly lethal cause of culture-negative disseminated infection.

LEARNING OBJECTIVE #2: Almost all cases of disseminated *Scedosporium prolificans* involve immunocompromised hosts.

CASE: A 49 year old man with multiple myeloma presented to the emergency room with chest pain and progressive shortness of breath. He was currently receiving chemotherapy after a bone marrow transplant five months before. His systolic blood pressure was 87 mmHg, heart rate 100, respiratory rate 16, and oxygen saturation 98 % on room air. An S3 heart sound was audible, but there was no murmur. He required ventilatory support within 4 h of admission. An echocardiogram demonstrated severe aortic insufficiency and a large aortic valve vegetation. Two months before, he had been diagnosed with a spinal abscess. Culture of aspirated fluid grew *Scedosporium prolificans* resistant to all tested antifungals, but result was not notified until his presentation at our hospital. Despite reported pan-resistance, we started voriconazole, as this drug has the best evidence for efficacy in cases of *Scedosporium prolificans*. The patient then underwent emergent aortic valve replacement. Massive induration and inflammation of the epicardial fat and soft tissue adjacent to the aortic root was found. Extensive excision and debridement followed, and a bioprosthetic aortic valve was placed. The patient developed complete AV block and ventricular pacing wires were placed. Gram stain of valvular tissue showed pseudohyphae and yeast consistent with *Scedosporium prolificans*. At that time we added terbinafine, Amphotericin B, and caspofungin since there is in vitro evidence of synergy during treatment of *Scedosporium prolificans*. Aortic valve cultures confirmed *Scedosporium prolificans* resistant to all four antifungal agents which were used for treatment. Post-operatively, the patient continued to require intubated ventilation, ventricular pacing, and vasopressors. On hospital day five, the patient's family elected to pursue comfort care, and he expired later that day.

DISCUSSION: *Scedosporium prolificans* is a globally ubiquitous mold found most commonly in soil and water. It is an opportunistic fungal pathogen and an increasingly recognized cause of severe infections among immunocompromised patients. Infection is caused by inhalation of spores or through direct contact with broken skin. The first reported case of *Scedosporium prolificans* infection was in 1984, when an immunocompetent six year-old boy developed osteomyelitis after penetrating foot trauma. In 2009 the Spanish National Center of Microbiology published a series of 162 cases of *Scedosporium prolificans* infection. The most common presentations were disseminated infection (44 %), pulmonary mycosis (29 %), and bone/joint infections (10 %). All of the patients with disseminated infection had some underlying illness which likely weakened their immune response. Eighty percent of those patients were immunocompromised due to a hematologic malignancy, as was the case for our patient. Increased survival was independently associated with surgical excision. *Scedosporium prolificans* is resistant to most antifungals and a high percentage of infections are fatal. In the aforementioned case series, 47 % of infections were fatal, and that increases to 88 % among patients with disseminated infections. Antifungal use was not associated with reduced mortality. Although various antifungal combinations have been associated with anecdotal success, no consensus approach to therapy currently exists. A new azole, albiconazole, is currently in Phase III clinical trials and may provide more effective coverage of otherwise resistant strains.

A PECULIAR CASE OF MULTICENTRIC CASTLEMAN DISEASE Gaurav Goyal²; Kayla J. Kendrick³; Renuka Vivekanandan¹. ¹Creighton University Medical center, Omaha, NE; ²Creighton university medical center, Omaha, NE; ³Creighton University School of Medicine, Omaha, NE. (Tracking ID #2199160)

LEARNING OBJECTIVE #1: Recognize important associations of multicentric Castleman Disease (MCD) with human immunodeficiency virus (HIV) and human herpesvirus 8 (HHV-8) infections, along with the possibility of a neoplastic process in the monoclonal variant.

LEARNING OBJECTIVE #2: Diagnose and manage MCD appropriately

CASE: A 49-year-old female presents with progressively worsening occipital and cervical lymphadenopathy for the past 3 years. The patient also reports fevers, night sweats, chills, malaise, and a non-productive cough. Laboratory studies showed anemia with hemoglobin of 11.3 g/dL and mildly elevated sedimentation rate at 29 mm/h. Other laboratory studies showed normal LDH and C-reactive protein. CT scan of the chest, abdomen and pelvis showed multiple enlarged bilateral axillary, supraclavicular, subpectoral, submental, retroperitoneal, and para-aortic lymph nodes. A right axillary lymph node biopsy was

performed and found to be positive for atypical lymphoid infiltrate, suggestive for MCD. Immediately following these results, a screening HIV1/HIV2 test was performed and found to be positive, with the confirmatory western blot resulting significantly positive as well. At this time, her HIV viral load was found to be 104,000 with a CD4 cell count of 84 cells/cubic mm. The specimen was negative for HHV-8 staining. The molecular studies on the lymph node showed positivity for monoclonal D_H-J_H rearrangement in the IgH gene. Fluorescent in-situ Hybridization (FISH) study on the specimen showed inverted CD4:CD8 ratio and was negative for BCL6, BCL2, MYC and MALT1 loci. A bone marrow biopsy was performed which did not show any tumor involvement. Patient was initially treated with antiretroviral therapy with a combination of elvitegravir, cobicistat, emtricitabine and tenofovir that improved her fatigue and malaise. For her MCD, she was recently started on combination of rituximab and etoposide and has been clinically improving since then.

DISCUSSION: Castleman disease (CD, angiofollicular lymph node hyperplasia) is a rare lymphoproliferative disorder first discovered in 1956. Clinically, CD presents in either a unicentric or multicentric manner. At the time of diagnosis, most patients with unicentric CD are asymptomatic and are often treated with surgical resection. MCD affects more than one lymph node area and tends to be aggressive. MCD presents with systemic symptoms including fever, chills, weight loss, fatigue and night sweats. MCD is often associated with human herpesvirus 8 (HHV-8) infections and predominates in HIV-positive individuals. CD is not a malignant condition. However, MCD has been associated with an increased risk of developing certain malignancies, notably large B-cell lymphomas, follicular dendritic cell sarcomas, and paraneoplastic pemphigus. Kaposi sarcoma is also commonly diagnosed concurrently or sequentially with MCD because the two entities share a common viral pathogenesis. Imaging studies like combined positron emission tomography (PET) and computed tomography (CT) show multiple areas of lymphadenopathy. Laboratory studies show anemia, thrombocytosis, hypoalbuminemia, polyclonal hypergammaglobulinemia and elevated inflammatory markers. Diagnosis is confirmed by excisional biopsy of one of the lymph nodes that shows polyclonal nodal expansion. In the limited number of studies performed to analyze the clonality of plasma cells in CD, very few cases have been found to be monoclonal ¹⁻³. Our case is a rare monoclonal variant of MCD with IgH restriction in the presence of HIV positivity. All HIV-positive patients should be treated with highly active anti-retroviral therapy (HAART) following diagnosis. Additional treatment of MCD depends on the presence of organ failure and performance status of the patient. Patients without organ failure and HIV/HHV-8 positivity can be treated by immunotherapy alone, using siltuximab, tocilizumab or rituximab. In the presence of organ failure and poor performance status secondary to disease itself, combining immunotherapy with chemotherapy in the form of etoposide is recommended. Antiviral therapy in the form of ganciclovir is indicated for HHV-8 positivity. Prognosis in MCD is variable, ranging from an indolent course to a rapidly progressive disease culminating in death if untreated. Presence of monoclonality among lymphocytes may indicate a concurrent neoplastic process. It is therefore, imperative to have a high degree of suspicion for appropriate management of such patients. **References** 1. Soulier J, Grollet L, Oksenhendler E, et al. ABIOTROPHIA DEFECTIVA MENINGITIS AFTER EPIDURAL STEROID INJECTION Jandark Yuseif¹; Omar Al-Shuwaykh¹; Sonikpreet Sonikpreet¹; marissa sardinha²; Talin Nemri²; Khalid Zakaria². ¹WSU/Crittendon hospital medical center, Rochester, MI; ²Wayne State University, Rochester, MI. (Tracking ID #2198667)

LEARNING OBJECTIVE #1: Recognize Abiotrophia Defectiva meningitis as a potential complication of epidural steroid injections.

LEARNING OBJECTIVE #2: Abiotrophia defectiva, also known as nutritionally variant streptococci, resides as oral and upper respiratory tract flora. It has been reported to cause culture-negative endocarditis and bacteremia. We report the first case of Abiotrophia defectiva meningitis.

CASE: An 82-year old female presented with 6 h of decline in mentation. She has a history of lumbar radiculopathy for which epidural steroid injections were administered. Two days prior to presentation, she received an epidural steroid injection which resulted in worsening low back pain and a new-onset severe headache. On the day of presentation, she developed progressive decline in mentation over 6 h and would only moan to painful stimuli. On examination, she was afebrile, had nuchal rigidity and a Brudzinski sign. Computed tomography of the brain revealed pneumocephalus within the lateral ventricles. Dexamethasone was administered and empirically started on vancomycin and cefepim. Fungal meningitis was also considered and voriconazole was added. Lumbar puncture had an opening pressure of 190 mmH2O. The cerebral spinal fluid (CSF) was cloudy. We

immediately examined the CSF gram stain under microscopy, which revealed gram-positive diplococci. We de-escalated antimicrobial therapy to vancomycin and ceftriaxone. CSF analysis revealed a white blood cell count of 1220/microL with 76 % neutrophils, protein of 47 mg/dL, CSF: serum glucose ratio of 0.39. The Patient's mentation returned to baseline the next day. She was discharged on 14-day course of vancomycin and ceftriaxone. Sixteen days later, identification and susceptibility on the CSF culture revealed *Abiotrophia* defective susceptible to both ceftriaxone (minimum inhibitory concentration (MIC) 1.0) and vancomycin (MIC<0.5). She was seen in our ambulatory clinic after completion of therapy with residual neurological deficit.

DISCUSSION: Epidural steroid injections are the most commonly performed intervention in the United States to manage chronic, and subacute low back and neck pain with radiculopathy. As the number of epidural steroid injections is increasing annually, physicians and patients should be aware of potential infectious complications. Fungal meningitis, Staphylococcal Meningitis, and epidural abscess have been reported as infectious complications of epidural steroid injections. The occurrence of *Abiotrophia* Defective meningitis after epidural steroid injections is extremely rare and has not been reported yet. In our case, the combination of worsening symptoms after epidural steroid injection, the forty-eight hours timeline of presentation and the presence of pneumocerebrum on CT of the brain; suggest potential meningeal penetration by the epidural injection. **Conclusion** *Abiotrophia* defective can be a cause of bacterial meningitis secondary to epidural steroid injections. Early recognition, and selection of appropriate management will help in potential cure of the disease.

ACUTE PANCREATITIS-INDUCED TAKOTSUBO CARDIOMYOPATHY IN AN AFRICAN-AMERICAN MALE John M. Franco¹; Saraschandra Vallabhajosyula¹; Saarvaani Vallabhajosyula²; Shashaank Vallabhajosyula²; Amy J. Arouni^{1,3}. ¹Creighton University School of Medicine, Omaha, NE; ²Kasturba Medical College, Manipal University, Manipal, India; ³Nebraska-Western Iowa Veterans Affairs Medical Center, Omaha, NE. (Tracking ID #2196211)

LEARNING OBJECTIVE #1: Recognize acute pancreatitis as a rare trigger for Takotsubo's cardiomyopathy and highlight appropriate management

LEARNING OBJECTIVE #2: Report the first male case and second African-American male presenting with this unique association

CASE: A 55-year old African-American male with a history of recurrent episodes of alcohol-induced acute pancreatitis and alcoholic steatohepatitis, and essential hypertension was admitted to the hospital after several hours of severe, sharp, stabbing, 10/10, non-radiating pain in the epigastrium and left lower sternal border. The pain was associated with diaphoresis, nausea, and yellow, non-bilious, non-bloody vomiting. He reported a 2-week alcohol binge prior to the intensity of the pain restricting his ability to drink alcohol the morning of admission. Abdominal examination revealed epigastric distension, involuntary guarding, and diffuse abdominal tenderness to palpation. Electrocardiogram (EKG) showed normal sinus rhythm with QT-segment prolongation and ST-T segment depression (STTSD) and T-wave inversions (TWI). Initial cardiac biomarkers i.e. troponin-I (TnI) and NT pro-beta natriuretic polypeptide were elevated at 0.29 ng/mL and 4420 pg/mL respectively. Additionally, laboratory parameters revealed elevated serum lipase and amylase at 773 IU/L and 97 IU/L respectively, and metabolic profile demonstrated elevated anion-gap metabolic acidosis with elevated serum lactate and ketones. Serial TnI was trended with peak level of 0.658 ng/mL. Transthoracic echocardiogram (TTE) showed decreased left ventricular (LV) systolic function with LV ejection fraction (EF) 30–35 %. Dilated and dyskinetic apex and hypokinetic segments in mid- and apical-anterior wall, apical lateral wall, mid- and apical-septum and apical inferolateral walls of the LV were noted. Compensatory hyperkinesia of basal segments was noted. Computerized tomographic scan of the abdomen revealed peripancreatic edema and infiltration without necrosis or fluid collections and hepatobiliary ultrasound was negative for obstructive pathology. Emergent coronary angiogram after stabilization demonstrated insignificant mild irregularities in left circumflex and right coronary arteries without obstructive coronary artery disease (CAD). Contrast left ventriculography demonstrated reduced LVEF (25 %) with apical ballooning and hyper-contractile basal segments, consistent with Takotsubo cardiomyopathy (TCM). The patient was medically stabilized on aspirin, metoprolol, and lisinopril. Due to concern for apical mural thrombus formation, the patient was started on warfarin with goal international normalized ratio of 2.0–3.0. Subsequently 3 weeks later, a repeat TTE demonstrated complete recovery of LVEF (60–65 %) with no akinetic or hypokinetic segments. His anticoagulation was stopped since no LV thrombus was noted. He continues to remain sober and is on regular follow-up with substance dependency services.

DISCUSSION: TCM, also variably known as LV apical ballooning, broken heart syndrome and stress cardiomyopathy, is characterized by LV apical ballooning and has been called that due to its resemblance of a Japanese octopus trap, a *tako tsubo*. Typically reported triggers include emotional stress, pheochromocytoma and sub-arachnoid hemorrhage. It has been hypothesized that the pathophysiology of TCM is related to coronary

micro vascular dysfunction, coronary artery spasm, catecholamine-induced myocardial stunning, reperfusion injury following acute coronary syndrome, myocardial micro infarction and abnormalities in cardiac fatty acid metabolism. The Mayo Criteria is the most widely accepted diagnostic criteria, where all four criteria must be met to make the diagnosis: (a) transient hypokinesis, akinesis, or dyskinesis of the LV mid segments with or without apical involvement, (b) absence of obstructive CAD or angiographic evidence of acute plaque rupture, (c) new electrocardiogram abnormalities (either STTS elevation or TWI) or modest elevation in cardiac troponin, (d) absence of pheochromocytoma or myocarditis. Ninety percent of patients diagnosed with TCM are postmenopausal women aged 61–76 years. This is hypothesized to be due to estrogen deficiency. Consistent with the same; the five reported cases of pancreatitis-induced TCM are females over the age of 40 years old. Alcoholic pancreatitis was first implicated as an antecedent physical stressor in a case of 'inverted' TCM in 2006. Since that time, two cases of acute gallstone, a post-endoscopic retrograde cholangiopancreatography study, and an unspecified pancreatitis-induced TCM have been described. In our case report, we described what we believe to be the first reported case of pancreatitis-induced TCM in an African-American male.

ATYPICAL CLAUDICATION IN A YOUNG ATHLETE Sumeet S. Pawar; Robert T. Eberhardt. Boston Medical Center, Boston, MA. (Tracking ID #2193947)

LEARNING OBJECTIVE #1: To review the differential diagnosis and stepwise work-up of exertional leg pain in young patients.

LEARNING OBJECTIVE #2: To recognize chronic exertional compartment syndrome and distinguish it from vascular causes of exertional leg pain.

CASE: A 26 year old male athlete presented with recurrent exertional calf tightness and foot numbness over 2 years. His symptoms only occur during vigorous sports related activities. They worsen if he does not stop and subside after rest. He does not have a history of any injuries. He had normal pulses in the lower extremities at rest. Systemic exam was unrevealing. His blood pressure in all four extremities was within normal limits. Plain radiographs and MRI of his lower extremities were unremarkable. Testing in the vascular laboratory at rest showed normal segmental pressure measurements with an ankle-brachial index (ABI) of 1.24, and normal pulse volume recording waveforms. On exercise testing, the patient developed moderate hemodynamic compromise bilaterally immediately after vigorous exercise with his ABI dropping to 0.74, but no compromise with a standard protocol. Provocative maneuvers did not cause worsening of ankle pressures. CT angiography showed normal arterial vasculature bilaterally. He then underwent exercise compartmental pressure testing that revealed exercise induced increased pressures in the antero-lateral fascial compartments of his legs bilaterally. He subsequently underwent bilateral fasciotomies. After the surgery, the patient experienced resolution of his symptoms.

DISCUSSION: Exercise induced leg pain in young patients has a broad differential of common mechanical causes such as medial tibial stress syndrome (MTSS), stress fractures, chronic exertional compartment syndrome and vascular causes such as popliteal artery entrapment and iliac artery fibroelastosis. This patient's exertional leg pain along with foot numbness resembles the symptomatology of intermittent claudication. Intermittent claudication is classically seen in peripheral arterial disease (PAD) which causes luminal narrowing and limitation of arterial flow. However, foot numbness is often a sign of advanced ischemia in patients with PAD. Various mechanical and vascular causes mentioned above can cause varying degree of exertional leg pain that mimics the pattern of intermittent claudication in the absence of occlusive PAD. Common mechanical causes such as MTSS and stress fractures are diagnosed with plain radiographs and MRI. Non-invasive testing in the vascular lab with the use of different exercise protocols and provocative maneuvers is useful to further characterize the different vascular causes of leg pain. Hemodynamic compromise from PAD, particularly involving the iliac vessels, can often be unmasked in patients with normal resting ABI after exercise testing. Popliteal artery entrapment is an anatomic (or functional) anomaly involving the gastrocnemius muscle that may cause entrapment of the popliteal artery. Exercise testing with provocative maneuvers such as passive plantar flexion and dorsiflexion causes a drop in ankle pressures and imaging reveals the anatomic impingement of the popliteal artery. Iliac artery fibroelastosis is a condition arising from endofibrotic disease and kinking of the iliac artery typically seen in long distance cyclists. Resting ABI are often <0.5 in the affected limb and imaging reveals kinking and intimal thickening of external iliac artery. Advanced vascular imaging with CT or MR angiography confirms the diagnosis of these different vascular causes. The abnormal drop in ABI after rigorous exercise in this patient with normal arterial imaging suggested that the cause may be chronic exertional compartment syndrome (CECS). CECS is an uncommon cause of atypical claudication. The diagnosis of CECS is confirmed by both resting and post exercise compartment pressure measurement. The only effective treatment for this condition is surgical compartment release.

BILATERAL FACIAL PALSY AFTER A CAMPING TRIP Sudhi Tyagi¹; Pinky Jha². ¹Medical College of Wisconsin, Wauwatosa, WI; ²medical college of wisconsin, Milwaukee, WI. (Tracking ID #2160015)

LEARNING OBJECTIVE #1: To recognize facial nerve palsy as a manifestation of Lyme disease

LEARNING OBJECTIVE #2: To learn about diagnosis and management of Lyme disease

CASE: A 19 year old male presented with bilateral facial droop, left worse than right, for 1 day before admission. His symptoms began 2 months prior while working at a summer camp in July in upper Michigan with fever to 104 along with headache and neck pain. Labs obtained then at an ED visit, including LP with CSF culture and West Nile titers, were normal. He was given 1 dose of minocycline which was discontinued since his labs were normal. His symptoms resolved within 2–3 days and did not recur until 10 days prior to admission with return of headaches and malaise. He developed conjunctival injection with bilateral eye watering and was unable to drink water without having it spill out of his mouth, could not smile, noticed slurring while he was talking and a different sensation of taste. His vital signs were within normal limits. Neck movement caused discomfort. He had left-sided weakness with eye closure, decreased left-sided nasolabial crease, was unable to close left side of mouth or puff out his cheeks. His CBC, monospot and West Nile titers were normal. HIV test was negative. His Lyme ELISA test was positive so he was initially treated with oral doxycycline. Subsequently, an LP was performed and CSF studies were consistent with meningitis. The infectious disease team was consulted. Doxycycline was discontinued in favor of IV ceftriaxone for 4 weeks. The diagnosis of Lyme meningitis was confirmed with a positive Lyme western blot test. At a clinic follow-up visit 1 month later, the patient's neurological symptoms had completely resolved.

DISCUSSION: Lyme disease is caused by infection with the spirochete *Borrelia burgdorferi*. The most commonly affected areas include the skin, joints and nervous system. In particular, about 12 % of patient's with disseminated Lyme disease develop nervous system effects. These effects range from central nervous system disease such as meningitis and nerve palsies to peripheral manifestations with radiculopathies. The diagnosis of Lyme meningitis involves a history with possibility of tick exposure, physical exam with focal neurological deficits or signs of meningitis and positive Lyme serologies in blood or CSF. The differential for facial nerve palsy includes Lyme disease, viral meningitis, atypical migraine and HIV. Establishing the correct diagnosis is crucial in determining treatment. Furthermore, distinguishing Lyme meningitis from disease that does not involve the nervous system is important in terms of therapy. Lyme meningitis frequently requires intravenous antibiotics whereas other manifestations of Lyme disease can be treated effectively with oral antibiotics

CANNABIS-INDUCED PSYCHOSIS IN A PATIENT WITH MAGICAL THINKING Laura E. Black²; Joseph Simonetti¹. ¹University of Washington, Seattle, WA; ²University of Washington School of Medicine, Seattle, WA. (Tracking ID #2199409)

LEARNING OBJECTIVE #1: Distinguish cannabis-induced psychosis from a primary psychotic disorder and manage it appropriately.

LEARNING OBJECTIVE #2: Recognize the recently identified relationship between cannabis use and schizotypal personality disorder.

CASE: A 25-year-old Hispanic man with no known psychiatric history was transported to the ED after new onset psychosis and a suicide attempt. On arrival, his family reported 2 months of increasingly reclusive behavior and heavy marijuana use. His father, with whom he lived, reported a "steady decline" in his daily functioning, abnormal sleep patterns, and depressed affect. He attempted suicide by cutting his wrists and throat. A neighbor called emergency responders, who intubated and sedated him prior to transport to a trauma center. On arrival, exam revealed a blood pressure of 138/94, heart rate of 108, 1 cm deep horizontal lacerations on both wrists, and a laceration across his throat. After emergent transfer to the operating room, he was found to have multiple wrist flexor tendon lacerations but no violation of the trachea or major neck vessels. After surgical recovery, he was transferred to the psychiatric service due to continued psychosis, including expansive affect and severely delusional thinking (e.g., he reported he was on a mission to destroy the anti-Christ). He gradually improved over a 29-day hospitalization after starting antipsychotic medications, demonstrating more organized thinking and improved reality testing. He endorsed heavy marijuana use (4 joints/day), longstanding magical thinking, odd dress, idiosyncratic religious beliefs, and preoccupation with conspiracy theories. He lacked close friendships and felt like an "outsider" due to social anxiety. He was subsequently diagnosed with schizotypal personality disorder and discharged home with follow-up.

DISCUSSION: Substance-induced psychosis is characterized by psychotic symptoms that develop in the setting of drug or alcohol use and in the absence of a primary psychotic

disorder. While cannabis intoxication causes transient psychosis-like symptoms (e.g. paranoia, hallucinations), cannabis-induced psychotic disorder (CIPD) persists beyond the period of acute intoxication, and is not attributable to a primary psychotic disorder (e.g., bipolar disorder). The prevalence of CIPD is unknown, in part due to the high prevalence of marijuana use among populations with primary psychotic disorders and difficulty in distinguishing between such disorders and CIPD. Differentiating between primary disorders and purely substance-induced psychosis is difficult acutely; it often requires stabilization of acute psychosis and follow up to monitor for underlying primary disorders. In a study comparing CIPD patients to those with primary psychotic disorders who also used cannabis, CIPD patients on average smoked more marijuana (9 vs. 5 joints/day) and more often had a family history of substance use disorder (28 vs. 10 %)[Rubio 2012]. Another study compared CIPD patients to those with acute schizophrenia and found that CIPD patients more frequently suffered expansive mood and ideation, depersonalization, and visual hallucinations (Nunez 2002), while those with schizophrenia more often present with auditory hallucinations and disorganized speech. A Finnish study of 18,000 patients admitted with substance-induced psychoses found that only 1 % were eventually attributed to cannabis use; 46 % of these eventually developed a psychotic disorder, usually within 3 years of the initial episode (Niemi-Pynttari 2013). While the association between cannabis use and schizophrenia is well known, the relationship between cannabis use and schizotypy is only recently identified. Prospective research has shown that childhood cannabis use is associated with a greater risk of developing schizotypal personality disorder (STPD)[Anglin 2012]. Data from the National Epidemiologic Survey on Alcohol and Related Conditions showed that cannabis users had a dose-dependent increase in psychotic and schizotypal symptoms. Compared to individuals with no lifetime cannabis use, users with cannabis dependence had the greatest risk of psychosis (odds ratio [OR] 3.69) and STPD (OR 7.32)[Davis 2013]. Several hypotheses have emerged regarding the relationship between cannabis use and schizotypy, including that cannabis use causes or accelerates the development of schizotypy through a direct pharmacologic effect (Davis 2013). Treatment of substance-induced psychosis requires stabilization with antipsychotic medications acutely, though medications are often discontinued within months without symptom recurrence. Psychotic symptoms may reoccur with resumption of substance use, underscoring the importance of treating underlying substance disorders. The best-known predictors of cannabis use cessation after a psychotic episode are higher premorbid social/occupational functioning and cannabis use only (vs. polysubstance)[Rebgetz 2013].

CASE REPORT: GROUP A STREPTOCOCCUS TOXIC SHOCK SYNDROME POST HEMITHYROIDECTOMY : REPORT OF A CASE AND LITERATURE REVIEW OF PRESENTING SYMPTOMS Mireille Sayegh¹; Mark Davis¹; Martin Black²; Vicky Tagalak¹. ¹McGill University, Beaconsfield, QC, Canada; ²McGill University, Montreal, QC, Canada. (Tracking ID #2195214)

LEARNING OBJECTIVE #1: Disseminated Group A Streptococcus (GAS) infection and streptococcal toxic shock syndrome following thyroidectomy has previously been described but remains a rare consequence of the surgery. We describe a case and review literature on presenting symptoms and modes of transmission.

CASE: Our patient was a 45 year-old woman admitted in October 2013 for an elective hemi-thyroidectomy for a nodule with pathology suspicious for papillary thyroid carcinoma. Her past medical history was pertinent for thalassemia minor and a remote provoked deep vein thrombosis (DVT). The day of surgery, the patient had reported mild upper respiratory tract symptoms. The surgery progressed in an uneventful fashion. No antibiotics were administered perioperatively. Twelve hours post-operatively, while hospitalized, the patient developed severe emesis, diarrhea, tachypnea and significant musculoskeletal pain. At the time, the patient was afebrile with normal laboratory investigations. During the next six hours, the patient became hypotensive and developed a lactic acidosis despite aggressive fluid resuscitation. The neck wound did not appear infected. Piperacillin tazobactam intravenously (IV), vancomycin per os (incidence of *Clostridium difficile* colitis being common in our institution) and oseltamivir IV were started. She required intubation and vasopressor support with maximal doses of norepinephrine, epinephrine and vasopressin. Continuous renal replacement therapy was initiated for anuric acute renal failure. An echocardiogram showed a globally depressed left ventricular ejection fraction of 30 % and abdominal computed tomography demonstrated pancolitis and the presence of an intrauterine device. Despite all efforts, the patient continued to require maximal support. Initial gram stain showed gram positive cocci in pairs and chains. Forty-eight hours later, blood cultures grew group A streptococcus (*Streptococcus pyogenes*). The serotype was serotype A, T12, emm12, Factor OF +. Her initial antibiotics were discontinued and she was started on Penicillin G IV, clindamycin IV, ceftriaxone IV and vancomycin IV as per protocol in our institution. Furthermore, a daily dose of intravenous immunoglobulin over 3 days was administered. Endotracheal aspirate grew GAS. A pelvic examination showed no purulent discharge, but a swab was positive for GAS. Her intrauterine device was removed. Further imaging and

drainage demonstrated the presence of a large purulent right pleural effusion which failed to grow GAS (Image 1). She was extubated on day 10 and had a favorable course thereafter.

DISCUSSION: Post-surgical GAS is defined as invasive GAS infection that occurs during the first 7 days following surgery [1]. Thyroidectomies are rarely complicated by infection, but invasive GAS has been described as a possible complication of the procedure. An extensive literature revealed 21 cases of severe GAS infections post-thyroid surgery through PubMed and Medline from 1996 to March 2014, in the form of case reports or audits. Of these 21 reported cases, at least 10 were associated with STSS. The case fatality rate of post thyroidectomy GAS is almost 50 % (10 out of 21) based on the reported cases identified. GAS infection post thyroidectomy presented within 24–48 h following surgery and, in many cases, has a fulminant course, requiring ICU admission for hemodynamic support of multi-organ dysfunction. The mode of acquisition appears variable: patient carrier, family member, surgeon or unknown (2–9). Of the cases where details about the clinical course was available (total of 20 cases), 17 reported evidence of a wound infection suggestive of a portal of entry for GAS during the operation. In only 3 cases was the wound intact with no need for exploration or debridement, similar to our case (2, 4, 7). In these three reported cases, the first presented with streptococcal pneumonia; the second with vomiting, hypotension, tachypnea and anuria and the third with fever, thoracic pain and tachycardia. In all three cases the symptoms began within 24–48 h of the thyroid surgery and in each case, the patient was admitted to the intensive care for septic shock and hemodynamic support. One of the three patients died [4]. It can be hypothesized that direct transmission/translocation of bacteria from the throat into the bronchopulmonary tree during intubation was a possible mechanism of spread in our patient's case, as well as the three other similar cases. In our case, the patient was colonized with GAS. Secondary transmission from a member of the operating team is unlikely since there was no evidence of fasciitis or surgical wound infection. As in our patient, the emm12 serotype of GAS has been reported in other STSS cases [10]. In view of our patient having a prior history of GAS pharyngitis treated with antibiotics, it is strongly suspected that endotracheal manipulation during intubation in the setting of GAS colonization resulted in bacterial translocation and invasive STSS.

CASE REPORT: SEVERE IRON DEFICIENCY ANEMIA AND POLYARTHRITIS AS A RESULT OF CHRONIC *ANCYLOSTOMA DUODENALE* INFECTION Caleb Doyle-Burr; Jessica Yee; Taiye Odedosu. New York University School of Medicine, New York, NY. (Tracking ID #219445)

LEARNING OBJECTIVE #1: Recognize hookworm, or *Ancylostoma duodenale*, infection in patients with severe iron deficiency anemia from endemic regions

CASE: Fifty-four year-old Bengali man with gastric reflux and hemorrhoids presented with 1-month onset of progressively worsening upper extremity joint pain and fatigue. The patient reported swelling, pain, stiffness and weakness bilaterally in his wrists, metacarpal, and distal and proximal interphalangeal joints. Daily naproxen had provided no relief. He denied any recent fevers, weight loss, night sweats, history of arthritis, blood disorders or autoimmune conditions. He had no sick contacts, no dietary changes and denied rashes of any kind. He had no changes in bowel habits. He denied a drinking history or excessive anti-inflammatory use. He has known asymptomatic hemorrhoids, but denied prior screening colonoscopy. Notably, the patient moved from Bangladesh two years prior to presentation. On presentation, vital signs were unremarkable, but scleral pallor and remarkable koilonychia of his finger nail beds were noted. Rectal exam was absent for masses or lesions. Fecal occult blood test was negative. Joint exam revealed tenderness to palpation on dorsal aspect of hands bilaterally with notable swelling of second and third metacarpophalangeal joints bilaterally. The patient was unable to make a fist or grasp objects. Routine laboratory revealed a hemoglobin of 7.4 g/dL, mean corpuscular volume of 54 and undetectable ferritin. He had a mildly elevated eosinophil percent count of 6 %. Rheumatoid factor, cyclic citrullinated peptide, Lyme serologies and erythrocyte sedimentation rate were negative. As part of his anemia evaluation, a colonoscopy was performed, and found numerous mobile, translucent nematodes within the cecum. Subsequent examination of stool for ova and parasite were unrevealing but images captured during colonoscopy were consistent with hookworm infestation. The patient was given oral albendazole 400 mg and discharged with oral iron supplementation and ibuprofen. Prior to discharge, the patient reported improved joint pain and range of motion. At 1-month follow-up, the patient's hemoglobin had recovered to 14.1 g/dL.

DISCUSSION: The global burden of hookworm infestation is substantial. With an estimated 438.9 million people infected in 2010, it is one of the three most common soil-transmitted infections along with *Ascaris lumbricoides* and *Trichuris trichiura*. Hookworm is thought to be responsible for the most years with lived with disability (4.98 million years) [1]. In Bangladesh, the birth place of our patient, a 2003 study revealed that more than 50 % of students aged 5 to 13 had stool samples indicative of intestinal parasites. Of those, 10.7 % were due to hookworm. [2] There are two common subtypes of hookworm known to infect humans: *Ancylostoma duodenale* and *Necator americanus*.

It is acquired via direct skin contact with soil contaminated by human waste. Hookworm larvae can penetrate dermis and migrate to blood vessels, where they eventually proceed to the lungs. The larvae penetrate alveoli and migrate superiorly into the pulmonary tree. Eventually they ascend far enough to be swallowed with saliva and enter the GI tract where they mature into adults typically 1 cm in length and can survive for up to 14 years. While uncommon in developed countries, helminthic infection, especially of hookworm, should be on the differentials in patients with iron deficiency anemia and eosinophilia from an endemic region. Iron deficiency anemia, as seen in our patient, is common to hookworm infections due to their large buccal cavities attached in the GI tract. Blood loss can be as high as 0.3 mL/day per adult hookworm, especially in *A. duodenale* infection. [3] As worm burden increases, so does the severity of anemia. Eosinophilia is a hallmark of hookworm infection, although not all patients with helminthic infection will present with eosinophilia. Numerous factors, including parasitic burden and duration of infection, can dampen immune response while an acute infection increases the likelihood of eosinophilia [4]. Although our patient's eosinophilia was unimpressive, his disease burden was high and the duration of his infection was likely prolonged given the severity of his anemia. Thus, we postulate his immune system became sensitized to the pathogen over time. Additionally, the patient presented with a bilateral, symmetric polyarthritis of unknown etiology, with partial resolution of symptoms after colonoscopy. There is one case report of a reactive arthritis with involvement of sacroiliac joint secondary to presumed hookworm infection, associated with significant eosinophilia [5] Given that a curious immunogenic relationship may exist between nematode infestation and reactive arthritis, perhaps it is not surprising to know that hookworm infection is currently investigated for its ability to suppress the immune system with potential for treating reactive diseases such as asthma. [6]

CATASTROPHIC PNEUMOCOCCAL MENINGITIS IN A PATIENT WITH AUTOSPLENECTOMY FROM LUPUS/ANTIPHOSPHOLIPID ANTIBODY SYNDROME Khushboo Sheth²; Aaron Snyder³; Ulysses Wu¹; Bimalin Lahiri¹; Prashant Grover¹. ¹Saint Francis Hospital, Hartford, CT; ²University of Connecticut, Hartford, CT; ³University of Connecticut, Farmington, CT. (Tracking ID #2191825)

LEARNING OBJECTIVE #1: To diagnose splenic infarction based on radiologic findings and the importance of vaccinations and early antibiotics in asplenic patients

LEARNING OBJECTIVE #2: To suspect and perform hypercoagulable workup in patients presenting with evidence of end organ damage (splenic infarcts and abdominal pain) due to ischemia

CASE: We present the case of a 26 year old female with past medical history significant for stercoral ulcer, complicated by bowel perforation who presented to the Emergency Department (ED) complaining of abdominal pain, vomiting, headache, subjective fever and facial pain. She was alert and oriented in the emergency department on arrival. She was given pain medications and fluids in the ED and basic labs were ordered. Four hours after her initial presentation, the patient was obtunded and minimally responsive to commands and intubated for airway protection. On repeat physical examination, her pupils were noted to be dilated and sluggish, with no corneal, cough or gag reflex. Stat computerized tomography (CT) scan of the head was negative for acute process and she was started on broad-spectrum antibiotics for suspected infection. Stat Magnetic Resonance Imaging (MRI) of the brain was suspicious for meningitis. Lumbar puncture was positive for *Streptococcus pneumoniae*, with protein 924 mg/dL, glucose <10 mg/dL, and white blood cells 3120 /UL with 86 % polynuclear cells. Old records were reviewed. The patient's spleen was small in size compared to prior abdominal CT. On an initial admission CT for bowel perforation, the spleen was 8.5 cm on coronal section with a wedge-shaped pattern appearing to be a splenic infarct. Three months later, on admission with meningitis diagnosis and repeat abdominal CT noted the spleen 5.5 cm on coronal section. She had received Pneumococcal polysaccharide vaccine (PPSV 23) on her previous admission with low *streptococcus pneumoniae* antibody response to the vaccine except for a few subsets. Pathologic report findings from her previous bowel perforation (documented as stercoral ulcer) showed ischemic mucosal injury pattern with mesenteric fat necrosis and intravascular organizing thrombi. During a prior admission, hypercoagulable workup was initiated and noted a positive antinuclear antibody (ANA) with a titer of 1:5120 and positive antiphospholipid antibodies (Lupus anticoagulant IgM 22 M units, Beta 2 Glycoprotein IgA 47 A units, Anticardiolipin IgM 39 M units). The rest of the hypercoagulable workup including protein C, protein S, antithrombin III, homocysteine, and Factor V Leiden mutation was negative. Further workup revealed positive anti double stranded (ds) DNA antibody; anti Ro/SSA antibody >8 and Anti La/SSB antibody >8. Her C3 was normal and C4 and CH50 were low. The patient underwent 2 weeks of meningitis treatment with ventilator support without any clinical or neurological improvement. Repeat CT head was consistent with cerebral edema and anoxic changes. Goals of care were addressed with family, treatment was withdrawn and unfortunately the patient passed away. Her autopsy findings were significant for a possibly infarcted spleen which weighed 35 g.

DISCUSSION: Systemic lupus erythematosus (SLE) is a chronic inflammatory disorder characterized by multiorgan involvement. Antiphospholipid (ApL) antibodies are positive in 33 % of patients with SLE. Antiphospholipid antibody syndrome (APS) is an acquired thrombophilia, caused by autoantibodies to beta 2 glycoprotein, lupus anticoagulant or anticardiolipin. Splenic involvement is seen in 9–20 % of patients with SLE. Autopsplenectomy can occur in patients with SLE due to vasculitis or due to splenic artery thrombosis. Splenic artery thrombosis is more commonly seen in patients with positive ApL antibodies. Thrombocytosis along with presence of Howell Jolly bodies, target cells, ovalocytes and spherocytes on peripheral smear, and evidence of atrophic spleen on imaging studies are imperative tip-offs of autopsplenectomy among these patients. Asplenic patients must be vaccinated against encapsulated organisms. Prompt initiation of antibiotics in asplenic patients with symptoms suggestive of infection; along with vaccination; have shown to reduce mortality. Mesenteric vasculitis and infarction are life threatening lower gastrointestinal manifestations of SLE. These patients may develop necrotic bowel segments, sepsis or perforation of their intestine. Patients with SLE can also develop thrombosis causing an acute presentation of the disease; more commonly seen among patients with coexisting APS. Autoimmune conditions, particularly SLE and APS are known causes of hypercoagulable state along with other hematologic conditions. Young patients with pathology findings suggestive of ischemia and vascular thrombosis must undergo a hypercoagulable workup, as early detection of these conditions and initiation of anticoagulants may decrease morbidity and mortality among these patients.

CHEST TIGHTNESS, AMONG OTHER THINGS... Megha Prasad. Mayo Clinic, Rochester, CA. (Tracking ID #2199408)

LEARNING OBJECTIVE #1: –Recognize the clinical findings in a patient with newly diagnosed scleroderma

LEARNING OBJECTIVE #2: –Maintain a wide differential and avoid premature closure or anchoring when managing a nonspecific chief complaint

CASE: A 49 year old gentleman presented to our tertiary referral center to outpatient internal medicine for evaluation of 8 months of shortness of breath and worsening chest tightness in the setting of a known history of asthma for the past 20 years. The patient described worsening symptoms of shortness of breath over the previous 6–7 months. HE denied any associated wheezing, weight loss, or skin rash. His symptoms did not improve with his inhalers. He had been extensively worked up for cardiovascular causes of symptoms to no avail. He had also been prescribed numerous courses of antibiotics and inhalers for presumed asthma exacerbations. After 2 months of shortness of breath, he developed diffuse abdominal pain, worse at the epigastric region. He was evaluated with laboratory testing and imaging, and was diagnosed with gastroesophageal reflux disease. An esophagogastroduodenoscopy revealed a small erosion at the gastric esophageal junction. HE was started on a proton pump inhibitor (PPI). After 2 months of PPI therapy, he continued to have nonspecific symptoms of dyspnea with exertion and at rest, as well as symptoms of gastroesophageal reflux disease. He also developed bilateral hand and forearm swelling, erythema and pain. One month later, he developed chest and neck skin tightness and erythema. He underwent consultation with dermatology in the outpatient setting, and was told that his swelling was likely secondary to PPI therapy. PPI was discontinued, but the patient continued to struggle with worsening symptoms. On presentation to the clinic, the patient described worsening shortness of breath, esophageal reflux and skin tightness over his neck and hands. His vital signs were within normal limits. Physical examination was significant for bilateral sclerodactyly. Skin appeared taut over face and neck as well. Cardiac examination was within normal limits. Pulmonary examination revealed bilateral coarse breath sounds. Bilateral lower extremities were normal in appearance. The patient underwent pulmonary function tests which were consistent with a restrictive pattern, and CT chest which showed NSIP interstitial fibrosis. The patient was positive for anti Scl 70 antibody, and was referred to rheumatology for further evaluation and management of scleroderma.

DISCUSSION: Scleroderma, also known as systemic sclerosis, is a chronic systemic autoimmune disease characterized by hardening of the skin, and can affect multiple organ systems. Our patient presents with signs and symptoms suggestive of limited scleroderma, as he mainly has cutaneous manifestation, esophageal dysfunction, and sclerodactyly. His rapidly progressive interstitial fibrosis, however, makes diffuse scleroderma the more likely etiology. Recent studies suggest that the prognosis for diffuse scleroderma is significantly worse than cutaneous scleroderma. Most often, death occurs due to pulmonary, heart and kidney complications. While there is no cure for scleroderma, relief of symptoms can be achieved with calcium channel blockers and immunosuppressants. There are several experimental therapies currently being studied, including endothelin receptor antagonists and tyrosine kinase inhibitors. Pulmonary involvement with scleroderma is an important finding. This patient struggled with shortness of breath for over 7 months, and his symptoms were attributed to asthma. PFTs did not demonstrate obstructive pattern consistent with asthma however. Interstitial fibrosis is commonly seen

in connective tissue disorders such as scleroderma, and this is important to diagnose early, to initiate appropriate treatment with hopes of preserving pulmonary function. We thus present case with a constellation of symptoms that seemed unrelated. The patient was seen by multiple specialists, but the timing of his symptoms did not allow synthesis of these into a single clinical picture. As the general internist, our evaluation of each component of the patient's complaints revealed a likely correlation between his symptoms. Our evaluation confirmed connective tissue disease as the underlying mechanism responsible for his longstanding symptoms. The patient was initiated on steroids, and will be followed for resolution of symptoms. When managing patients with multiple complaints, it is important to consider a unified diagnosis. Careful history taking and physical examination plays a key role in making the appropriate diagnosis. Moreover, premature closure and anchoring can lead to missed diagnoses, as seen in this patient who was dismissed as having asthma for several months before receiving further evaluation.

CLINICAL DISCORDANCE BETWEEN PAIN AND HYPERBILIRUBINEMIA SHOULD INITIATE EVALUATION FOR REASONS OTHER THAN A HEMOLYTIC OR VASO-OCCLUSIVE CRISIS IN PATIENTS WITH SICKLE CELL DISEASE Ahmad Masroor Karimi; Medhavi Gupta; Abdulrahman Alhathif; Ramen Sakhi; Cherian Verghese. University of Toledo, Toledo, OH. (Tracking ID #2153479)

LEARNING OBJECTIVE #1: Diagnose Gilbert Syndrome in a patient of Sickle Cell Disease with indirect hyperbilirubinemia

CASE: A 33 year old African American gentleman who has known homozygous SCD has been on regular follow up with infrequent hospitalizations. His usual clinical complaints include mild aches and pain only in his arms and legs. Interestingly he has had overt yellow discoloration of the sclera at all times, including when his pain was well controlled and other features of a pain crisis were absent. His medications included Hydroxyurea, Folic acid and Percocets. Over a period of one year, Hct has ranged from 21.5 to 25.4 %. Total bilirubin levels ranged from 12.4 to 13.5 mg/dl with the direct fraction amounting to only 0.6–0.8 mg/dl. Hgb Electrophoresis showed a Hgb S fraction of 84.3 %, A2 of 3.3 % and Hgb F at 12.4 %. He appeared compliant with Hydroxyurea as suggested by his MCV of 107.4. AST was mildly elevated but stable at 48 IU/L. ALT and ALP levels remained well within normal limits. UGT1A1 mutational analysis showed two copies of the 37(TA)8 variant. Presence of this Homozygous UGT1A1(TA)8 gene supports the diagnosis of Gilbert Syndrome.

DISCUSSION: Gilbert Syndrome is a hereditary disorder of bilirubin metabolism with a prevalence of 3–6 % in the general population. It is also known as Benign Familial Hyperbilirubinemia. Co-inheritance of Gilbert Syndrome and homozygous sickle cell disease is uncommon, but needs to be considered in the appropriate clinical setting. This condition results in impaired hepatic conjugation of bilirubin, the final metabolite of heme catabolism. In the liver, Uridine Diphosphate-Glucuronosyltransferase 1A1 (UGT1A1), helps in the conjugation of bilirubin into a water-soluble form that is excreted in bile. A dinucleotide repeat polymorphism, (TA)5–8, in the TATA box of the UGT1A1 gene leads to lower expression of this enzyme leading to chronic unconjugated hyperbilirubinemia. Co-inheritance of Gilbert Syndrome with disorders that increase the turnover of red blood cells can lead to disproportionate elevation of bilirubin levels. These include homozygous Sickle Cell disease, β -thalassemia, G6PD deficiency as well as interestingly with hydroxyurea therapy as well. Regardless of the level of hyperbilirubinemia, patients for the most part remain asymptomatic. Within the context of sickle cell hemoglobinopathies, patients can present with severe indirect hyperbilirubinemia even in the absence of acute pain or hemolytic crisis. If pain is much less than the indirect hyperbilirubinemia and common causes are ruled out, then Gilbert Syndrome should be considered. UGT1A1 mutational analysis will confirm the diagnosis.

EMPHYSEMATOUS GASTRITIS: A RARE CAUSE OF ABDOMINAL PAIN AND SYSTEMIC TOXICITY Andrew C. Rettew; Bilal Shaikh; Kyle M. Bennett; Asad Jehangir; Jonathan M. Nesfeder. Reading Health System, Reading, PA. (Tracking ID #2199203)

LEARNING OBJECTIVE #1: Differentiate gastric emphysema from emphysematous gastritis

LEARNING OBJECTIVE #2: Recognize appropriate management options for emphysematous gastritis

CASE: A 61-year-old male with a past medical history of insulin-dependent diabetes mellitus and ulcerative colitis status post total colectomy with ileo-anal anastomosis 12-years prior presented to the emergency department with severe and diffuse abdominal pain of 24 h duration. The pain was initially associated with non-bloody diarrhea, which then transitioned to multiple, violent episodes of non-bloody emesis with nausea, fevers, and chills. Upon arrival the patient was hypotensive and toxic-appearing. Initial laboratory investigation revealed an elevation in serum creatinine to 3.38 mg/dL (range: 0.50–

1.50 mg/dL) from a baseline of approximately 1.2 mg/dL, as well as a leukocytosis of 20.9×10^3 cells/ μ L (range: 4.8 – 10.8×10^3 cells/ μ L). A mild anion gap metabolic acidosis was also identified with a serum bicarbonate of 14.6 mEq/L (range: 24–31 mEq/L) and a lactate of 3.5 mEq/L (range: 0.5–2.2 mEq/L). A non-contrast computed tomographic study was obtained, which identified several distinct, yet potentially worrisome findings—air within the wall of the stomach, portal venous gas involving the left hepatic lobe, and air within the peri-gastric veins. Given the preceding clinical picture in addition to the radiographic findings, a diagnosis of emphysematous gastritis was made and emergent surgical consultation was obtained. Given the patient's previous history of a total colectomy the decision was made to attempt to manage him medically in an effort to prevent significant morbidity related to absence of both colon and stomach. The patient was admitted to the surgical intensive care unit and started on broad spectrum antibiotics, in this case piperacillin-tazobactam, provided aggressive fluid hydration, and started on a proton pump inhibitor drip. Over the ensuing week the patient's abdominal pain subsided, laboratory studies returned to baseline, and repeat computed tomographic evaluation revealed resolution of the previous findings. The patient was discharged home on hospital day 8 without complication on oral proton pump inhibitor therapy and several additional days of oral antibiotics.

DISCUSSION: Emphysematous gastritis is a rare clinical entity that is associated with significant morbidity and mortality. A result of local infection with gas-forming microorganisms by way of a mucosal defect or hematogenous spread from a distant site, this condition is quite rare given the innate defenses of the stomach, including its acidity, mucosal barriers, and plentiful blood supply. Diagnosis is based on clinical features and characteristic radiographic findings. Radiographically, air within the wall of the stomach can represent one of two clinical entities, emphysematous gastritis or gastric emphysema, the latter being an asymptomatic and benign incidental finding. Gastric emphysema is characterized by thin, linear lucencies within the stomach wall, while emphysematous gastritis is characterized by gas bubbles within the stomach wall with a "mottled" appearance as well as gas within the portal venous system. Our patient had a classic presentation including radiographic features as well as clinical and laboratory findings. Interestingly enough, our patient did not have any of the oft reported risk factors such as recent abdominal surgery/trauma, ingestion of corrosive substances, chronic alcohol abuse, or significant use of non-steroidal anti-inflammatory agents. Prompt diagnosis of this condition is quite important as early initiation of broad spectrum antibiotics and fluid resuscitation are paramount as mortality has been reported as high as 60–80 % and morbidity (e.g. gastric strictures) as high as 25 %. Surgical intervention is warranted in the setting of perforation, gastric infarction, or failed medical management. Early recognition and aggressive therapeutic intervention of emphysematous gastritis is crucial for successful patient outcomes.

EXTRA! EXTRA! SHORTAGE OF FLUCYTOSINE! Charmi Patel^{1,2}; Hiren Patel²; Dustyn E. Williams^{1,2}. ¹Tulane University, New Orleans, LA; ²Baton Rouge General Internal Medicine Residency, Baton Rouge, LA. (Tracking ID #2158483)

LEARNING OBJECTIVE #1: Contrast the limited modalities of treating Cryptococcal Meningitis in an AIDS patients

LEARNING OBJECTIVE #2: Provide risk benefit analysis for nephrotoxic medications and nephron sparing therapies

CASE: A 26 year-old African American male presents with a witnessed seizure. Upon arousal he complains of headache, neck stiffness, photophobia and phonophobia. He has a history of recently diagnosed AIDS with a known CD4 count of 34 cells/dL, for which he is not yet taking medications. His vitals are 150/60 mmHg, 64 beats per minute, 14 respirations per minute, and he has a temperature of 38.4 °C. He is no longer post-ictal and demonstrates nuchal rigidity, mild ptosis on the left eye and overt phonophobia. Jolt-acceleration test is positive. Kernig and Brudzinski signs are negative. Creatinine is 0.6 mg/dL on admission. Complete blood count reveals microcytic anemia. Computed Tomography of the brain is unremarkable. Lumbar puncture has an elevated opening pressure of 31cmH2O, gram stain showing yeasts, and a Cryptococcal antigen of >1:2560. He is started on Flucytosine and liposomal preparations of Amphoterecin. Culture of cerebrospinal fluid grows Cryptococcal Neoformans. On day six a national shortage of Flucytosine is announced, and Flucytosine is switched to high-dose Fluconazole (800 mg daily). On day eight his creatinine rises to 1.1 mg/dL, and rises again to 1.3 mg/dL on day nine. Intravenous fluid boluses of normal saline are administered prior to and after Amphoterecin administration which is delivered via slow-infusion protocol. He successfully completes a 14 day-course of Amphoterecin induction and is discharged with a creatinine of 2.0 mg/dL to complete a 21-day course of single-agent fluconazole consolidation therapy.

DISCUSSION: The standard of therapy for HIV-associated Cryptococcal meningitis is an induction phase with Amphotericin B in combination with Flucytosine for fourteen days, followed by a consolidation phase with high-dose fluconazole for 21 days. Flucytosine is

not widely available world-wide and we present a case during a time of Flucytosine shortage in the United States. Therefore, it is imperative that the general internist understand the potential alternative therapies and their comparative efficacy. In general, fungicidal therapy is superior to fungistatic therapy. The rate of fungal clearance predicts 10 week survival. CSF sterilization by 14 days predicts long term prognosis. Rapid sterilization is associated with decreased rates of relapse. Amphoterecin+Flucytosine has shown to be superior to Amphoterecin+Fluconazole in both mortality and CSF clearance of infection. Fluconazole+Flucytosine has been shown to be effective, but not moreso than Amphoterecin+Fluconazole. Fluconazole monotherapy is ineffective and should not be considered for induction therapy, whether at high-dose or low-dose Fluconazole. If we would have discontinued Amphoterecin for a rising creatinine with Flucytosine still unavailable, it would have left us with single-agent fluconazole for induction. This was an unacceptable alternative. The hospitalist should anticipate renal failure during Amphoterecin administration. Efficacy of nephron-protective strategies during the administration of amphotericin has been poorly studied, though data suggests that diuretics and mannitol are ineffective, liposomal preparations are effective, while salt loading may be beneficial in alleviating amphotericin-induced nephrotoxicity. Given the option of sub-optimal therapy with single-agent fluconazole or risk renal compromise by continuing Amphoterecin, we opted to treat with intravenous normal saline prior to and after Amphoterecin administration. A lipid formulation on a slow-infusion protocol was used as well. The patient safely completed induction despite a rise in the creatinine. These authors recommend a risk-benefit analysis on discontinuation of Amphoterecin based on clinical course, duration of therapy at the onset of nephrotoxicity, and degree of rise in the creatinine.

HICKAM'S DICTUM OF GI: DOES THE PATIENT HAVE CELIAC'S OR CROHN'S? HE CAN HAVE BOTH! Jose Ruiz. University of Miami Miller School of Medicine, Fort Lauderdale, FL. (Tracking ID #2192510)

LEARNING OBJECTIVE #1: Raise awareness of the association of Crohn's and Celiac's disease

CASE: Twenty-six year old male with chronic iron deficiency anemia presented with recurrent self-limiting episodes of abdominal pain and nausea relieved by vomiting that started a few months prior and were attributed to Irritable bowel syndrome. No other bowel movement abnormalities were present such as diarrhea, constipation or changes in consistency or composition of stool. He denied any other symptoms on review of systems. Physical examination was remarkable for diffuse abdominal pain only, with no rebound tenderness, no mucosal or skin lesions and normal rectal examination with no blood in stool as per testing. Due to the recurrence of his symptoms, imaging of the abdomen with CT was performed with unexpected findings of high grade small bowel obstruction. Further work-up with small bowel barium follow through revealed multiple areas of narrowing and irregularity in the small bowel suggesting an inflammatory disease. EGD yielded findings of duodenum with cobblestoned appearance, scalloping of the ridges and several shallow erosions. Colonoscopy was remarkable for mild inflammatory changes of the terminal ileum and erosion in the sigmoid colon. This presentation and findings were highly suggestive of Crohn's disease and treatment for it was initiated with mesalamine; however, the results of testing ordered days earlier at the beginning of the work up were surprising for a positive tissue transglutaminase IgA ab suggesting Celiac's disease which would explain this patient's chronic iron deficiency anemia. Pathology report of the duodenal biopsies was also surprising for villous blunting and increased number of intraepithelial lymphocytes which is pathognomonic for Celiac's disease. As the patient continued to have further work-up and treatment, it became more evident that his symptoms were due to a combination of both diseases: Celiac's and Crohn's. Colonoscopy was remarkable for mild inflammatory changes of the terminal ileum and erosion in the sigmoid colon. Microscopic findings of lymphoid aggregates of the entire colon were noted and focal areas of eroded epithelium. Serologic tests were positive HLA-DQ2 mutation which is consistent with his diagnosis of Celiac's disease. Other pertinent results included: negative cANCA/pANCA, borderline high sedimentation rate and elevated CRP at 1.3. Based on these findings, patient was started on a gluten free diet with significant improvement of his symptoms, increased energy and weight gain. However, sporadic relapses of symptoms and imaging showing worsening intestinal strictures prompted concomitant treatment with mesalamine, azathioprine and Humira for better control of both diseases.

DISCUSSION: This case shows an unusual finding of two disease processes as causes for a patient's symptoms. We learn that in most cases, a one diagnosis that explains the signs and symptoms is preferable and more likely than multiple diagnoses. However, for this patient, uncovering a second etiology of gastrointestinal pathology helped him to control his diseases better and to have a better quality of life. On review of literature, we found evidence that there is actually an association of Celiac's and Crohn's diseases which is

being recognized more often with the new advances in testing and increased numbers of case reports. Our learning point and suggestion to the medical community is to be aware of this association and consider testing for Celiac's disease in patients with Crohn's disease.

HIDDEN HEREDITARY HEMOCHROMATOSIS Kaylee J. Shepherd; Yonas Getachew. UT Southwestern, Dallas, TX. (Tracking ID #2195190)

LEARNING OBJECTIVE #1: Recognize that liver dysfunction can be caused by more than one disease process.

LEARNING OBJECTIVE #2: Recognize demographics, laboratory and physical exam findings that should lead to screening for Hemochromatosis.

CASE: A 62 year old Caucasian male with a history of alcohol abuse, recurrent malaria on artemether-lumefantrine, and recent travel to West Africa, presented with 104 F fever, diarrhea, hematuria, and emesis. Evaluation of the peripheral smear showed 5 % parasitemia with *Plasmodium falciparum*. Further workup revealed anemia, severe thrombocytopenia, elevated liver functions tests (AST: 1225 IU/L, ALT: 425 IU/L, total bilirubin: 7.0 mg, direct bilirubin: 4.1 mg, normal alkaline phosphatase and INR), acute kidney injury, and a new diagnosis of HIV (CD4: 438; viral load: 13,398). He rapidly improved with doxycycline and quinidine. He denied any personal history of liver disease, family history of liver/autoimmune diseases, herbal/acetaminophen use, intravenous drug use, high risk sexual behaviors, and tattoos. He had a 30 year history of consuming 3 bottles of wine per week. Physical exam was significant for morbid obesity with no stigmata of liver disease. Abdominal ultrasound (US) revealed hepatic steatosis, hepatomegaly, and increased echogenicity. Other pertinent labs were iron: 170mcg/dL, ferritin: 79,054mcg/L, and transferrin saturation: 69 %. Chronic liver disease studies were significant only for homozygous C282Y mutation. Following treatment of his malaria, his liver function tests normalized at his 4 week follow up visit, but still had evidence of iron overload: iron: 350 mcg/dL, ferritin: 2846 mcg/L, and transferrin saturation: ~ 100 %.

DISCUSSION: Malaria is known to cause elevated LFTs secondary to hemolysis, cytokines, endotoxemia, and hepatic ischemia. The pattern of liver dysfunction in malaria is typically hepatocellular with AST (2–3x ULN) > ALT (2–3x ULN) and decreased echogenicity and hepatosplenomegaly on US. In rare occasions, AST and ALT over 1000 IU/L have been reported. His degree of hepatocellular injury led us to investigate for underlying chronic liver disease. The American Association for the Study of Liver Disease (AASLD) criteria to screen for hemochromatosis are transferrin saturation > 45 %, ferritin > 200 mcg/L in men and 150 mcg/L in women, with or without common features of hyperpigmentation, hepatomegaly, or diabetes. Laboratory finding suggesting iron overload prompted us to evaluate for a HFE gene mutation. Although the diagnosis can be made based on genetic testing, liver biopsy is recommended to assess for cirrhosis in patients with elevated LFTs and ferritin levels > 1000mcg/L as this determines prognosis. Although malaria can rarely cause this degree of elevations in transaminases, in the right clinical and laboratory setting, other causes of elevated liver tests should be investigated, including testing for hemochromatosis.

HOW MANY CASES OF LADA (LATENT AUTOIMMUNE DIABETES IN ADULTS) ARE WE OVERLOOKING IN OUR OFFICE? Ana Abaroa-Salvatierra; Richard Alweis. Reading Health System, West Reading, PA. (Tracking ID #2170940)

LEARNING OBJECTIVE #1: Due to the current lack of guidelines that include diagnostic criteria and early interventions for patients with LADA, primary care providers need a high suspicion to identify and start early intervention in these patients.

CASE: A 33 year old male retired Olympic athlete with presumed type 2 diabetes mellitus on the basis of presentation one year prior with hyperglycemia, absence of ketosis, and obesity (BMI 32 kg/m²), presented to the office due to suddenly uncontrolled blood sugars. He indicated that his fasting glucoses were now above 300; confirmatory fructosamine was 476 mcMol/L. This was after a year of excellent control on metformin (latest A1C was 5.1 % 2 months prior after initial A1C was 9.1 %) and significant weight loss. Patient was compliant with diet and medications, was completely asymptomatic other than noting his high blood sugars, and had no evidence of current infectious process or other diseases identified. He had no evidence of nephropathy, neuropathy, or retinopathy. Family history was positive only for one cousin with type 1 diabetes. Before adding a second oral agent, additional lab work was performed to rule out autoimmune diabetes. The fasting C-peptide was low 0.9 ng/ml (normal 1.1–4.4) and anti-GAD was positive 0.13 nmol/l (normal < 0.02). Patient was then started on Insulin in a basal/bolus regimen and has remained under control since.

DISCUSSION: There is still a wide open discussion about the real existence of an intermediate form of diabetes between type 1 and type 2 diabetes, also known as LADA or type 1.5 diabetes. Since the first description in 1994 of this entity, multiple studies have confirmed a unique form of diabetes with special immunological, clinical, genetic and metabolic characteristics that cannot be classified according to the current Diabetes

guidelines. Studies indicate that this subgroup of patients have a faster progression from diagnosis to insulin requirement in conjunction with insulin resistance and high titers of antibodies, not only against islet cell antibodies but also against other endocrine or non-endocrine organs. With the current lack of a clear definition or guidelines, this case could have been overlooked since the patient did not meet all of the previously proposed criteria of normal BMI and age older than 35. Delay in diagnosis has long-term detriment to patients in this subcategory, as individualized treatment with the early initiation of insulin therapy and possible concomitant usage of some oral agents, e.g. thiazolidinediones, can influence the beta cell loss progression and improve metabolic control. As with all other forms of diabetes, early intervention with the appropriate therapy can decrease progression to the micro- and macro-angiopathic complications.

METHEMOGLOBINEMIA: UNLIKELY CULPRIT Raju Khanal³; Paras Karmacharya¹; Ranjan Pathak²; Anene Ukaigwe⁴; Dilli R. Poudel³; Ana Abaroa-Salvatierra²; Richard Alweis¹. ¹Reading Health System, West Reading, PA; ²Reading Hospital, West Reading, PA; ³Reading Health System, Wyomissing, PA; ⁴The Reading Health System, West Reading, PA. (Tracking ID #2157028)

LEARNING OBJECTIVE #1: To recognize acquired methemoglobinemia even in absence of classical inducing agents.

LEARNING OBJECTIVE #2: To diagnose and manage complications of methemoglobinemia treatment in previously unrecognized G6PD deficiency.

CASE: A 56-year-old-male, on R-CHOP chemotherapy and rasburicase for Stage IV mantle cell lymphoma, presented with shortness of breath and chest tightness for 1 day. He had been using EMLA cream around his port to minimize pain during infusion. Pulse oximetry showed SpO₂ of 86 %, which did not improve even with BiPAP on 100 % FIO₂. Arterial blood gas (ABG) revealed PaO₂ 215 mmHg and SaO₂ 99 %. His EKG, cardiac enzymes and computed tomography scan of the chest were unremarkable. Saturation gap between pulse oximeter and ABG prompted to think about methemoglobinemia. His initial serum methemoglobin was 8.4 %. Repeat methemoglobin was 7.6 % after IV methylene blue and hemoglobin dropped by 3 g/dL with evidence of hemolysis. Peripheral smear showed bite cells and few Heinz bodies, and the G6PD level was low (1.5 u/g Hb). Hemoglobin stabilized after 4 units of packed RBCs and methemoglobin level normalized the next day.

DISCUSSION: Two mechanisms exist in the body to reduce constantly formed methemoglobin by autooxidation to hemoglobin: NADH dependent MetHb reductase (physiologically active) and NADPH dependent MetHb reductase, physiologically inactive, which is clinically important pathway in the treatment of methemoglobinemia. The incidence of EMLA induced methemoglobinemia is unknown, but the risk is increased with large application, application on broken skin, and concomitant oxidizing agents use or drugs that compete for metabolism by CYP450 system or compete for plasma protein binding. Rasburicase induced methemoglobinemia usually occurs within 24 h of its use. However, it can develop as early as 90 min to more than 6 h. So, in our case, methemoglobinemia might have been precipitated by EMLA in the setting of prior rasburicase use, which had likely already saturated the reduction potential of NADH MetHb reductase activity. Our case also developed hemolysis after second dose of IV methylene blue. Screening of G6PD deficiency before rasburicase therapy would have cautioned against the use of methylene blue and subsequently avoided the hemolysis. It could have encouraged the physician to use an alternative therapy such as high dose vitamin C especially in a mild case of methemoglobinemia. Infact it is the drug of choice in G6PD deficiency acting independent to NADPH pathway. It is suggested that high risk ethnicity for G6PD deficiency, including African-American, Africans, Mediterranean and south Asians should be screened for G6PD deficiency before rasburicase administration. However, it may not be practical in emergency situation, such as severe tumor lysis syndrome and severe methemoglobinemia, because it takes 24 to 48 h for test results to be available. To summarize, although uncommon, EMLA can cause fatal methemoglobinemia if used concomitantly with other oxidizing agents such as rasburicase. It is recommended to test G6PD deficiency before rasburicase in people of high ethnicity prevalence, to avoid therapy related complications. However, it may be impractical in emergency situations. In cases like ours with mild symptomatic methemoglobinemia, history of recent rasburicase use, a high risk group for G6PD deficiency, treatment with ascorbic acid would be a safer first option.

NEUROLOGIC ADVERSE EVENTS IN A PATIENT RECEIVING ANTI-TNF THERAPY Dietlind L. Wahner-Roedler. Mayo Clinic, Rochester, MN. (Tracking ID #2192769)

LEARNING OBJECTIVE #1: Recognize the occurrence of neurologic adverse events in patients receiving anti-TNF therapy.

LEARNING OBJECTIVE #2: Reinforce the need of careful patient evaluation by the clinician regarding benefits versus potential harm prior to initiating anti-TNF therapy.

CASE: A 57 year old male patient presented to our institution in July 2014 for evaluation of spells consisting of intermittent blurred vision associated with light-headedness and imbalance of about 6 months duration. These episodes would occur several times a day and lasts for half an hour to one hour at a time. The blurring was described as being exacerbated by increased temperature including warm environments, a hot shower, or even drinking hot soup. The imbalance had been gradually getting worse during the last 6 months and was associated with fatigue and loss of energy. He was seen by a local ophthalmologist and underwent cataract surgery without benefit. This was followed by LASIK surgery, again without help. The patient further had a 13 year history of psoriasis treated with methotrexate which resulted in hepatic fibrosis. In November of 2013, he was started on Enbrel, which he was still receiving at the time of presentation. On physical examination there were plaques of psoriasis involving the scalp, ears, hands and elbows. On neurologic examination Lhermitte's sign was positive. Mild right lower extremity weakness was noted. The right knee reflex was lightly more brisk than the left. The plantar responses were upgoing. There was some reduction in vibration sense in his feet. His gait was somewhat broad-based, and he had difficulty with tandem gait and walking on his heels. Ophthalmologic examination revealed findings consistent with bilateral optic neuropathy. Important laboratory evaluation included a MRI of the head without evidence suggesting demyelinating plaques. However, the MRI of the cervical and thoracic spine showed an abnormal T2 signal on the left at C2 and a second lesion in the lower thoracic cord on the left. Spinal fluid exam showed a raised protein of 93 mg/dL, a low normal glucose of 54 mg/dL, raised IgG and albumin, and was positive for oligoclonal bands. Taking into account the nature of his symptoms, including Uhthoff symptom, Lhermitte symptom, and the MRI findings on the cervical and thoracic spinal cord and considering the CSF results, the diagnosis of MS was made by our neurologists. It was felt that the most likely precipitant for the development of MS in this patient had been the use of a TNF inhibitor. The Enbrel was discontinued and the patient was advised to use narrowband UVB phototherapy, Dovonex 0.005 % cream, and Synalar 0.01 % solution for his psoriasis.

DISCUSSION: Tumor necrosis factor (TNF) is a cell signaling protein involved in systemic inflammation and is one of the cytokines that make up the acute phase reaction. Inhibitors of TNF represent important treatment advances for a number of inflammatory conditions, including rheumatoid arthritis, the seronegative spondyloarthropathies, and inflammatory bowel disease. Five inhibitors of TNF are approved for the treatment of a variety of inflammatory illnesses by the FDA. These are: Etanercept, Infliximab, Adalimumab, Certolizumab pegol and Golimumab. However multiple adverse effects of TNF inhibitors have been identified. These include infections, malignancy, injection site reactions, and infusion reactions, induction of autoimmunity, heart failure and demyelinating diseases. The patient presented here gradually developed symptoms of a demyelinating disease after initiation of Enbrel (Etanercept) and was diagnosed with MS approximately 9 months after begin of TNF inhibitor therapy. The estimated rate of neurological adverse events in patients with rheumatic diseases treated with TNF antagonists has been reported to be 4 %. The mechanisms underlying the predisposition to demyelination or exacerbation of demyelination in patients treated with TNF antagonists is not well-understood. Several hypotheses have been proposed (Kaltsonoudis 2014). In patients who are candidates for anti-TNF therapy a detailed clinical and neurological examination is necessary. Close follow up and appropriate monitoring are essential and when the patients develop symptoms or signs of neurological adverse events TNF antagonists should be discontinued immediately and appropriate tests should be performed. Some rheumatology experts are also cautious about using TNF inhibitors in patients with family histories of MS.

NOT ALL COLIC IS CHOLELITHIASIS: AN UNCOMMON CAUSE OF EPISODIC RIGHT UPPER QUADRANT PAIN Gregory B. Summerville. University of California, San Francisco, San Francisco, CA. (Tracking ID #2195245)

LEARNING OBJECTIVE #1: Recognize the clinical manifestations of extra-pulmonary sarcoidosis of the abdomen.

LEARNING OBJECTIVE #2: Diagnose hepatic sarcoidosis in a patient with biopsy confirmed pulmonary sarcoidosis.

CASE: A 42 year old previously healthy woman, recently diagnosed with biopsy proven pulmonary sarcoidosis, presented with 8 weeks of intermittent epigastric and right upper quadrant (RUQ) abdominal pain. She described the abdominal pain as a constant non-radiating, dull ache that was exacerbated after meals into a sharp crampy pain lasting 30–60 min. She denied nausea, vomiting, diarrhea, melena, hematochezia, fevers, chills, jaundice, or pruritus. She endorsed decreased appetite and weight loss over the last several months. Exam revealed hepatomegaly with liver span measuring 18 cm, negative Murphy's sign, and mild tenderness to palpation and percussion in the RUQ. RUQ ultrasound

revealed marked portal and gastrohepatic lymphadenopathy with mild hepatomegaly, no definite evidence of gallstones, and a normal common bile duct (CBD) with no evidence of intra- or extra-hepatic biliary ductal dilation. Computed tomography (CT) showed an unremarkable gallbladder, diffuse periportal and mesenteric lymphadenopathy, and a hypodense nodule of the spleen. Liver function tests (LFTs) revealed a total bilirubin of 0.9 mg/dL, alkaline phosphatase of 709 u/L, gamma-glutamyl transferase (GGT) of 970 u/L, alanine aminotransferase of 83 u/L, and aspartate aminotransferase of 79 u/L. Despite a normal appearing CBD on imaging, she underwent endoscopic retrograde cholangiopancreatography (ERCP) which revealed a normal ampulla, no obstruction or biliary dilation, mild attenuation in the secondary branches, and draping over the bile ducts suggesting associated lymphadenopathy. Based upon the laboratory, imaging, and ERCP findings, the preponderance of evidence pointed to hepatosplenic sarcoidosis, and the patient was referred to hepatology for evaluation and consideration of systemic therapy for hepatic sarcoidosis.

DISCUSSION: Sarcoidosis, with a prevalence of 10–20 per 100,000, is a clinically important entity with a variety of presenting manifestations, most commonly pulmonary in nature (approximately 90 % have pulmonary disease). However, up to 30 % of patients with sarcoidosis present with extra-pulmonary disease, affecting the integumentary, cardiac, nervous, musculoskeletal, gastrointestinal, and reticuloendothelial systems. Fifty to sixty-five percent of individuals with sarcoidosis have hepatic granulomas on biopsy, and of those with hepatic sarcoid, 25–35 % have LFT abnormalities and only 5–15 % are symptomatic. Symptoms of hepatic sarcoidosis include hepatomegaly, pruritus, pain, fever, nausea, weight loss, and jaundice. African-Americans are twice as likely to have hepatic sarcoidosis as Caucasians. Patterns of LFT abnormalities seen include cholestatic (43 %), hepatocellular (23 %), and combined (34 %). The degree of LFT abnormality is associated with the extent of fibrosis and granuloma burden. Sarcoidosis can involve both the intra- and extra-hepatic biliary tree. Intrahepatic involvement is granulomatous, and usually produces both hepatocellular and cholestatic LFT abnormalities. Extra-hepatic involvement results in stricture, and produces predominantly cholestatic LFT abnormalities. Criteria for diagnosing hepatic sarcoidosis in biopsy-confirmed sarcoidosis without hepatic biopsy, per "A Case Control Etiologic Study of Sarcoidosis" (ACCESS), are: 1) LFTs greater than three times normal, or 2) CT scan compatible plus elevated alkaline phosphatase. On CT, the liver appears homogeneous, with 10–15 % of patients showing hypoattenuating nodules. The gold standard for diagnosis involves percutaneous liver biopsy, which will demonstrate non-caseating granulomas. However, biopsy is usually not initially performed unless there are severe LFT or synthetic function abnormalities. Diagnosis of isolated hepatic sarcoidosis should be one of exclusion given that numerous other clinical entities can cause hepatic granuloma formation, including but not limited to tuberculosis, fungal and parasitic infections, malignancies, drug reactions, and primary liver diseases. Hepatic sarcoidosis is an important entity to diagnose given that it can mimic many other common conditions, some of which include cholelithiasis, biliary dyskinesia, dyspepsia, gastritis, gastroesophageal reflux disease, irritable bowel syndrome, and gastroparesis. Recognition of the clinical signs and symptoms, along with the laboratory and radiographic findings of hepatic sarcoidosis by internists, allows for an expeditious diagnosis without subjecting the patient to unnecessary testing.

QUETIAPINE-INDUCED HYPERTRIGLYCERIDEMIA CAUSING ACUTE PANCREATITIS John M. Franco¹; Saraschandra Vallabhajosyula¹; Timothy J. Griffin^{1,2}. ¹Creighton University School of Medicine, Omaha, NE; ²Nebraska-Western Iowa Veterans Affairs Medical Center, Omaha, NE. (Tracking ID #2196388)

LEARNING OBJECTIVE #1: Recognize rare triggers of acute pancreatitis such as hypertriglyceridemia caused by a rare complication of antipsychotic medications

LEARNING OBJECTIVE #2: Highlight the frequently ignored metabolic complications of quetiapine use for the education of the general internist

CASE: A 50 year-old Caucasian veteran presented with progressive 10/10 epigastric pain radiating to the back, associated with nausea since six days. Additionally, he endorsed fatigue, polyuria, and polydipsia for the past one month. He had a history of bipolar disorder, hyperlipidemia, type-2 diabetes mellitus, morbid obesity, irritable bowel syndrome, generalized anxiety disorder and a history of alcohol abuse. The previous day his primary physician, for these complaints, saw him where routine laboratory parameters revealed triglycerides 3590 mg/dL, lipase 2079 IU/L and elevated blood glucose of 533 mg/dL with a hemoglobin A_{1c} of 10.4 gm%. Admission laboratory parameters revealed pancytopenia with 3.9 leucocytes/mm³, hemoglobin of 12.4 gm/dL and platelets of 129/mm³. Differential leukocyte count revealed 40.8 % neutrophils and 44 % lymphocytes. Metabolic panel demonstrated normal electrolytes, hepatic and renal function. Abdominal ultrasound was unrevealing for gall bladder or bile duct pathology. He was managed conservatively for acute pancreatitis with bowel rest, intravenous hydration and adequate pain controlled. He was started on intravenous insulin for suspected hyperglycemic hyperosmolar syndrome and triglyceridemia. Additionally, he was started on oral gemfibrozil and within 24 h of initiating treatment, the patient's triglycerides decreased to

1334 mg/dL and blood glucose levels were better controlled. The triglyceride levels continued to improve to 684 mg/dL at 72 h. He started to tolerate an oral diet and was transitioned to his home medications of atorvastatin with the addition of fenofibrate. The combination of hypertriglyceridemia, hyperglycemia, and pancytopenia with predominant neutrophil depression made us suspect quetiapine as the cause for these abnormalities. The patient was tapered off of quetiapine over the subsequent two days and ziprasidone was initiated. He was subsequently discharged on hospital day seven with triglyceride levels of 628 mg/dL and serum glucose <200 mg/dL for over 24 h. His leukocyte count was 6,0/mm³ with additional normalization of other cell lines. At 2-month post-hospitalization follow-up, the patient continued to improve with good medication compliance and remained symptom-free.

DISCUSSION: Quetiapine is a second-generation antipsychotic (SGAs) that is frequently-prescribed for patients with major depressive and bipolar-type disorders, shown to significantly reduce the number of psychiatric admissions ($P < 0.001$) and episodes of emergent suicidality compared to placebo (0.3 and 0.5 %, respectively). Metabolic disturbances including hyperglycemia, hypertriglyceridemia are well-documented side effects of SGAs, seen in up to 10 % of patients treated with olanzapine or quetiapine. The mechanism by which quetiapine causes hyperlipidemic disturbances is not entirely understood. Some hypothesize that the medication stimulates hepatic triglyceride production and secretion or alters lipase-mediated triglyceride hydrolysis. Medications are attributed as the cause for only 0.1–7 % of acute pancreatitis cases. Acute pancreatitis caused by hypertriglyceridemia side effects of quetiapine use has only been reported in as few as five published case reports. Hypertriglyceridemia (>600 mg/dL) is frequently reported with quetiapine use in asymptomatic patients, but severe hypertriglyceridemia (>1000 mg/dL) has been reported in fewer than 10 patients treated with quetiapine. SGAs also possess a well-documented side effect of blood dyscrasias, such as agranulocytosis. While this side effect is documented most frequently with clozapine use, seen in up to 3 % of patients taking this medication, quetiapine has also been shown to depress leukocyte cell lines with unknown incidence. Leukopenia associated with quetiapine is most predominantly pronounced by selective absolute neutrophil depression. We reported a case of hypertriglyceridemic pancreatitis likely as a result of caused by quetiapine use. This case also emphasizes the importance of routine laboratory follow-up when initiating therapy with SGAs. We believe that this case study will aid clinicians identify, with confidence, a rarely published serious side effect of a common antipsychotic medication.

RISK OF COLORECTAL CANCER SCREENING IN A PATIENT WITH ADVANCED KIDNEY DISEASE Kaylee J. Shepherd; Anil N. Makam. UT Southwestern, Dallas, TX. (Tracking ID #2192947)

LEARNING OBJECTIVE #1: Polyethylene glycol based preparations can cause volume overload in patients with heart failure and/or renal insufficiency so caution is needed.

LEARNING OBJECTIVE #2: The decision for colorectal cancer screening should be individualized based on life expectancy given the inherent lag time to benefit.

CASE: A 65 year-old male with advanced chronic allograft nephropathy following kidney transplant in 2004 with plans for hemodialysis initiation presented to the hospital's endoscopy lab with shortness of breath and hypoxia. His medical history was significant for heart failure with preserved ejection fraction and 4 tubular adenomas (one 1.5 cm in size) removed in 2011 during a screening colonoscopy. Family history was remarkable for a brother with colorectal cancer (CRC) in his 40s. His initial surveillance colonoscopy 5 months prior was inconclusive because of inadequate preparation, therefore a repeat colonoscopy was ordered with instructions to drink two full doses of polyethylene glycol (PEG)-based preparation during the two days preceding the procedure. When he presented to the endoscopy lab, he was hypoxic with an oxygen saturation of 86 % on room air with symptoms of leg edema and shortness of breath, at which time he was admitted to the Internal Medicine service. Upon examination, his pulse oximetry was 96 % on 3 l of oxygen; he was in mild respiratory distress, had bilateral rales in the lower lung fields, and pitting edema in his lower extremities. Chest X-ray showed moderate bilateral pulmonary edema. He improved following diuresis with furosemide and was discharged two days later.

DISCUSSION: PEG-based preparations are considered to be the safest options, but are still recommended to be used with caution in patients with impaired renal function and heart failure. The dose of PEG that our patient received contained approximately 70.68 g of sodium, the equivalent of 19 l of normal saline. This massive fluid and salt intake was ultimately responsible for his volume overload necessitating hospitalization. Given that this patient was at higher risk for developing CRC due to his family history and personal history of tubular adenomas, surveillance colonoscopy is recommended every 3 years. However, the decision for CRC screening should be individualized based on life expectancy. The rationale for forgoing further CRC screening in patients with short life expectancy is that these patients are unlikely to benefit from screening due to the inherent

time lag, but remain exposed to the risks of the procedure. On average, it takes 10.3 years to prevent 1 death from CRC for every 1000 patients screened. Furthermore, surveillance colonoscopy yields a low incidence of CRC and has a relatively high rate of peri-procedural complications among older adults. For our patient nearing end-stage renal disease, his limited life expectancy and high comorbid burden highlight the importance of shared decision making. During this hospitalization, he decided to forgo further CRC screening, since the risks of CRC screening likely outweigh the benefits. However, in such patients with advanced kidney disease and heart failure who opt to undergo a screening colonoscopy, we recommend a more cautious bowel preparation.

SEROTONIN SYNDROME IN THE SEPTIC PATIENT Maria Nardell. Cambridge Health Alliance, Cambridge, MA. (Tracking ID #2181288)

LEARNING OBJECTIVE #1: Recognize serotonin syndrome in the setting of severe sepsis

LEARNING OBJECTIVE #2: Recognize methylene blue as a precipitating cause of serotonin syndrome

CASE: A 25-year-old male on 80 mg fluoxetine daily presented with peritoneal signs and in severe sepsis with lactic acid of 10. CT showed a perforated appendix. Intraoperatively he received sevoflurane. The surgeon injected two doses of methylene blue intravenously due to difficulty visualizing the ureters. In the recovery room, the patient had a temperature of 103.1 F, heart rate 180 beats per minute, and blood pressure 166/106 mm Hg. He was diaphoretic, agitated and confused. This was initially interpreted as postoperative delirium, and he was given 1 mg haloperidol. Upon careful exam, he had horizontal ocular clonus and rigidity but normal reflexes. Creatinine kinase was 5875 but leukocytosis and lactic acidosis were resolved. Serotonin syndrome, malignant hyperthermia, and neuroleptic malignant syndrome were high on the differential. The patient was intubated and started on midazolam for serotonin syndrome. He was briefly on dantrolene to treat malignant hyperthermia but it was discontinued after it was established that carbon dioxide levels had remained within normal range intraoperatively and on blood gas post-intubation. After initial improvement, several hours later his temperature was 104.5 F despite upward titration of midazolam, a cooling blanket, and acetaminophen. Cyprohepadine, a serotonin antagonist, was given with improvement in temperature and continued with maintenance doses for two days. A low-grade fever with episodes of hypotension and a distended abdomen were concerning for ongoing infection. Repeat CT scan revealed a pocket of fluid in the abdomen and percutaneous drain was placed. Peritoneal fluids grew *Pseudomonas aeruginosa* and antibiotics were broadened. He was extubated on day 8 and discharged on day 12.

DISCUSSION: This case highlights a fulminant presentation of an often unrecognized yet potentially life-threatening condition. Serotonin syndrome is an adverse drug reaction resulting from excess serotonergic agonism of central and peripheral receptors. A clinical diagnosis classically described as a triad of mental status changes, autonomic hyperactivity, and neuromuscular abnormalities, it can be challenging to diagnose given non-specific symptoms and range of clinical severity. This case was additionally challenging due to severe sepsis on presentation and exposure to a volatile anesthetic. The normal white count and resolved lactic acidosis argued against a worsening septic picture. Ocular clonus and rhabdomyolysis were also not explained by sepsis. Decrease in temperature with a benzodiazepine and serotonin antagonist and not with an antipyretic suggested hyperthermia due to serotonin syndrome and not fever alone.[i] Hyperthermia in serotonin syndrome involves serotonin's role in thermoregulation, excess skeletal muscle activity, and vasoconstriction impairing heat dissipation.[ii] Additional features of serotonin syndrome, lower extremity clonus and hyperreflexia, were not significant in this case, but hypothermia induced by anesthesia can suppress these signs.[iii] Neuroleptic malignant syndrome (NMS) and malignant hyperthermia (MH) were also on the differential. In both, rigidity is typically more striking. In contrast to this acute presentation, NMS usually begins one to three days after the administration of a dopamine antagonist. History from family indicated that he did not use antipsychotics, and he received 1 mg haloperidol only after his neurologic symptoms had presented. MH was less likely with no rise in carbon dioxide levels. Alcohol withdrawal or other illicit drug interactions were considered though drug screens were negative, and retrospectively the patient confirmed no ingestions. Thyroid storm was on the differential but TSH was normal. The clincher for serotonin syndrome was discovering the precipitant—two doses of methylene blue used intraoperatively to visualize the ureters. The patient had taken fluoxetine (half-life ~7 days) the day of presentation. There are multiple case reports of serotonin syndrome resulting from the co-administration of methylene blue (half life ~6 h) and a selective serotonin reuptake inhibitor.[iv] Methylene blue is a potent reversible inhibitor of monoamine oxidase (MAO) subtype A. Such inhibitors are strongly associated with severe cases of the syndrome, especially in combination with SSRIs.[v] [i] Florian E, Zilker T. Bench-to-bedside review: Mechanisms and management of hyperthermia due to toxicity. *Crit Care*. 2007;11:236. [ii] Rusyniak DE. severe serotonin toxicity following co-administration of methylene blue and serotonin reuptake inhibitors. *Jr Psychopharm.* 24;2010:1433–8. [iv] Stanford, Risk serotonin, *Jr Psych.* 2010. [v] Boyer E, Shannon M. The Serotonin Syndrome. *N Engl J Med* 2005; 352:1112–1120.

SEVERE HEMOLYTIC ANEMIA : AN EXTREME EXTRAPULMONARY MANIFESTATION OF MYCOPLASMA PNEUMONIAE, IT'S MANAGEMENT AND SUCCESSFUL RECOVERY. kaushik Mandal; Ashir Shah; Craig Thurm; Ritesh Kumar Patel; Apurwa Karki; Sudheer Chauhan. Jamaica Hospital Medical Center, Jamaica, NY. (Tracking ID #2190364)

LEARNING OBJECTIVE #1: About 3 to 10 % of patients with *mycoplasma pneumoniae* develop clinical pneumonia and upto 10 % of the patients develop extrapulmonary complications, involving the central nervous system, cardiovascular, gastrointestinal, and hematological systems. Cold agglutinins specific for I antigen of RBCs are present in 50–60 % of the patients and responsible for subclinical to mild hemolysis; but severe hemolysis is rare. We report a case of severe autoimmune hemolytic anemia secondary to *Mycoplasma pneumoniae*, its early recognition and prompt management of the extreme crisis.

CASE: A 53-year-old female with no known past medical history was admitted to ICU with severe anemia. She was seen by her physician for nonproductive cough 15 days ago and was prescribed amoxicillin-clavulanate for seven days. Patient's symptoms remained the same without worsening until last five days before presentation with rusty productive sputum, associated shortness of breath, fatigue and paleness. No family history of hematological disorder. On physical examination, the patient was very pale and tachycardic (123 beats/min). Blood pressure was 93/56 mmHg and body temperature was 36.3 °C. Chest examination showed rales and rhonchi in the left upper lobe posteriorly otherwise clear without wheeze. Respiratory rate was 26/min. no murmurs. The rest of the examination was unremarkable. Initial blood count showed hemoglobin of 3.9 g/dL, mean corpuscular volume of 97.7 fL, and WBC count of 70,400/mm³, with 54 % neutrophils, 6 % lymphocytes, 1 % monocytes, and a platelet count of 710,000/mm³, reticulocytosis of 12 %. Lactate dehydrogenase (LDH) was 7510 U/L (reference range: 313–618 U/L). Total bilirubin was 2.7 mg/dL (normal 0.2–1.3 mg/dL), of which 2.5 mg/dL was indirect. Haptoglobin was 8 mg/dL (normal 43–212 mg/dL). Liver enzymes ALT: 138, AST: 235, Alkaline phosphatase: 135. Serum chemistry revealed Na⁺: 131, K⁺: 6, HCO₃⁻: 17, BUN/creatinine 21/1.1. Coagulation studies significant for INR: 1.5, D-DIMER: 15092. Lactic acid level was 9.60 (normal 0.00–2.10 mmol/L). A peripheral blood film showed marked leukocytosis and agglutination. Blood, sputum and urine cultures were negative. The chest X-ray showed left upper lobe infiltration. Patient was started treatment with aggressive hydration and broad spectrum antibiotic. Direct Coombs test was positive. *Mycoplasma pneumoniae* IgM and IgG antibody titers were positive too. Cold agglutinins were positive with high titer of 1:5120. CT scan thorax revealed left upper lobe pneumonia with prevascular lymph nodes measuring up to 1.6 × 1.2 and 1.0 × 0.5 cm noted, small right interlobar arteries. The patient was diagnosed with severe hemolytic anemia complicating *M. pneumoniae* infection. She was continued treatment with IV azithromycin 500 mg/day for 2 days, followed with oral therapy, once daily to complete 10 days, 1 mg folic acid daily and packed red cell transfusion (6 units) using in-line blood warmer. She received plasmapheresis once on day 2 to remove IgM antibodies contributing to severe hemolysis. Anticoagulation was not started because of severe hemolytic anemia and also the tiny pulmonary embolus was very unlikely the cause of patient's presentation. The symptoms were rapidly improved and hemoglobin increased to 12.0 gm/dL. The antibiotic was continued for a total of 10 days. The patient was discharged in good health after 7-day hospital stay. On discharge, Hb, blood chemistry and coagulations studies were normal, Cold agglutinins were undetectable. Patient was started on Rivaroxaban for pulmonary embolus. One month after the discharge follow up, she remained clinically well, her physical examination was normal; her hemoglobin was 13.8 gm/dL.

DISCUSSION: Cold agglutinins for I antigens of red blood surface attributes to hemolysis. Ninety percent of these cold agglutinins are mediated by IgM molecules which usually causes hemolysis about six days after pulmonary manifestation. Treatment in setting of severe hemolytic anemia is challenging. In such setting packed red blood cell transfusions can aggravate hemolysis, but evidence has shown the risk of transfusion-related hemolysis could be reduced by using an in-line blood warmer at 37°C and keeping the patient warm as in our case [1]. Use of Corticosteroids, plasmapheresis and cytotoxic drugs has been reported in severe refractory cases [2]. In our case we did early plasmapheresis clearing the agglutinins, which improved patient's condition with supportive treatment and antibiotic dramatically. The purpose of our case report is to emphasize on early recognition and management of such crisis aggressively with all modalities available. **References:** 1. SIPE: A PRICE FOR A PRIZE Mekhala Chandra; Thomas J Nuckton. California Pacific Medical Center, San Francisco, CA. (Tracking ID #2182940)

LEARNING OBJECTIVE #1: To recognize the clinical features and imaging findings of swimming-induced pulmonary edema (SIPE).

LEARNING OBJECTIVE #2: To recognize that SIPE is typically self-limited, but can recur.

CASE: A 37 year-old woman developed sudden-onset dyspnea after completing a long distance swim from Northern Ireland to Scotland (North Channel; total distance 35 km/21 mi). She had previously completed multiple open-water swims, including solo crossings of the English Channel, the Cook Strait, and others. On the day of her North Channel swim, the water temperature was 12.8 °C (55 °F). During the swim she was stung multiple times by jelly fish (*Cyanea capillata*). She successfully completed the swim in 13 h and 6 min. Rough seas required her to swim at maximal effort during the final hour. Shortly after completing the swim, she developed acute-onset dyspnea without chest pain. She was admitted to a local hospital with a respiratory rate of 28, room-air SPO₂ of 83 %, and crackles on exam; BP and HR were normal. CXR revealed diffuse bilateral opacities. She was given supplemental oxygen and antibiotics, but no diuretics. She improved and was discharged the following day. After flying back to her home in the U.S., dyspnea with pleuritic pain persisted. 6 days after the swim she was again admitted to a hospital with mild tachypnea and room-air SPO₂ of 87 %. BP and HR were normal. Chest CT was negative for emboli and showed modest bilateral pleural effusions (R>L) with minimal airspace consolidation. She was started on antibiotics, given a single dose of Furosemide 20 mg IV, and admitted with supplemental oxygen to a telemetry ward. 2-D Echo was normal. She improved gradually and was discharged to home on hospital day 3.

DISCUSSION: SIPE was first described in 1981 by Wilmshurst, et al., and has been reported in previously healthy swimmers, divers, and military personnel. SIPE is characterized by sudden-onset cough, dyspnea, confusion, and hypoxia. While the exact pathophysiology remains uncertain, it has been associated with exertion and colder water. Hydrostatic pressure from water on the extremities, combined with cold-induced vasoconstriction, may increase central blood volume. Pulmonary hypertension related to exertion may cause an increased pressure gradient across the pulmonary capillaries. Overhydration and maximal exertion may have contributed to SIPE in our patient. Jelly fish stings and aspiration of seawater may have also contributed. Treatment of SIPE consists of supportive measures. Diuretics are of questionable benefit but have been used in some case series. Recurrence of SIPE is difficult to predict. Careful questioning revealed that our patient had dyspnea after a long-distance swim in cold water 2 years earlier. Slower-paced swimming in warmer water may be of benefit.

SPORADIC SUPERIOR MESENTERIC ARTERY DISSECTION WITH BACK PAIN Tamaki Kakuwa²; Christine Kwan¹. ¹Teine Keijinkai Hospital, Arlington, TX; ²Teine Keijinkai Hospital, Sapporo, Japan. (Tracking ID #2199948)

LEARNING OBJECTIVE #1: Recognize that superior mesenteric artery (SMA) dissection can present with back pain

LEARNING OBJECTIVE #2: Treat SMA dissections according to the guidelines for Stanford type B dissections

CASE: A 59 years old Asian man presents with 5 h worsening lower back pain that starts while eating lunch. He describes his pain as located in the mid-lumbar area, stabbing, constant, 10/10, non-radiating, and not improved or worsened by anything. Other review of systems is within normal limits (WNL). The patient's past medical history includes untreated hypertension. He smokes 2 packs/day for 40 years and drinks 2–3 times/month but denies any recreational drug use. His father also has hypertension. On physical exam, vital signs include temperature 36.3, pulse 70, blood pressure 208/124, respiratory rate 20, and O₂ saturation 99 % room air with body mass index 33 kg/m². Generally, the patient is diaphoretic and restless. His conjunctiva is pale on head exam. His abdomen is soft, tender peri-umbilically, and flat with positive bowel sounds but no rebound, guarding, rigidity, bruit, Murphy's/Cullen's sign, McBurney's point tenderness, pulsatile mass, or costovertebral angle tenderness. Dorsalis pedal pulse is 1+ on the right and 2+ on the left. The rest of the exam, including the back, is WNL. Labs, including complete blood counts and chemistries, are WNL except white blood cell 12,900 /mCL, fibrinogen 444 mg/dL, and triglyceride 226 mg/dL. Given suspicions of abdominal aortic dissection, abdominal computed tomography (CT) shows a mural thrombus around an abdominal aortic aneurysm (maximum diameter: 45 mm), proximal SMA dissection, thrombus in proximal inferior mesenteric artery (IMA), and collateral vessels from the distant SMA to distant IMA. He is thus kept on bed rest while nil per os with antihypertensive treatment on intravenous (IV) nitroglycerin and landiolol with oral olmesartan, amlodipine, and

bisoprolol. Repeat CT the next week incidentally shows a new pulmonary embolism although he reports no new symptoms or signs; lower extremity Doppler ultrasound also shows a left deep venous thrombus. He is thus started on heparin and warfarin bridge. Because the CT does not showing enlargement of the SMA dissection, he is discharged with follow-up CT in 1 month.

DISCUSSION: SMA dissection usually presents with acute abdominal pain although nausea, diarrhea, melena, and back pain, such as the above patient, may rarely occur; in fact, a literature search shows only 9 other reports about SMA dissection's presenting with back pain. A bruit may occasionally be heard along with weak bowel sounds. Because of the few number of SMA dissection cases, no guidelines exist yet on its treatment; instead, the guidelines for the treatment of Stanford type B dissections are used. The mainstay of therapy, conservative medical management of blood pressure, includes the use of IV beta-blockers; lifelong oral beta-blocker therapy is thereafter recommended to maintain blood pressure <120/80. After obtaining a baseline chest/abdomen CT or magnetic resonance imaging, follow-up imaging should be performed at 3, 6, and 12 months with subsequent studies every 1–2 years if no progression is found.

SYNCOPE WITH AN ABNORMAL EKG: NOT ALWAYS BRUGADA Jien Shim; Athanasia Vasiladis. Mount Sinai Hospital, New York, New York, NY. (Tracking ID #2194828)

LEARNING OBJECTIVE #1: Identify apical hypertrophic cardiomyopathy as a cause of syncope in young adults & Recognize clinical features of apical hypertrophic cardiomyopathy.

LEARNING OBJECTIVE #2: Distinguish EKG abnormalities in apical hypertrophic cardiomyopathy from other hypertrophic cardiomyopathies.

CASE: A 27 year old Chinese male with no significant past medical history presented to the outpatient clinic with a history of syncope 3 months prior to the visit. It occurred while he was playing basketball. He denied any associated chest pain, shortness of breath, dyspnea on exertion, lower extremity edema, nausea, vomiting, dizziness, or lightheadedness. He reported going to the hospital at that time after regaining consciousness after a few seconds. He had a work up, including an electrocardiogram, echocardiogram, and holter monitoring. He was told that he had an abnormal EKG, but otherwise a normal work up. The patient had two previous similar episodes; one at age 16 and the other at age 24. He did not get full medical work up at those times. The patient denied taking any medications, including over the counter medications or herbal products. The patient denied any family history of heart disease, sudden death and the rest of his family history was unremarkable. He was a nonsmoker and denied any alcohol and illicit drug use. On exam, vital signs were within normal limits: blood pressure: 123/75 and heart rate: 75. The patient was well appearing and in no acute distress. His JVP was normal. His heart exam had normal s1 and s2 with regular rate and rhythm, and no audible murmurs, rubs, or gallops. Lungs were clear to auscultation bilaterally. His extremities were warm and well-perfused without pitting edema. The laboratory results were within normal limits with a normal complete blood count, platelets, and differential, liver function tests, and basic metabolic panel. His electrocardiogram showed normal sinus rhythm at 84 bpm with normal axis, but with voltage criteria for left ventricular hypertrophy and significant ST segment elevations anteriorly in leads V1-V2, ST depressions in inferior leads II, III, and aVF with deep T wave inversions diffusely in leads I-III, aVF, V3-V6, suggestive of acute ischemia. At this point, patient was sent to the emergency room for further management of these findings and was ruled out for acute coronary syndrome. The transthoracic echocardiogram showed apical hypertrophic cardiomyopathy without outflow obstruction with otherwise normal left and right ventricular size and function. With the history of several syncopal episodes and evidence of apical hypertrophic cardiomyopathy on the TTE, the patient was referred for an electrophysiology study due to concern for exertional ventricular tachycardia in the setting of cardiomyopathy and possible AICD placement.

DISCUSSION: Apical hypertrophic cardiomyopathy is a morphologic variant of hypertrophic cardiomyopathy, involving predominantly the apex of the left ventricle. It is more common in Asia, up to 41 % of hypertrophic cardiomyopathy patients in China and 25 % of hypertrophic cardiomyopathy patients in Japan.¹ In non-Asian population, the prevalence is 3 % of hypertrophic cardiomyopathy patients. Patients may present with syncope, chest pain, palpitations or dyspnea. However, often times they may be asymptomatic. 12-lead electrocardiogram typically shows giant T wave inversions with ST segment depressions. Giant T wave inversions are thought to be due to apical hypertrophy leading to local ischemia.² This is different from other types of hypertrophic cardiomyopathy which may have normal ECG, prominent Q waves in inferior leads, P wave abnormalities suggesting atrial enlargement, or left axis deviation. All patients with suspected hypertrophic cardiomyopathy should get an echocardiogram for accurate diagnosis. Cardiac magnetic resonance imaging can assist in characterizing extent and distribution of hypertrophy and fibrosis. Unlike typical hypertrophic cardiomyopathy, this apical variant does not have left ventricular outflow tract obstruction, and have been shown to have a relatively benign prognosis.³ Long-term complications include apical aneurysms, apical myocardial

infarctions, and arrhythmia.⁴ ¹ Ho AM, Chui PT, Lee AP, Wan S. Hypertrophic cardiomyopathy apical variant. *Cleve Clin J Med.* 2014 Sep;81(9):517–9. ² Freitas A, Canovas E, Rubio J. THE HEART OF ATTENTION DEFICIT Patrick A. Proctor²; Thomas Montgomery¹; Theodore A. Frank¹; Markus Scherer¹. ¹Carolinas Healthcare System, Charlotte, NC; ²Carolinas Medical Center, Charlotte, NC. (Tracking ID #2180067)

LEARNING OBJECTIVE #1: Stimulant medications used in the treatment of ADHD can cause serious and potentially life-threatening side effects, including pulmonary hypertension.

LEARNING OBJECTIVE #2: Side effects of stimulant medications appear to be dose dependent, and care should be taken to use the lowest effective doses for treatment of ADHD.

CASE: A 19-year-old Caucasian man presented to the hospital after loss of consciousness and limb shaking lasting 1 min. Witnesses reported confusion after he regained consciousness. The event was preceded by sudden onset of dyspnea and inspiratory chest pain at rest. He endorsed 5 days of dry cough diagnosed as bronchitis and 2 years of exertional chest pain and dyspnea. Home medications were doxycycline, methylphenidate, and dexamethylphenidate. The patient's only medical history was attention-deficit/hyperactivity disorder diagnosed in elementary school. He was adopted as an infant. His mother died due to complications of an unspecified cardiac condition after delivery. He denied alcohol, tobacco, or illicit drug use. On presentation, the patient was alert and well-appearing. His temperature was 98.9 °F, heart rate was 112, and blood pressure was 158/111. Examination revealed a split S2 with loud pulmonic component and a 1/6 systolic murmur over the left sternal border. Lungs were clear to auscultation. Blood counts and metabolic panel were unremarkable. A CT angiogram found no pulmonary embolus, but demonstrated perivascular ground-glass opacities and marked enlargement of the main pulmonary artery, right ventricle, right atrium, and inferior vena cava. Symptoms resolved spontaneously 4 h after arrival. The patient was discharged with cardiology follow up, where echocardiography revealed a dilated, hypokinetic right ventricle with systolic pressure of 120 mmHg. Right heart catheterization confirmed severe pulmonary hypertension and cardiac index 1.76 L/min/m². Methylphenidate and dexamethylphenidate were discontinued. Continuous treprostinil was started. He was hospitalized three more times in 5 months with similar symptoms. Repeat catheterization found no improvement of pulmonary vascular resistance. Six months ago treprostinil was increased to the maximum recommended dose. He has remained free of hospitalizations since then despite lifestyle-limiting chest pain and dyspnea.

DISCUSSION: According to the CDC's 2011 National Survey of Children's Health, 11.0 % of US children between ages 4 and 17 years are diagnosed with Attention-Deficit/Hyperactivity Disorder. Prevalence has increased from 7.8 % in 2003. More than 6 % are treated with stimulants. This patient was diagnosed with attention-deficit/hyperactivity disorder in elementary school and had been on stimulant medications for eleven years. Prior clinic notes documented concern about high stimulant doses, although his regimen always fell within recommended dosing guidelines. One third of patients with idiopathic pulmonary hypertension report prior amphetamine or cocaine use. The odds ratio for prior stimulant use was 10.14 in patients with idiopathic disease compared to patients with known risk factors. A pathogenic mechanism linking stimulant use and pulmonary vascular disease has not been discovered. Proposed mechanisms include toxic endothelial injury, hypoxic insult, direct spasm, vasculitis, and dysregulation of vascular tone mediators. Amphetamines increase serum levels of serotonin, which is both a pulmonary vasoconstrictor and pulmonary artery smooth muscle mitogen. Stimulant medications carry a warning label recommending that anyone being considered for their use undergo screening for family history of sudden death or ventricular arrhythmia and physical examination to screen for cardiopulmonary abnormalities. Patients who develop exertional chest pain, syncope, or other symptoms suggestive of cardiac disease should undergo immediate cardiac evaluation.

THE MENINGITIS THAT WASN'T Sonali Advan²; Sumant Arora¹; wickliffe Many². ¹UAB Montgomery Health Center, Montgomery, AL; ²University of Alabama at Birmingham, Montgomery, Montgomery, AL. (Tracking ID #2200180)

LEARNING OBJECTIVE #1: To understand that the underlying immunodeficient state in patients with sarcoidosis puts them at risk for opportunistic infections.

LEARNING OBJECTIVE #2: To rule out other etiologies of chronic meningitis in sarcoid patients with neurologic findings suggestive of neurosarcoidosis.

CASE: We report a case of a 41-year-old man with a 6-year history of sarcoidosis who presented with complaints of generalized weakness, progressive dysphagia (solids > liquids), and hoarseness for 1–2 weeks. Review of systems was positive for moderate dyspnea, nausea, and unintentional weight loss (14 lbs) over 6 months. On exam, he was cachectic and in moderate distress. He was afebrile, tachycardic and tachypneic but saturating well on room air. Pertinent positive physical exam findings included neck stiffness and drowsiness on presentation, rest of the neurologic exam was within normal limits. Complete blood count and serum electrolytes were normal, except for mildly elevated bicarbonate. HIV screen, sputum and blood cultures were negative. Chest imaging showed stable bilateral extensive reticulonodular ground glass opacities. Lumbar puncture was performed which revealed clear colorless cerebrospinal fluid (CSF) with opening pressure of 20 cm of water, elevated protein (227 mg/dl), low glucose (13 mg/dl), 20 WBCs/mm³ (90 % mononuclear), but negative CSF gram stain, bacterial and Acid fast bacilli cultures. Testing for cryptococcal antigen was not done, but fungal cultures were pending at the time. During his hospital stay, patient failed all swallow evaluations including barium swallow evaluation. He underwent endoscopy for evaluation of his dysphagia, which showed a normal esophagus, normal antrum and body of the stomach. It was felt that further workup should be done for evaluation of his dysphagia. As his dysphagia failed to improve, eventually a percutaneous endoscopic gastrostomy (PEG) tube was placed. Magnetic resonance imaging (MRI) of the brain revealed enlarged temporal horn of the right lateral ventricle with multiple leptomeningeal implants and parenchymal lesions. Neurology and neurosurgery were consulted. A diagnosis of neurosarcoidosis was made, and he was treated with intravenous steroids, which led to clinical improvement. Follow up with serial CT scans were recommended and he was discharged on oral steroids. However, he returned within 2 weeks with high grade fever (102.9 F), headache, confusion, abdominal pain, and vomiting. Repeat lumbar puncture was done which revealed clear colorless fluid with an opening pressure of 18 cm of water, elevated protein (124 mg/dl), and low glucose (23 mg/dl). The cryptococcal antigen test was positive (1:1024) and cultures were positive for *Cryptococcus neoformans*. Induction phase therapy with amphotericin and flucytosine was initiated, and he was discharged home on maintenance therapy with fluconazole. His dysphagia improved with antifungal treatment and speech therapy, and his PEG tube was removed on discharge. Follow up MRI of the brain one month after discharge showed decrease in enhancement of lesions and edema.

DISCUSSION: Sarcoidosis is an idiopathic disease, characterized by non-caseating granulomas in various organs. Sequestration of CD4 cells in sarcoid granulomas affects cell-mediated immunity. Impairment of cell-mediated immunity and concurrent steroid therapy in sarcoidosis puts patients at risk for various opportunistic infections. Cryptococcal meningitis (CM) is an opportunistic fungal infection that often occurs in immunodeficient patients. CM is often misdiagnosed as neurosarcoidosis, because of similar clinical presentation as well as CSF picture. However, hypoglycorrhachia is more common in CM. Both CM and neurosarcoidosis are chronic meningitis, and can also co-exist in the same patient. In sarcoid patients with neurologic signs and symptoms, CM should be ruled out by Polymerase Chain Reaction on CSF samples, even if MRI findings point towards neurosarcoidosis. It is critical to evaluate these patients for other infectious and neoplastic etiologies prior to administering immunosuppressive medications or steroids for neurosarcoidosis. Serologic testing and brain biopsy should be considered to confirm the diagnosis prior to empiric treatment.

THE NOSE IS IN THE HEART OF IT Victoria Gutgarts^{1,2}; Rosemarie Conigliaro^{1,2}.
¹Albert Einstein College of Medicine, Bronx, NY; ²Montefiore Medical Center, Bronx, NY. (Tracking ID #2199364)

LEARNING OBJECTIVE #1: Define chronic rhinosinusitis (CRS) and describe the pathophysiology and complications of the disease.

LEARNING OBJECTIVE #2: Recognize *Streptococcus pneumoniae* as a cause of CRS and pneumococcal endocarditis as a rare complication.

CASE: A 64 year-old man presented with ten days of subjective fevers and chills, bilateral lower quadrant abdominal pain, and a dry cough. Temperature was 101.9 F with a grade three out of six systolic murmur heard best at the second left intercostal space. Initial white blood cell count was 31.4 k/uL; creatinine was elevated at 1.4 mg/dL. CT scan of the abdomen and pelvis revealed bilateral wedge shaped areas of decreased enhancement in both kidneys. Endocarditis was suspected. A vegetation was found at the aortic valve on transthoracic echocardiogram. Blood cultures grew *Streptococcus pneumoniae*, sensitive to ceftriaxone. Further history revealed that the patient has not felt "like himself" for over a year, with decreased appetite, fatigue, and a twenty pound weight loss. He recounted a history of multiple sinus infections involving purulent nasal discharge, facial pressure, with the most recent infection treated with antibiotics one year prior. CT scan of the sinuses

revealed a defect within the floor of the right maxillary sinus where a sino-oral fistula was present. Surgical repair was recommended, and patient was treated with 4 weeks of intravenous ceftriaxone for Pneumococcal endocarditis thought to be secondary to seeding from a chronic rhinosinusitis.

DISCUSSION: Chronic rhinosinusitis (CRS) is defined as an inflammatory disorder of the paranasal sinuses that lasts 12 weeks or longer. It is a common disease that affects roughly 15 % of people in the United States each year. In addition to the time course, two or more signs must be present to make the diagnosis, including nasal purulent discharge, nasal congestion, facial pressure, and/or reduction of olfactory senses. CRS has been classified into three subtypes; CRS with nasal polyposis, CRS without nasal polyposis, and allergic fungal rhinosinusitis (AFRS). CRS without nasal polyposis is the most common, comprising roughly 60 % of cases. CT imaging often shows sinus opacification or obstruction with nonpolypoid mucosal thickening. Studies have suggested bacterial biofilms to be the mechanism of disease. Biofilms are aggregates of bacteria that irreversibly adhere to mucosa and form a protective outer layer of cells, which allow them to become resistant to host defenses and antimicrobial agents. The most common bacterial causes of CRS include *Streptococcus pneumoniae*, *Haemophilus influenzae*, and *Moraxella catarrhalis*. Complications of CRS may be caused by local extension, leading to meningitis, otitis, or orbital cellulitis. Recurrent inflammation of the sinuses may also form fistulas, and result in bacteremia and systemic diseases such as endocarditis. During the preantibiotic era, *Streptococcus pneumoniae* endocarditis was seen in roughly 15 % of cases. After penicillin became available, the incidence fell to 1 to 3 %. *Streptococcus pneumoniae* endocarditis tends to have an aggressive evolution, often with high mortality. The aortic valve is preferentially affected, which has a higher frequency of complications as compared to other valves. Treatment involves weeks of intravenous antimicrobial therapy, often with penicillin if sensitive, and management of the underlying cause. Recognition and early treatment of recurrent sinus infections is crucial in preventing local and systemic complications such as endocarditis.

THE SOMETIMES DEVASTATING NEUROLOGICAL SEQUELAE OF SLE
 Nicholas Joza. Tufts Medical Center, Boston, MA. (Tracking ID #2200162)

LEARNING OBJECTIVE #1: Appreciate the neurological complications of SLE

LEARNING OBJECTIVE #2: Understand that transverse myelitis has a wide spectrum of etiologies, which requires prompt exclusion of reversible causes

CASE: A 22 year-old man with history of systemic lupus erythematosus (SLE) with renal involvement, who had been well-controlled for years on Cellcept and prednisone, was admitted for acute onset of lower extremity paralysis. Four days earlier he presented with headache, fever and myalgias. Spinal tap at that time revealed pleocytosis with neutrophilic predominance. MRI brain was unremarkable. His headache and fever spontaneously resolved without antibiotics, a presumed diagnosis of viral meningitis was made, and he was discharged. One day later, he developed acute lower extremity weakness bilaterally which progressed over hours to paraplegia and urinary retention, and he was readmitted. Examination revealed 0/5 muscle strength and areflexia in the lower extremities, and a sensory level approximately at the umbilicus. MRI spine revealed T2 hyperintensity involving the thoracic cord from T7 extending to the conus medullaris, compatible with transverse myelitis. Labs were notable for elevated dsDNA and hypocomplementemia, consistent with lupus flare. An extensive infectious workup was unrevealing. He was started on pulse dose steroids and Cytoxan, and underwent plasmapheresis. At 3 months, he had largely regained the ability to ambulate, though continued to complain of residual lower extremity pain and urinary incontinence.

DISCUSSION: Although neuropsychiatric manifestations of SLE are common, transverse myelitis (TM) occurs in only 1 to 1.5 % of these patients [1]. Acute TM is a spinal cord inflammatory disorder characterized by rapid onset of paresis, a sensory level and bowel and bladder dysfunction. The differential diagnosis of TM is very broad and includes infection (eg. West Nile virus, herpes, Lyme disease), a systemic autoimmune disorder, a paraneoplastic syndrome, or a multifocal neurologic disease (eg. multiple sclerosis) [2]. A spine MRI is crucial to exclude mimics of TM such as neoplasms and vascular myelopathies, and typically reveals a gadolinium-enhancing signal abnormality. CSF analysis often reveals a moderate pleocytosis and elevated protein level. In our patient, there was initial diagnostic uncertainty when he presented with headache and fever—did this represent an infectious meningitis in the setting of immunosuppression or a new manifestation of a lupus flare? Indeed, these prodromal symptoms typically herald the onset of an SLE myelopathy [2]. Subsequent CSF analysis failed to point to an infectious cause. Early initiation of potent immunosuppression was crucial, and leads to the best chance for recovery. **References:** 1. Saison, J. et al. Systemic lupus erythematosus-associated acute transverse myelitis: manifestations, treatments, outcomes, and prognostic factors in 20 patients. (2014). Lupus. Aug 12, 2014 issue. 2. Beh, S. C., et al. Transverse myelitis. (2013). Neurol Clin 31: 79–138.

THE UNUSUAL SUSPECT: A RARE AND MORBID CAUSE OF ACUTE POST-PARTUM CHEST PAIN Anand D. Jagannath; David B. Gomez; Martin Cohen; Sheira Schlair. Albert Einstein College of Medicine/Montefiore Medical Center, Bronx, NY. (Tracking ID #2199094)

LEARNING OBJECTIVE #1: Recognize unique features of coronary artery vasospasm and available treatments

LEARNING OBJECTIVE #2: Identify pregnancy-related risk factors contributing to coronary artery vasospasm

CASE: A 36 year old woman presented with sudden-onset, 8/10, dull, midsternal chest pain that radiated to the back 2 weeks after elective Cesarean section and an uncomplicated pregnancy. There was no associated shortness of breath, palpitations, diaphoresis, lightheadedness, nausea, vomiting, diarrhea, or fever. The pain resolved without intervention within 15 min of onset. Blood pressure was 172/93, which improved with nifedipine, and the patient was discharged home. The patient returned the following day with concern for post-partum pre-eclampsia after blood pressure was again elevated at outpatient follow up. A short, 2/6 non-radiating systolic murmur was heard loudest at the base. New, pronounced T-wave inversions were noted in leads I, II, aVL, V2-V6. Peak troponin-T was 0.13 ng/ml, peak CPK 174 U/L, and pro-BNP 994 pg/ml. No pulmonary embolism was seen on ventilation-perfusion scan. Cardiac catheterization revealed diffuse vasospasm in the mid to distal left anterior descending coronary artery and focal 30 % vasospasm in the mid left circumflex coronary artery, with a left ventricular ejection fraction of 40 %. Vasospasm responded to intracoronary (IC) nicardipine. Left circumflex vasospasm initially worsened to 80 % stenosis but eventually improved with sedation and continued IC nicardipine. The patient was discharged two days later, symptom-free, on oral nicardipine and enalapril, with return of ejection fraction to 60 % at outpatient cardiology follow-up.

DISCUSSION: Chest pain is a frequent complaint assessed by the internist. Though myocardial infarction (MI) and pulmonary embolism are common differentials, coronary vasospasm is a potentially morbid diagnosis worth considering. The pathophysiology of coronary vasospasm is thought to involve endothelial dysfunction and hyperreactivity of coronary artery smooth muscle cells. Certain aspects of the history may help the internist differentiate between typical angina and coronary vasospasm. Most patients with vasospasm are under 50 years of age, do not have cardiac risk factors, or have a history of drug abuse (e.g. cocaine). Chest pain is not brought on by exertion however hyperventilation can provoke "attacks". Physical examination is not revealing; however, some patients will be hypertensive, tachycardic, or diaphoretic during episodes. EKG is essential for diagnosis and should be obtained during and also following chest pain episodes. Transient ST segment elevation during a chest pain episode is the classic electrocardiographic finding in coronary vasospasm resulting from transient transmural myocardial ischemia. ST depression and negative U waves may also be seen, likely related to the severity of vasospasm and resultant degree of myocardial ischemia. Coronary angiography is essential in any patient suspected to have coronary vasospasm to confirm the diagnosis and to rule out fixed obstruction. Therapeutic options in confirmed cases include calcium channel blockers and nitrates with the former class independently predicting MI-free survival in one study. In the acute setting, intra-coronary delivery of these drugs, as in our case, can relieve spasm and may have survival benefit especially in patients with concurrent severe CAD or multi-vessel spasm. Of particular relevance to internists is that long-term disease management is enhanced by statin use and smoking cessation. In fact, long-term MI-free survival may be improved with these two interventions. Coronary vasospasm in pregnancy and the post-partum period is uncommon. A report of 208 cases of pregnancy-related acute MI found only 1.8 % of cases caused by coronary vasospasm. Post-partum uterine hypoperfusion causes an increase in angiotensin II which can trigger vasospasm. Pre-eclampsia and eclampsia have been postulated to cause systemic and coronary vasospasm mediated by endothelial dysfunction leading to myocardial ischemia. Drugs frequently used in pregnant or post-partum women such as ergonovine, bromocriptine, and prostaglandin E2, are also known to cause coronary vasospasm via unclear mechanisms. Of the published cases of post-partum coronary vasospasm, most have occurred within 2-4 weeks of delivery though reported cases more than 5 months from delivery make post-partum vasospasm relevant to the internist. This case highlights several features important to the internist for diagnosing and treating coronary vasospasm. First, coronary vasospasm should be considered in "atypical" patients presenting with typical angina and rapidly triaged to initiation of empiric treatment if typical EKG findings are present. Second, long-term therapy with calcium channel blockers likely improves ischemia-free survival. Finally, internists should give special consideration for coronary vasospasm in post-partum patients presenting with chest pain.

THROMBOSIS IN A BLEEDING DISORDER Sheryl K. Ramdass; Leslie Howard. Baystate Medical Center, Springfield, MA. (Tracking ID #2197446)

LEARNING OBJECTIVE #1: Recognize patients with a bleeding disorder can be at risk of thrombosis

LEARNING OBJECTIVE #2: Discuss challenges in managing FVII deficient patients including anticoagulation therapy

CASE: A 73 year old man presented with an episode of chest tightness, dyspnea and pre-syncope one month after a right femoral neck fracture requiring internal fixation. CT angiogram of the chest demonstrated multiple bilateral filling defects involving the lobar, segmental and sub-segmental pulmonary arteries of all lobes, consistent with pulmonary emboli. Doppler ultrasounds of the lower extremities revealed bilateral deep venous thromboses. His past medical history was significant for factor VII deficiency (FVIID), diagnosed elsewhere at age 44 following incidentally noted abnormal coagulation testing. He had never experienced significant bleeding episodes. He had no family history of bleeding disorders. He had received a single prophylactic dose of recombinant Factor VIIa prior to cataract surgery and dental extractions with no bleeding complications. Laboratory testing prior to his recent hip surgery was significant for PT 27.8 s (ref. range 9.7-12.2 s), INR 2.7, PTT 25.9 (ref. range, 24.1-33.1 s) and factor VII activity level <5.0 % (ref. range, 50-200 %); no inhibitor was present. He received recombinant Factor VIIa 20ug/kg immediately prior to surgery as well as every 8 h postoperatively for a total of 4 doses. PT corrected to 8.8 s, INR 0.9 and factor VII activity level >200 %. There was minimal blood loss during surgery and no postoperative bleeding. He did not receive postoperative prophylactic anticoagulation. Following the diagnosis of venous thromboembolism, he was started on standard doses of intravenous unfractionated heparin followed by subcutaneous low molecular weight heparin (LMWH) 1U/kg twice daily. His anti-factor-Xa level measured 4 h following administration was 0.91 IU/ml (ref. range, 0.6-1.1 IU/ml). Since the thromboses were provoked, 3 months of anticoagulation was planned and following 2 months of therapy he had not experienced bleeding.

DISCUSSION: Activated FVII binds to tissue factor exposed by vascular injury and initiates coagulation through the extrinsic pathway. FVIID is the only congenital bleeding disorder characterized by an isolated prolongation of PT, corrected by administration of plasma. FVIID, the most frequent among the rare inherited bleeding disorders, accounts for one symptomatic individual per 500 000 population.¹ Clinical manifestations are heterogeneous ranging from no symptoms to mild mucosal bleeding to life threatening hemorrhage.^{2,3} There is a poor correlation between FVII coagulation activity (FVII:C) and bleeding tendency^{4,5} leading to difficulty in predicting bleeding risk, hence specific guidelines on preoperative management are lacking. This is exemplified by our patient whose baseline FVII:C level was <5 % but he had no prior history of bleeding. Additionally thrombotic events have been reported to occur paradoxically in bleeding disorders. In FVIID, thrombosis is mainly venous with a reported incidence of 3-4 %.⁶ Although spontaneous thrombosis is extremely rare, severe FVIID is not protective from strong thrombosis risk factors such as surgery and replacement therapy especially activated products.^{4,5,6} Our patient had both these risk factors; he underwent orthopedic surgery as well as received activated FVII preoperatively. Literature on anticoagulation (AC) strategies suitable for FVIID individuals with thrombosis is not well established. It remains a challenge to find an effective AC that carries a low bleeding risk as well as thrombosis recurrence. The baseline INR is elevated in FVIID and therefore this precludes the use of oral vitamin K antagonist with monitoring INR for management of thrombosis. Alternatively, factor II levels may be monitored as a measure of antithrombotic protection⁷, however the assay time is long. Furthermore, evidence for other recommended AC agents is sparse in this population group. Limited literature suggest heparin may be safe with monitoring of anti-FX activity as an indicator of optimal antithrombotic therapy.^{4,8} Our patient was started on intravenous heparin and transitioned to LMWH on discharge without any reported bleeding episodes. In conclusion, the discerning clinician must be aware that thrombosis can occur in FVIID under certain provoked circumstances and severe deficiency does not offer protection against thrombosis. Prophylactic AC therapy should be considered in patients with predisposing risk factors and therapeutic AC in cases of thrombosis can be safe, though future studies on the choice of AC is warranted.

TUBERCULOSIS IN A SINGLE LYMPH NODE PRESENTING AS FLANK PAIN Kathy M. Tran; Arthur A. Winer; Jennifer Liu; Jessica Taff. New York University Langone Medical Center, New York, NY. (Tracking ID #2196835)

LEARNING OBJECTIVE #1: Recognize that extraperitoneal tuberculosis, and particularly tuberculous lymphadenitis, can present as a single nodule and should be strongly considered in the appropriate clinical setting.

LEARNING OBJECTIVE #2: Identify classic imaging characteristics of tuberculous lymphadenitis.

CASE: A 45-year-old Peruvian male prisoner with human immunodeficiency virus/acquired immunodeficiency syndrome (HIV/AIDS) presented with right flank pain, intermittent fevers, chills, and night sweats for 3 weeks. Prior to 7 months of incarceration, he traveled internationally throughout Central and South America and eastern Asia. He denied weight loss, abdominal pain, dysuria, or hematuria. He was never treated for his HIV. As a child, he received the Bacillus Calmette-Guerin vaccination, but had no known

exposure to tuberculosis. Sputum cultures and Quantiferon Gold were negative 3 weeks prior to presentation. On initial exam the patient was febrile to 101.3 °F with tachycardia to 112, with otherwise normal vital signs. The patient complained of R flank pain, however his abdomen and back were non-tender to palpation and there were no palpable lymph nodes on exam. Laboratory testing revealed a CD4 count of 24/μL, white blood cell count of 4100/mm³, hemoglobin of 12.3 g/dL, and hematocrit of 36.3 %. Other labs tests were within normal limits. Blood cultures showed no growth. Sputum for acid-fast bacilli was negative on three occasions but Quantiferon Gold assay was positive. Computed tomography (CT) of the chest was negative for pathology. CT of his abdomen and pelvis with contrast revealed a solitary enlarged retroperitoneal lymph node located posterior to the transverse duodenum (1.8×2.1×3.9 cm) with a central area of low attenuation. Endoscopic ultrasound was used to assist with biopsy the lesion given its precarious location. Ziehl-Neelsen stain of the specimen demonstrated numerous acid fast bacilli. Polymerase chain reaction assay was positive for *Mycobacterium tuberculosis*. The patient was started on rifampin, isoniazid, pyrazinamide, and ethambutol for treatment of tuberculosis and antiretrovirals for treatment of his HIV. He experienced resolution of symptoms within 1.5 weeks and was discharged without complications.

DISCUSSION: The differential diagnosis for an HIV patient with an isolated enlarged lymph node includes malignancy, infection, and inflammatory conditions. However, in patients with several known risk factors (incarceration, immunodeficiency and recent travel to endemic areas), tuberculosis should be strongly considered even in cases of atypical presentation. Isolated extra-pulmonary tuberculosis accounts for 21 % of tuberculosis in the United States, usually presenting as tuberculous lymphadenitis. Most (60 %) tuberculous lymphadenitis is localized to the cervical lymphatic region. Abdominal tuberculosis comprises only 12 % of extra-pulmonary tuberculosis although the rate is increased in patients with immunodeficiency. Within the abdomen, gastrointestinal and genitourinary tuberculosis are the most common, followed by tuberculous lymphadenitis. Isolated retroperitoneal lymph node enlargement in tuberculosis remains more rare, as most cases of tuberculous lymphadenitis present as several matted lymph nodes, often palpable on exam. CT imaging usually reveals low attenuating central necrosis with a hyper-attenuating area of rim enhancement, consistent with an inflammatory response. In our patient, CT revealed a central area of caseation without rim enhancement. Biopsy by EUS provided a minimally invasive method to help identify active tuberculosis in a solitary nodule at an atypical location with localized symptoms of flank pain. Therefore, in patients at risk for tuberculosis, biopsy of even a single lymph node must be pursued vigorously in order to establish a diagnosis and provide appropriate treatment for the patient.

VENTRICULAR TACHYCARDIA AS A PRESENTATION OF CHAGAS CARDIOMYOPATHY Jensen A. Law²; Rebecca Witt¹. ¹George Washington University, Arlington, VA; ²Medstar Georgetown University Hospital, Washington, DC. (Tracking ID #2194025)

LEARNING OBJECTIVE #1: Recognize and treat ventricular tachycardia.

LEARNING OBJECTIVE #2: Identify Chagas Disease as an etiology of cardiac arrhythmias

CASE: Fifty-six year old healthy man from El Salvador presented to the hospital after 3 days of pleuritic chest pain and 2 syncopal episodes. While in the ED, he had three episodes of sustained ventricular tachycardia. The first episode converted spontaneously to sinus rhythm. The second converted after the patient received an amiodarone bolus. The third required another amiodarone bolus and lidocaine. He was admitted to the CCU and started on an amiodarone drip. Myocardial infarction was ruled out with negative cardiac enzymes and the patient had a left heart catheterization that revealed mild apical hypokinesis and mild coronary spasm in the mid distal LAD, but normal ejection fraction and no significant coronary artery disease. A cardiac MRI was performed to further evaluate for a structural focus of VT. It demonstrated myocardial edema, wall motion abnormality, and delayed enhancement involving the lateral wall at the level of the mid cavity. Labs for infiltrative disease and myocarditis such as ACE levels and viral antibody titers were sent and the patient then underwent an EP study. The ventricular tachycardia was inducible but not able to be entrained due to self termination. No ablation was performed, and the patient received an ICD for secondary prevention. The patient was transitioned to oral amiodarone. He was discharged home to follow-up with cardiology. Laboratory results subsequently returned positive for Chagas disease.

DISCUSSION: Ventricular tachycardia (VT) is a potentially life-threatening arrhythmia, though presentation can range from mild symptoms such as palpitations, an abnormal chest sensation, lightheadedness, and weakness, to more significant symptoms resulting from hemodynamic instability causing syncope, angina, and cardiogenic shock. While there are multiple criteria to differentiate VT from supraventricular tachycardia with aberrancy, when there is uncertainty or instability, a wide complex tachycardia should be treated as VT until proven otherwise. In patients such as this one, who are hemodynamically stable, pharmacologic cardioversion may be attempted with amiodarone,

lidocaine, procainamide, or sotalolol. If antiarrhythmics are unsuccessful, or if the patient becomes unstable, external cardioversion is required. Ventricular tachycardia most commonly occurs as a result of structural heart disease, usually from coronary artery disease and prior myocardial infarction, making up approximately 70 % of cases in the United States. The evaluation to establish the type of heart disease present can include, in addition to coronary angiography, exercise testing, echocardiography, signal-averaged electrocardiogram, endomyocardial biopsy, or MRI. This patient's MRI was consistent with myocarditis, and given the patient's exposure in El Salvador, *Trypanosoma cruzi* serologies were ordered and returned positive. Chagas disease is caused by *Trypanosoma cruzi*, a protozoan parasite endemic from the southwestern United States to central Argentina and Chile, and transmitted by the Triatominae. The acute phase can cause severe acute disease, such as acute myocarditis, pericardial effusion, or meningoencephalitis, but more commonly, patients are asymptomatic or have mild nonspecific symptoms such as malaise, fever, or anorexia. Chronically, patients can develop heart disease and gastrointestinal disease. Cardiac disease is more common than gastrointestinal, and patients frequently develop cardiac arrhythmias, as in this patient. The role of antitrypanosomals in chronic disease is limited, and management is focused on supportive care. Antiarrhythmics and optimization of medical therapy for heart failure are the mainstay of treatment of Chagas, with ICD placement for secondary prevention as indicated.

VISION LOSS: A UNIQUE PRESENTATION OF SLE WITH CONCOMITANT CATASTROPHIC ANTIPHOSPHOLIPID SYNDROME (CAPS) Brian Hachey; Hassan I. Ahmad; David Paje; Niral M. Patel; Ruchira Sengupta; Bronwyn L. Small. Henry Ford Hospital, Detroit, MI. (Tracking ID #2198969)

LEARNING OBJECTIVE #1: Diagnoses and Treatment of Antiphospholipid and Catastrophic Antiphospholipid Syndrome

CASE: The patient is a 21 year-old female presenting with headache and decreased vision over 1 week. She had no history of trauma. Physical exam was pertinent for an apical holosystolic murmur, right eye blindness with left eye inferior temporal and nasal deficiencies. A fundoscopic exam was consistent with central retinal artery occlusion. Labs were significant for a platelet count of 115, 000/μL, creatinine of 1.56 mg/dL and partial thromboplastin time of 56 s. A hypercoagulable and autoimmune work-up was positive for ANA and anticardiolipin IgG. A genetic hypercoagulable work-up (Factor V, Protein C/S) was negative. Imaging with CT head revealed parieto-occipital lobe infarct, determined on MRI to be multiple embolic infarcts to bilateral cerebral and cerebellar hemispheres. A transesophageal echocardiogram (TEE) demonstrated severe mitral regurgitation (MR) with mitral leaflet thickening and leaflet mass concerning for Libman-Sacks Endocarditis. The patient was diagnosed with systemic lupus erythematosus (SLE) meeting 4 SLICC criteria (alopecia, thrombocytopenia, positive ANA and anti-smith). The constellation of symptoms with multi-organ involvement in <1 week led to the diagnosis of CAPS. The patient was evaluated by ophthalmology for central retinal artery occlusion (CRAO); neurology consulted for embolic stroke; and both cardiology and cardiac surgery for valvular disease. The patient received methylprednisone 1 g IV daily for 3 days, which was continued as prednisone 15 mg daily. A Heparin drip was initiated with bridge to Coumadin targeting an INR of 2–3. Aspirin 81 mg daily was initiated given high risk for cerebrovascular events. Ophthalmology preformed pan-retinal photocoagulation x2 for CRAO and the patient's vision remained stable thereafter. At time of discharge approximately 3 weeks after initial presentation creatinine had returned to baseline. Patient continued to follow-up with multiple subspecialists as an outpatient. She was started on steroid-sparing agent mycophenolate mofetil with tapering prednisone. Given the severity of retinal disease on presentation she was deemed a poor candidate for hydroxychloroquine given the side effect profile. Cardiothoracic surgery performed mitral valve repair for prolapse leading to severe regurgitation. At 9 month follow-up the patients vision remained unchanged without evidence of new thrombotic events.

DISCUSSION: Systemic lupus erythematosus (SLE) is a heterogeneous autoimmune disease characterized by multi-organ system involvement. Lupus patients can present with simple constitutional symptoms or organ specific complaints. Many of these specific complaints, (e.g. oral ulcers, joint pains, malar rash) are characteristic features defined in clinical criteria for formulating a diagnosis. Along with clinical criteria there are laboratory criteria, including antiphospholipid antibodies (APL). While the laboratory presence of APL alone in a patient may be clinically insignificant; however when there is evidence of thrombosis (i.e. venous/arterial thrombosis or unexplained pregnancy morbidity) in conjunction with APL positivity, this establishes the diagnosis of Anti-Phospholipid Syndrome (APS). Patients with SLE and APL are at an increased risk of thrombotic complications. Although commonly associated with SLE, APS can occur either as an independent clinical syndrome (Primary APS) or associated with other autoimmune disorders (e.g. SLE, rheumatoid arthritis). Treatment of SLE with hydroxychloroquine has been well established as being thromboprotective by reducing thrombotic events. Of patients diagnosed with APS a small subset may be affected by a rare and aggressive variant known as catastrophic antiphospholipid syndrome (CAPS). CAPS is defined by evidence of

thrombosis involving 3 or more organs, development simultaneously or in <1 week, confirmation by histopathology of small vessel occlusion and lab confirmation of APL antibody. Given the widespread thrombotic disease there is an associated high mortality of CAPS up to 46 %. Of those that survive the initial event, recurrence rate of thrombosis approximates 20 %; however it is rare to have recurrence of CAPS related (multi-organ) thrombosis. In patients with CAPS, glucocorticoid therapy and long-term anticoagulation are the foundation of therapy. Current treatment recommendations support the use of heparin as bridge to warfarin to target INR 2–3. High dose intravenous glucocorticoids are used during the initial three days with transition to oral maintenance steroids. In patients resistant to these therapies additional proposed treatments include plasma exchange, which has shown therapeutic benefits and improved survival. At present time a precise treatment strategy for CAPS requires further investigation and therapy may need to be individualized based on severity of symptoms and patient risk factors.

WHEN IVC FILTER FAILS TO FILTER: A CASE OF RECURRENT PULMONARY EMBOLISM AND INTRAATRIAL CLOT STATUS POST IVC FILTER PLACEMENT Bilal Shaikh⁴; Asad Jehangir⁴; Anam Qureshi⁵; Qasim Jehangir¹; Andrew C. Rettew²; Ahmed Salman²; Shoaib Fareedy³; Manoj Singla². ¹Rawalpindi Medical College, Rawalpindi, Pakistan, Lahore, Pakistan; ²Reading Health System, Wyomissing, PA; ³Reading Health System, Reading, PA; ⁴Reading Health System, West Reading, PA; ⁵King Edward Medical University, Lahore, Pakistan. (Tracking ID #2197836)

LEARNING OBJECTIVE #1: Recognize the possibility of recurrence of pulmonary embolism (PE) in patients presenting with shortness of breath after the placement of IVC (inferior vena cava) filters.

LEARNING OBJECTIVE #2: Be prepared for the worse: include not only recurrent PE but also widespread intravascular thrombus with clogged filter in the differential of such cases.

CASE: A 74-year-old male presented to the emergency department with complaints of pleuritic midsternal chest pain and worsening shortness of breath for the past 1 week. He had a past medical history of recurrent PE and deep venous thrombosis with recent discontinuation of warfarin in the last 6 months after gastrointestinal bleeding from a duodenal ulcer with subsequent placement of Vena Tech permanent IVC filter. On examination, he was hemodynamically stable with a benign examination of the cardiovascular and pulmonary systems. The EKG showed normal sinus rhythm without any evidence of acute coronary syndrome or SIQ3T3, and troponin was normal. Computerized tomography of the chest/abdomen/pelvis with intravenous contrast revealed bilateral acute pulmonary emboli with moderate clot burden. Moreover, an elongated faint 2.7 cm × 4.5 cm filling defect within the inferior vena cava extending beyond the superior margin of the IVC filter compatible with intravascular thrombus was visualized. Transthoracic echocardiogram was performed which revealed preserved ejection fraction, a clot originating from the IVC filter and extending 2 cm into the right atrium, and aneurysmal interatrial septum with stretched patent foramen ovale (PFO). The patient was started on IV heparin and bridged to warfarin, which he tolerated well without any evidence of hemorrhage. He was evaluated by cardiothoracic surgery, vascular surgery, and interventional radiology who recommended continuing lifelong anticoagulation because of high risks involved with the manipulation of interatrial clot. He was discharged home in stable condition with a therapeutic INR, and repair of PFO as well as possible removal of IVC filter was advised after the resolution of the clot.

DISCUSSION: Recurrence of pulmonary embolism after placement of IVC filter is an uncommon phenomenon, which has been reported in 1–4 % of the cases in various studies. This can occur via small clots passing through the filter or the collaterals around the filters, or direct extension of the clot through the filter. Rule out recurrence of pulmonary embolism in patients with history of IVC filter placement presenting with shortness of breath, especially in those who are not being anticoagulated. These patients may have a benign physical examination; hence a high degree of suspicion is warranted for timely diagnosis and effective management or there is a high risk of clinical deterioration. A multi-disciplinary approach is needed to devise the appropriate management plan which is dictated by various factors including the clot burden and hemodynamic status of the individual.

WHEN NORMAL IS ABNORMAL: IDENTIFYING VITAMIN B12 DEFICIENCY Rachel Solomon²; Jenny J. Lin¹; Aparna Sarin¹. ¹Mount Sinai, New York, NY; ²Mount Sinai Medical Center, New York, NY. (Tracking ID #2196125)

LEARNING OBJECTIVE #1: Recognize signs and symptoms of vitamin B12 deficiency in patients with history of alcohol dependence.

LEARNING OBJECTIVE #2: Diagnose B12 deficiency in the presence of a normal serum B12 level

CASE: A 56 year-old woman was seen for primary care follow-up after an emergency room visit where she had presented with a five-minute episode of dizziness and blurred vision. Her past medical history was significant for hyperthyroidism for which she was no longer taking medication. During the visit, the patient described one year of fatigue, weakness, shortness of breath, episodic pre-syncope and bilateral lower extremity paresthesias worsening over the past few months. She also acknowledged long-standing depression and disclosed a history of alcohol dependence (1 l of vodka / day) for the past 40 years. Physical exam was notable for mental sluggishness with an odd affect, photophobia and a slow, shuffling gait. Cranial nerves, strength, and sensation to light touch were grossly intact. Romberg and vibration sense were not checked. Review of labs drawn in the ER revealed normal TSH and a mild pancytopenia (hemoglobin 9.2, white blood cells 3.5, platelets 114) with macroovalocytes and hypersegmented neutrophils. Additional blood tests performed at the time of her visit showed a normal vitamin B12 level of 624 pg/mL and folate level of >25 ng/mL. Further blood work, however, revealed significantly elevated homocysteine (109 mmol/L, normal <11) and methylmalonic acid levels (8.44 mmol/L, normal <0.4) confirming a diagnosis of vitamin B12 deficiency.

DISCUSSION: Vitamin B12 deficiency is a reversible cause of bone marrow failure and demyelinating disease frequently seen in alcoholics and the elderly. A cofactor for methionine synthase and L-methylmalonyl-coenzyme A mutase, vitamin B12 (cyanocobalamin) is needed for DNA and RNA synthesis and red cell production. It is also critical for the myelination and maintenance of the central nervous system. Because cyanocobalamin cannot be manufactured by the body, it must be obtained through diet (in animal protein or supplements). Its uptake in the intestines depends on intrinsic factor (produced by gastric parietal cells) and absorption in the terminal ileum. The most common causes of vitamin B12 deficiency are lack of intrinsic factor (seen in pernicious anemia and atrophic gastritis), dietary deficiencies (particularly among chronic alcohol users or vegans), malabsorption syndromes (including Crohn's disease) and chronic use of medications including H2 blockers, proton pump inhibitors and metformin. Our patient presented with classic neurologic and hematologic findings. In addition to commonly seen paresthesias and gait instability, she displayed weakness, fatigue, altered mental status ("megaloblastic madness"), cognitive deficits and autonomic instability causing episodic postural hypotension. Consistent with a well-described inverse correlation between degree of neurologic dysfunction and anemia in B12 deficiency, her anemia was mild. Her blood count and smear showed typical hematologic findings of pancytopenia, macroovalocytes, and hypersegmented neutrophils. Patients may also present with pallor, edema, jaundice, impaired vibration sense or a positive Romberg test. Our patient also illustrates an important diagnostic conundrum: her B12 level was normal. Vitamin B12 assays are problematic largely due to issues isolating cyanocobalamin from its binding proteins (transcobalamin and intrinsic factor) and they have shown poor agreement across laboratories. False negative and false positive values occur in up to 50 % of tests. Given the limitations of existing assays, the B12 level alone is not sufficient to rule out deficiency in the setting of clinical abnormalities. In cases where serum B12 levels are normal or borderline (200–350 pmol/L) but there is a high suspicion for B12 deficiency, serum homocysteine and methylmalonic acid levels should be checked. Elevated levels of homocysteine and methylmalonic acid have been shown to be highly sensitive and specific for vitamin B12 deficiency. As is likely in our patient, hepatic stores of cyanocobalamin often delay symptom onset for 5–10 years from onset of deficiency. At diagnosis, patients require high dose repletion in the form of 1 mg daily, then weekly, then monthly intramuscular injections or 1–2 mg daily oral supplementation. Our patient showed rapid symptom response to injections and will likely benefit from oral supplementation for long-term maintenance.

A RARE CASE OF DEXTROCARDIA ASSOCIATED WITH AN ABDOMINAL AORTIC ANEURYSM Robby Singh. Wayne State University / DMC, Detroit, MI. (Tracking ID #2199394)

LEARNING OBJECTIVE #1: Recognize dextrocardia and its various subtypes

LEARNING OBJECTIVE #2: Appreciate the imaging findings of dextrocardia associated with an infrarenal abdominal aortic aneurysm

CASE: Sixty-seven year old male with a known history of dextrocardia, smoking, CABG, and coronary stenting had multiple admissions for chest pain syndrome. On one of those admissions, CT of the chest was performed after acute coronary syndrome was ruled out. The CT scan of the chest showed an infrarenal aortic aneurysm that measured 3.8 cm × 3.7 cm. Repeat CT of chest and abdomen was done one year later showed an infrarenal abdominal aortic aneurysm measuring 4.2 × 4.4 cm extending a length of approximately 7.5 cm. Both common iliac arteries also showed aneurysmal dilatation measuring 1.7 cm on the right and 1.6 cm on the left. Patient was referred to vascular surgery who assessed him stable to be followed as outpatient in a few months with repeat surveillance CT scans.

DISCUSSION: Dextrocardia is a rare congenital abnormality characterized by reversal of the position of the heart to the right side of the thoracic cavity. The incidence is estimated

to be about 1 in 12,109 pregnancies in the US. Situs inversus totalis is a rare congenital abnormality that is reported to occur in 0.0025–0.01 % of the population. Situs inversus has been reported in association with abdominal aortic aneurysm in one case but dextrocardia alone has never been reported in association with abdominal aortic aneurysm. We herein report an interesting case of dextrocardia with an abdominal aortic aneurysm. Dextrocardia is a very rare congenital abnormality and there are no reported cases of dextrocardia with abdominal aortic aneurysm in the medical literature. Though this patient had other risk factors for abdominal aortic aneurysm including smoking and atherosclerotic disease, it cannot be said with certainty if dextrocardia did have any relationship with the aneurysm. Should every patient with dextrocardia have a CT abdomen to rule out abdominal aortic aneurysms? At present, there is no literature to support it but we believe that the findings of this case warrant further discussions on the topic.

FATIGUE: A COMMON COMPLAINT WITH MULTIPLE MEANINGS Gene R. Conley; Tony Chon; Adam P. Sawatsky. Mayo Clinic, Rochester, MN. (Tracking ID #2198960)

LEARNING OBJECTIVE #1: Use the history and clinical presentation to better understand the meaning of “fatigue” as a chief complaint.

LEARNING OBJECTIVE #2: Perform age-appropriate, sequential evaluation based on the clinical presentation of fatigue, a common primary care complaint.

CASE: A 73-year-old man presented to clinic with the chief complaint of increasing fatigue that began insidiously and had been gradually worsening over the past 2 months. He was unable to identify any inciting factors. He described his fatigue as a generalized decrease in energy that prevented him from being active in his retirement hobbies. He did not experience any decreased desire to be active in his daily activities. He did not have any increased daytime sleepiness. Both he and his wife endorsed that he had 7 h of sleep per night, without any snoring or snort arousals. He awoke 1–4 times per night to urinate. He did not endorse any fevers, chills, weight loss, decreased appetite, night sweats, lightheadedness, shortness of breath, cough, chest pain or palpitations, melena, muscle weakness, joint or back pains, myalgia or symptoms of depression apart from decreased energy. During the initial evaluation, he was noted to have a long-standing history of sleep-disordered breathing diagnosed in the 1990's. He was unable to complete formal sleep study on more recent evaluation due to inability to sleep with any device placed on the body. In addition, he suffered from chronic sinusitis. He drank 5–7 oz of liquor per week and had a 10 pack-year smoking history, quitting 40 years prior to presentation. He was not on any new medications or over-the-counter medicines or supplements. He had normal heart, lung, thyroid and neurologic exams. Nasal passages were swollen and erythematous. There was no palpable lymphadenopathy or palpable organomegaly on abdominal exam. There was no peripheral edema. His hemoglobin was 12.9 with macrocytosis of 95.2. His erythrocyte sedimentation rate was elevated at 57. His vitamin B12, folate, thyroid-stimulating hormone, electrolyte panel and creatinine and liver enzymes were normal. At the initial visit, we discussed decreasing his alcohol intake, treating his chronic sinusitis with fluticasone and sleep hygiene, including limiting afternoon coffee and fluids in the evening. He returned to clinic in one month with worsening symptoms of fatigue. He had cut down on his alcohol intake to 1–2 drinks per week. His sinusitis was improved. He had implemented the sleep hygiene measures with no nocturia. Given his anemia and elevated erythrocyte sedimentation rate, along with his unimproved fatigue, serum and urine protein electrophoresis were obtained. These studies revealed an IgA lambda monoclonal gammopathy with an M-spike. A bone marrow biopsy was performed, which showed focal marrow involvement consistent with a B-cell lymphoproliferative disorder. A PET/CT revealed a hypermetabolic retroperitoneal mass and CT-guided biopsy revealed an indolent B-cell lymphoma.

DISCUSSION: This case highlights the complexity of diagnosis of fatigue, a prevalent complaint in primary care that has a multitude of potential etiologies. It is important to take a systematic approach, to avoid missing important clues to serious underlying disease. One proposed approach to the work-up of fatigue is the following: 1) Take a thorough history to understand what patient means by fatigue, which can mean shortness of breath, excessive daytime sleepiness, dizziness, muscle weakness or decreased desire to perform pleasurable activities. 2) Ensure that the patient has appropriate sleep hygiene, as one proposed definition for chronic fatigue is decreased energy that does not improve with adequate sleep. 3) With the history and physical exam, elicit clues that can lead to the underlying cause. The differential includes endocrine disorders, neurological disorders, infection, malignancies, psychiatric disorders, hematological disorders, liver disease, fibromyalgia and underlying sleep disorders. 4) Obtain appropriate laboratory testing based on the differential. Most useful initial laboratory tests are CBC, TSH, electrolyte panel with BUN and creatinine, ESR, liver enzymes. HIV testing should be obtained on all adults and hepatitis C screening for adults born between 1945 and 1965. 5) If chronic fatigue is worsening or not improving with treatment of potential inciting factors, reviewing the case again with the above differential in mind may help to elicit an underlying cause. 6) If no cause elicited for chronic fatigue, acknowledge the patient's

symptoms and frankly discuss the lack of diagnosis underlying their fatigue. Encourage physical activity and continued emphasis on sleep hygiene. Additional laboratory testing is not of high value. Finally, consider a diagnosis of chronic fatigue syndrome with long-standing idiopathic fatigue.

THE METAMORPHOSIS OF A HORSE INTO A ZEBRA: A CASE OF ATYPICAL SARCOIDOSIS Manaf Assafin; Anand Jagannath; Sheira Schlair. Albert Einstein College of Medicine/Montefiore Medical Center, Bronx, NY. (Tracking ID #2200025)

LEARNING OBJECTIVE #1: Recognize the neurologic and cardiac presentations of sarcoidosis

LEARNING OBJECTIVE #2: Describe the workup for a patient with suspected sarcoidosis

CASE: A 41 year-old woman with a 20-year history of atrial flutter and hypertension presented with dysgeusia, xerostomia, and a 30-lb unintentional weight loss for 3–4 months with associated lower extremity edema. Subsequently she developed paresthesias over her right forehead and anterior right thigh. She denied any fevers, chills, night sweats, cough, arthralgias, exertional intolerance, or unilateral weakness. An electrocardiogram revealed a normal sinus rhythm with a left bundle branch block which had been previously present. Thoraco-lumbar magnetic resonance imaging (MRI) was performed which revealed massive supraclavicular, mediastinal, and hilar lymphadenopathy. A supraclavicular lymph node biopsy revealed non-caseating granulomas. An echocardiogram performed to evaluate her pedal edema revealed new systolic dysfunction with a LVEF of 30 %. Serum ACE level was elevated at 302 U/L (normal 8–53 U/L). Cardiac MRI was consistent with sarcoidosis. A diagnosis of sarcoidosis with neurologic and cardiac manifestations was made. She was started on oral prednisone therapy, with improvement in her xerostomia, dysgeusia, and paresthesias. She eventually underwent placement of biventricular implantable cardioverter defibrillator for primary prevention of sudden cardiac death.

DISCUSSION: Sarcoidosis is a multi-system disease that can present in a multitude of ways. Our patient did not present with classical pulmonary manifestations, but with a rare combination of peripheral neuropathies and pedal edema and was found to have advanced cardiac involvement with severe systolic impairment at the time of her diagnosis. This cadre and profundity of symptom burden is quite rare in her age bracket. Our patient represents the approximately 5 % of cases who present with neurologic involvement. Cranial mononeuropathies are the most common manifestation of neurosarcoidosis, as in the case of our patient. Other neurologic involvement may present with neuroendocrine dysfunction, encephalopathy, myelopathy, or aseptic meningitis. Similarly, 5 % of clinical sarcoidosis presents with cardiac involvement, which can manifest variably, ranging from asymptomatic disease to sudden cardiac death - including arrhythmias, pericardial disease, valvular heart disease, conduction disease, and heart failure, the latter two of which our patient suffered. Of particular note, she had been diagnosed with atrial flutter in her 20's, which may have been an initial manifestation of cardiac sarcoidosis heralding development of systolic dysfunction. Workup for suspected sarcoidosis includes a tuberculin skin test and a posteroanterior chest radiograph or chest CT. Biopsy of affected tissue consistent with non-caseating granulomas is usually required to confirm the diagnosis. In neurosarcoidosis, an effort should be made to locate extra-neural tissue for biopsy, with special attention paid to the skin, lungs, and lymph nodes, as neurodiagnostic testing is difficult and has low sensitivity. In cases of suspected cardiac sarcoidosis, a cardiac MRI or PET scan should be obtained to enhance disease detection and monitor response to therapy. Endomyocardial biopsy is controversial as it may not alter outcomes. For patients with symptomatic or progressive sarcoidosis, including neurologic disease or advanced cardiac involvement as in our patient's case, oral glucocorticoids are the mainstay of therapy, with immunomodulation in the longterm. Cardiac ejection fraction is monitored to determine medication titration. Internists often encounter diagnostic challenges when patients present with a broad constellation of seemingly unrelated multi-system symptoms and findings. As our case highlights, clinicians should consider atypical sarcoidosis when faced with an atypical multi-system syndrome.

ESCHERICHIA COLI THORACIC SPINE SPONDYLODISCITIS AFTER GENITOURINARY TRACT INFECTION Chiara J. Chong. Singapore General Hospital, Singapore, Singapore. (Tracking ID #2197462)

LEARNING OBJECTIVE #1: Recognise that genitourinary tract infections can cause thoracic spine spondylitis.

LEARNING OBJECTIVE #2: Manage pyogenic spine infections.

CASE: Two patients presented with similar complaints of subacute back pain and were both found to have thoracic spine spondylitis on radiological imaging. The first patient, Mr A, is a 74 year old gentleman with diabetes who complained of fever of one month's duration. This was accompanied by left sided loin pain. Total white cell count was 19×

10^9 /L, C-reactive protein 90.4 mg/L, prolactin 16.2 ug/L, and erythrocyte sedimentation rate 66 mm/h. Urine cultures did not reveal any bacterial growth, but blood cultures grew pan sensitive *Escherichia coli*. Computed tomography of the abdomen was suspicious for bilateral prostatic abscesses, T7/8 endplate destruction with perivertebral and right epidural soft tissue suggestive of infective discitis. Magnetic resonance imaging of the spine confirmed T7/8 osteomyelitis and discitis with mild cord compression. He subsequently underwent biopsy of the T7/8 inter-vertebral disc. Gram stain, aerobic cultures, acid fast bacilli smear and culture, tuberculous quantiferon returned negative for any growth. Histology showed mild chronic inflammatory infiltrate in keeping with chronic discitis. He was planned for a total of 6 weeks of intravenous cefazolin but was re-admitted in the fourth week of treatment for new onset bilateral lower limb weakness and numbness. During his second admission, repeat magnetic resonance imaging showed interval progression of the T7/8 infection with a new focus at the T9 body and worsening cord compression. He underwent early decompression laminectomy of T7-9 and was found intra-operatively to have cord compression secondary to epidural abscess. Intra-operative tissue culture, acid fast bacilli culture and tuberculous PCR returned negative. Histology showed lamellar bone and fibroconnective tissue. Post operatively he completed the planned duration of 6 weeks of antibiotics. Lower limb neurological power remained between two to three on the Medical Research Council score and he was started on intense physiotherapy. The second patient, Mr B, is an 81 year old gentleman with diabetes and a recent admission for extended spectrum beta-lactamase *E. coli* urinary tract infection and bacteremia. He was treated with 2 weeks of ertapenem and discharged well. He represented with lower back pain of 1 month duration, with no fever or neurological symptoms. Laboratory investigations were as follows: white cell count 9×10^9 /L, C reactive protein 79 mg/L, prolactin 1.5 mcg/L, erythrocyte sedimentation rate 140 mm/h. Magnetic resonance imaging showed T8/9 marrow infiltration with high T2 signal compatible with spondylodiscitis, without any evidence of cord compression. Similarly, he also underwent biopsy of the spine and tissue cultures grew *E. coli* sensitive to ertapenem and amikacin. He was planned for a total of 6 weeks of ertapenem and transferred to a step down hospital for further rehabilitation.

DISCUSSION: Both cases illustrate how genitourinary tract infections can give rise to spondylodiscitis of varying severity. Both patients have diabetes which is a known risk factor of spinal infection¹. They presented with classical symptoms of fever, back pain, limb numbness and neurological deficits.¹ Early recognition and surgery when indicated is crucial in limiting neurological progression. Spinal infections can be classified by infective organism into pyogenic or tuberculous infections. Biochemical features such as markedly raised white cell count, erythrocyte sedimentation rate and C reactive protein are suggestive of pyogenic infections.¹⁻⁴ Radiological features - location of abscess, contrast enhancement, site/ number/ position of vertebral involvement, degree of disc destruction, are useful in providing clues to the infective etiology. Pyogenic infections tend to affect the lumbar spine and tuberculous infections the thoracic spine. The above patients had both normal and markedly abnormal infective markers, and radiologic involvement of the thoracic (not lumbar) spine. This illustrates the importance of obtaining tissue cultures to determine etiology, so that appropriate treatment can be instituted. References 1. S-J Jeong, S-W Choi, Y-Y Youm et al. ROUTELLA ORNITHINOLYTICA BACTEREMIA IN THE SETTING OF BLADDER CANCER: A NOVEL PRESENTATION OF A RARE PATHOGEN Ramy Sedhom¹; Tanaya Bhowmick. Rutgers- Robert Wood Johnson, New Brunswick, NJ. (Tracking ID #2193523)

LEARNING OBJECTIVE #1: Recognize the association of *Routella ornithinolytica* bacteremia with malignancy.

LEARNING OBJECTIVE #2: Identify a novel presentation of a rare pathogen increasing awareness of its clinical importance.

CASE: Reported cases of *Routella* infections are well described for histamine poisoning following consumption of stale scombroid fish. *Routella* is a rare pathogen in human infection and bacteremia is infrequently reported. Risk factors include biliary pathology, particularly in the setting of malignancy. We report the first case of *Routella ornithinolytica* bacteremia associated with bladder cancer. A 60-year old male presented with fever, dysuria, and shaking chills of two days duration. Past medical history included DM II, HTN, HLD, and newly diagnosed bladder carcinoma. He denied any history of hepatic or biliary disease. Medications included metformin and Lantus daily. He reported a 60 pack-year smoking history and no recreational drug use. His father died of lung cancer.

He was diagnosed with bladder carcinoma 1 week prior to hospital admission following an episode of gross hematuria and urinary retention. Cystoscopy revealed a 10×14 cm mass at the left lateral bladder wall. At the time of admission, he complained of decreased oral intake for 3 days, shaking chills, lethargy, and generalized weakness. He denied abdominal pain, jaundice, easy bruising, or recurrence of hematuria. On admission, patient was afebrile, normotensive, with pulse 102, respiratory rate 30, and O2 sat 98 % on room air. Physical exam revealed dry mucus membranes and hypoesthesia of the bilateral lower extremities. There was no stigmata of chronic liver disease or presence of asterixis. Basic profile included mild acute kidney injury, with creatinine of 1.6, from baseline of 1. Blood sugar was 536 and an anion gap of 32 was noted. Lactate was 14.1. CBC was notable for a white count of 17.8, with neutrophil predominance and left shift. Platelets were 188. Hepatic function panel was within normal limits. Urinalysis was significant for 4+ glucose, 2+ blood, 3+ Leukocyte esterase, negative nitrites, and 45 WBC/HPF. There were rare hyaline casts and trace proteinuria. Urinary ketones were not present. Renal ultrasound did not show any abnormalities. The patient was admitted to the ICU for DKA and sepsis likely secondary to bladder pathology. He was empirically started on vancomycin and piperacillin/tazobactam. Two days following admission, gram-negative rods were found in the urine. His anion gap closed quickly on an insulin drip and AKI resolved with fluids. Urine culture was positive for *Routella ornithinolytica*. The bacillus was sensitive to levofloxacin, piperacillin/tazobactam, trimethoprim/sulfamethoxazole, tobramycin, and resistant to ampicillin. Bladder scans during hospitalization showed minimal urinary retention. Treatment was narrowed to levofloxacin to complete 14-day treatment. He was seen following discharge by urology for tumor staging and noted to be well. Of note, the biliary and portal system were within normal limits.

DISCUSSION: *Routella ornithinolytica* is a gram-negative aerobic bacillus belonging to the Enterobacteriaceae family. It rarely causes human infections. Of those reported, the majority of isolates are associated with gastrointestinal malignancy and biliary pathology. The patient reported was not on antibiotics, had no history of hepatic or biliary disease, and no recent biliary intervention. In addition, he had not eaten fish for over 6 months. With respect to antibiotic susceptibility, *R. ornithinolytica* has been known to be resistant to ampicillin. Our patient's case paralleled the literature. In almost all cases, the final diagnosis was biliary tract infection with bacteremia and no rash indicative of a histamine reaction. Further investigation is necessary to assess the importance and prognosis of *R. ornithinolytica* bacteremia. This is the first case of bacteremia in the setting of underlying bladder cancer to our knowledge. *R. ornithinolytica* remains a causative pathogen of infection in the immunocompromised and post-surgical patients, especially those with underlying malignancy.

MARIJUANA INDUCED BILARY DYSKINESIA Reem Al-Mahdawi¹; Larry J. McMann¹; Tiba Alwardi²; Maliha Naseer¹; Hussam Sabbagh²; Zain Kulaini¹. ¹Wayne State University, Rochester, MI; ²Wayne State University, Rochester Hills, MI; ³Wayne state university, Rochester Hills, MI. (Tracking ID #2197522)

LEARNING OBJECTIVE #1: Recognize that chronic marijuana usage can be an independent risk factor for biliary dyskinesia. Propose a possible mechanism based on the current literature and provide a platform for further investigation.

CASE: A19 year old female with no significant past medical history was admitted to our internal medicine service after being seen in the emergency room on two previous occasions in the prior week for abdominal pain, nausea, diarrhea, and vomiting. She had a social history significant for daily marijuana usage over the last 5 years. Work up during the first two presentations included a computed tomography (CT) of the abdomen which was negative. Labs were unremarkable. She was given antiemetics, narcotic pain medication and sent home with a diagnosis of gastroenteritis. On the day of her second discharge she returned 8 h later with severe nausea and vomiting. The patient reported that she now had severe colicky abdominal pain. Labs and vitals were unremarkable. Physical exam was positive for diffuse abdominal pain with palpation, worse in the right upper quadrant. An upper endoscopy was done which showed gastritis. She continued to have nausea and pain despite treatment. Surgery evaluation was obtained and a hepatic biliary scan was ordered. The results demonstrated a gallbladder ejection fraction of 19 %. She subsequently underwent a laparoscopic cholecystectomy and her symptoms of pain and nausea resolved.

DISCUSSION: Biliary dyskinesia related to cannabis use has never been reported in the literature. The patient in the above case is the first suspected case. In a study in 2001 they looked at the effect of CB1 cannabinoid receptors in rat hippocampal slices and it's effect on cholecystokinin (CCK) release. They concluded that activation of the CB1 receptors in the brain lead to less release of CCK which could contribute to learning and memory deficits. Many studies in the literature have pointed that cannabinoid receptor activation in the gut have lead to a decrease in peristalsis. We hypothesize that cannabinoid receptors in the gut inhibit CCK release and lead to biliary dyskinesia. In Conclusion, cannabis use and it's effects on the gastrointestinal system have focused primarily on it's anti peristaltic properties in the gut. Research and prevalence on the biliary dyskinesia associated with

cannabis has not been studied. This observation and hypothesis leads the way for a possible case series and further study.

5-FLUOROURACIL CARDIOTOXICITY MANIFESTING AS ST-ELEVATION MYOCARDIAL INFARCTION Krithika Krishnarao; Orestis Pappas; Moneal Shah; Indu Poomima. Allegheny General Hospital, Pittsburgh, PA. (Tracking ID #2196692)

LEARNING OBJECTIVE #1: Recognize cardiotoxicity in patients receiving 5-fluorouracil (5-FU)

LEARNING OBJECTIVE #2: Assess other options of chemotherapy in patients with underlying cardiac disease

CASE: We present the case of a 56-year-old Caucasian male with a previous history of atrial fibrillation on anticoagulation with rivaroxaban and recently diagnosed adenocarcinoma of the high rectum who presented with acute onset of left arm pain 3 days following initiation of chemotherapy with 5-fluorouracil, leucovorin, and oxaliplatin (FOLFOX). He did not have any other prior history of malignancy, treatment with anthracyclines, or previous radiation therapy to the chest. Plain radiographs of the elbow, radius, and ulna were negative for fracture or dislocation and his arm pain resolved. Electrocardiogram (ECG) revealed normal sinus rhythm with heart rate of 72 beats per minutes. His arm pain recurred and ECG was repeated, which showed new ST-segment elevation in leads I, II, aVL, V4-V6 consistent with acute anterolateral injury. Troponin I was elevated from 0.04 to 0.08 and he underwent emergent cardiac catheterization. Results showed 40–50 % stenosis of the mid left anterior descending coronary artery and 80–90 % stenosis of the first diagonal branch with Thrombolysis in Myocardial Infarction (TIMI) angiographic grade 3 flow. Left ventricular ejection fraction was 60 % with normal wall motion. Anticoagulation with heparin infusion was continued and he was transferred to the cardiac intensive care unit. The following morning, he developed left arm pain associated with nausea and diaphoresis. ECG was repeated and showed ST-elevation in I, II, aVL, V5, and V6. His symptoms resolved spontaneously and repeat ECG showed resolution of his ST-segment elevations. Given his transient symptoms and associated ECG changes, he was diagnosed with ST-elevation myocardial infarction secondary to coronary vasospasm. This was attributed to his recent initiation of chemotherapy with 5-FU, which has known cardiotoxic effects. Transthoracic echocardiography showed an ejection fraction of 35–40 % with moderate left ventricular systolic dysfunction, mild concentric left ventricular hypertrophy, and moderate to severe inferior wall hypokinesis. He was started on therapy with metoprolol succinate, lisinopril, spirinolactone, isosorbide mononitrate, atorvastatin and continued on rivaroxaban for anticoagulation for atrial fibrillation. His chemotherapy will be adjusted to exclude further use of 5-FU.

DISCUSSION: 5-fluorouracil (5-FU) is commonly used as a chemotherapeutic agent in the treatment of gastrointestinal malignancies. Cardiotoxicity, in the form of angina, myocardial infarction, cardiomyopathy, arrhythmias, and sudden cardiac death have been described with use of 5-FU in patients with and without underlying coronary artery disease. Although not well understood, coronary vasospasm, endothelial dysfunction, direct myocardial injury, and accumulation of toxic metabolites have been described as suggested mechanisms of cardiotoxicity. There have been case reports and studies describing the cardiotoxicity associated with 5-FU; however, it is not well recognized by clinicians. The common use of 5-FU as part of a chemotherapeutic regimen may pose a risk, especially in those with underlying coronary artery disease in whom the incidence of ischemia has been shown to be higher. Many cases have been described in those with no prior cardiac history, making it difficult to determine who would be more susceptible to the cardiotoxic effects of this agent. Markers of injury may need to be discovered to predict cardiotoxicity and guide therapy. Direct injury to the myocardium from some chemotherapeutic agents may lead to troponin elevation, which is not readily recognized. Jensen et al. (2010) showed N-terminal pro-brain natriuretic peptide (NT-proBNP) levels increased during FU therapy in a prospective study of 106 colorectal cancer patients. This may need to be explored further to discover more accurate measurements of predicting future cardiotoxicity. Although some effects may be reversible upon discontinuation of 5-FU, more serious adverse cardiotoxic effects have been described. There are also cases of recurrent cardiac events following re-challenge with 5-FU in those with reversible effects. Prophylaxis with vasodilators such as nitrates or calcium channel antagonists have shown inconclusive results in preventing cardiotoxicity. Chemotherapy may need to be adjusted, particularly in patients with underlying coronary artery disease, and newer chemotherapeutic agents may need to be discovered, which pose fewer cardiotoxic effects.

A 21-YEAR- OLD WOMAN WITH FEVER AND SORE THROAT: LEMIERRE'S SYNDROME WITH FUSOBACTERIUM NECROPHORUM BACTEREMIA Utibe R. Essien. Massachusetts General Hospital, Boston, MA. (Tracking ID #2193416)

LEARNING OBJECTIVE #1: Recognize the clinical features and diagnostic challenges of Lemierre's Syndrome.

LEARNING OBJECTIVE #2: Recognize and manage the complications associated with Lemierre's Syndrome.

CASE: A 21-year-old Saudi-Arabian woman with a past medical history of G6PD deficiency presented to an outpatient clinic with one day of subjective fevers, fatigue and left-sided throat pain. The patient denied any associated symptoms of cough, difficulty swallowing or dyspnea. The patient had not traveled to Saudi Arabia since arriving in the United States 3 months prior and denied any other local travel, tick or mosquito exposure or additional sick contacts. Clinical exam of the oropharynx revealed mild erythema without exudate. There was no cervical lymphadenopathy or tenderness appreciated. A rapid strep test was performed and was negative for streptococcus group A. The patient was sent home with antipyretics for a presumed viral upper respiratory infection. Six days later, the patient returned to the Emergency Department with persistent fevers, malaise, sore throat and a new non-productive cough. Her exam was notable for an ill-appearing woman, tachypneic and tachycardic with a heart rate in the 130 s and a blood pressure of 100/70. Her temperature was noted to be 101.4. Oropharyngeal exam remained unremarkable. Initial workup included an elevated white blood cell count of 12.7 K/uL with a neutrophilic predominance. Lab work was also notable for a negative heterophile antibody, Lyme titer, malaria antigen test, Ehrlichia DNA PCR, HIV-1 RNA PCR and viral respiratory panel. A chest x-ray was obtained and was normal. Urine and blood cultures were sent as the patient was admitted to the medical service for further management. On hospital day 2 the patient was noted to be acutely hypoxic, dropping her oxygen saturation to 88 % despite supplementation with a non-rebreather mask. A repeat chest x-ray was obtained which revealed diffuse bilateral interstitial opacities. The patient was started on ceftriaxone and azithromycin and transferred to the intensive care unit (ICU) for management of noncardiogenic pulmonary edema. On transfer to the ICU, preliminary blood culture data confirmed that 2/4 anaerobic bottles had grown gram-negative rods and the patient's antibiotic coverage was broadened to vancomycin and meropenem. On arrival to the ICU, the patient was intubated and placed on mechanical ventilation. Persistent hypotension necessitated the placement of a central venous catheter for vasopressor initiation. During catheter placement, a thrombus was seen on ultrasound of the left internal jugular vein. Of note, a computed tomography (CT) scan of the neck had been obtained the day prior with normal enhancement of all vascular structures reported. A CT of the chest also revealed cavitary subpleural lower lobe opacities concerning for septic emboli. A formal ultrasound was obtained which confirmed the presence of a partially occlusive thrombus along the posterior wall of the left internal jugular vein. A few hours later, the patient's gram-negative rod bacteremia was confirmed to be *Fusobacterium necrophorum*.

DISCUSSION: Lemierre's Syndrome (jugular vein suppurative thrombophlebitis) is an extremely rare cause of fever and sore throat in a young woman, with only a few case reports available in the literature. *Fusobacterium necrophorum* is the typical pathogen associated with the syndrome, and bacteremia with this organism is an uncommon complication of Lemierre's Syndrome. As such, it is important to recognize the key features of the syndrome including fevers, chills, exudative tonsillitis, sore throat, dysphagia, cervical lymphadenopathy and unilateral neck pain in the background of a preceding pharyngeal illness. Radiographic imaging to determine the presence of septic thrombophlebitis is essential to the diagnosis, and while evidence supports CT-scan of the neck with contrast as the key imaging tool, ultrasonography can be considered on the basis of its ability to identify and assess the extent of thrombus. The mainstay of management of the various complications of Lemierre's Syndrome, including bacteremia, meningitis and metastasis to the lungs, brain, heart, GI tract, kidneys and joints, is a prolonged (up to 6 weeks) course of antibiotics. While no clinical trials are available, carbapenem, a penicillin/beta-lactamase inhibitor combination, or metronidazole are recommended for antibiotic coverage.

A BIOPSY PROVEN IRREVERSIBLE TENOFOVIR-INDUCED RENAL TOXICITY PRESENTING AFTER 10 YEARS OF USE Javier Rodriguez Sanchez; Mark D. Faber; Norman Markowitz. Henry Ford Hospital, Detroit, MI. (Tracking ID #2196684)

LEARNING OBJECTIVE #1: Recognition of tenofovir-induced nephrotoxicity.

CASE: We describe a case of biopsy proven irreversible renal toxicity secondary to tenofovir. A 65-year-old African American 50 kg male with history of HIV, first diagnosed in 1991, treated with TDF, emtricitabine and nevirapine since 2004 presented to clinic with chief complaint of lower extremity swelling and difficulty concentrating. Physical exam was significant for fluid overload and decrease mentation. Initial laboratory studies revealed a creatinine of 24.4 mg/dL and BUN of 109 mg/d. The patient had a renal injury 6 months prior to his last known creatinine level, that resolved (creatinine 0.9 mg/dL and BUN 14 mg/dL on 11/2013) without further work up at that time. He is not diabetic, but has a history of well-controlled hypertension. On 11/2013 CD4 count had been approximately 900 cells/mm³ and HIV RNA undetectable. Urine microscopy revealed muddy brown granular casts consistent with acute tubular necrosis. TDF therapy was discontinued. Renal replacement therapy was started. Kidney biopsy was done confirming acute tubular necrosis and revealing global glomerulosclerosis, tubular atrophy and

interstitial fibrosis; electron microscopy reported tubular epithelial cells containing swollen and structurally abnormal mitochondria consistent with TDF-induced toxicity. Upon follow up; renal function did not improve. Renal replacement therapy was continued and kidney transplant evaluation was started.

DISCUSSION: Tenofovir (TDF) is a nucleotide reverse transcriptase inhibitor. In combination with other antiretroviral agents, TDF is the first line treatment for HIV-1 infection. It is the most prescribed antiretroviral and is the drug of choice in HIV and hepatitis B co-infection. Renal toxicity has been reported in only 0.5 % of patients on tenofovir but is being increasingly recognized. Risk factors include older age, preexisting renal impairment, uncontrolled HIV infection, low body weight and concomitant nephrotoxic medication use. The main adverse effect in tenofovir toxicity is in the proximal tubule cells secondary to the high mitochondrial activity of such cells. Clinical presentation is proximal tubular dysfunction with or without decrease in renal function. Most reported cases describe a generalized proximal tubular dysfunction consistent with complete or incomplete Fanconi's syndrome. Close monitoring of renal function and management of known risk factors are necessary yet not entirely sufficient for a proper renal function evaluation making prompt recognition of toxicity and discontinuation of the drug necessary. Tubular proteinuria precedes the decrease in renal function; reason why recent guidelines recommend at least biannual monitoring of renal function, serum phosphorus, proteinuria, and glycosuria to assist in the early recognition of tenofovir toxicity before renal function decreases. Additional testing might be considered to improve renal safety follow up including urine-beta 2 microglobulin and cystatin C. During renal biopsy; proximal tubular injury, ranging from diffuse and severe to mild and localized, was the major finding and the distinctive finding is prominent eosinophilic intracytoplasmic inclusions representing giant mitochondria with abnormal structure. The main line of treatment is discontinuation of tenofovir with renal recovery back to previous baseline observed in 50 % of the patients.

A BLEEDING HEART: CORONARY ARTERY BYPASS GRAFT IN THE SETTING OF IDIOPATHIC THROMBOCYTOPENIC PURPURA Ramy Sedhom; Jalal Baig; Charles L. Liu; Ranita Sharma. Rutgers-Robert Wood Johnson Medical School, Harrison, NJ. (Tracking ID #2195039)

LEARNING OBJECTIVE #1: Recognize the dilemma in treating acute coronary syndrome in the setting of idiopathic thrombocytopenic purpura.

LEARNING OBJECTIVE #2: Illustrate the absence of evidence based guidelines in treating ACS with low platelets.

CASE: Myocardial infarction in patients with chronic thrombocytopenia is rare. Dual antiplatelet therapy is integral to coronary stenting procedures. The coexistence of idiopathic thrombocytopenic purpura (ITP) poses serious challenges to this management strategy. Case reports describe success holding antiplatelet therapy and initiating thrombopoietic agents prior to coronary interventions. Published data to guide management is limited. We describe a case of ITP presenting with Acute Coronary Syndrome (ACS) with triple vessel disease. A 67-year old male presents with sub-sternal exertional chest pain, which progressed to pain at rest over a one month period along with progressive dyspnea of 1 week duration. There was no history of syncope, palpitations or lower extremity edema. He denied recent illness, constitutional symptoms, mucosal bleeding, easy bruising or a petechial rash. Past medical history includes ITP (platelets last known 40,000), hypertension, hyperlipidemia, schizophrenia and mental retardation. He does not take any medications. He denies smoking, drinking or illicit drug use. He lives and works on the grounds he maintains. He was estranged from his family. Surgical history includes successful inguinal hernia repair, pre-dating ITP diagnosed one month prior to presentation. Initial diagnosis of ITP responded to IVIG and prednisone. He was lost to follow up for several weeks. On admission, patient was afebrile, normotensive, with pulse 107, respiratory rate 17, and O2 sat 98 % on room air. Physical exam revealed a disheveled appearance, no evidence of JVD, clear lungs, non-displaced PMI, normal heart sounds, no murmurs, 2+ peripheral pulses and trace lower extremity edema. He was unable to participate in critical decision-making and guardianship through the courts was obtained. Renal function, PTT/INR and Hgb were normal. Basic profile was normal. Platelet count was 7000. Chest X-ray did not reveal mediastinal widening or pulmonary vascular congestion. Troponins were positive. EKG revealed sinus rhythm, with bi-atrial enlargement and new T-wave inversions in the anteroseptal leads. Cardiology and hematology were consulted for NSTEM co-management in the setting of ITP. Echocardiography revealed a dilated cardiomyopathy with global hypokinesis and EF of 20 %. Patient was classified as NYHA Stage III. Lisinopril, spironolactone, metoprolol and high dose atorvastatin were started. Aspirin and heparin were held due to thrombocytopenia. IVIG and prednisone were initiated to increase platelets. With consent, a femoral catheterization was performed and demonstrated stenosis in the mid LAD 99 %, LCX 80 % and RCA 99 %. The patient was a poor candidate for PCI due to compliance with dual antiplatelet therapy, even if for a brief period with bare metal stenting. Patient underwent a CABG with a platelet count of 124,000. After placement in a facility, longitudinal medical follow

up was established with a last platelet count, reported one year after presentation, of greater than 150,000.

DISCUSSION: ACS is rare in patients with ITP and precise recommendations for treatment are unavailable. A challenge exists due to conflicting goals in therapeutic management. The tendency to bleed due to both quantitative/qualitative deficiencies in platelets is a concern during cardiac interventions. Meanwhile, thrombolytic therapy is contraindicated in patients with ITP. Though case reports show success with bare metal stent placement, situations exist where adherence to medical therapy complicate management. In addition, no safe platelet cutoff is described. Our case describes success with CABG. However, a clinical trial is needed to better define optimal therapy in patients with co-existing thrombocytopenia.

A BONE TO PICK WITH TENOFOVIR: RECOGNIZING FANCONI SYNDROME AND OSTEOMALACIA AS SIDE EFFECTS Tanya Nikiforova²; Monica A. Gombert¹; R. Harsha Rao¹; Peter Veldkamp². ¹University Of Pittsburgh Medical Center, Pittsburgh, PA; ²University of Pittsburgh Medical Center, Pittsburgh, PA. (Tracking ID #2198675)

LEARNING OBJECTIVE #1: Identify nephrotoxicity as a common side effect of tenofovir and the importance of routinely screening patients on tenofovir for renal tubule dysfunction.

LEARNING OBJECTIVE #2: Recognize the clinical and diagnostic features of osteomalacia.

CASE: A 54-year-old woman with Human Immunodeficiency Virus (HIV) well controlled on over 10 years of emtricitabine/tenofovir/efavirenz (Atripla) and untreated Hepatitis C presents with one year of proximal muscle weakness and myalgias. She describes progressive difficulty ambulating, especially with rising from a seated position and walking up stairs, and severe pain in her hips, thighs, shoulders and right foot. On examination, she has decreased strength in her hip flexors (4/5) but normal strength in the rest of her upper and lower extremities, normal sensory exam, and 2+ symmetric reflexes throughout. She experiences pain with palpation of her upper thighs and shoulders bilaterally. Labwork is notable for a rising creatinine (1.2 to 2.0 over 3 months), hyperchloremic non-gap metabolic acidosis, hypophosphatemia (1.7), elevated alkaline phosphatase (258), and urinalysis with proteinuria, glucosuria, and hematuria. She has an elevated RF (73) but otherwise normal CPK, ESR, CRP, ANA, C3, C4, and anti-CCP levels. X-rays of her hips show sclerosis in the subtrochanteric regions concerning for subacute incomplete fractures (Looser's zones). X-rays of her right foot demonstrate subacute healing fractures in the first and third metatarsals. A bone scan shows multiple areas of increased bone turnover. Together, these findings suggest hypophosphatemic osteomalacia in the setting of Fanconi syndrome from tenofovir toxicity. The patient's tenofovir based regimen was changed to abacavir/lamivudine (Epzicom) and raltegravir (Isentress). She was started on calcitriol and phosphate repletion, and her renal function and phosphate levels normalized. Her symptoms of weakness and pain improved significantly over the next 2-4 weeks.

DISCUSSION: Tenofovir (TDF), a nucleotide reverse transcriptase inhibitor, is one of the first line medications for HIV treatment and is frequently used in the 'back bone' of antiretroviral therapy. More recently it is also being used to treat chronic Hepatitis B. The most common side effect of TDF is nephrotoxicity. Patients present with varying degrees of increased serum creatinine, hypophosphatemia, metabolic acidosis, and urinary wasting of glucose, protein, phosphate, and bicarbonate, a constellation known as Fanconi syndrome. While the incidence of overt renal failure is rare (<1 %), the frequency of proximal tubule dysfunction is common, with up to 20 % of patients affected in one prospective study. If unrecognized, renal wasting of phosphate can lead to hypophosphatemic osteomalacia, as identified in this patient. The HIV Medicine Association recommends screening patients on TDF every 6 months with serum creatinine, serum phosphate, and urinalysis for proteinuria and glucosuria. Osteomalacia is a metabolic bone disease characterized by decreased mineralization of the bone matrix. Commonly caused by vitamin D deficiency, it also occurs from phosphate wasting in proximal tubule disorders. Common clinical features include bone pain, muscle weakness, and fractures. Laboratory findings include elevated alkaline phosphatase, low serum calcium and phosphate, elevated PTH, and possibly low vitamin D levels depending on the etiology. The characteristic radiographic finding is pseudofractures, termed Looser's zones. While the gold standard for diagnosis is bone biopsy, the diagnosis can be made clinically, as in this patient. Treatment of osteomalacia includes correction of the underlying metabolic disorder and repletion of phosphate, calcium, and vitamin D. This case demonstrates an example of Fanconi syndrome leading to osteomalacia in the setting of tenofovir induced renal toxicity, and illustrates the importance of appropriately screening patients on TDF to prevent complications.

A CASE OF *STREPTOCOCCUS GALLOLYTICUS* MENINGITIS RAISING SUSPICION FOR COLORECTAL CARCINOMA Neal George, Conemaugh Memorial Medical Center, Johnstown, PA. (Tracking ID #2198785)

LEARNING OBJECTIVE #1: Recognize that *Streptococcus gallolyticus* can play a role in colon carcinogenesis.

LEARNING OBJECTIVE #2: Recognize that *Streptococcus gallolyticus* warrants workup to exclude underlying colon neoplasm.

CASE: An 84-year-old male with history of mechanical aortic valve replacement, sick sinus syndrome with pacemaker, and atrial fibrillation presented to emergency room with complaints of headache, confusion, and increasing lethargy over the last 48 h. At the time of admission, the patient was febrile with temperature of 38.9 °C and an elevated pulse at 115 beats/min. Nuchal rigidity was present on physical examination. Due to suspected meningitis, the patient was promptly started empirically on intravenous dexamethasone, acyclovir, ceftriaxone, vancomycin, and ampicillin. Non-contrast computed tomography of the brain revealed no acute abnormalities. A lumbar puncture was performed after the initiation of antibiotics in the ER with an opening pressure of 19 cm and cloudy appearing cerebrospinal fluid. CSF analysis revealed WBC of 2640/cumm with 94 % neutrophils, 3 % lymphocytes, 3 % monocytes, protein of 507.8 mg/dL, and glucose of 22 mg/dL, consistent with bacterial meningitis. CSF culture was negative for any growth. Two blood cultures obtained at the time of admission were positive for *streptococcus gallolyticus*. Transthoracic echocardiogram was negative for any vegetations. The patient was informed of the strong correlation of *S. gallolyticus* infection and possible underlying colorectal malignancy however the patient refused colonoscopy given his advanced age and comorbidities. He was treated successfully with 14-day course of IV ceftriaxone.

DISCUSSION: The *Streptococcus bovis* group non-enterococcal group D streptococcus includes *S. gallolyticus*, *S. infantarius*, *S. macedonicus*, and *S. pasteurianus*. All are found in the human gastrointestinal tract. These pathogens are associated with colorectal carcinogenesis and endocarditis. It is believed that these pathogens spread hematogenously via underlying ulcerations of neoplastic colorectal lesions. There are numerous case reports describing the relationship between *S. gallolyticus* and colorectal carcinoma, and questions remain surrounding whether the presence of the bacteria could facilitate carcinogenesis. Ruoff et al. 2007 and Corredoira et al. 2008 report associations between patients with *S. bovis* infections who underwent colonoscopy and were found to have increased incidence of colorectal adenocarcinoma as well as tubular adenomas, confirming the notion that *S. bovis* infections can be associated with premalignant colonic lesions. Abdulmir et al. 2011 elucidate possible mechanisms in which *S. gallolyticus* participates in the carcinogenesis of colorectal mucosal tissues by increased tumor tissue-selective adhesion, induction of inflammatory mediators, selective colonization of tumor cells, and subsequent local disruption of tumor tissues and capillaries aiding in its hematogenous spread. Biarc et al. 2004 reported that *S. bovis* releases proteins that stimulate inflammation and has been associated with COX-2 over expression, suggesting that the pro-inflammatory potential of *S. bovis* can play a role in colon carcinogenesis. The association between *S. bovis* infections and colon cancer should not be underestimated and full bowel examination is highly recommended especially when it concerns *S. gallolyticus* bacteremia. Further studies are needed to elucidate the pathogenesis, possible pro-carcinogenic properties, and detection of the *S. bovis* group.

A CASE OF A RENAL “CODE STEMI” Priscilla Givens²; Jasna Ikanovic²; Thomas Montgomery¹. ¹Carolinas Healthcare System, Charlotte, NC; ²Carolinas Medical Center, Charlotte, NC. (Tracking ID #2199272)

LEARNING OBJECTIVE #1: Management of acute presentation of renal artery stenosis

CASE: A 53 year old man with past medical history of obstructive sleep apnea presented to the hospital after he was found to have systolic pressures over 200 mmHg and hypoxemia to oxygen saturation (O2 sat) of 90 % at a local clinic where he sought to address orthopnea and paroxysmal nocturnal dyspnea that began three days prior. Chest x-ray showed diffuse pulmonary edema prompting administration of nitroglycerin and diuretics. Initial evaluation showed a beta natriuretic peptide of 851 pg/mL (ULN 100 pg/mL), a troponin of 0.02 ng/mL, and a cardiac ejection fraction of 18 %. Blood pressure control was regained over the course of the day, but symptoms recurred overnight. Given the above findings, the leading diagnosis was flash pulmonary edema secondary to congestive heart failure as a result of hypertensive emergency. The patient, a very reliable historian, denied a history of hypertension. Well-controlled sleep apnea, benign thyroid studies, and negative urine drug screen narrowed the differential diagnosis further. Renal ultrasound showed occlusion of L renal artery that was later confirmed on left heart catheterization showing a 99 % occlusion. The episodic flash pulmonary edema recurred over the following 48 h prompting renal artery dilation and stenting that resulted in 100 % patency and complete resolution of symptoms.

DISCUSSION: Renal artery stenosis (RAS) is categorized as non-atherosclerotic or atherosclerotic. Non-atherosclerotic RAS, such as fibromuscular dysplasia, accounts for less than 10 % of RAS.¹ Atherosclerotic RAS, accounting for 90 %, is more prevalent amongst the older population with multiple cardiovascular risk factors.² Management of RAS has remained predominantly medical, focusing on renin-angiotensin-aldosterone axis modulation, with other acceptable approaches including calcium channel or beta receptor blockade. The remainder focuses on atherosclerosis prevention with lifestyle changes, aspirin, and statins.³ Treatment strategies are based on randomized prospective clinical trials including Cardiovascular Outcomes in Renal Atherosclerotic Lesions (CORAL), Angioplasty and Stenting for Renal Artery Lesions (ASTRAL), and the Stent Placement and Blood Pressure and Lipid-Lowering for the Prevention of Progression of Renal Dysfunction Caused by Atherosclerotic Ostial Stenosis of the Renal Artery (STAR). CORAL showed that medical treatment has no mortality benefit. ASTRAL and STAR trials support medical therapy, showing higher risk-to-benefit ratio from stenting versus medical therapy, and a meta-analysis by Riaz et al. echoed previous findings showing no advantage of endovascular stenting compared to medical treatment alone.⁴ The reason for sparse randomized data to support revascularization for atherosclerotic RAS is the lack of a subgroup of acutely-presenting patients in the large randomized studies such as CORAL, ASTRAL, and STAR. Navaravong details a case of acute renal artery occlusion presenting with acute worsening heart failure, concluding that this subset of patients should be considered for revascularization, likening its role to that in myocardial infarction caused by plaque rupture.⁵ Percutaneous transluminal renal angioplasty (PTRA), which initially won favor as the less invasive option than surgery, has been a debated modality of treatment of acute RAS but has less evidence for resolution of persistent hypertension or renal function.⁶ Small prospective trials, however, support its reduction of mortality compared to medical therapy alone in the acutely presenting patient.³ Whichever mode was employed, however, flash pulmonary edema appears to be the factor consistently supportive of revascularization.⁷ We present a case of renal artery occlusion from an acute plaque rupture in a previously normotensive patient, who presented with resistant hypertension resulting in myocardial stunning with flash pulmonary edema. This presentation placed our patient in the subset that may benefit from stenting and we elected to proceed. After the stent was placed, the patient's blood pressure normalized with no recurrence of flash pulmonary edema. He did not require antihypertensives at discharge. Though medical therapy remains the standard of care in clinically stable patients, the acute unstable presentation, such as flash pulmonary edema, can cause increased mortality if endovascular stenting is deferred. The patient presented in this case was an ideal candidate given his critical presentation with renal artery plaque rupture and occlusion, just as the endovascular stenting is a life saving measure for the acute myocardial infarction. In clinically stable patients, medical therapy is superior to endovascular stenting, but in presentations of plaque rupture resulting in acute renal artery stenosis with resulting flash pulmonary edema, endovascular stenting can decrease mortality

A CASE OF ACTIVE PULMONARY TUBERCULOSIS ASSOCIATED FIBROSING MEDIASTITIS John L. Vo; Nader Kamanger. Olive View-UCLA Medical Center, Studio City, CA. (Tracking ID #2195274)

LEARNING OBJECTIVE #1: Recognize the clinical and radiographic manifestations of fibrosing mediastinitis

LEARNING OBJECTIVE #2: Understand the pathophysiology of fibrosing mediastinitis

CASE: We report a case of a patient with fibrosing mediastinitis associated with active pulmonary tuberculosis. The patient is an 80 year old Iranian female with chronic obstructive pulmonary disease who presented with subacute on chronic dyspnea on exertion. Her radiographic studies disclosed chronic pulmonary embolic disease, broncho-mediastinal fistula, narrowing of the right main stem bronchi and superior vena cava, extensive mediastinal and hilar calcifications consistent with FM. Subsequent bronchoscopy yielded sputum positive for acid fast bacilli, eventually cultured as mycobacterium tuberculosis complex. She was subsequently started on RIPE therapy (rifampin, isoniazid, pyridoxine, and ethambutol). How this intervention will halt progression of FM remains to be seen. Treatment of FM is particularly challenging as no studies have shown substantial efficacy in combating evolution of disease. Treatment is primarily palliative with efforts concentrating on ameliorating the resultant vascular or airway obstruction through surgical means.

DISCUSSION: Fibrosing mediastinitis (FM) is a pathological process characterized by an inappropriate and excessive fibrotic reaction in the mediastinum. The resultant expansion within the restricted space results in variable compromise of airways, central systemic veins, the esophagus, and pulmonary arteries or veins which subserves as the pathologic basis of clinical manifestation. The cause is unknown in the majority of cases but several associations have been delineated as possible impetuses. The most common in the United States is prior history of Histoplasma capsulatum. Other rare infectious associations

include tuberculosis, aspergillosis, mucormycosis, blastomycosis, coccidioidomycosis, and cryptococcus. Non-infectious associations include Behcet's disease, radiation therapy, sarcoidosis, and idiopathic fibrotic diseases. Given the lack of a salient cause and effect relationship, a genetic predisposition to the pathologic fibrotic reaction has been theorized. It has been postulated that the relative risk of FM is three times higher in individuals with the HLA (human leukocyte antigen)-A2 antigen suggesting host specific factors contributing to progression of malady. Several propositions have been presented to explain the underlying mechanism and the natural history of FM. In general, it is thought to be an abnormal host response to an infectious or inflammatory challenge that involves the mediastinal lymph nodes. It has been theorized that FM is a spectrum of disease with less severe disease representing mediastinal granulomas, which are often benign. Many believe this is a precursor lesion to more diffuse FM. It is hypothesized that the rupture of mediastinal granulomas into the mediastinal space precipitates progression to FM. Symptoms are often variable and nonspecific but when present often reflect compression of structures within the mediastinum. Based on a retrospective study evaluating 71 cases of FM, it was found that 41 % had cough, 23 % had chest pain, 31 % had dyspnea, and 31 % had hemoptysis. Airway obstruction is a frequent sequela which reflects clinically as dyspnea and can potentially lead to post obstructive pneumonia. Superior vena cava (SVC) syndrome is also often a sequela of obstruction of the SVC from thrombosis or external compression. The right paratracheal nodes are often responsible for compressing the SVC, leading to distension of the face, neck and arms and engorgement of the veins distal to the SVC. The diagnostic study of choice for FM is high resolution computed tomography of the chest. CT radiographs display either a focal or more diffuse pattern of involvement. The focal form often displays a localized, calcified mass in the paratracheal or subcarinal region. The diffuse type displays more involvement of the whole mediastinum, often obliterating normal mediastinal fat planes and encases or invades adjacent structures. Often there is discrete calcified paratracheal, hilar, and subcarinal lymphadenopathy. FM is a radiographic diagnosis; the need for more invasive diagnostic measures, such as mediastinoscopy or thoracotomy, are often unnecessary. No data exists to substantiate the efficacy of any treatment modality for FM. Corticosteroids, antifungals, and estrogen receptor modulators have been used with limited results. Often treatment lies in ameliorating the obstructive effects of the mass with surgery being the mainstay. SVC bypass with spiral vein graft and endovascular interventions such as stenting or balloon angioplasty are often modalities pursued to mitigate the vascular manifestations of FM. Resection of stenotic airway and/or distal lung parenchyma or bronchoscopically placed airway stents are used to alleviate the airway manifestations of FM.

A CASE OF CERVICAL MANIPULATION CAUSING STROKE & EXPLORING ITS BIOMECHANICS. Larry J. McMann¹; Rudin Gjeka¹; Reem Al-Mahdawi¹; Hussam Sabbagh¹; Dustin Reynolds²; Firas Ido²; Sarwan Kumar¹; Zain Kulairi¹; Maliha Naseer¹. ¹Wayne State University, Rochester, MI; ²American University of the Caribbean, Coral Gables, FL. (Tracking ID #2181779)

LEARNING OBJECTIVE #1: Recognize characteristic clinical scenario for vertebral artery dissection after cervical manipulation.

LEARNING OBJECTIVE #2: Judicious prescribing habits for cervical manipulation.

CASE: A 43-year-old female presents to the emergency room with left sided upper and lower extremity weakness after cervical manipulation. She had been having occipital headaches and neck discomfort over the preceding 3 days. On the morning of admission she visited a chiropractor where they performed cervical manipulation. Later that afternoon, while driving her vehicle she developed vertigo. She then attempted to ambulate to her front door when she got profoundly weak and paralyzed on her left side. In the Emergency Department her blood pressure was 227/139, remainder of her vital signs were within normal limits. On Physical exam she had hemiparesis on the left side of her body. Given her focal neurological deficits a stroke was suspected, Computed Topography (CT) of the brain without contrast was ordered and was unremarkable. Tissue plasminogen activator was administered in the emergency room. CT angiography was later performed to localize the lesion and it demonstrated a vertebral artery dissection on the right side. It was decided that the patient would benefit from endovascular intervention and was transferred to an institution in the local area for the procedure.

DISCUSSION: Manipulation of the cervical spine has been considered an effective treatment modality by alternative healers, predominately chiropractors. The risk of having trauma to the vertebral-basilar system resulting in a stroke is of major concern. The internist should always be vigilant of possible vertebral artery dissection in a young patient presenting with vertigo or weakness after cervical manipulation. Since this is a rare entity and many practitioners are unaware of this complication, there can be oversight in obtaining a proper history of cervical manipulation. Arterial dissection due to cervical manipulation is rare. Studies suggest that 1 in 2,000,000 cervical manipulations results in a dissection in the vertebral-basilar system.

A CASE OF CRYOGLOBULINEMIC VASCULITIS SECONDARY TO HEPATITIS C VIRUS (HCV) Mahjabeen Haq¹; Alexandra Perel-Winkler³; Nazia Hussain². ¹Mount Sinai St Luke's-Mount Sinai Roosevelt, New York, NY; ²Mount Sinai St Luke's-Roosevelt Hospital, New York, NY; ³Mt. Sinai St. Luke's-Roosevelt, New York, NY. (Tracking ID #2199013)

LEARNING OBJECTIVE #1: Recognize clinical features of Cryoglobulinemic Vasculitis

CASE: Fifty-eight year old female with history of Hepatitis C virus (HCV), anemia, and chronic diastolic heart failure, recently emigrated from Egypt, presented to the emergency department complaining of 1 year of intermittent pleuritic chest pain and progressive rash on her extremities. Review of systems revealed arthralgias in her knees and elbows and forty pound weight loss over the past year as well. In the ER, she was hemodynamically stable and in no acute distress. Physical exam was significant for decreased breath sounds at bilateral bases and a purpuric rash in upper extremities. Initial laboratory abnormalities included elevated creatinine of 2.0 and hemoglobin of 7.9. A CT chest showed a loculated right pleural effusion causing a compressive atelectasis. A thoracentesis revealed exudative fluid with elevated white blood cells. Rheumatology, dermatology, and nephrology were consulted. The rheumatologic workup was significant for a positive Rheumatoid Factor of 1510 and low complement C3 level at 63. Skin biopsy of the purpuric rash showed a leukocytoclastic vasculitis. Kidney function continued to decline. Urinalysis showed microscopic hematuria but urine sediment did not show dysmorphic RBC or casts. Renal biopsy showed diffuse endocapillary proliferative glomerulonephritis with membranoproliferative features and immune complexes. The immunofluorescence findings of granular global glomerular capillary wall and meningeal staining for IgM, kappa, and C3, with weaker staining for IgG and lambda, supported the diagnosis of immune complex-mediated glomerulonephritis and were suggestive of cryoglobulinemic glomerulonephritis. Pleural biopsy for recurrent pleural effusions revealed chronic lymphoplasmacytic inflammation. Patient's hospital course was complicated by pulmonary edema. Given the clinical picture with renal biopsy results, the patient was diagnosed with cryoglobulinemic glomerulonephritis secondary to Hepatitis C virus. Patient was treated with Prednisone at 60 mg daily and has received her first dose IV Cytoxan 1000 mg with plan to treat Hepatitis C virus. There has been stabilization of renal function and improvement in joint pain and rash.

DISCUSSION: Cryoglobulins consist of immunoglobulins and complement components that precipitate in cold and dissolve upon rewarming. There are three types of cryoglobulins. Type II, Essential Mixed Cryoglobulinemia, is associated with HCV. It is characterized as mixed polyclonal Ig with monoclonal Ig that has rheumatoid factor activity. In HCV, cryoglobulins contain anti HCV antibodies, HCV RNA and IgM Rheumatoid factor. Cryoglobulinemic vasculitis is an inflammatory syndrome involving small to medium sized vessel vasculitis with cryoglobulin immune mediated complexes. Typically, patients present with purpuric rashes and glomerulonephritis along with renal insufficiency. Less commonly, pulmonary and cardiovascular symptoms have been described. Renal injury includes microscopic hematuria and proteinuria and severe hypertension. Kidney biopsies have shown several histological pathologies including membranoproliferative glomerulonephritis, subendothelial deposits, and intraluminal thrombi of cryoglobulins. Lung involvement is an uncommon manifestation of cryoglobulinemic vasculitis. There are cases of respiratory failure, ARDS, and hemoptysis with mixed cryoglobulinemia. Also high levels of cryoglobulins and immune complexes increase blood viscosity and blood pressure causing pulmonary edema. Our patient is a case where there was significant pulmonary involvement.

A CASE OF EBV-ASSOCIATED HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS Chelsea E. Pearson, Barnes-Jewish Hospital, St Louis, MO. (Tracking ID #2198719)

LEARNING OBJECTIVE #1: Recognize Lymphoproliferative Complications of EBV infection

LEARNING OBJECTIVE #2: Diagnose and manage EBV-related HLH

CASE: EE was a 22 year old Caucasian male with no past medical history who presented with low-grade fevers, chills, and drenching night sweats that had been progressively worsening over the prior 3 weeks. These symptoms were accompanied by daily headaches without phono- or photophobia or neck stiffness. He also endorsed poor appetite with a 15 lb total weight loss, malaise, and generalized weakness. He denied abdominal pain or distension, nausea, changes in stool, skin changes, cough, infectious symptoms, or easy bruising or bleeding. At that time he was not taking any medications and he was not aware of any allergies. Family history was noncontributory. He was a student at a nearby community college and rarely drank alcohol; no tobacco or drug use. He was not sexually active. Immunizations were up to date. On examination, the patient was a pleasant, well-developed young male in no distress. Physical exam was unremarkable except for

conjunctival pallor and spleen tip palpable 4–5 cm below the costal margin. Vital signs were all within normal limits and the patient had a BMI of 25.5 kg/m². Complete blood count was significant for total white blood cell count of 1.2 k/mm³ (ANC 0.6 k/mm³), hemoglobin 10.8 g/dL, and platelets of 55 k/mm³. Basic metabolic panel was normal. Hepatic function panel revealed total protein 5.9 g/dL, albumin 3.2 g/dL, total bilirubin 0.6 mg/dL, alkaline phosphatase 533 u/L, aspartate transaminase 583 u/L, alanine transaminase 608 u/L. INR was 1.2. Given his B-type symptoms and pancytopenia, PET was obtained and revealed splenomegaly as well as diffuse abdominal lymphadenopathy. Bone marrow biopsy was negative for lymphoma, although flow cytometry showed a small abnormal population of CD16-NK cells. Liver biopsy revealed erythrophagocytosis and severe hepatitis with necrosis and was EBV positive. Peripheral blood EBV PCR was also greater than 437858 copies/ml. Based on this, patient was started on acyclovir and discharged with the diagnosis of chronic active EBV infection. However, he continued to have severe night sweats, fevers, and chills so he was readmitted about 5 days later. Further laboratory studies were obtained and revealed elevated ferritin and triglycerides (at 795 and 453, respectively) and low fibrinogen at 123. He also had a tonsillar biopsy that showed benign lymphoid tissue. As lymphoma was ruled out, the patient was found to meet criteria for EBV-associated Hemophagocytic Lymphohistiocytosis (HLH) and was transferred to the oncology service for initiation of chemotherapy. EE was treated per the HLH-94 protocol, and received a regimen of dexamethasone, etoposide, and rituximab. He continued on acyclovir. Clinical markers including transaminases, ferritin, blood counts, and EBV viral load improved and the patient reported resolution of his B-type symptoms.

DISCUSSION: EBV infection usually manifests with infectious mononucleosis (IM), typically following a self-limited course and not requiring specific therapy. However, EBV uncommonly presents fulminant manifestations, such as fever, severe hepatosplenomegaly, cytopenias, coagulopathy, CNS abnormalities, and vascular dysfunction. EBV typically targets B-lymphocytes but can also cause lymphoproliferative disorders affecting T- or NK-cell lymphocytes. The former causes fulminant IM, but the latter can result in a spectrum of diseases including chronic active EBV, EBV+ lymphoma-associated hemophagocytic syndrome, and EBV-associated hemophagocytic lymphohistiocytosis (EBV-HLH). HLH is a disease of uncontrolled immune activation, characterized by proliferation of morphologically benign lymphocytes and macrophages that secrete high amounts of inflammatory cytokines. To meet criteria for EBV-HLH, one must meet five of eight criteria as established by the Histiocyte Society for HLH and have definite evidence of EBV infection (by either viral DNA or mRNA assay). The eight criteria include fever, splenomegaly, cytopenias (affecting at least two of three lineages in the peripheral blood), hypertriglyceridemia and/or hypofibrinogenemia, hemophagocytosis in bone marrow, spleen or lymph nodes, low or absent NK cell activity, ferritin >500 ng/ml, and soluble CD25 (soluble IL-2 receptor) >2400 U/ml. EE was diagnosed with EBV-HLH given that he met six criteria: fevers, splenomegaly, cytopenias, hypertriglyceridemia, ferritin elevation, and hemophagocytosis. Given that the pathogenesis of EBV-HLH is driven by the activation and proliferation of EBV-infected T-cells, treatment usually consists of steroids, cyclosporine A, and etoposide. Fulminant IM is usually treated with rituximab to target infected B-lymphocytes. Allogeneic stem cell transplant is necessary for therapy-resistant or refractory EBV-HLH. Recognizing the spectrum of EBV-related disorders is important as the focus shifts from treating an infectious disease to treating a lymphoproliferative one.

A CASE OF HEADACHE NECK PAIN AND RASH WHAT IS IN YOUR DIFFERENTIAL Jocelyn A. Carter², Kathleen M. Finn¹, ¹MGH, Boston, MA; ²Massachusetts General Hospital, Lebanon, NH. (Tracking ID #2199822)

LEARNING OBJECTIVE #1: Appreciate the overlap and subtle differences expected in lumbar puncture results seen in meningitis caused by infection vs ruptured aneurysm

LEARNING OBJECTIVE #2: Recognize the clinical manifestations, morbidity and mortality associated with a ruptured aneurysm

CASE: A 63 year old gentleman with a history of throat cancer and hypertension was transferred from a community hospital with a diagnosis of meningitis. Ten days prior, the patient awakened with a severe headache, facial rash, periorbital edema and conjunctival injections followed by the development of neck pain and stiffness hours later. He had been doing yard work the day prior and was prescribed steroids for poison ivy. His periorbital swelling and rash resolved but the headache and neck pain persisted. Seven days later he underwent a CT brain (normal) and a lumbar puncture which revealed 256 white blood cells (WBCs) with 56 % neutrophils, 45 % monocytes, 24 red blood cells (RBCs), glucose of 64 mg/dl, and protein of 56 mg/dl. Intravenous vancomycin and ceftriaxone were started and he was transferred to our hospital for further management of meningitis. The patient reported frequent tick bites with an untreated targetoid rash one month prior. He endorsed drinking untreated well water before his illness and had facial zoster 3 years earlier. On transfer, the patient described the headache/neck pain as 10/10 in severity and diffuse. Home medications were MS Contin 100 mg twice daily, lorazepam 1 mg daily,

trazodone 150 mg nightly and hydrochlorothiazide 25 mg daily. On exam he was ill appearing with a heart rate 60 bpm, blood pressure 161/77 mmHg, and positive Jolt, Kernig and Brudzinski signs. A slightly disconjugate gaze was noted and an MRI brain was obtained demonstrating left sylvian fissure enhancement suggestive of meningitis but significant motion artifact. Ampicillin and acyclovir were added and a CT brain was ordered. On hospital day 2, the patient felt improved with no headache/neck pain. The CT demonstrated left middle cerebral artery signal enhancement consistent with ruptured aneurysm. All infectious serologies/cultures returned negative.

DISCUSSION: Over 6 million people in the United States have cerebral aneurysms and rupture occurs in 30,000 individuals yearly. Cerebral aneurysm rupture has a high mortality and morbidity requiring timely assessment and management. Both aneurysm rupture and infectious meningitis can present with headache, altered mental status and signs of meningeal irritation. While large numbers of CSF RBCs and xanthochromia point to aneurysmal rupture (unless it is a traumatic tap), xanthochromia can dissipate after 1–2 weeks as RBCs breakdown. Irritation caused by the blood products and an invasion of WBCs into the CSF may result in concurrent meningitis. Up to 32 % of ruptured aneurysms are initially missed. The sensitivity of CT in detecting ruptured cerebral aneurysm varies- 98 % at 12 h, 80 % at 72 h, and 50 % at 1 week. As seen in this case, heuristic bias (framing) may delay diagnosis, however intracranial aneurysm rupture should always be on the differential in patients with headache and meningeal signs despite CSF WBC predominance.

A CASE OF LATE-NIGHT PARALYSIS OF THE EXTREMITIES Kenji Yoshida; Tatsuya Fujikawa; Hisanori Morimoto. Mitoyo General Hospital, Kan-onji City, Japan. (Tracking ID #2191653)

LEARNING OBJECTIVE #1: Recognize hypokalemic thyrotoxic periodic paralysis (HTPP) as hyperthyroidism-related hypokalemia and paralysis of the extremities, typically occurring in young Asian males.

LEARNING OBJECTIVE #2: Manage hypokalemia of HTPP to prevent or reduce the symptoms of cardiac arrhythmias, although long-term definitive therapies for hyperthyroidism are indispensable.

CASE: A 33-year-old man who worked as a firefighter presented with late-night paralysis of the extremities. He had been previously healthy, except for occasional paralysis of the extremities. His symptoms always occurred at around midnight every 2 months for 3 years and had always resolved without intervention. On the day of admission, he had eaten dinner with alcohol and fell asleep as usual. Two hours later, he woke up feeling weakness in both his legs. He realized that he could neither stand nor raise his legs. Because his symptoms had not resolved for several hours, he visited our emergency room in a wheelchair. He reported no remarkable past medical history besides paralysis, no medicine consumption, no family history, or no appreciable social history, except occasional alcohol consumption. He felt slight palpitation in the emergency room. On physical examination, his body temperature was 36.8 °C; blood pressure, 139/72 mmHg; and pulse rate, 77 beats/min. Goiter was slightly palpable but not visible with the neck extended. Muscle strength was 4/5 in the biceps and triceps bilaterally and 2/5 in the quadriceps femoris and biceps femoris bilaterally. Deep tendon reflexes were low normal (1+) in the patellar and Achilles tendons bilaterally. Electrocardiography (ECG) revealed ST-segment depressions, T-wave inversions, and U waves, particularly in the mid-precordial leads, V2 and V3. Laboratory results revealed that the serum potassium level was extremely low at 2.2 mEq/L (normal range, 3.5–5.0 mEq/L). Treatment with potassium supplementation was started using intravenous drip injection under close monitoring with an ECG monitor and 12-lead ECG. Four hours after initiation of treatment, the symptoms of paralysis, which were probably derived from hypokalemia, improved. In addition, the ST-segment depressions, T-wave inversions, and U waves disappeared on ECG. A thyroid function test revealed: Thyroid-stimulating hormone (TSH), 0.01 µIU/mL (normal range, 0.35–5.00 µIU/mL); free-T3, 12.4 pg/mL (1.7–3.7 pg/mL); and free-T4, 2.5 ng/dL (0.7–1.5 ng/dL). Ultrasound examination of the thyroid gland revealed an increase in thyroid volume and blood flow, which were compatible with diagnosis of hyperthyroidism. Finally, the TSH receptor antibody level was 8.7 IU/L (0–1.0 IU/L) later; thus, we diagnosed him with hypokalemic thyrotoxic periodic paralysis (HTPP) most likely associated with Basedow's disease. After administering thiamazole and propranolol for hyperthyroidism, the patient has remained euthyroid and has not experienced further episodes of hypokalemic weakness.

DISCUSSION: HTPP is a potentially life-threatening complication of thyrotoxicosis, such as in Basedow's disease, toxic nodular goiter, iodine-induced thyrotoxicosis, and excessive thyroxine use. It is characterized by acute and reversible episodes of muscle weakness and hypokalemia due to a massive intracellular shift of serum potassium. The mechanism is considered as a thyroid hormone increase in the activity of the Na⁺-K⁺-ATPase-dependent K⁺-channel and subsequent increase in catecholamine-mediated intracellular potassium shift. This mechanism may explain the male dominance of HTPP

(20:1) because males produce greater concentrations of catecholamines, resulting in stronger $\text{Na}^+\text{-K}^+\text{-ATPase}$ activity as compared with females. $\text{Na}^+\text{-K}^+\text{-ATPase}$ activity is also augmented by insulin as an effect of high carbohydrate intake. Precipitating factors of HTPP include strenuous physical activity, followed by rest, ingestion of a high carbohydrate food load, and alcohol consumption. On the occasional day, our patient trained strenuously for his job and had a relaxing dinner and alcohol at home. Thus, we can assume that his physical activity and endogenous insulin triggered by carbohydrate intake increased the $\text{Na}^+\text{-K}^+\text{-ATPase}$ pump activity. This phenomenon could cause an inflow of potassium into the cells and reduce the level of serum potassium, thereby explaining the late-night paralysis of his extremities. As treatment, potassium supplementation may improve symptoms. Based on the implication of hyperadrenergic activity in the pathogenesis of HTPP, nonselective β -blocker administration has also been reported as an alternative therapy. However, definitive therapies to control hyperthyroidism, including antithyroid drugs, surgical thyroidectomy, and radioiodine therapy, are indispensable to abolish attacks of HTPP. Because patients of Asian ethnicity are frequently encountered even in the Western world, HTPP should be included in the differential diagnosis of muscle weakness as a symptom.

A CASE OF PARTIAL MUSCLE PHOSPHORYLASE DEFICIENCY UNCOVERED AFTER SEVERE RHABDOMYOLYSIS SECONDARY TO A DRUG INTERACTION BETWEEN AMLODIPINE AND SIMVASTATIN Rekha Kambhampati; Giovanna Olivera; James Prister; Gabriela Ferreira. Rutgers-Robert Wood Johnson Medical School, North Brunswick, NJ. (Tracking ID #2200010)

LEARNING OBJECTIVE #1: Recognize that statins can cause life-threatening rhabdomyolysis in patients who are heterozygous for glycogen storage diseases.

CASE: Muscle phosphorylase deficiency is due to an inborn error of glycogen metabolism. We present a case of severe statin induced rhabdomyolysis secondary to a drug interaction between amlodipine and simvastatin that ultimately uncovered the diagnosis of underlying partial muscle phosphorylase deficiency. The patient was a 60 year old man with a past medical history of hypertension, hyperlipidemia, type 2 diabetes mellitus who was hospitalized 2 weeks prior to admission for non-ST segment elevation MI treated with bare metal stenting to the left circumflex coronary artery. He subsequently presented with fever and oliguria secondary to a urinary tract infection. The patient's initial presentation was notable for a temperature of 100.6 °F, normal muscle mass and strength, white blood cell count of 13, CPK 153, and pyuria on urinalysis. He was started on ceftriaxone for his urinary tract infection and his home medications, including simvastatin 80 mg nightly, were continued. Amlodipine 10 mg daily was added for hypertension control. Two days later, he began complaining of proximal muscle pain and weakness and decreased deep tendon reflexes were observed on physical exam. His CPK rose to 3000 and his simvastatin and amlodipine were discontinued. EMG showed no signs of motor neuropathy. He developed acute kidney injury despite supportive care and his CPK peaked at 420,000 on hospital day 13. He required transfer to the intensive care unit for decreasing vital capacity and respiratory distress, likely secondary to diaphragmatic myopathy. A muscle biopsy was performed and revealed severe myonecrosis, partial deficiency of myophosphorylase and myofiber type 2 atrophy. The patient was started on tapering steroids and his CPK improved rapidly, with slower resolution of his weakness. His acute kidney injury resulted in end-stage renal disease necessitating permanent hemodialysis.

DISCUSSION: A study conducted by Vladutiu, et al. demonstrated that heterozygotes for myophosphorylase deficiency may be at increased risk for myopathic outcomes. The proposed mechanism involves a statin-mediated reduction in already impaired intracellular myophosphorylase activity resulting in severe myopathy. This case highlights several important issues in clinical practice. The increased propensity for rhabdomyolysis when using high-dose simvastatin or during the concomitant administration of simvastatin with amlodipine is well described. Although these safety concerns were amended to the simvastatin label in 2011, recognition of this phenomenon in the medical community has lagged behind. This patient's presentation also underscores the importance of the evaluation for hereditary metabolic diseases in patients presenting with drug-induced myopathies, as the frequency of heterozygotes for glycogen storage diseases is more common than once thought.

A CASE OF PERNICIOUS ANEMIA MASQUERADING AS THROMBOTIC THROMBOCYTOPENIC PURPURA Krishnalatha Devakiamma; Tsering Dhondup; Adarsh Goyal; Puneet Tejsinghani; Raj Ghimire; Jayamohan Nair. Mercy Catholic Medical Center, Drexel Hill, PA. (Tracking ID #2199108)

LEARNING OBJECTIVE #1: Recognize pernicious anemia as a cause of schistocytosis.

LEARNING OBJECTIVE #2: Manage a potentially life threatening, but completely reversible manifestation of B12 deficiency.

CASE: A 67 year old gentleman presented to emergency department with complaints of progressively worsening fatigue for 2 weeks. Neurological examination showed moderate confusion and gait ataxia. His laboratory results revealed anemia with hemoglobin of 3.5, high mean corpuscular volume (108) and thrombocytopenia (platelet count of 66). Peripheral smear showed numerous schistocytes and macroovalocytes. Serum LDH level was high (4875) and serum haptoglobin level was low (<10). Liver function tests showed indirect hyperbilirubinemia and mildly elevated transaminases. Constellation of the findings of anemia, thrombocytopenia, schistocytes, elevated levels of LDH and low levels of haptoglobin in a patient with worsening fatigue and confusion led to the diagnosis of TTP and he was started on plasmapheresis. However the high MCV, macro ovalocytosis in the smear, low reticulocyte count and normal coagulation panel were not fitting entirely with the syndrome of TTP and so serum B12 level was ordered. The platelet counts did not improve significantly with plasmapheresis. The serum B12 levels were low (<30 pg/ml). Patient was treated with intramuscular vitamin B12 injections. Reticulocyte counts immediately showed improving trends. Patient improved both symptomatically and hematologically with continued B12 injections. His anti-intrinsic factor antibodies later came back positive confirming the diagnosis of pernicious anemia.

DISCUSSION: Schistocytes in peripheral smear in appropriate clinical setting may point to micro angiopathic hemolytic anemia. However there are other causes of schistocytes in peripheral smear which may need totally different treatment strategies. B12 deficiency is one of them which can cause a syndrome very similar to thrombotic thrombocytopenic purpura (TTP). Vitamin B12 is required for normal synthesis of DNA and metabolism of homocysteine to methionine. B12 deficiency would lead to ineffective erythropoiesis, maturation arrest of the red blood cell precursors, hemolysis in the bone marrow, decreased erythrocyte deformability and increased red blood cell membrane fragility. As homocysteine can not be converted back to methionine in the absence of Vitamin B 12, the homocysteine levels goes up causing endothelial dysfunction. Endothelial dysfunction in the setting of increased cell fragility, is the presumed reason for schistocyte formation in Vitamin B12 deficiency. The presentation is very similar to TTP and therefore referred to as pseudo TTP. However, these patients will not respond to plasmapheresis and they need Vitamin B12 injections for resolution of clinical findings. High index of suspicion and clinical awareness of the condition is required to spot the correct diagnosis. Although a TTP like clinical syndrome is a well described manifestation of B12 deficiency, many practicing physicians are unaware of the entity. Our case report aims to make clinicians aware of the condition. It is extremely important to spot the diagnosis early as it is a potentially life threatening condition but completely reversible if treated early in the course.

A CASE OF PYODERMA GANGRENUM ORIGINATING IN THE SPLEEN

Tatsuya Fujikawa¹; Kenji Yoshida¹; Takayasu Suzuki². ¹Mitoyo General Hospital, Kan-onji, Japan; ²Osaka Medical College, Takatsuki, Japan. (Tracking ID #2144481)

LEARNING OBJECTIVE #1: Recognize the clinical features of pyoderma gangrenosum, particularly features that occur all over the body, and trauma or surgical scars that may develop into PG.

LEARNING OBJECTIVE #2: Treat pyoderma gangrenosum with systemic steroids and even with immunosuppressive agents.

CASE: A 51-year-old woman with type 2 diabetes and hyperlipidemia visited our hospital for a regular visit. Her past history included right lower limb amputation for diabetic foot and pyoderma gangrenosum (PG) in her right neck. The patient complained of slight discomfort in the left upper quadrant, and on clinical examination, high-grade fever (38.5 °C), tachycardia, and splenomegaly were noted. Laboratory results revealed leukocytosis (white cell count: 20,100 cells/ μl) and elevated C-reactive protein levels (22.28 mg/dl). Contrast enhanced computed tomography (CT) of the abdomen after plain CT revealed multiple hypodense lesions in the spleen, which were speculated to be splenic abscess. Splenic abscess was initially suspected due to bacterial infection; therefore, broad-spectrum antibiotic therapy was initiated under hospitalization. Two sets of blood cultures tested negative for any bacteria, and procalcitonin was within the normal range. The high-grade fever continued, and clinical symptoms of the left abdominal distension and laboratory data did not improve, in spite of antibiotic therapy. Follow-up CT after a week revealed multiple and rapidly enlarging splenic hypodense lesions, which compressed the stomach, and a further enlarged spleen was observed compared with that observed in the previous week. The patient underwent an open splenectomy due to the risk of splenic rupture. Pathological findings revealed splenic abscess-like nodules containing large amounts of inflammatory cells, mainly neutrophils, but without specific inflammation. Splenic pus cultures tested negative for any bacteria. At this point, the patient was diagnosed with PG originating in the spleen. After splenectomy, her condition improved once prednisolone was administered and she was discharged from the hospital. However, in the process of tapering the dose of prednisolone, intra-abdominal abscess and skin abscess on the old scar after a central venous catheter on the neck were observed, and

exacerbation of PG was assumed. Then, after addition of cyclosporin A with prednisolone, intra-abdominal abscess or skin abscess were improved. Although prednisolone is currently being tapered off, no abscesses have been observed.

DISCUSSION: PG is a rare, non-infectious, ulcerative skin disorder, occurring mainly in females. Approximately 50 % of cases are associated with systemic diseases, such as inflammatory bowel disease, arthritis, and leukemia. The clinical condition is thought to be an immune system disorder with non-specific extensive neutrophil inflammation of the skin with vasculitis-like features. Diagnosis is made by clinical presentation and failure to improve after conservative or antibiotic treatment, which is diagnosed by exclusion, and is therefore often delayed. Although PG often develops on the skin at sites of trauma, such as biopsy and surgical scars, it may occur all over the body. Splenic PG, as in this case, is rarely reported in the literature. With regard to splenectomy in the present case, surgical scars did not develop into PG, owing to the prophylactic administration of systemic steroids to prevent PG. The first choice of treatment for PG generally is systemic steroids combined with conservative wound care. However, additional immunosuppressive agents such as cyclosporine and azathioprine may be necessary.

A CASE OF QUESTIONABLE MEDICAL CAPACITY AND IMMUTABLE INDIVIDUAL AUTONOMY Kathryn M. Lohmann; Jeffrey Talbot. Emory University, Kennesaw, GA. (Tracking ID #2199906)

LEARNING OBJECTIVE #1: Assessing medical capacity and distributive justice

CASE: A 51 year old female with a history of acquired immunodeficiency syndrome, End Stage Renal Disease on hemodialysis, Chronic Obstructive Pulmonary Disease, diastolic heart failure with reduced ejection fraction, and poly-substance abuse presented in severe sepsis with volume overload and respiratory failure secondary to inconsistency attending HD and taking her medications. Over the course of the last year, the patient had a longstanding history of medical non-compliance with multiple admissions to the primary city hospital and also the midtown hospital. One week previously, after treatment for renal failure and pneumonia, the patient elected to elope from the city hospital. During that admission she initially requested and then refused dialysis as well as forcibly removing her access (Permacath). She also refused administration of antibiotics for multi drug resistant *S. aureus* pneumonia. Psychiatry and Ethics were consulted. The patient was deemed to be without capacity for medical decision making. Subsequently, her family decided to withdraw care and transfer the patient to hospice. Before transportation to hospice could be arranged she left her room without warning and could not be located. On her return admission, she rapidly developed respiratory failure and was intubated. After transfer to the MICU and chart review, the above information was revealed. The patient was discharged to hospice for terminal care.

DISCUSSION: This case emphasizes several critically important aspects of medical ethics: the appropriate evaluation of medical capacity, individual autonomy, and distributive justice. The complexity of her medical course is founded upon the question of the patient's decision-making capacity versus her individual autonomy at a basic level. After she had been admitted for similar presentations on multiple occasions (volume overload, pneumonia, bacteremia and electrolyte abnormalities), it was noted repeatedly that she would initiate her medical stay by requesting full treatment and then eventually would decline all interventions, stating that she wanted to die. The patient would then leave only to return in rapidly declining health each time. Though psychiatry was involved and corroborated the lack of medical capacity evaluation, they did not feel it was thorough enough to give her any diagnosis except "mild cognitive impairment". Her sister, the patient's power of attorney, determined that given the patient's ongoing substance abuse as well non-compliance with medical therapies and the advanced nature of her multiple comorbidities, hospice with comfort care would be the most reasonable option. However, this would require the patient's complicit behavior, which was discussed with her at length. Before this measure could be implemented, the patient eloped - expressing a clear desire to live despite non-adherence to medical treatment. Though this decision was made with the patient's best interest in mind, it was in direct opposition to the patient's own judgment, an illustration of the power of individual autonomy. Regarding distributive justice, in the interim prior to the admission referred to in this case, the patient presented to the midtown hospital with respiratory distress and was treated accordingly, including a brief MICU stay. She was discharged home only to re-present 6 days later in respiratory failure at the primary city hospital. There was no communication between the two facilities. A resolution had already been reached at the city hospital regarding her care. Given that the patient regularly refused and left treatment, multiple admissions at differing hospitals with very similar treatment courses argues for a significant waste of precious resources in a resource-scarce area with a heavy population burden. Of course, this did not affect her care as she was treated accordingly on each presentation. Such a situation evinces the disconcerting point of futility of care - care beyond the bounds of what is reasonable when given the ultimate outcome. Resources dedicated to one that may have benefited the many if allocated differently. Beyond the startling realities and moral conflict that such a patient inspires, her medical course required a significant amount of integration

of care. Every level of provider affected her care, including LPNs, RNs, social workers, intensivists, residents and attendings. Our strength and ability to provide the highest quality of compassionate care resulted from our collaboration. First among our collective ethical principles: Do No Harm.

A CASE OF STAPHYLOCOCCUS AUREUS BACTEREMIA COMPLICATED BY LEUKOCYTOCLASTIC VASCULITIS Christina A. Mosher; Joshua L. Owen; Blake R. Barker. UT Southwestern Medical Center at Dallas, Dallas, TX. (Tracking ID #2188729)

LEARNING OBJECTIVE #1: Recognize LCV as a possible presentation of methicillin-sensitive *Staphylococcus aureus* (MSSA) bacteremia.

CASE: A 34-year-old Hispanic man with a history of alcoholic cirrhosis and type two diabetes mellitus presented with 2 weeks of diarrhea, nausea, vomiting, abdominal pain, rash, and syncope. Five days prior to presentation, he developed an erythematous petechial rash on his right hand that spread sequentially to his left hand, forearms, feet, legs and flanks. The rash was not pruritic or painful. He reported no prior history of a similar rash. On admission, he was afebrile, hypotensive (82/69), and tachycardic (104), which resolved after normal saline boluses. Physical exam was significant for petechiae on the hard palate and diffuse palpable petechiae in the distribution described above. His exam was otherwise notable for right elbow erythema and purulent drainage. His serologies were negative for HIV, hepatitis B and C, and rheumatoid factor, and he had a low serum complement component 3 (C3) of 56, low-normal complement component 4 (C4) of 10, positive perinuclear anti-neutrophil cytoplasmic antibodies (p-ANCA), and equivocal proteinase 3 (PR3). A punch skin biopsy of the rash showed an infiltrate of lymphocytes, histiocytes, neutrophils, and eosinophils with minimal fibrin deposition in blood vessel walls. Direct immunofluorescence was positive for immunoglobulin G (IgG) and C3 deposition with trace IgA in the walls of papillary dermal vessels. These findings were consistent with early leukocytoclastic vasculitis (LCV). Two of four admission blood cultures and an elbow wound culture were positive for MSSA. Echocardiogram was negative for vegetations. He was treated for 2 weeks with a third-generation cephalosporin, and his renal function and rash slowly improved.

DISCUSSION: LCV is a small vessel hypersensitivity vasculitis commonly caused by antibiotics (e.g., penicillins, cephalosporins, and macrolides), but it can also arise secondary to connective tissue disease, infections and certain malignancies as a paraneoplastic syndrome.^{1,2,3} This LCV case demonstrates how MSSA bacteremia presents in clinically diverse ways, including as vasculitis. LCV has been described in the setting of MSSA bacteremia previously, but the LCV was attributed to indomethacin.⁴ Additionally, LCV has complicated *Klebsiella* bacteremia; however, it is more often associated with chronic or subacute species such as *Yersinia enterocolitica*, *Mycoplasma pneumoniae*, and *Mycobacterium tuberculosis*, or subacute disease such as cystic fibrosis or endocarditis.⁵ Clinical suspicion for bacteremia should be raised if the rash is asymptomatic, which is uncharacteristic for LCV. If LCV is diagnosed, identify and stop or treat the offending factor, elevate the legs, and use compression stockings.⁶ If the rash persists, colchicine and dapsone are first-line medical therapy.⁶ Hemorrhagic and/or necrotic lesions require corticosteroids.⁷ If the vasculitis is refractory to treatment, plasmapheresis and intravenous immunoglobulin have been successful.⁶ 1. A CASE REPORT OF CHRONIC RIGHT HEART FAILURE WITH NORMAL LEFT VENTRICULAR FUNCTION AFTER AN ACUTE RIGHT VENTRICULAR INFARCTION Benjamin Koo; James Tauras. Montefiore Medical Center, Bronx, NY. (Tracking ID #2180701)

LEARNING OBJECTIVE #1: Diagnose and manage acute right ventricular infarction

LEARNING OBJECTIVE #2: Treatment of isolated right sided heart failure after right ventricular infarction

CASE: Patient is a 70 year-old woman with end stage renal disease on hemodialysis, hypertension, diabetes and hyperlipidemia. She presented with sub-sternal, "burning"

chest pain associated with diaphoresis and shortness of breath for one day. Physical examination showed elevated JVP but normal heart and lung exams and no peripheral edema. Electrocardiogram showed normal sinus rhythm, inferior lead q-waves, right bundle branch block without ST changes. She was found to have elevated troponin-t which peaked at 2.46 (normal <0.11) and was treated with aspirin, clopidogrel, heparin and beta blocker. Echocardiogram showed new severe right ventricle (RV) dilation and hypokinesis, severe tricuspid regurgitation with preserved left ventricle function and ejection fraction of 75 %. Lung ventilation/perfusion scan was negative for pulmonary embolism. Left heart catheterization revealed 100 % occlusion of proximal right coronary artery with left to right collaterals and diffuse disease in the left coronary system. Right heart catheterization revealed elevated right sided pressures with a normal pulmonary capillary wedge pressure. Cardiothoracic surgery deemed the patient a poor surgical candidate for coronary artery bypass grafting and tricuspid valve repair due to her severe RV dysfunction. Percutaneous revascularization of the LAD was not pursued due to a lack of angina symptoms and its technical difficulty. Repeat echocardiogram 2 weeks after her initial presentation showed persistence of severe right ventricular failure.

DISCUSSION: We present a unique case of chronic right heart failure with normal left ventricular function after an acute right ventricular infarction. A repeat echocardiogram performed even one year later revealed persistent RV failure with some modest improvement in tricuspid regurgitation. Right ventricular infarction (RVI) is predominantly a complication of inferior myocardial infarctions.^{1,2,8} Its occurrence is reported as approximately 20–50 % of patients suffering from inferior wall MI and most often will involve the right coronary artery.^{2,3,8} Initially those with RVI are at risk for cardiogenic shock, bradycardia and high grade AV block that increases in-hospital mortality. Yet those who survive the acute infarction period have a good prognosis and excellent recovery of RV function whether or not they are revascularized.^{1–4} This suggests that the RV is particularly resistant to infarction and some authors have even described RV “infarction” as a misnomer, as in most patients with RVI have predominantly viable myocardium.^{3,7} Chronic unilateral right heart dysfunction after right ventricular infarction, as witnessed in our patient, is rare.^{3,7,13,15} The difference in anatomy and physiology between the RV and LV allows the RV to be much more resistant to ischemia and necrosis. These differences include 1) lower RV myocardium oxygen demand due to its smaller muscle mass and work load 2) greater perfusion of RV throughout systole and diastole and 3) greater diffusion of oxygen through the thinner wall of the RV.^{2–4,8} These theories help to explain how patients with chronic RCA occlusions can still have the preserved RV function.^{3,8,13} When significant RV infarctions do occur, they most often are due to proximal occlusions of the RCA, proximal to the marginal branches which supply the anterolateral wall of the RV. It is possible that our patient’s concomitant left coronary vessel disease increased her risk for RVI by disrupting left to right collateral circulation.^{2,4,8} Due to the lack of literature, our patient’s long term clinical prognosis is not well known. RV dysfunction in the setting of left heart failure is known to be an independent predictor of mortality, but its significance in the setting of normal LV function is less well known.^{6,9,10,14} Several studies have shown exercise tolerance as a major prognostic tool in chronic right heart failure.^{1,5,10} The evidence that guides the management of isolated RV failure is not nearly as well established as the evidence behind LV failure. General guidelines include optimization of RV preload, fluid and salt restriction and graded physical activity. The standard therapies for LV systolic function (eg. beta blockers, ace inhibitors, mineralocorticoid receptor antagonists) are not validated in isolated RV dysfunction.^{7,10,11} Our patient was treated with beta blockers and spironolactone for neuro-hormonal blockade and her volume status was managed with dialysis. An ace inhibitor was unable to be initiated due to hypotension. Though her RV function one year later on echocardiogram remained unchanged, she did show improvement in her exercise tolerance and overall functional capacity.

A COMMON DIAGNOSIS AFTER AN UNCOMMON ILLNESS IN A COMMON PATIENT Meena N. Hasan; Omar Al Dhaybi. George Washington University, Rockville, MD. (Tracking ID #2159694)

LEARNING OBJECTIVE #1: Recognize cirrhosis as an immunodeficient state.

LEARNING OBJECTIVE #2: Identify acute stroke as a possible side effect of treatment of Cryptococcal meningitis.

CASE: A 52-year-old African American male with a history of cirrhosis and alcohol dependence was admitted after a generalized tonic-clonic seizure, believed to be due to alcohol withdrawal. His last drink was two days prior to presentation. He was on no medications and had no history of neurologic disorders. Other social history and family history was noncontributory. At presentation, his vitals showed tachycardia and his exam indicated a thin appearing male who was tremulous and only oriented to person and place. Neurologic exam was otherwise normal. Labs showed a moderate metabolic acidosis, thrombocytopenia, and elevated PT/PTT/INR. White blood cell count and hemoglobin/hematocrit were normal. His blood alcohol level was slightly elevated, as was his lactate. The patient was admitted. The morning after admission, the patient developed a fever to

39.3 °C. Lumbar puncture (LP) showed an opening pressure of 19 cmH₂O, a white blood cell (WBC) count of 23 mm³ with 88 % lymphocytes, protein 81 mg/dL, and glucose 58 mg/dL. He was diagnosed with presumed viral meningitis. Herpes simplex virus polymerase chain reaction (PCR) was negative in the cerebrospinal fluid (CSF). The patient started to spike daily high-grade fevers in the subsequent week. Human immunodeficiency virus (HIV) serology was negative, and his CD4 count was 867 mm³. Magnetic resonance imaging (MRI) of the brain showed a focal area of enhancement in the right temporal lobe of unclear significance. LP was repeated, showing increased opening pressure (23 cmH₂O), increased WBC count (101 mm³), and a further decreased glucose (28 mg/dL). Further CSF testing was positive for cryptococcal antigen and CSF culture grew *Cryptococcus neoformans*. The patient was treated with amphotericin B and flucytosine. His fevers subsequently resolved and his clinical condition improved. Several days later, he developed acute left sided weakness of the upper and lower extremity. MRI brain showed a new right putamen infarct with multiple small foci of subarachnoid and periventricular enhancement in the cerebellum and throughout the basal ganglia. He was managed supportively, and antifungal therapy was continued. His neurologic deficits subsequently improved, and he was discharged to an acute rehabilitation facility.

DISCUSSION: *Cryptococcus neoformans* is an encapsulated round yeast with narrow based buds. Cryptococcal meningitis usually affects immunodeficient patients, classically with AIDS and a CD4 count under 100 cells/mL. Our patient did not have HIV, but did have cirrhosis, which is also an established risk factor for cryptococcal infections. Cirrhotic patients are believed to be immunodeficient due to elevated endogenous glucocorticoids, complement deficiency, and neutrophil/reticuloendothelial system dysfunction. Central nervous system inflammation with secondary strokes should be anticipated in patients with Cryptococcal meningitis upon initiation of antifungal therapy. A form of immune reconstitution inflammatory syndrome (IRIS) has been reported in patients with Cryptococcal meningitis following initiation of antifungal therapy, typically manifesting as a cerebral infarction in the basal ganglia and thalamus. The underlying pathophysiology is thought to be a reduction in the burden of *Cryptococcus neoformans*, thereby facilitating the reversion of T helper 2 response to a T helper 1 response and a subsequent exuberant host response against residual sites of disease. The use of steroids as therapy in these patients is controversial. Central nervous system inflammation with secondary strokes should be anticipated in patients with Cryptococcal meningitis upon initiation of antifungal therapy. This case highlights the importance of considering cirrhotic patients as immunodeficient when considering work up for infectious etiologies. This case also highlights the link between cryptococcal meningitis and stroke as a known and common phenomenon during treatment.

A COMPARISON OF LABETALOL AND OTHER ANTIHYPERTENSIVES IN TREATMENT OF HYPERTENSIVE ISCHEMIC STROKE Michael J. Damit. Wayne State University, Detroit, MI. (Tracking ID #2198510)

LEARNING OBJECTIVE #1: Manage hypertensive crisis in the setting of cerebrovascular accident with the appropriate IV pharmacological therapy

CASE: Mr. M, a 62 year old African-American male with no past medical history presented with two episodes of falling and complaint of right-sided weakness for 1 day. He had an associated pulsatile ringing in his ears but denied any other symptoms. In the emergency department (ED), he was found to be hypertensive at 233/124. CT scan demonstrated no intracranial hemorrhage, however lacunar infarcts were noted. After some debate regarding how to appropriately manage his blood pressure, labetalol was administered. Initially, a 100 mg IV bolus was given, however blood pressure measurements were not taken in appropriate intervals to measure the therapeutic response. One hour later, the ordering physician unaware of this information, and seeing only the previous measurement, assumed a poor response and a second bolus was ordered. Thirty minutes later the blood pressure had dropped precipitously to 140/104.

DISCUSSION: Hypertensive crisis is defined by a blood pressure ≥180 systolic (SBP) or ≥120 diastolic (DBP) and can be classified into either emergency or urgency. The former describes elevated blood pressures manifesting in acute end organ damage. Urgency, in contrast, is defined as elevated blood pressures in the absence of acute hypertensive complications. Hypertensive crises typically superimpose on existing essential hypertension. In these instances, the marked elevation in blood pressure is often well tolerated owing to chronic pathophysiological changes to persistently elevated blood pressures. However, pressures exceeding the exaggerated autoregulation capabilities lead to endothelial injury, fibrinoid necrosis and failure of the vessel autoregulatory function. To interfere with this process, immediate blood pressure reduction in the form of an IV antihypertensive is indicated. However, abrupt reduction in blood pressure with an overly potent antihypertensive regimen to a relative hypotension can result in worsening ischemia in the context of ischemic stroke. Also, patients with comorbid conditions may not tolerate certain antihypertensives. Therefore, the selection of an agent for gradual reduction in blood pressure should be carefully considered. In practice, the choice of antihypertensive in a hypertensive emergency is often dictated by hospital formulary or the individual

clinician's discretion, despite competing considerations. In patients presenting with hypertensive crisis does labetalol confer an advantage in reduction of blood pressure over other commonly used antihypertensives? CLUE was a multicenter, randomized, comparative effectiveness trial in which patients presenting with blood pressures ≥ 180 SBP or ≥ 120 DBP were randomized to treatment with either labetalol or nicardipine. Patients receiving nicardipine were more likely to reach the target reduction in blood pressure when compared with labetalol. A Cannon et al. post hoc analysis of CLUE, limited to only the parameters of hypertensive emergency also demonstrated nicardipine superiority in blood pressure reduction. Liu, DeRyke et al. demonstrated in a prospective, pseudo-randomized study in which patients presenting in hypertensive crisis with ischemic stroke were administered either nicardipine or labetalol in 24 h following admission. Assessment of the therapeutic response in the form of achieving the blood pressure target goal and time spent within goal demonstrated superiority for nicardipine. Clinical outcomes such as length of stay and mortality were unchanged between both groups. Grassi et al. conducted a randomized, parallel comparison cohort study of perindopril, amlodipine and labetalol. Patients presenting with blood pressures ≥ 180 SBP or ≥ 120 DBP were treated with one of the three antihypertensives. After the first hour of administration, labetalol showed superiority in blood pressure reduction but all three drugs were equal after two hours after administration. The literature suggests that with hypertensive urgency, perindopril, amlodipine and labetalol are equally effective in controlling blood pressure. In hypertensive emergent ischemic stroke, such as with Mr. M, nicardipine demonstrates a statistically significant advantage in blood pressure reduction when compared with labetalol, with no difference in clinical outcomes. As is the case with Mr. M, treatment with labetalol, which requires IV bolus, coupled with constant monitoring, made optimal management difficult. The second bolus of IV labetalol, overcorrected to 140/104 (a decrease in MAP of 27% in 1 h) because infrequently taken blood pressure measurements mislead the ordering physician. Therefore, despite labetalol and nicardipine being equally effective with respect to clinical end points, given the therapeutic response and convenience of drip infusion, nicardipine represents a superior modality in practice, particularly in the setting of ischemic stroke.

A COMPLICATED BUT VITAL RED BLOOD CELL TRANSFUSION Leland E. Hull; Katharine Downes. University Hospitals of Cleveland Case Medical Center, Cleveland, OH. (Tracking ID #2195700)

LEARNING OBJECTIVE #1: 1. Identify when transfusion may be necessary in the setting of warm autoimmune hemolytic anemia

LEARNING OBJECTIVE #2: 2. Recognize the limitations of crossmatching red blood cells in the setting of warm autoantibodies.

CASE: A 74-year-old Caucasian female with chronic anemia (baseline Hb10 g/dL), psoriasis, and osteoarthritis with knee replacement 1 month prior, presented as a transfer to the medical intensive care unit for acute hemolytic anemia, lactic acidosis, acute liver failure, and respiratory failure. She felt well until 2 days prior to presentation when she developed nausea, vomiting, worsening fatigue and jaundice and went to an outside hospital emergency room where her Hb was 3.5 g/dL. Patient had warm autoantibody and was unable to be crossmatched. She subsequently developed confusion and lethargy, was intubated for respiratory failure and worsening acidosis without adequate respiratory compensation and transferred to academic medical center ICU not sedated. Her ABG prior to intubation was pH 7.044, pCO₂ 16.1 mmHg, and pO₂ 16.4 mmHg, with calculated bicarbonate of 4.3 mmol/L. She was not responsive to verbal stimuli, but withdrew to noxious stimuli, and was diffusely jaundiced. No appreciable organomegaly. Labs upon transfer were significant for WBC 34.1×10^9 /L with 59% PMNs, 23% bands, Hb 3.2 g/dL, Hct 10.9% anion gap metabolic acidosis with bicarbonate of 9 mmol/L and AG of 31. She had new AKI and elevated troponin. AST and ALT were elevated and peaked at 5362 and 3397 U/L respectively. Total bilirubin was 10.6 mg/dL with direct bilirubin 6.8 mg/dL. Urinalysis showed large blood and only 3 RBCs. LDH was 6964 U/L, haptoglobin < 8 mg/dL, and lactate was 22.4 mmol/L at peak. DAT was IgG and C3 positive. Transfusion medicine was contacted given worsening lactic acidosis. She was transfused 4 units of antigen-matched but still incompatible RBC secondary to warm autoantibody, with subsequent resolution of her lactic acidosis and transaminitis, and improved mental status. The time from intubation to the start of transfusion was about 15 h, and included transfer between hospitals. She received treatment with corticosteroids and 5 day course of intravenous immunoglobulin (IVIG) for warm autoimmune hemolytic anemia (WAIHA). The trigger for her hemolysis was unclear (infectious work-up negative, ANA panel with positive anti-SSA Ab but without clinical features of Sjögren's syndrome, and CT Abdomen pelvis showed lymphadenopathy more suggestive of reactive process than primary lymphoma). She was discharged on prednisone taper with outpatient hematology follow-up.

DISCUSSION: The hallmark of treatment for patients with WAIHA is corticosteroids, with IVIG, and splenectomy for patients who are unresponsive or fail to maintain remission. However, prior to these therapies inducing remission of antibody production,

patients may require transfusion. The decision to transfuse can be a difficult one because autoantibodies may bind transfused RBC decreasing their survival with hemolysis and can interfere in pretransfusion alloantibody identification and compatibility testing necessitating time consuming specialized testing to remove the autoantibody to permit identification of alloantibodies. In some cases emergency released blood may be needed before testing is complete. The autoantibody activity may mask alloantibodies which, if present and not evaluated, may worsen the patient's hemolysis if antigen unscreened units are transfused. Anywhere from 12 to 40% of patients with warm autoantibodies have alloantibodies that could cause a hemolytic transfusion reaction. The risk of a hemolytic transfusion reaction is higher in this patient as she is a woman with risk of alloimmunization due to history of pregnancy and prior transfusion during surgery. In the end, the patient received antigen matched RBCs that were still incompatible because of reactivity with warm autoantibody. No set criteria exist to indicate transfusion is necessary. It may be indicated in the presence of reticulocytopenia suggesting aplastic anemia, and be urgently required with confusion and neurologic deterioration. Additionally, her worsening lactic acidosis suggests a conversion to anaerobic metabolism in the setting of anemia, with Hct less than 10% at lowest value. The patient did not have known coronary artery disease, but in a patient of older age one should also consider underlying CAD for lower transfusion threshold. For the managing clinician, in such a situation close coordination with the transfusion medicine team is necessary to expedite transfusion. The responsibility of the clinician is to contact transfusion medicine as soon as transfusion is being considered to discuss the urgency of the situation so that the risk of delaying transfusion for alloantibody testing (which can take upwards of 6 h at referral laboratories) can be weighed against the risks of delaying transfusion in an informed conversation.

A COMPLICATED PNEUMONIA Amrit Lamba; Deepa Bhatnagar. Tulane University Health Sciences Center, New Orleans, LA. (Tracking ID #2196386)

LEARNING OBJECTIVE #1: Identify an unusual cause of community acquired pneumonia

LEARNING OBJECTIVE #2: Discuss one complication of severe bacterial infections

CASE: A 54-year-old man was transferred from an outside hospital with refractory septic shock secondary to community acquired pneumonia. He had no prior hospitalizations and was otherwise healthy. He was empirically started on vancomycin and piperacillin/tazobactam. He had positive respiratory cultures collected on admission with *Acinetobacter baumannii* and microbiologic studies showed the organism was sensitive to all antibiotics. Despite antibiotic coverage, he experienced acute respiratory, liver and kidney failure. He required intubation with mechanical ventilation, dialysis for electrolyte abnormalities, and medical management of atrial fibrillation with rapid ventricular response. For his persistent hypotension he required four different vasopressor agents for several days. He also experienced complications of purpura fulminans—originally seen as edema of the hands and feet that gave way to dusky appearing distal extremities. These lesions progressed to complete necrosis with large bullae formation, sloughing of the skin and eventual auto-infarction of his digits. He recovered after a fourteen-day antibiotic course with improvement in his multi-organ failure. Following extubation, he suffered multiple seizures. MRI/MRA of the head revealed lesions in frontal, parietal, and occipital regions compatible with sub-acute ischemia and areas of hemorrhagic conversion. These ischemic areas were initially believed to be septic emboli. Extensive workup for a source of the emboli included lower extremity venous duplex studies, transesophageal echocardiogram, transcranial dopplers and pelvic MRA. Imaging failed to identify a source and CNS findings were subsequently believed to be thrombotic phenomena secondary to purpura fulminans. After a prolonged hospitalization, he continued to recover in a skilled nursing facility. Further history for risk factors of *Acinetobacter* was obtained once the patient stabilized. He was a longtime Louisiana resident and had a history of significant tobacco and alcohol abuse. He reported living in a FEMA trailer following Hurricane Katrina. His neighbor was in the US military with overseas deployments and recently died from an unknown respiratory illness.

DISCUSSION: *Acinetobacter baumannii* is an aerobic Gram-negative coagulase negative bacillus that is becoming increasingly important as a nosocomial infection. This bacteria is notorious for its significant methods of resistance to antibiotics and ability to survive on inanimate surfaces. However, it can also have a fulminant course when acquired in the community, even when sensitive to most antibiotics. Articles from Australia, Taiwan and Hong Kong have documented cases of this uncommon pathogen and its role in community acquired pneumonia. While it has been identified in fresh water and soil along with in normal skin and oropharyngeal flora, there is thought to be a link to this organism as a pathogen to wounded American soldiers returning from Iraq and Afghanistan, as well as a connection to people involved in natural disasters. This patient also exhibited another life-threatening condition of purpura fulminans. This condition is characterized by fever, hypotension, hemorrhagic infarction of the skin with tissue necrosis, DIC, and thrombotic occlusion of small and medium sized blood vessels. While mostly associated with severe infection from meningococemia, *Streptococcus* species, and *Haemophilus influenzae*, it

can be seen with other bacteria such as *Staphylococcus aureus* among others. According to a current literature review, it has not been previously seen with *Acinetobacter baumannii*. While it is common in the hospital to see a patient admitted with fever, cough and an infiltrate on chest x-ray, this case highlights an unusual organism causing community-acquired pneumonia. This particular case also demonstrates the rare complication of purpura fulminans and unusual CNS findings that may also manifest.

A CONFUSED, CARIBBEAN MAN WITH CALCIUM AND CELL LINE CONDRUMS Andrew Ip; Stuart Malcolm; Joyce Doyle. Emory University, Atlanta, GA. (Tracking ID #2200115)

LEARNING OBJECTIVE #1: Recognize Paraneoplastic syndromes, common and rare, in solid tumors

LEARNING OBJECTIVE #2: Understand electrolyte abnormalities due to paraneoplastic syndromes

CASE: A 61 year old Afro-Caribbean male, with recently diagnosed and untreated esophageal squamous cell carcinoma extending to the neck, was brought to clinic by his wife for altered mental status. Over the prior five days, the wife noted increasing confusion, decreased oral intake but no other specific complaints. The patient was sent to the ED where he was combative and oriented only to person. Vitals were BP 116/90, pulse 133, RR 18, and temp 37C. Notable on PE was a right sided neck mass measuring 11×15 cm. It was firm, warm and erythematous with a necrotic and purulent inferior region. Neurologic examination revealed no additional focal abnormalities and the rest of the exam was unremarkable. Labs showed a WBC of 112,000 (78 % neutrophil), Hemoglobin 13.2, Calcium 16.4, PTH 13.0, Magnesium 1.0, Phosphorus 1.9, Alkaline phosphate 235. EKG demonstrated sinus tachycardia, QT interval 312 ms and ST interval elevation consistent with hypercalcemia. Hypercalcemia of malignancy was suspected and the patient was started on aggressive IV normal saline, calcitonin, and bisphosphonates. The markedly elevated WBCs raised concern for infection vs leukemia vs a leukemoid reaction. Previous levels of WBC obtain through hospital records showed a rapidly rising WBC from 30,000 6 weeks ago, to 50,000 3 weeks ago raising the possibility of a paraneoplastic syndrome. On further review, a PET-CT 2 weeks prior demonstrated diffusely increased osseous uptake, a sign noted to be related to anemia or G-CSF administration. The patient's mental status improved with decreased calcium. Chemotherapy with carboplatin and paclitaxel and radiation were initiated. A decline in WBC to 38,000 resulted within 10 days. Throughout stay, the patient's potassium and phosphate remained low, requiring regular repletion until chemoradiation was started.

DISCUSSION: The patient's clinical course is exemplary of the devastation of paraneoplastic syndromes. Hypercalcemia of malignancy can be due to osteolytic metastases or due to PTH related protein (PTHrP). The calcium on admission was 16.4, which caused a comatose state and EKG changes. His PTH was 13.0 on admission (normal lab range 12.0–88.0), and there was no evidence of bony metastases, indicating his hypercalcemia was humoral from his squamous cell tumor. With reduction of calcium via binders and chemoradiation, calcium normalized. Granulocytosis, or leukemoid reaction, due to paraneoplastic syndrome, has also been described, but is less common in clinical practice. G-CSF, a glycoprotein that stimulates the bone marrow to produce granulocytes and stem cells, has been shown to be produced by particularly aggressive solid tumors. Although reported elsewhere, the combination of G-CSF and PTHrP producing tumor is very rare. Upon review of literature of Japanese cases, it is postulated that cell lines from squamous cell tumors that produce PTHrP may also produce G-CSF and IL-1a, which would explain why leukocytosis and hypercalcemia can occur in the same patient with a squamous cell carcinoma. Of interest is the plausible explanation of the patient's other lab values. Phosphate remained continually low until chemoradiation, an effect of the phosphaturia induced by PTHrP. Hypokalemia persisted, requiring daily repletion until chemoradiation resulted in stabilization at normal values. A possible explanation for initial hypokalemia may be attributed by the higher respiratory consumption of greatly increased numbers of leukocytes with NaK-ATPase activity resulting in decreased extracellular levels. The case provides an example of the important of literature review for guidance and the necessity of prompt cancer treatment; the astute physician should always suspect paraneoplastic syndromes despite rarity when tumor growth is so rapidly visible.

A CORTISOL CONDUNDRUM IN AN HIV-POSITIVE PATIENT ON ARVS Jonathan M. Giftos; Stella Safo. Montefiore Medical Center, Bronx, NY. (Tracking ID #2199083)

LEARNING OBJECTIVE #1: To highlight a rare but reversible mimick of lipodystrophy commonly seen in HIV-positive patients on ARVs

LEARNING OBJECTIVE #2: To describe the pharmacodynamics underlying exogenous Cushing syndrome in patients receiving co-administered ritonavir and an inhaled corticosteroid

CASE: A 50 year old man with HIV and asthma presented with 6 weeks of progressive lower extremity swelling and an 80 lbs weight gain over the past year. Exam was notable for a normal JVP, bilateral expiratory wheezes and a distended abdomen with marked caput medusae. There was no fluid wave or shifting dullness. He had a round face, a dorsocervical fat pad and striae over his upper extremities. He had 2+ pitting edema in both legs extending to the groin. Lab tests were notable for normal pro-BNP, normal liver function tests, preserved kidney function and lack of proteinuria. Duplex of the IVC and the deep veins of the legs showed no obstructed flow. CXR revealed multiple healing rib fractures. A review of prior pelvic MRI revealed avascular necrosis of the hips bilaterally. A random cortisol level was determined to be undetectable (0.0) consistent with exogenous Cushing syndrome. On further questioning, it was determined that for the past 2 years patient was on an antiretroviral regimen that included ritonavir. We also discovered that one year prior to admission patient was started on an inhaled corticosteroid, fluticasone, for poorly controlled asthma.

DISCUSSION: This case represents an example of exogenous Cushing syndrome in a patient taking an inhaled corticosteroid co-administered with ritonavir. It highlights a rare but reversible mimick of lipodystrophy commonly seen in HIV-positive patients taking antiretroviral medications. Lipodystrophy is marked by the abnormal production and storage of fat. It includes both the loss of fat (lipoatrophy) and the abnormal accumulation of fat (lipohypertrophy) in certain parts of the body. Lipodystrophy is prevalent in the HIV-positive population with studies reporting 30–80 % of patients affected. While there remains some dispute over the precise etiology of the disorder in HIV-positive patients, it is thought to be a side-effect of certain antiretroviral (ARV) medications such as protease inhibitors (PI) and thymidine analogue nucleoside reverse transcriptase inhibitors (NRTI). ARV-induced lipodystrophy presents clinically with a dorsocervical fat pad (“buffalo hump”), central adiposity (“protease paunch”) and thin extremities. Cushing syndrome, which results from increased endogenous or exogenous glucocorticoid exposure, represents another important cause of acquired lipodystrophy and presents with many overlapping symptoms. An important distinction between the disorders can be noted in the patient's face: ARV-induced lipodystrophy commonly presents with temporal wasting and loss of subcutaneous buccal fat while Cushing syndrome presents with fat accumulation in these areas leading to the classic “moon facies” finding on physical exam. Given the prevalence of lipodystrophy in patients with HIV, signs of overt cortisol excess may be mistakenly attributed to simple ARV-induced lipodystrophy. As our case illustrates, however, inhaled corticosteroids co-administered with ritonavir also can cause exogenous Cushing syndrome and represents a unique and reversible cause of lipodystrophy in the HIV-positive population. Ritonavir is an integral part of protease inhibitor based ARV regimens that is used to boost the plasma concentration of other PIs. Ritonavir inhibits the enzyme cytochrome P450-3A4 (CYP3A4), which allows for lower levels of other PIs to be used, thereby reducing the adverse effects and pill burden that historically made adherence to these regimens so difficult. Fluticasone is an intranasal or inhaled glucocorticoid that is also metabolized by CYP3A4. The effects of inhaled corticosteroids are usually limited to the upper and lower airways with negligible systemic effects. However, when fluticasone is taken with ritonavir, the decreased function of CYP3A4 may result in increased systemic levels of the steroid. As our case illustrates, levels of the steroid may increase to such a degree that Cushing syndrome and lipodystrophy become apparent. The lipophilic properties and long half life of fluticasone make it a common candidate for this adverse reaction. Therefore, it is recommended that patients on ritonavir containing ARV regimens who require inhaled corticosteroids be placed on an alternative inhaled steroid such as beclomethasone or budesonide, both of which have a lower affinity for the glucocorticoid receptor and shorter elimination times. Although considered safer, there are recent case reports of Cushing syndrome caused by these steroids as well. Alternatively, decreasing the prescribed dose of ritonavir or changing ARV regimens altogether may be required to prevent the development of exogenous Cushing syndrome.

A CURIOUS CASE OF CERVICAL GOUT Tahmina Begum¹; Mashrafi Ahmed². ¹TTUHSC, Amarillo, TX; ²Texas Tech University, Amarillo, TX. (Tracking ID #2197340)

LEARNING OBJECTIVE #1: Recognize the diagnostic approach and pathophysiology of gout involving cervical vertebral column

LEARNING OBJECTIVE #2: Focus on the importance of early diagnosis and management of gout at unusual anatomical sites

CASE: A 73-year-old male presented with headache, neck pain, confusion and fever for 2 days. He mentioned that his pain initially started over the neck and gradually extended over the back of the head within 24 h. He also developed fever in last two days which was intermittent and never exceeded 101 F. His family members noticed occasional confusion in his behavior during this period. He did not experience any trauma. There was no sick contact. His past medical history was significant for hypertension, congestive heart failure, chronic kidney disease and gout. He mentioned that he was on allopurinol before but was not taking it during this illness. At presentation, his temperature was 99.8 F and mildly

tachycardic; other vital signs were within normal limits. On physical examination he had significant pain on neck movement on side to side and on both flexion and extension. Paraspinal muscles were taut but there was no erythema. His cranial nerves were intact and there was no focal neurological deficit. The remainder of the physical examination was normal. Upon admission, a lumbar puncture was done and the CSF analysis revealed mild rise in protein without any pleocytosis. The CSF culture was negative as well. An MRI of the cervical spine revealed multifocal facet arthropathy with facet joint effusions in C4-C6. Within 48 h of admission, the patient developed painful swelling of the left elbow and left 3rd metacarpophalangeal joint. Although the uric acid level was normal, but synovial fluid analysis from both the cervical joint and left elbow revealed typical monosodium urate crystals. The patient was started on prednisone and his symptoms started to reduce within 24 h. His symptoms completely resolved within 3 days of starting treatment.

DISCUSSION: Gout is the most prevalent inflammatory arthritis. It is an intensely painful disabling condition that occurs due to an inflammatory response towards monosodium urate (MSU) crystals in joints, bones, and soft tissues. The prevalence of gout among US adults in 2007–2008 was 3.9 % and it has been increasing for last two decades. The presence of MSU crystals in the joint is the main provocative factor for inflammation in the affected joint in acute gouty arthritis. Phagocytosis of MSU crystals by neutrophils and other cells like synovial cells, monocytes, and endothelial cells induces a cascade of complex reactions with subsequent release of various inflammatory cytokines. Gout usually presents as acute inflammatory monoarthritis, typically affecting the great toe MTP joint. In the present case, gout-related cervical spine lesions were apparent. This is a rare condition; only 16 such cases have ever been reported. In the literature, most of these patients were males. The lesions can occur in any area of the cervical spine, but are most frequently seen in C4-7. If severe neurological symptoms are present, orthopedic surgery is usually performed; otherwise a course of drug treatment is prescribed. Physicians are reminded to keep gout in the differential of acute or chronic neck pain in older patients with a history of gout.

A CURIOUS CLOT: PULMONARY VEIN THROMBOSIS WITH ATRIAL EXTENSION Natalie Chavarria¹; Dr. Daniel Wang¹; Radha M. Rao²; Jeffrey T. Bates¹. ¹Baylor College of Medicine, Houston, TX; ²Michael E DeBakey, Houston, TX. (Tracking ID #2198472)

WITHDRAWN BY AUTHOR

A DIFFERENTIAL TO REMEMBER: PYLEPHLEBITIS IN A PATIENT WITH HIV PRESENTING WITH ABDOMINAL PAIN AND FEVER. Donielle F. Sliwa; Stephen Ryzewicz. Baystate Medical Center/Tufts University School of Medicine, Belchertown, MA. (Tracking ID #2197906)

LEARNING OBJECTIVE #1: Recognize pylephlebitis as part of the differential diagnosis in a patient with abdominal pain and fever, especially in patients with HIV/AIDS.

LEARNING OBJECTIVE #2: Recognize the challenge of deciding whether to initiate anticoagulation given the underlying etiology of pylephlebitis.

CASE: A 46-year-old male with a background history of HIV on HAART, Hepatitis C in remission, hypertension, hyperlipidemia, GERD and depression presented to the emergency room with epigastric pain, associated with mild nausea and loose, black stools. He took ibuprofen, pepto bismol and Alka-Seltzer at home without relief. In the emergency room, the patient developed a fever of 102.7, rigors and vomiting. Two weeks prior the patient had similar symptoms, which resolved. He denied sick contacts, recent travel or new food exposure. The remainder of the physical exam was significant for a heart rate of 120 and a stable blood pressure and respiratory rate. He had mild epigastric and right upper quadrant tenderness. There was no organomegaly or icterus. Initial laboratory studies demonstrated leukocytosis and elevated transaminases and total bilirubin. Lactate and lipase were normal. His most recent CD4 count was >1000 with a viral load of <50. Chest x-ray and abdominal CT with IV contrast were negative for acute processes. An abdominal ultrasound revealed biliary sludge without acute cholecystitis. EKG showed sinus tachycardia. The patient was started on IV fluids and antibiotics and admitted for further evaluation of a probable intraabdominal infection. Due to a continuing rise in the patient's transaminases and bilirubin, an MRI of the abdomen was completed and revealed thrombosis of the left portal vein, enlarged porta hepatis and reactive peripancreatic lymph nodes. Blood cultures grew *Klebsiella pneumoniae*, however stool and urine cultures were negative for growth. A diagnosis of pylephlebitis was made based on the presence of leukocytosis, fever and portal vein thrombosis. The patient was treated for 4 weeks with Levofloxacin. An outpatient work-up for thrombophilia was negative and due to the bacteremia being the likely cause of the portal vein thrombosis, anticoagulation was not initiated.

DISCUSSION: Pylephlebitis is an uncommon but critical diagnosis to make in patients presenting with abdominal pain and fever, especially those with HIV/AIDS. Diagnostic criteria include portal vein thrombosis, fever, and often, bacteremia. Although

pylephlebitis was universally fatal in the preantibiotic era, the morbidity and mortality have decreased with early identification and antibiotic management. There is data suggesting that people living with HIV and AIDS are at a 2 to 10 fold greater risk of venous thromboembolic disease compared to age-matched controls. Therefore, it is important to consider pylephlebitis in the differential diagnosis when evaluating HIV/AIDS patients presenting with these symptoms. Furthermore, anticoagulation in pylephlebitis is not well described in the literature, making the decision to anticoagulate these patients a difficult one. In the case of our patient, the etiology of the portal vein thrombosis was the pylephlebitis, making anticoagulation unnecessary with adequate antibiotic treatment. However, it is prudent to rule out underlying hypercoagulable states and to ensure complete response to antibiotics before deciding against anticoagulation.

A DIZZYING DIAGNOSIS Elisa H. Ignatius. Emory University School of Medicine, Atlanta, GA. (Tracking ID #2199589)

LEARNING OBJECTIVE #1: Recognize an atypical presentation of an increasingly diagnosed complication of breast cancer: leptomeningeal metastasis

LEARNING OBJECTIVE #2: Recognize that despite improvement in peripheral disease, systemic chemotherapy may not fully cross the blood-brain barrier and patients can still develop CNS metastasis

CASE: A 52-year-old female with a history of prior stroke and stage III triple negative breast cancer treated with cyclophosphamide and doxorubicin presented with nausea and vomiting 6 days after her third cycle. She was diagnosed with chemotherapy-related nausea, started on multiple anti-emetics, and discharged home on hospital day 7 after gradual improvement. Three days later, the patient returned with nausea, vomiting, and dizziness at rest that worsened with ambulation and sitting upright. She denied headache, vision loss, or seizures but had left eye fullness and low back pain. She admitted excessive use of prochlorperazine since discharge, initially thought to be contributing to her presentation. On physical exam, her blood pressure was 160/100 mm Hg, heart rate 76 BPM, temperature 36.6 °C, respirations 14 per minute, with pulse oximetry 100 %, and non-orthostatic vital signs. Her exam was notable for intact extra-ocular movements, symmetric and reactive pupils, no nystagmus or papilledema and normal hearing. She was alert with intact cranial nerves, sensation, and reflexes, no dysmetria but decreased (4/5) strength of her left leg that was chronic. Her dizziness prevented gait assessment. She had tenderness of her left maxillary sinus and right sternocleidomastoid. Laboratory studies were notable for blood urea nitrogen 9 mg/dL, creatinine 1.8 mg/dL, white blood cell count (WBC) 8.3 K/mcL, hemoglobin 9.9 g/dL (mean corpuscular volume 82), and platelets 228 K/mcL. Cardiac enzymes were negative. Brain computerized tomography showed chronic microvascular changes and layering fluid in her sphenoid sinus. X-ray of her lumbar spine showed degenerative changes. She was started on meclizine, scopolamine patch, anti-emetics, nasal spray, and amoxicillin clavulanate. After failing to improve, magnetic resonance imaging (MRI) of her brain redemonstrated chronic microvascular disease. A positron emission tomography (PET) scan showed decreased size and hypermetabolic intensity of her right breast mass and diffusely resolved FDG nodal activity. She developed pre-syncope episodes concerning for seizures but EEG showed no epileptiform activity. Her dizziness and neck pain remained refractory to numerous therapies so lumbar puncture was performed. LP showed opening pressure 50 cm water, glucose <10 mg/dL, total protein 294 mg/dL, and WBC 33, 38 % of which were undifferentiated cells. Her dizziness and neck pain immediately resolved. Cytology showed malignant cells with identical cytologic features as her prior breast biopsy, confirming the diagnosis of leptomeningeal carcinomatosis. Neurosurgery placed an intraventricular catheter and she was started on dexamethasone and intrathecal chemotherapy prior to discharge.

DISCUSSION: This clinical vignette demonstrates an atypical presentation of an increasingly recognized complication of breast cancer and the need for high clinical suspicion to diagnose leptomeningeal metastasis (LM). LM occurs when there is spread to the subarachnoid space and cerebrospinal fluid (CSF); it is most often associated with melanoma, breast and lung adenocarcinoma. Approximately 2-5 % of patients with metastatic breast cancer have symptomatic LM disease but higher rates (5-16 %) have been shown on autopsy. Prognosis is dismal with average survival 4-6 months. Symptoms reflect increased intracranial pressure and include headache, cranial nerve deficits, cerebellar signs, nausea, vomiting, and mental status changes. Diagnosis is based on CSF cytology, yet 45 % are negative on first attempt. Diagnostic yield improves to 80 % with a second pass, but little more is gained from additional attempts. Classic CSF findings include elevated opening pressure, high protein, and low glucose. MRI with gadolinium may demonstrate leptomeningeal or cranial/spinal nerve enhancement but has a 30 % false negative rate. Treatment is palliative and includes intrathecal chemotherapy with methotrexate (plus systemic chemotherapy/radiation) and medications to reduce intracranial pressure. As shown by this patient's PET, CNS metastases may develop despite improving peripheral disease due to the selective permeability of the blood brain barrier to systemic chemotherapy. This apparent contradiction may be appropriate to discuss with patients.

LM represents a clinical challenge given its diverse presentations, frequently delayed diagnosis, and late treatment initiation. Diagnosis was gradual in our patient due to an atypical presentation and unremarkable imaging. Although swift recognition of LM results in earlier treatment that may halt neurologic progression and maintain neurologic quality of life, overall prognosis remains very poor.

A FULL HOUSE: RENAL DISEASE IN AN HIV-POSITIVE PATIENT Thomas Middour; Stacey Ullman; Margaret P. Huntwork. Tulane University Health Sciences Center, New Orleans, LA. (*Tracking ID #2198542*)

LEARNING OBJECTIVE #1: Explore the differential diagnosis of acute renal failure in patients with HIV

LEARNING OBJECTIVE #2: Discuss treatment options in immune complex mediated renal disease

CASE: A 55 year-old man with HIV presented with 6 months of intermittent nausea and vomiting in the absence of abdominal pain. He had no history of opportunistic infections, and was compliant with HAART therapy for 20 years. He denied fever, chills, change in bowel habits, or recent illness. On examination, a petechial rash was visible on the lower extremities and myoclonus was elicited in the left lower extremity. Initial screening labs demonstrated new onset pancytopenia (ANC 900/mm³) and acute renal failure (serum creatinine 4.0 mg/dL). Urinalysis and basic metabolic panel revealed new onset hematuria and proteinuria and renal tubular acidosis. The patient underwent workup for his new acute renal failure plus pancytopenia. Infectious testing was negative for hepatitis B, hepatitis C, CMV, or EBV. Bone marrow biopsy was normocellular and showed no evidence of infiltrative disease. Serologic evaluation revealed a positive direct Coombs' test, a polyclonal gammopathy (IgG and IgM), a weakly positive ANCA PR3, and hypocomplementemia. Tests for anti-nuclear antibody, anti-double stranded DNA, anti-Smith, anti-Ro, anti-La, and cryoglobulinemia were negative. Flow cytometry was negative for paroxysmal nocturnal hemoglobinuria and hematologic neoplasm. Due to progressively worsening renal failure (peak serum Cr 8.5 mg/dL), a kidney biopsy was performed. Biopsy revealed "full-house" immunoglobulin (IgA, IgM, IgG) and complement (C3, C1Q) deposition and severe tubulointerstitial nephritis. These findings are usually characteristic of type IV diffuse proliferative lupus nephritis. Repeat antinuclear antibody testing was again negative. Serology was weakly positive for anticardiolipin antibodies and negative for lupus anticoagulant. The patient met only 3 of 11 ACR lupus criteria and was ultimately diagnosed with lupus-like immune complex glomerulonephritis. He was initiated on the EuroLupus lupus nephritis induction protocol with methylprednisolone and cyclophosphamide. The patient's renal function moderately improved (serum creatinine to 1.5 mg/dL), although he was discharged on continued outpatient hemodialysis, glucocorticoids, and HAART.

DISCUSSION: Internists frequently encounter HIV in the inpatient and outpatient setting and must be able to recognize both common and uncommon HIV related complications. Although we commonly encounter kidney disease in HIV patients, a diverse spectrum of pathophysiological processes drives renal disease in HIV with varying prognoses and treatments. This case highlights a rare type of acute renal failure seen in HIV patients. Immune complex lupus-like proliferative glomerulonephritis in HIV patients is a form of kidney disease described in a limited number of case series. It may cause up to 4 % of CKD in HIV and is a distinct entity apart from HIV associated nephropathy (HIVAN) and HIV immune complex kidney disease. Biopsy series have shown nearly 40 % of suspected HIVAN, the most prevalent renal complication of HIV, receive alternative diagnoses on biopsy with immune complex disease an unexpectedly frequent incidental finding. This lupus-like nephropathy tends to occur more frequently in Caucasians and patients with high CD4 counts, and studies suggest a more aggressive course. This disorder's relationship to HIV and its therapies remain unknown and essentially unevaluated. Small studies have delivered contradictory evidence as to the risks and benefits of immunosuppression and HAART. Further, rare cases of concomitant SLE and HIV cloud the diagnostic picture, and may mask one another until treated due to the interplay of immunologic pathology in each disease. Our case demonstrates a rare, complex condition in an HIV patient that requires further study to understand its pathogenesis and treatment. In conclusion, HIV and SLE have rarely been reported in the same patient. A rare "lupus-like" glomerulonephritis has been recognized in patients with renal failure and HIV who fail to meet American College of Rheumatology SLE criteria.

A HAIRY SITUATION: COEXISTENT HAIRY CELL LEUKEMIA AND CHRONIC LYMPHOCYTIC LEUKEMIA Ramy Sedhom; Charles L. Liu; Jalal Baig; Ranita Sharma. Rutgers-Robert Wood Johnson Medical School, Harrison, NJ. (*Tracking ID #2195047*)

LEARNING OBJECTIVE #1: Identify the importance of flow cytometry in the diagnosis of hematologic malignancies.

LEARNING OBJECTIVE #2: Recognize the increased risk of secondary malignancy in both Chronic lymphocytic leukemia and Hairy Cell Leukemia.

CASE: Hairy cell leukemia (HCL) is a rare malignancy compromising only 2 % of leukemias. It is a risk factor for future development of secondary malignancies. It is not uncommon for hairy cell leukemia to evolve from a prior chronic lymphocytic leukemia (CLL) clone. However, simultaneous diagnosis of HCL and CLL is rare, with only few cases reported. We report a case of a 66-year-old male with simultaneous HCL and CLL who responded well to cladribine and rituximab chemotherapy. A 66-year old male presented with sub-sternal chest pain and progressive dyspnea of 3 days duration. He has no known past medical history. He denies medication, IV drug or alcohol use. He has 60 pack-year smoking history. Prior surgeries include appendectomy and tonsillectomy. His father died of leukemia. His chest pain was sudden in onset, sub-sternal, with radiation to his left arm. Pain was non-pleuritic and relieved by rest. Review of symptoms included easy bruising and night sweats of several weeks duration. He denied recent illness, fevers, weight loss, abdominal pain, epistaxis or mucosal bleeding. On admission, patient was afebrile, normotensive, with a pulse 70, respiratory rate 16, and O2 sat 99 % on room air. Cardiopulmonary and lymph node examination were unremarkable. Pertinent abnormal findings included diffuse petechiae on bilateral arms and legs. The spleen tip was palpated 3 cm below left costal margin. Basic profile was normal. CBC showed pancytopenia, with hemoglobin of 8.3 and platelets of 62. Troponins were positive and peaked at 0.9. EKG was normal sinus rhythm, with no dynamic ST changes or T-wave inversions. Chest pain resolved with one dose of nitroglycerin. Chest X-ray did not reveal active cardiopulmonary process. CT chest was negative for pulmonary embolism, with no masses or mediastinal lymphadenopathy. Cardiac echo showed no regional wall motion abnormalities. Abdominal ultrasound confirmed splenomegaly. Blood test work-up for pancytopenia revealed normal B12, folate, TSH level, ESR, and negative ANA. Serologies were equivocal for CMV, positive for EBV IgG and negative for parvovirus. HIV was negative. Kappa/Lambda free light chain ratio was normal. Peripheral smear showed numerous small mature lymphocytes with smudge cells. Hematology/oncology was consulted. Bone marrow aspirate was consistent with two separate populations of CD19 positive B-cells. A small population had immunophenotyping consistent with CLL. A separate distinct population of cells was positive for HCL markers CD 130, CD25, with co-expression of FMC7 and marker annexin A1. The patient was placed on neutropenic precautions. Induction chemotherapy consisted of cladribine and rituximab, specifically chosen with the aim of rapid improvement to allow intervention for suspected cardiac disease. Cardiac catheterization was held given chemotherapy induced thrombocytopenia and the risk of dual anti-platelet therapy. He tolerated his eleven day cycle of chemotherapy well without complaints. His platelets had a nadir of 23 and responded well to one unit of platelets. Cardiac catheterization was performed after platelet recovery and revealed 50 % stenosis of the mid LAD, 60 % stenosis of the circumflex, and 100 % occlusion of the mRCA. Despite triple vessel disease, he did not require PCI. He was discharged on metoprolol, aspirin, and atorvastatin. At his last follow-up visit, he reported being chest pain free. Repeat bone marrow has shown remission of his hairy-cell leukemia. His CLL is well controlled. He no longer requires treatment and is monitored every 6 months.

DISCUSSION: CLL and HCL are B-cell derived lymphoproliferative disorders with distinct morphologic features, immunophenotypes and clinical presentations. The simultaneous diagnosis of both is exceedingly rare. CLL is the most common leukemia in the western world and commonly encountered by internists. Hairy cell leukemia is 10 times more rare, often not seen even by practicing oncologists. Our case emphasizes the importance flow cytometry and the advantages of monoclonal antibodies in the diagnosis of lymphoproliferative disorders. Flow cytometric analysis was important diagnostically as two distinct clones of mature B-cells were revealed. Though clinical response was seen to cladribine and rituximab, future clinical trials are needed to standardize therapy.

A HEAD-TURNING CASE OF SYNCOPE Clark A. Veet. UPMC, Pittsburgh, PA. (*Tracking ID #2192928*)

LEARNING OBJECTIVE #1: Recognize the clinical features and pathophysiology associated with Bowhunter's or rotational vertebral artery syndrome.

LEARNING OBJECTIVE #2: Identify limitations in static imaging modalities when assessing patients with syncope.

CASE: A 62 year old female with history of coronary artery disease, type II diabetes mellitus, remote traumatic brain injury with subsequent seizures, and moderate aortic stenosis presented to the emergency department with three discrete episodes of syncope. The syncopal events occurred exclusively when she moved her head or arms, particularly when she looked upward and reached above her head. The patient had no prodromal symptoms including palpitations, dizziness, or diaphoresis. She denied any confusion, incontinence, or tongue biting after the episodes. Cardiac examination was regular and notable for systolic murmur. Neurological examination was unremarkable except for symptoms of vertigo and nausea with provoked horizontal head motion. With a presumed neurovascular etiology, the patient underwent multiple imaging studies. Non-contrast CT

of the head was negative for acute pathology. Brain MRI showed generalized cerebral volume loss and chronic microangiopathic changes. MR angiography of the neck showed atherosclerotic changes without hemodynamically significant stenosis. MR angiography of the brain showed no high grade stenosis. Carotid and vertebral ultrasonography with doppler showed no stenosis in carotid or vertebral systems. CT angiography of head and neck showed diffuse atherosclerotic calcifications in bilateral carotid bulbs but no significant stenosis. The vertebral arteries showed diffuse calcifications but no significant stenosis. The patient continued to have witnessed syncopal episodes with head movement and physical therapy. A cardiogenic source was considered and tilt-table testing was performed illustrating a bradycardic response. However, her symptoms of vertigo and syncope were not reproduced, making vasovagal syncope an unlikely cause. An alternative diagnosis was considered, that of transient and dynamic arterial obstruction, and the patient was consented for catheter-based cerebral angiography with provocative movements. The test revealed normal bilateral carotid vasculature and normal co-dominant vertebral arteries in neutral stance. However, when the patient extended both arms overhead and turned her head to the left, occlusion of left vertebral artery in the V3 segment was seen and her symptoms were replicated. This finding was consistent with Bowhunter's, or rotational vertebral artery syndrome, with dynamic occlusion in the C1-C2 range.

DISCUSSION: Bowhunter's syndrome, also known as rotational vertebral artery syndrome, is a rare condition that occurs when dynamic, posturally-induced obstruction of head and neck arteries causes vertebrobasilar insufficiency. The phenomenon is a diagnostic challenge and often remains a mystery despite a plurality of traditional static imaging. Symptoms are reliably reproduced with head or arm movement and resolve with neutral positioning. Clinical findings most often include vertigo, tinnitus, syncope, or blurred vision that resolves with neutral gaze. Nystagmus is seen in the vast majority of patients with downbeating the most predominant feature. Pathophysiologically, the dynamic occlusion is thought to be caused by fibrous muscular insertions, osteophytes, or degenerative changes that cause a reduction in cerebral bloodflow by extrinsic impingement of vessels and resultant occlusion. The lesions are most often seen in the upper cervical levels. Given the need for movement to provoke occlusion, lesions are not detected on static imaging. Even non-invasive dynamic imaging may fail in diagnosis. One case series with angiographically proven Bowhunter's showed that dynamic doppler ultrasonography fails to detect stenosis in 50% of cases. Given the rarity of this syndrome, there is no universally agreed upon gold standard in diagnosis, though most sources recommend conventional angiographic testing in cases with high clinical suspicion. Along with history, physical, and imaging findings, this patient did have other features classically seen in Bowhunter's. Case series suggest that patients with satisfactory collateral flow in the Circle of Willis via communicating arteries tended to have longer latent periods before symptoms. In this patient, diffuse atherosclerotic disease and absent posterior communicating arteries contributed to the severity and immediacy of symptoms which occurred seconds after motion. Management of this rare phenomenon is not standardized. Conservative treatment includes lifestyle modifications and avoidance of precipitating movements, which was recommended in this patient. Neurosurgical referral should be considered when symptoms continue despite optimal conservative management and often includes cervical decompression.

A HEMATOLOGIC TWIST ON JOINT PAIN IN AN ELDERLY MALE Jill B. Feffer; Diane L. Horowitz; Jonathan E. Kolitz. North Shore-LIJ/Hofstra School of Medicine, Lake Success, NY. (Tracking ID #2152961)

LEARNING OBJECTIVE #1: Recognize the need to rule out an underlying hematologic neoplasm in an elderly patient who presents with new onset of inflammatory polyarthralgias

LEARNING OBJECTIVE #2: Include RS3PE on the differential diagnosis of joint pain and swelling as a less commonly known rheumatologic entity

CASE: Seventy-seven year-old man with history of Crohn's disease treated with 6-mercaptopurine complained of progressive diffuse joint pain associated with fatigue and distal extremity swelling, ankles worse than wrists, for 3 weeks. Prior to onset, he ambulated independently; at presentation, movement involving his lower extremities or back elicited severe pain. He denied personal or family history of rheumatologic disease, including enteropathic arthritis, or hematologic malignancy. Admission findings included low-grade fever and pancytopenia. Infectious workup was negative and bone marrow biopsy showed >10% blasts, so the patient was transferred to our tertiary center. Bilateral wrists and ankles were tender to palpation and markedly swollen but not warm nor erythematous, with 2+ nonpitting edema in his hands and 3+ nonpitting edema in his feet. ESR was markedly elevated (113) and nucleolar pattern ANA was borderline (1:40), but serologies including cryoglobulins and antibodies against dsDNA, Smith, CCP, SS-A, SS-B, RF, p- and c-ANCA and RNP as well as testing for HLA-B27 antigen were negative. X-rays of bilateral hands, wrists and knees were consistent with osteoarthritis without erosions. Repeat bone marrow biopsy and aspirate results were consistent with

MDS; cytogenetics showed a complex, highly adverse karyotype. Diagnosis was therapy-related myeloid neoplasm treated with prednisone taper followed by 5-azacitidine. Pains and mobility gradually improved although diuresis with furosemide did not reduce pedal edema.

DISCUSSION: Links between rheumatologic conditions and hematologic malignancies have been documented but are not widely known. We present a case of remitting symmetric seronegative synovitis with pedal edema (RS3PE)—defined as bilateral inflammatory polyarthralgias associated with prominent hand and/or pedal edema and negative RF, most commonly in elderly males—leading to new diagnosis of myelodysplastic syndrome (MDS). Retrospective cohort studies have identified statistically significant links between hematologic malignancies and seronegative polyarthralgias, and case reports have associated acute myeloid leukemia and MDS with specific rheumatologic conditions. New onset of inflammatory arthralgias in older patients should therefore prompt consideration of an underlying myeloid neoplasm, and studies are needed to investigate whether rheumatologic illness is a true paraneoplastic manifestation or shares a causative mechanism which could offer potential therapeutic targets.

A KILLER COMBINATION: HONEYDEW MELON AND METHADONE INDUCED HYPERKALEMIA Naveen Nannapaneni. Wayne State University, Royal Oak, MI. (Tracking ID #2190200)

LEARNING OBJECTIVE #1: Recognize the EKG changes seen with hyperkalemia.

LEARNING OBJECTIVE #2: Manage hyperkalemia in the acute setting.

CASE: Electrolyte abnormalities are prevalent in patients with end-stage renal disease as they have impaired mechanisms of regulation. Amongst them, hyperkalemia is common as the primary modality of potassium removal is absent. As a result, these patients must follow a specific diet to minimize the amount of intake and their serum level is closely monitored by nephrologists. Occasionally, lapses in this diet can lead to dangerous results, as presented in this case. A 62 year-old female with end-stage renal disease, hypertension and diabetes was brought to the emergency room via ambulance for a 1-day history of generalized weakness. She reported being in her usual state of health the day prior, enjoying a honeydew melon on a warm summer's day, and when she woke up the next morning she was unable to stand up and had to crawl on the floor to call an ambulance for help. She reported going to her last hemodialysis session two days prior where she had a full run of dialysis. Concurrently, she affirmed constipation after her dose of methadone for chronic back pain was increased several days prior. On physical exam the patient was noted to be bradycardic, 45 beats per minute. Neurological exam revealed decreased strength in all muscles along with a waxing and waning mentation. Laboratory studies showed a potassium >7mM/L. EKG showed peaked T-waves, prolonged PR-intervals & QRS-durations, and decreased p-wave amplitudes. In the ER calcium chloride, kayexelate, insulin, and dextrose were given. Nephrology was consulted and the patient underwent emergent dialysis with resolution of EKG changes and generalized weakness. She was discharged the next day after overnight monitoring and counseling on the importance of adherence to a renal diet.

DISCUSSION: Hyperkalemia is common in end-stage renal disease patients. While symptoms can include muscle weakness, the most concerning are the changes that manifest in the EKG: peaked T-waves, prolonged PR-intervals & QRS durations, decreased p-wave amplitudes, and bundle branch blocks which foretell of impending arrhythmia from a sine-wave. Our patient's hyperkalemia was precipitated by her eating an entire honeydew melon, a fruit high in potassium, compounded with her decreased ability to excrete potassium in the gut due to constipation, a mechanism of minimal excretion in normal patients but one which is up regulated in chronic kidney disease patients. Emergent treatment can be done with mechanisms of cellular shifts and total body removal of potassium. If EKG changes are present, cell membrane stabilization is also performed. Reiteration of the renal diet to patients with chronic kidney disease is crucial as hyperkalemia can result in mortality for these patients.

A LIFE-THREATENING COMBINATION: A SUPPLEMENT-DRUG INTERACTION IN A WOMAN WITH ACUTE CORONARY SYNDROME Elisabeth Poorman; Pieter Cohen. Cambridge Health Alliance, Cambridge, MA. (Tracking ID #2197857)

LEARNING OBJECTIVE #1: Diagnose side effects of dietary supplement use in unexpected drug-drug interactions

LEARNING OBJECTIVE #2: Learn how to report adverse effects of dietary supplements

CASE: A 43-year-old obese woman with a history of asthma presented to the hospital with right-sided chest pain and shortness of breath. Two weeks prior, she presented to her primary care office with dyspnea on exertion. Over the following 2 weeks, her shortness of

breath occurred with progressively less exertion. A few days prior to admission, she began to feel right-sided chest pain with exertion. Medications included albuterol, fluticasone and a weight loss dietary supplement, SlimXtreme. Because of her chest pain, she was referred to the emergency department for evaluation. In the emergency department, her initial vitals were heart rate of 63, body mass index of 41, blood pressure 150/92, oxygen saturation of 100 % on room air. Her troponin was 0.09, and an electrocardiogram showed T wave inversions in leads V3 through V6. She was given a dose of sublingual nitroglycerin, and became acutely hypotensive, with a heart rate in the 30s. She was resuscitated with intravenous fluids. She also received aspirin 324 mg, clopidogrel 600 mg, atorvastatin 80 mg, and intravenous heparin. Her pain was not controlled with morphine, and her T wave inversions in V3 and V4 deepened. Troponin rose to 0.43. An urgent cardiac catheterization demonstrated a mid left anterior descending subtotal occlusion. The occlusion was stented with a 2.2 mm Boston Scientific Premier RX 24/2.25, and the patient was discharged home 2 days later in excellent condition. Her weight loss supplement was analyzed for the presence of active pharmaceutical ingredients using liquid chromatography- quadrupole time-of-flight mass spectrometry. Analyses revealed the presence of both sildenafil and papaverine.

DISCUSSION: The use of weight loss supplements is widespread across the United States. A recent cross-sectional survey of 9403 adults found that 15.2 % reported ever having used weight loss supplements. Only one in three users of weight loss supplements reported the use of their supplement to their health care provider. The law permits manufacturers to advertise supplements as weight loss aides even without evidence of their efficacy or safety. This has created a perverse incentive for manufacturers to include pharmaceutical products in weight loss supplements in order to achieve the advertised effects. Over the past decade, a variety of pharmaceuticals have been found in weight loss supplements, including fluoxetine, phenytoloin, and subitramine. However, to our knowledge, no weight loss supplement has before been found to contain both sildenafil and papaverine, two vasodilators more likely to be found in adulterated male enhancement supplements. Because the patient in our case was unknowingly consuming two pharmaceutical vasodilators, she had a life-threatening drug-drug reaction when she was treated with nitroglycerin for her acute coronary syndrome. This case illustrates that patients may be consuming pharmaceutical-adulterated supplements without their knowledge, and clinicians should consider supplements when unanticipated drug reactions occur. Clinicians should report cases of harm from supplements to the Food and Drug Administration because the FDA relies on these reports to identify dangerous supplements.

A MASQUERADING DIAGNOSIS: DISTINGUISHING BRACHIAL ARTERIAL EMBOLISM FROM ACUTE ISCHEMIC STROKE Tiffanie K. Jones; David J. Aizenberg. University of Pennsylvania, Philadelphia, PA. (Tracking ID #2197935)

LEARNING OBJECTIVE #1: Distinguish between acute limb arterial embolism and acute ischemic stroke as the cause of monoparesis

LEARNING OBJECTIVE #2: Treat limb arterial embolism with prompt surgical embolectomy rather than thrombolytic therapy

CASE: An 89-year-old gentleman presented to the outpatient clinic with a 1-day history of right arm weakness, pain, and paresthesias. The patient described his awakening from sleep with weakness and abnormal sensations in his arm ranging from pain to paresthesias including tingling and poikilothermia. His past medical history is significant for congestive heart failure, hypertension, hyperlipidemia, atrial fibrillation on anticoagulation, and paroxysmal ventricular tachycardia requiring an implantable cardioverter-defibrillator. One week prior to presentation, the patient's warfarin was held in anticipation of a generator change for his device. Prior to the procedure, his INR normalized, and his generator was changed without perioperative complications. His physical examination was notable for normal vital signs, grossly intact cranial nerves, mild cognitive impairment, reduced strength of the distal right upper extremity, preserved reflexes, and a non-palpable right radial pulse. The patient's cardiopulmonary examination demonstrated an irregularly irregular heart beat and clear lungs. EKG showed atrial fibrillation at 78 bpm. The patient was referred to the emergency department where his laboratory studies were notable for normal coagulation studies (INR 1.3, PTT 32.9), acute kidney injury (Cr 1.45), and a mild anemia (Hb 13.1). A head CT showed no acute intracranial abnormality. His CT angiogram of the right upper extremity revealed a right brachial artery occlusion after the origin of the profunda brachii. The patient was started on intravenous heparin, and a vascular surgery consultation was obtained. The patient was taken to the operating room on the following day for an embolectomy. While hospitalized, his strength improved, his acute kidney injury resolved, and a palpable radial pulse returned. He was discharged after 1 week to his primary care clinic with a low molecular weight heparin bridge to warfarin.

DISCUSSION: Acute brachial artery embolism is an important cause of monoparesis and acute limb ischemia [1]. Based on guidelines from the 2007 Inter-Society Consensus for the Management of Peripheral Arterial Disease, acute limb ischemia is characterized by the "sudden decrease in limb perfusion, usually producing new or worsening symptoms

and signs, and often threatening limb viability" [2]. This decreased perfusion may clinically manifest as pain, pallor, paresthesia, and pulselessness [1], which are features typically absent from acute ischemic stroke. Since brachial arterial embolism may result in acute limb ischemia, delayed or late diagnosis carries the risk of limb loss. Diagnostic tests including Duplex imaging, Doppler ultrasonography, and angiography are used to confirm the clinical diagnosis as well as to identify the suspected location of the emboli for operative planning [3]. Urgent surgical intervention is required to restore circulation to the compromised limb. This ambulatory patient presented to the outpatient clinic with a surgical emergency. The patient's history of weakness and paresthesias was consistent with a central nervous system ischemic event. Without the identification of an absent radial pulse, an acute ischemic stroke may have been the leading element of the differential diagnosis. In this case, the patient's physical exam increased the clinical suspicion for acute limb ischemia of the upper extremity. This patient had a known diagnosis of atrial fibrillation, which is thought to be the precipitating factor in approximately 80 % of the cases [1,4]. His INR was also subtherapeutic due to a recent procedure. Since an acute brachial artery embolus requires a surgical embolectomy within 24-h of presentation [3], immediate surgical referral is imperative. With prompt intervention, this patient had a successful outcome with full functionality restored to the affected limb. Literature Cited: [1] Holmstedt C, Chimowitz M. A MATTER OF PATIENT AUTONOMY: CODE STATUS IN THE PERIOPERATIVE PERIOD Alexandra Marchetta²; Gina Luciano¹; Christine L. Bryson¹. ¹Baystate Medical Center, Springfield, MA; ²Baystate Medical Center, Ware, MA. (Tracking ID #2198283)

LEARNING OBJECTIVE #1: Recognize the importance of discussing goals of care and contingency plans for potential procedural complications, and development of a specific DNR/DNI re-implementation plan periprocedurally

CASE: A 78-year-old male with end-stage chronic obstructive pulmonary disease on home oxygen was admitted to the ICU after developing respiratory failure as a complication of a lung nodule biopsy. His code status was do not resuscitate/do not intubate (DNR/DNI) prior to the biopsy, but this had been reversed as per standard protocol for the procedure. A formal discussion with the patient concerning periprocedural code status was not documented. After the biopsy, the patient developed intrapulmonary hemorrhage and pneumothorax requiring intubation and chest tube placement, with his family's consent. He improved and was extubated on his second day of hospitalization. Later that day, the patient again developed respiratory failure and was re-intubated. The DNR patient consent form states that if the DNR order has been suspended during the perioperative period, discussions with the patient for reinstituting the DNR order must take place within the first 48 h postoperatively. Only a few hours occurred between intubations, and the patient was not clinically well enough to participate in a meaningful code discussion, thus leading the team to continue with the full code order. The next day, a family meeting was held during which many of the patient's family members expressed concern that the patient was re-intubated despite his previously documented DNR/DNI order. The family and patient ultimately decided to attempt extubation, with the understanding that he not be re-intubated. On day 4, the patient passed the weaning parameters and was extubated; he died soon after.

DISCUSSION: Patient autonomy can be compromised when a previously documented DNR/DNI code status is routinely reversed for a procedure. A preoperative or preprocedural discussion regarding code status and patient wishes in the setting of a procedural complication can mitigate this to a certain extent. This conversation ideally includes information about how anesthesia may be similar to resuscitation and how resuscitation is more likely to be successful in the OR. If the patient decides to suspend a DNR/DNI order for a procedure, a reinstatement plan can be discussed and agreed upon pre-procedurally to maximize patient autonomy in the event of a complication. In 1993, the American Society of Anesthesiologists recommended that the automatic reversal of DNR status for perioperative patients conflicted with a patient's right to self-determination. Despite these guidelines and the emphasis currently placed on respecting patient autonomy, many hospitals and institutions do not have a policy regarding DNR/DNI status in the perioperative period. Many institutions that do have a policy require automatic perioperative suspension of DNR/DNI orders. For all hospitalists and care team members of patients with clearly stated DNR/DNI orders, pre-procedure discussions should be held and documented to ascertain patient preferences in the event of a complication in order to maximize patient autonomy.

A MIXED UP CASE OF DYSPNEA Jessica Hohman; Michael T. Martyn. UCSF, San Francisco, CA. (Tracking ID #2199871)

LEARNING OBJECTIVE #1: Recognize the symptomatic triad of atrial myxomas

LEARNING OBJECTIVE #2: Develop a cost-effective approach to the workup of chronic dyspnea

CASE: A 56-year-old Caucasian woman with a history of anxiety presented to our academic primary care clinic to establish care. Since 2010, the patient had noted progressive dyspnea. A former competitive cyclist, she had been unable to ride for several years. On presentation, she reported that she was only able to walk ten feet before needing to stop secondary to shortness of breath and lower extremity discomfort. The patient endorsed palpitations, headaches, and sub-sternal cramping pain that would radiate to her jaw accompanying these episodes. She denied associated lightheadedness, vision changes, paroxysmal nocturnal dyspnea, orthopnea, lower extremity edema, numbness, or tingling. The patient reported a fragmented prior workup at several local urgent care centers in recent years, including a reportedly normal electrocardiogram and pharmacologic stress test. The patient's past medical history was otherwise unremarkable, and her family history was notable for the absence of cardiopulmonary disease. The patient was a former 30-pack-year smoker, and denied alcohol and drug use. She was not on any medications and denied any allergies. The patient was self-employed and paid for care out-of-pocket, repeatedly requesting judicious use of resources in her workup. On exam, the patient's vital signs were normal as was her ambulatory oxygen saturation. She was well appearing, but anxious. Her cardiac exam was notable for a regular rate and rhythm, a loud P2, and a soft systolic ejection murmur heard at the left lower sternal border; there was no jugular venous distension or lower extremity edema. The patient's lungs were clear, and she had no skin or nail findings. The rest of her exam was unremarkable. The patient's initial complete blood count, chest radiograph, and basic metabolic panel were within normal limits. Her electrocardiogram was notable for left atrial enlargement, but was otherwise normal without ischemic changes. A transthoracic echocardiogram was ordered, which showed severe left atrial enlargement, a pulmonary artery systolic pressure of 85 mm Hg, and a 4x4x7cm friable mass with multiple mobile components attached to the atrial septum that prolapsed into the left ventricle, causing near obstruction of the mitral valve. The patient was sent directly to the hospital for cardiac catheterization, which showed no evidence of coronary artery disease, and was admitted to cardiac surgery for urgent surgical resection of the mass given its high risk for embolization and complications, including sudden death. Pathology of the mass was consistent with an atrial myxoma. At the patient's follow-up visit 4 months later, she noted resolution of her dyspnea. She had just started cycling for the first time in several years.

DISCUSSION: Chronic dyspnea—or subjective difficulty breathing lasting for longer than a month—accounts for a significant number of primary care visits each year. Over 85 % of these cases are attributable to chronic obstructive pulmonary disease, heart failure, asthma, pneumonia, ischemic heart disease, interstitial lung disease, psychogenic causes, and anemia. Primary cardiac tumors—particularly atrial myxomas—are rare though with an incidence of less than 0.1 %. Early recognition and surgical intervention is key. Myxomas more commonly occur in women in the third to sixth decade of life and are usually sporadic. The majority are located in the left atrium and present with the classic triad of obstructive cardiovascular, embolic, and constitutional symptoms. Electrocardiogram (showing left atrial enlargement), transthoracic echocardiogram, and cardiac magnetic resonance imaging/computed tomography can be useful in making the presumptive diagnosis of an atrial myxoma. If a myxoma is suspected, transvenous biopsy should be avoided given the high risk of embolization, and a patient should proceed to immediate resection. Although atrial myxomas are rare, this case also highlights elements of a cost-effective approach to chronic dyspnea, a common primary care problem. An initial workup consisting of a chest xray, electrocardiogram, complete blood count, basic metabolic panel, and pulse oximetry are evidence-based and affordable for charge-sensitive patients. When heart failure or pulmonary hypertension is suspected, a transthoracic echo represents value-based second-line testing (high-resolution chest computed tomography or exercise testing would alternatively be appropriate if other etiologies were more strongly suspected). In retrospect, it appears this patient likely was experiencing the classic symptomatic triad of an atrial myxoma dating back to 2010. Her case though highlights the difficulties encountered by primary care physicians in overcoming fragmented care and uninsurance and the importance of cost-effective diagnostics.

A NEAR MIX-UP: CHRONIC PALPITATIONS AS PRESENTATION OF ATRIAL MYXOMA Chadwick S. Richard. University of Pittsburgh Medical Center, Pittsburgh, PA. (Tracking ID #2200654)

LEARNING OBJECTIVE #1: List the indications for echocardiography when a cardiac murmur is detected

LEARNING OBJECTIVE #2: Describe the management of atrial myxoma

CASE: The patient is a 54 year old female with hypertension who presented with palpitations that began 2 years ago. Initially, the palpitations occurred a few times per day and lasted several minutes in all positions, equally at rest and with exertion. She had no associated symptoms and no known history of rheumatic fever, atrioventricular valve pathology, coronary artery disease, or arrhythmia. Her mother had atrial fibrillation and her father had unspecified 'valvular disease'. She worked as a car salesperson, drank 4 cups of coffee daily, was a 29 pack-year smoker, occasionally consumed alcohol, and smoked marijuana daily. Her cardiopulmonary examination at this time was normal. Her 24 h Holter monitor revealed premature atrial and ventricular beats and several bouts of supraventricular tachycardia which did not correlate to timing of symptoms. She was treated more aggressively for her hypertension with lisinopril and atenolol. Over the ensuing two years, her palpitations increased in frequency to upwards of ten per day and duration up to several hours. She also began experiencing lightheadedness. Palpitations were now triggered by rising from a seated position and did not improve after she discontinued her lisinopril and atenolol. A week before admission to our service, she had prolonged palpitations with new non-exertional chest pressure and a sense of 'uneasiness.' She also suddenly developed palpitations associated with sweats, a choking sensation in her throat, and severe breathlessness. She was admitted to our service where her exam revealed a mid-diastolic 'plop' followed by a late apical diastolic murmur with a soft apical S1. Echocardiogram revealed a pedunculated 5x4cm mobile left atrial mass with dynamic obstruction of the mitral valve inlet and late mitral regurgitation. While awaiting surgical removal of her mass, she developed atrial fibrillation with rapid ventricular response which led to acute pulmonary edema and hypotension requiring aggressive Trendelenburg positioning and intravenous fluid boluses on the cardiac floor and later, continuous nodal blocking agents in the cardiothoracic ICU. Successful left atrial mass excision two days after her admission confirmed a benign atrial myxoma. The patient was discharged within a week of her surgery and is doing well.

DISCUSSION: This is a characteristic case of atrial myxoma with progressive palpitations and associated symptoms of intracardiac obstruction in a female who is thirty to sixty years old. Her presentation was notable for the absence of syncopal events or embolic phenomena, which occur in about a third of cases. Ninety percent of cases are sporadic, as was presumed in this case due to lack of definite family history, multiple tumors, or ventricular tumors to suggest familial myxoma. Although intracardiac tumors of all types are rare, lipoma, sarcoma, malignant myxoma, and metastatic carcinoma can all present in a similar fashion to benign myxoma. This case is consistent with the classic teaching to pursue echocardiography when a new diastolic murmur is detected. This is also in accordance with class 1 recommendations from the 2008 ACC/AHA guidelines for echocardiography which indicate evaluation in the presence of cardiorespiratory symptoms or a high probability for structural heart disease such as with a diastolic murmur. Perioperative care of this patient was notable for altered hemodynamics caused by the myxoma. Intermittent mitral inlet obstruction requires rapid maximization of end diastolic volume to decrease the obstruction. Thus the use of Trendelenburg and IV fluids is effective despite the presence of pulmonary edema. A profound intolerance to rapid atrial fibrillation was likely due to uncoordinated atrial contractions allowing prolonged tumor obstruction. The resultant drop in cardiac output and increased left atrial filling pressures resulted in worsened pulmonary edema and hypotension. Surgical resection is the definitive management of atrial myxoma. Identification of an intracardiac tumor should prompt urgent cardiothoracic surgical evaluation and appropriate surgical risk assessment.

A NEGATIVE QUANTIFERON-TB GOLD IN-TUBE ASSAY IN ACTIVE MILIARY TUBERCULOSIS Nena S. Auraha; Ruchir Patel; Herman Dyal; Juan Fernandez; Bruno Digiovine. Henry Ford Hospital, Detroit, MI. (Tracking ID #2194110)

LEARNING OBJECTIVE #1: To recognize and interpret QFT-GIT appropriately

CASE: A 73-year-old female was admitted with cyclic fevers for 6 months associated with weakness, headache, and one episode of cough with blood-tinged sputum. History revealed that in her 20s, she was exposed to a co-worker with TB and had negative PPD skin test after this exposure. Examination did not reveal any significant findings. Lab studies showed hemoglobin 9.9 g/dL, platelet count 21 K/uL, and white blood cell count 2.4 K/uL with 92 % neutrophil, 8 % lymphocyte. Quantiferon-TB Gold assay was negative. Chest radiography revealed opacities in bilateral lung fields. CT showed diffuse miliary nodules, as well as ground glass opacities and scattered larger nodules. After intubation for acute respiratory failure, AFB cultures showed positive result with rRNA by direct amplified nucleic acid probe. Patient was started on Rifampin, Isoniazid, Pyrazinamide, and Ethambutol.

DISCUSSION: Clinical presentation of miliary TB is highly variable. Diagnosis of active miliary TB may be achieved through testing including the tuberculin skin test, chest radiography, nucleic acid amplification test of *Mycobacterium tuberculosis* and/or pathological examinations. The QFT-GIT test has gained popularity in use for diagnosis because of reported rates of high sensitivity and specificity. Retrospective studies have recently shown that indeterminate or false negative results with QFT-GIT may be higher in elderly patients, severely ill patients requiring ICU stay, and those with lymphocytopenia. When

patients present with testing concerning for miliary TB, QFT-GIT results should be interpreted carefully as false negative results may occur in some patient populations—this includes the elderly, severely ill patients, and those with lymphocytopenia.

A NONINFECTIOUS CAUSE OF FEVER AND BANDEMIA Erica Altschul; Wei-Lin Yang; Varinder Kambo. Lenox Hill Hospital, New York, NY. (*Tracking ID #2153941*)

LEARNING OBJECTIVE #1: Recognize noninfectious causes of recurrent fever

LEARNING OBJECTIVE #2: Diagnose Adult Onset Stills disease

CASE: A 22 year old female was admitted to the hospital for workup of a 4 week history of fevers, chills, arthralgias, and new onset of a rash. The symptoms started several days after an upper respiratory infection and was initially associated with conjunctivitis, which had resolved. Prior to admission she was seen by multiple providers in various healthcare settings including emergency departments, urgent care centers, and primary care offices. She had extensive laboratory testing that was negative for mononucleosis, strep throat, hepatitis, acute HIV, and rheumatoid arthritis. During ED visits, she presented with fever and tachycardia that would improve with oral Tylenol and IV fluid hydration, and subsequently be discharged home with a diagnosis of an unspecified viral syndrome. On two separate occasions, she completed a course of oral antibiotics (Augmentin and azithromycin) without a change in her clinical status. Her symptoms resolved temporarily while she was taking a short course of oral prednisone for suspected sinusitis. Days prior to the hospital admission she noted the appearance of a pink-colored, patchy rash on her extremities that were painful to touch. Her past medical history included IBS, gluten sensitivity, and lactose intolerance. Her home medications included Prilosec and Tylenol. Family history was noncontributory and her social history was unremarkable. On arrival to the hospital, she had a fever of 101.0 F and heart rate of 144 bpm. Her blood pressure and respiratory rate were within normal limits. Her physical exam was pertinent for cervical lymphadenopathy, bilateral upper abdomen tenderness, hepatosplenomegaly, and a maculopapular non-blanching rash on bilateral legs that was tender to palpation. Abnormalities in her blood work included bandemia of 27 % without leukocytosis, hemoglobin of 10 gm/dl, elevated CRP and ESR at 10.6 mg/dl and 120 mm/hr respectively, elevated LDH at 437 U/L, elevated ferritin at 613.7 ng/mL, as well as mild transaminitis with AST at 108 U/L and ALT 195 U/L. Serology studies including Parvovirus B19 resulted in normal IgM but elevated IgG levels. Urinalysis was within normal limits. Multiple sets of blood and urine cultures were negative for bacterial growth. A transthoracic echocardiogram to assess for endocarditis was negative and a CT abdomen/pelvis confirmed splenomegaly, but was otherwise unremarkable. During hospitalization the patient noted that the severity of her rash coincided with her peaks in temperature. Given her presenting symptoms, hepatosplenomegaly, and elevated LDH and ferritin, the patient was diagnosed with Adult Onset Stills Disease. IV Solu-medrol, 16 mg every 12 h was initiated and complete resolution of her symptoms occurred within 24 h. She was discharged home on Prednisone 40 mg oral daily with outpatient rheumatology follow up.

DISCUSSION: AOSD is a rare multisystemic complex autoinflammatory disorder. The most common symptoms include high fever, polyarthritis, lymphadenopathy, evanescent rash, sore throat, and leukocytosis. It usually affects young adults with a mean age of 36 and incidence of less than 0.16–0.4 per 100,000 persons worldwide. Diagnosis is challenging as the clinical presentation mimics a wide variety of infectious, neoplastic, and autoimmune disorders. Several classification criteria exist, the most sensitive and accurate being Yamaguchi. It requires 5 or more criteria, of whom 2 must be major (fever >39 °C lasting 1 week or longer, arthralgias or arthritis lasting 2 weeks or longer, typical rash, and leukocytosis >10,000 with 80 % PMNs). Our patient met 6 of the Yamaguchi major and minor criteria. Corticosteroids control the disease in 65 % of patients with a rapid response, and is often tapered after 4–6 weeks. Data is limited, but DMARDs, IVIG, and biological agents have shown some efficacy when steroids fail. The etiology remains unclear, though it is theorized that infection can act as a trigger. Given the elevated IgG levels in our patient, a prior parvovirus infection may have been the cause. Patients with self limited or intermittent disease typically have systemic symptoms (fever, rash, serositis, and organomegaly), and are often able to achieve complete or a favorable prognosis. Though rare, AOSD should always be considered in patients with fever of unknown origin after infection or neoplasm has been ruled out as missed or misdiagnosed cases may result in lack of appropriate rheumatologic follow up and prevention of severe musculoskeletal complications.

A PAIN IN THE NECK Chelsea Rhoades; David Irwin; Blake Gregory. Alameda Health System—Highland Hospital, Oakland, CA. (*Tracking ID #2193030*)

LEARNING OBJECTIVE #1: Recognize a case of multiple myeloma in a woman presenting with clavicular masses.

CASE: A 42 year-old African American woman with hypertension presented to primary care reporting 6 months of left anterior shoulder pain. She denied recent traumatic injury, weight changes, or fatigue. She had a slight bony prominence over the medial aspect of the left clavicle that was mildly tender to palpation, without fluctuance or erythema. She had full range of motion of the shoulder, neck, and elbow. Her blood work revealed a white blood cell count of 3.7 thousand/ μ L with 15 % monocytes. There was no anemia or thrombocytopenia. Creatinine was 1.0 mg/dL, calcium was 9.5 mg/dL and albumin and total protein were normal at 4.0 g/dL and 7.6 g/dL respectively. Urinalysis was significant for trace protein. X-ray of the clavicles did not show fracture, lytic lesions, dislocation or arthritis. Two months later, her primary care provider ordered a CT angiogram of the head and neck to evaluate a neurologic complaint. The CT incidentally showed a left clavicular mass, approximately in 7 cm diameter, associated with destructive changes of the clavicle. Two 4 cm right clavicular masses with destructive bony changes were noted as well. Percutaneous biopsy of the masses revealed plasmacytoma. Bone marrow biopsy demonstrated hypercellularity with >90 % plasma cells. A bone survey showed lytic lesions in the left iliac wing and erosion of the bilateral clavicles. Immunofixation electrophoresis revealed a monoclonal band with lambda light chains. Quantitative lambda light chain level was 14,578 mg/L. Beta-2-microglobulin was elevated at 10.8 mg/L. IgE and IgD levels were low. These findings confirmed the diagnosis of light chain multiple myeloma. The clavicular masses were treated with external beam radiation with marked improvement in her shoulder pain. Chemotherapy with cyclophosphamide, bortezomib, and dexamethasone was subsequently started and the patient continues to follow up closely with oncology.

DISCUSSION: The above report describes a woman with multiple myeloma and medullary plasmacytomas who initially presented with rapidly enlarging clavicular masses. Her case has many unusual features and departs from the classical description of multiple myeloma in the literature. The median age of onset for multiple myeloma is 70 years. Anemia is present in the majority of cases (78 %). Renal insufficiency is commonly present (48 %), as is high serum calcium (28 %) and elevated total serum protein. Bone pain is a very common presenting symptom (58 %), with lytic lesions usually evident on x-ray. Our patient was significantly younger than is typical for multiple myeloma and she had few if any of the lab abnormalities associated with this disease on initial presentation. While she reported bone pain, she did not have lytic lesions on x-ray. Biopsy of the rapidly growing neck masses enabled swift diagnosis in this case. Plasmacytomas are localized plasma cell tumors, which can be solitary or a manifestation of systemic disease with multiple myeloma. Plasmacytomas are characterized as extramedullary, arising outside the bone, or medullary, arising from the bone in the form of lytic lesions. In the case of our patient, the presence of soft tissue masses with bony destruction was diagnostic of medullary plasmacytomas (MP). A review of the literature reveals that the vast majority of plasmacytomas of the head and neck are nasopharyngeal rather than clavicular masses. While we have found several cases in the literature that describe MPs presenting as masses arising from the clavicle, most of these plasmacytomas remained a solitary mass or evolved to multiple myeloma months to years after initial presentation. It is exceedingly rare for multiple myeloma to initially present as rapidly enlarging clavicular masses, as was the case in our patient. While an unusual cause of clavicular masses, this case demonstrates that multiple myeloma with MPs can rarely present in younger patients who have normal basic labs.

A PAIN IN THE STOMACH: A CASE OF ACE-INHIBITOR INDUCED ANGIOEDEMA OF THE INTESTINE. Mugdha Agrawal¹; Lisa Sanders². ¹Yale New Haven Hospital, New Haven, CT; ²Yale School of Medicine, New Haven, CT. (*Tracking ID #2196690*)

LEARNING OBJECTIVE #1: To distinguish and treat a relatively rare condition, ACE-inhibitor induced angioedema of the intestine (AI) from other common etiologies of non-specific abdominal pain, nausea, vomiting. To underscore this, we describe the case of a 34 year old female who presented with episodic nausea, vomiting and abdominal pain. She was thought to have AI after an unremarkable work up. Upon cessation of lisinopril, her symptoms resolved and she remains symptom free 4 months after discharge.

CASE: A 34 year old woman with history of hypertension and adenomyosis presented to the emergency department with nausea, vomiting, abdominal pain and anorexia. Her symptoms were intermittent and in between the episodes, she was in no distress and able to tolerate a normal diet. Over the seven hours since the start of her symptoms to our team's examination, the patient noted she had about 25 episodes of non-bloody, non-billious vomiting. Upon questioning, it was revealed that this was her fifth visit to a health care facility over the past month and a half for the same constellation of symptoms. Her home medications were lisinopril, HCTZ and OCP. Of these, only the OCPs were new, started not long before her symptoms started. She had been on lisinopril for several years. Her physical examination was unremarkable. Her work up before coming to the ED included a RUQ ultrasound and an abdominal x-ray which were unremarkable. In the ED, she had a CT of the abdomen and pelvis with IV and oral contrast which revealed ascites

and several loops of mild thickening of the small bowel walls. Her blood work which included comprehensive metabolic panel and lactic acid were normal. She had a mild leukocytosis with left shift on her CBC. The differential diagnosis at that time included ischemic bowel, gall bladder disease, infectious enteritis, vasculitis or ACE-inhibitor induced angioedema of the intestine. The patient was admitted to the hospital and started on IV hydration and pain control. Her lisinopril and OCPs were held. She was noted to be symptom free and tolerating a normal diet 24 h after her presentation. The patient was then discharged with the presumed diagnosis of AIAI precipitated by addition of OCP. Four months after discharge and discontinuation of lisinopril and OCP, the patient remains symptom free and has not had any additional visits to the emergency department. We therefore strongly believe that the patient had ACE-inhibitor induced angioedema of intestine precipitated by the addition of OCPs.

DISCUSSION: ACE-inhibitor induced angioedema of the intestine is a rare entity causing episodic and recurrent abdominal pain accompanied by nausea, vomiting and anorexia in patients. Although rare, this condition has been described in several case reports over the years. OCP use has also been shown to induce angioedema, both hereditary and idiopathic. OCPs and ACE-I work on separate pathways in the pathogenesis of angioedema. We believe that the addition of a second medication that could affect the pathway that leads to angioedema was the trigger resulting in AIAI. AIAI is a diagnosis established by exclusion. It should be suspected in a patient on an ACE-inhibitor with specific findings noted on imaging. The findings on CT abdomen in the appropriate clinical setting include ascites, small bowel wall thickening, dilatation, mesenteric edema and a “donut” appearance. The diagnosis is established by resolution of symptoms after cessation of the ACE-inhibitor. AIAI can occur after months to years of being on an ACE-I. This condition usually goes unrecognized for several years and causes significant emotional and financial trauma to the patient. The awareness of AIAI is important among clinicians given the high frequency of use of ACE-I in patients, delays in making diagnosis and high costs endured by the health care system as a result of this. Further, dysfunction of alternate diagnosis coupled with conservative and inexpensive treatment make the knowledge of AIAI an indispensable tool for physicians.

A PECULIAR PRESENTATION OF PAINLESS PRINZMETAL’S ANGINA
Naveen Nannapaneni. Wayne State University, Royal Oak, MI. (Tracking ID #2190203)

LEARNING OBJECTIVE #1: Recognize an atypical presentation of Prinzmetal’s Angina.

LEARNING OBJECTIVE #2: Distinguish Prinzmetal’s Angina from myocardial infarction.

CASE: A 48-year-old female with recurrent ovarian cancer, hypertension, and a history of mitral-valve replacement secondary to rheumatic fever presented to the ER with a 2-week complaint of intractable nausea, vomiting, and anorexia after her most recent round of chemotherapy. She reports having associated epigastric fullness with no bowel movement or flatus for approximately 4 days. On initial evaluation she was found to be hypotensive and borderline tachycardic. Physical examination exhibited dry oral mucosa, a mechanical heart sound radiating to the left axilla and diminished bowel sounds. Laboratory investigations revealed hyperkalemia, 6.5mMol/L, and an acute kidney injury, creatinine 2.45 mg/dL. Abdominal x-ray showed a high grade proximal small-bowel obstruction. Initial EKG showed sinus tachycardia without hyperkalemic changes. Hyperkalemia was treated with calcium gluconate, insulin and dextrose with gradual improvement. Serial EKGs revealed new J-point ST-segment elevations in the inferolateral leads with reciprocal changes. Cardiology was consulted for a possible STEMI, bedside echocardiogram revealed no wall motion abnormalities and serial troponins were negative while the patient had no chest pain. Coronary angiography revealed only mild luminal irregularities and the patient was started on isosorbide dinitrate for suspected coronary vasospasm. She underwent an exploratory laparotomy with lysis of adhesions, jejunostomy and feeding-tube placement for management of her small bowel obstruction. Her overall clinical condition subsequent to the surgery progressively deteriorated due to sepsis, leading to multi-organ failure and her eventual passing in palliative care after a month-long hospitalization.

DISCUSSION: The typical presentation of Prinzmetal’s Angina involves episodic anginal chest pain and ST-segment EKG changes suggestive of infarction without fixed obstruction on coronary angiography which is instead attributed to coronary vasospasm. Our patient showed these ST-segment changes without chest pain and had non-obstructive disease on coronary catheterization. Pseudoinfarction, a manifestation of hyperkalemia which can also have ST-segment changes, was ruled out given the normal EKG upon admission in the setting of hyperkalemia and the continued silent episodes in spite of hyperkalemia treatment. While unprovoked episodes of Prinzmetal’s Angina are common, this characterization of painless spasm is rare. There have been infrequent case reports associating painless presentations of coronary vasospasm with ventricular arrhythmias and even sudden cardiac death, highlighting the seriousness of the phenomenon. Ideally,

intracoronary acetylcholine challenge during coronary catheterization, which causes nitric oxide mediated coronary vasospasm, can be done for confirmation of the diagnosis. Risk factor reduction includes smoking cessation while treatment focuses on calcium channel blockers, nitrates and statins to reduce the frequency of episodes.

A PUFF OF SMOKE IN THE BRAIN: MOYAMOYA DISEASE IN A 25-YEAR-OLD FEMALE Anita Mulye; Christine L. Bryson; Farhad F. Bahrassa. Baystate Medical Center, Springfield, MA. (Tracking ID #2152136)

LEARNING OBJECTIVE #1: Recognize the clinical features, risk factors and relevant imaging of moyamoya disease

LEARNING OBJECTIVE #2: Describe the current options for management of moyamoya disease

CASE: A 25-year-old morbidly obese Caucasian woman Type 2 Diabetes Mellitus (hemoglobin A1c 10.1 %) presented to an outside facility with 1 day of acute right arm weakness and numbness with dysarthria. Family history included stroke in a great-grandmother and multiple sclerosis in a grand-aunt. She did not smoke or drink alcohol. The patient was non-adherent to medications including lisinopril, metformin and glargine but used a contraceptive patch. On presentation, vital signs were stable and she was afebrile. On physical exam she was alert and oriented with disordered speech. There was a slight drift of her right upper extremity and a decrease in rapid alternating movements. Sensation to pinprick was diminished from the right axilla to the digits. Laboratory studies included a sedimentation rate of 56 and C-reactive protein of 2.2. Antinuclear antibody was weakly positive with a homogenous pattern. Complement C3 level was elevated at 187. Complement C4 was within normal limits. Lupus anticoagulant, anticardiolipin, p-ANCA, c-ANCA, and Sjogren’s antibodies were normal. Protein C and S were normal. There was no prothrombin G20210A mutation. Prothrombin time, partial thromboplastin time, and thrombin time were all normal, thus coagulopathy was not suspected. Computed tomography of the head showed abnormal white matter hypointensities in the supratentorial brain with possible demyelination. Magnetic resonance imaging of the brain showed white matter changes, acute ischemia of the left frontal and parietal lobes, and areas of blood-brain barrier breakdown of the left corona radiata and centrum semiovale extending subcortically. Magnetic resonance angiography showed minimal flow in the right MCA, studded disease in the left MCA suggestive of vasculitis and irregularity of the right external carotid without narrowing at the aortic arch to suggest Takayasu’s arteritis. An echocardiogram with bubble study showed left ventricular ejection fraction of 55 % and no valvular abnormalities. The patient received aspirin and high-intensity statin therapy and returned to her baseline neurological status five days after symptom onset, but was transferred due to concern for an underlying vasculitic or rheumatological process. Computed tomography angiogram showed multifocal irregularity of the M1 branches with loss of enhancement in the distal right MCA. Finally, the patient underwent diagnostic cerebral angiogram, which revealed 99 % stenosis of the right MCA M1 segment and 50 % stenosis of the left MCA M1 segment with collateral flow via enlarged lenticulostriate arteries, as well as pial collaterals from PCA to MCA and ACA to MCA territories bilaterally. This was most consistent with a moyamoya disease pattern, hypothesized as the underlying etiology of the ischemic event.

DISCUSSION: The moyamoya condition is an entity first described in 1957 as bilateral hypoplasia of the internal carotid arteries. The Japanese term translates to “something hazy like a puff of cigarette smoke drifting in the air.” (1) It is a vasculopathy that predisposes an individual to cerebrovascular events such as stroke due to progressive narrowing of the internal carotid arteries and their branches. This does not involve atherosclerotic changes of the vessels, but rather hyperplasia of smooth muscle and luminal thrombosis resulting in vessel occlusion. Although thought to be more prominent in those of Asian descent, moyamoya has been described in various ethnicities, albeit at an incidence approximately 10 % of that found in Japan. There may be either polygenic or autosomal dominant inheritance, but identical twin studies in which only one sibling is affected seem to indicate that environmental factors play a larger role (2). Conventional angiography is the gold standard for diagnosis of moyamoya disease. Characteristic findings include stenosis or occlusion at the distal internal carotid artery and origin of the anterior and middle cerebral arteries. Abnormal vascular networks at the basal ganglia, or moyamoya vessels, represent the characteristic “puff of smoke.” Management of moyamoya is symptomatic with primary and secondary preventive treatments for acute stroke. Aspirin and lifestyle modification are recommended, but thrombolytic and antithrombotic therapies have not been investigated thoroughly. Surgical revascularization techniques such as angioplasty and bypass have been implemented to reduce the risk of ischemia. Although no randomized controlled trials have been done to evaluate the effectiveness of surgery, a systematic review found that 87 % of pediatric patients had complete resolution of symptoms over a mean post-operative period of 58 months (3). Nevertheless, Japanese studies have not shown a statistical significance in outcomes between medically and surgically treated groups (4).

A PULMONARY EMBOLISM THAT COULD KILL? Cameron Long; Jacey Jones. Tulane University Health Sciences Center, New Orleans, LA. (Tracking ID #2197884)

LEARNING OBJECTIVE #1: Identify criteria for submassive pulmonary embolism (PE)

LEARNING OBJECTIVE #2: Describe current treatment options for PE

CASE: A 34-year-old woman presents to the ED with 3 days of shortness of breath, chest tightness and scant hemoptysis. She has a history of hereditary anti-thrombin III deficiency (diagnosed in 1984) with recurrent deep vein thromboses in the left proximal leg veins and two pulmonary emboli. She is currently on warfarin with a therapeutic of INR 2.7. In the ED she is afebrile, has a blood pressure of 160/80 mm Hg, is saturating 95 % on room air, and is breathing at 20 breaths per minute. Her exam reveals vesicular breath sounds, jugular venous distension, and tachycardia with no other abnormalities. Given her known history of hypercoagulability and prior PEs, she undergoes a CT with PE protocol. The CT shows no contrast in right pulmonary artery as well as an enlarged right ventricle (RV), IVC dilation, and peripheral right lung infarcts. An emergent echocardiogram shows moderately enlarged RV, positive McConnell sign (minimal RV wall motion in diastole and systole with apical sparing), RV to left ventricle dimension ratio of 0.94 and increased pulmonary artery pressure at 65 mmHg. Doppler studies of her legs are also performed and show high clot burden in bilateral common femoral, external iliac, and popliteal veins. EKG is only remarkable for right atrial enlargement and tachycardia.

DISCUSSION: The patient has a PE conundrum. Pulmonary emboli are common and the vast majority of emboli are sub-segmental occurring in 1–1.5 % of asymptomatic patients detected by helical CT scanner. However, sub-massive PEs can be deadly due to acute hemodynamic compromise. The patient has objective data characterizing her PE as submassive due to RV strain on echocardiogram. However, her clinical picture reveals a stable patient who is actually hypertensive and saturating well on room air. The consensus statement from the 9th ed. ACCP in 2012 recommends administration of tPA in patients with submassive PE in the context of hypotension, increased RV strain, and no increased bleeding risk (grade 2C). In patients without hypotension, the guidelines recommend against tPA (Grade 1C). The patient, in this case, does not meet eligibility criteria for tPA for two reasons: she is normotensive and her INR is therapeutic. Another concern is whether this is an acute presentation of a PE. The CT imaging depicts a clot obstructing the entire right pulmonary artery which if acute would likely cause dramatic hemodynamic perturbations and shock. Her stability suggests a chronic process of her adapting to an obstructed right pulmonary artery. There are currently no guidelines for management of chronic PE. One study has investigated managing acute submassive PE initially with heparin alone vs. heparin+tPA and found that 27 % of those patients receiving heparin alone had significant pulmonary hypertension at a six month follow up, likely secondary to pulmonary artery remodeling due to hypoxic vasoconstriction. Therefore PEs left to dissolve on their own with oral anti-coagulation may place the patient at significant risk for pulmonary hypertension and morbidity long-term. Because the patient presents therapeutically anti-coagulated on warfarin, tPA is a contraindication. Taking the patient off anticoagulation to make her eligible for tPA will introduce the risk of clot formation and progression of her PE. Other options to consider in this circumstance are catheter directed thrombolysis, embolectomy, or anti-coagulation with a direct thrombin inhibitor. The patient ultimately decides to pursue the most conservative approach: opting for an argatroban drip followed by an oral factor Xa inhibitor at discharge. She remains stable during her hospitalization and is discharged with close follow up.

A RARE CASE OF CYTOMEGALOVIRUS INFECTION IN THE IMMUNOCOMPETENT PATIENT Erica V. Tate¹; Richard Hu². ¹Olive View UCLA Medical Center, North Hollywood, CA; ²Olive View UCLA Medical Center, Sylmar, CA. (Tracking ID #2194030)

LEARNING OBJECTIVE #1: Recognize Cytomegalovirus (CMV) infection in an immunocompetent host

LEARNING OBJECTIVE #2: Diagnosis CMV gastric infection with the study of choice, Esophagogastroduodenoscopy (EGD)

CASE: Fifty-one year old female with hypertension and diabetes presented with 1 month history of non-bloody diarrhea, abdominal bloating, mild abdominal pain, fatigue, and 20 lb weight loss after a trip to Mexico where she reported drinking well water. She experienced no fevers, chills, nausea, vomiting, blood, or mucus in her stool. Two weeks prior to hospitalization patient was examined at a nearby medical center and diagnosed with an uncomplicated urinary tract infection and giardia infection. Patient was treated with cefotaxime and metronidazole, EGD evaluation revealed 'large irregularly shaped antral mass with multiple ulcerations and erythema extending to the distal gastric body', routine biopsy samples were negative for H. pylori, CMV, and malignancy. Physical exam was not remarkable. Laboratory studies revealed eosinophils 31 %, negative Hepatitis A, B, C, and HIV.

Given the reported gastric antral mass and persistent symptoms along with previous non-diagnostic biopsy, a repeat EGD was performed which found multiple small gastric ulcers and one larger shallow gastric ulcer with irregular border. Extensive biopsy of the base and the rim of the ulcer were obtained, pathology exam showed evidence for CMV, no malignancy or H. Pylori. Patient was treated with valganciclovir 900 mg twice daily for a total of 14 days with resolution in symptoms.

DISCUSSION: Cytomegalovirus (CMV) is recognized as a common pathogen in immunocompromised patients, the colon and stomach are the most common sites of gastrointestinal infection by CMV [1]. However CMV infection is not common and rarely encountered in the stomach of immunocompetent patients. In immunocompetent patients physicians must have a high index of suspicion to make the appropriate diagnosis. In this case recent travel history, exposure to waterborne infections, and prior non-diagnostic EGD all made the final diagnosis elusive. The determining factor was the repeat EGD with extensive and targeted sampling. In diagnosis of CMV gastric infection the study of choice is EGD, as it allows direct visualization and biopsy. Often large solitary shallow ulcers or multiple lesions appear on EGD [2]. Some studies have shown at least ten biopsy specimens should be obtained to yield a significant result [2]. This was further supported by our case. Despite its infrequent presentation in immunocompetent patients, CMV infection should be considered in a patient with a gastric ulcer although PUD is the most common clinical entity. References: 1. A RARE CASE OF GRANULOMATOUS INTERSTITIAL NEPHRITIS DUE TO RENAL SARCOIDOSIS Asma Khatoon¹; Salman Raheem². ¹Methodist Dallas Medical Center, Dallas, TX; ²Physician Associates of Southwest Dallas, Dallas, TX. (Tracking ID #2151366)

LEARNING OBJECTIVE #1: Sarcoidosis received its name because the condition causes lesions resembling a sarcoma. It is an idiopathic multisystem granulomatous disorder primarily involving the reticuloendothelial system. It is pathologically characterized by the presence of noncaseating epithelioid granulomas in affected organs. A definitive diagnostic test for sarcoidosis does not exist. Instead, the diagnosis requires three elements—exclusion of other diseases that may present similarly, compatible clinical and radiographic manifestations and histopathologic detection of noncaseating granulomas. Renal involvement, defined by either histologic changes in the kidney or a decline in renal function in the absence of a biopsy, occurs in approximately 15 to 35 % of patients. The classic renal lesion is noncaseating granulomatous interstitial nephritis, but this rarely causes clinically significant renal disease.

CASE: A 26 year old African-American male with past medical history of pancytopenia and hepatosplenomegaly was transferred to our facility for evaluation of his acute kidney injury in early 2013. Patient presented with nausea, vomiting, anorexia and weight loss. The hepatosplenomegaly and pancytopenia was found in spring 2011. At that time lymph node, bone marrow and liver biopsies were nondiagnostic. He was found to have a serum creatinine of 4 mg/dL, his creatinine the year before was 1.4 mg/dL. There was no improvement of creatinine with hydration. Upon presentation to our facility, he was found to be normotensive and physical exam revealed pallor, hepatosplenomegaly but no lymphadenopathy, skin lesions or ocular involvement. His labs showed pancytopenia, elevated alkaline phosphatase and creatinine but normal calcium and angiotensin converting enzyme levels. The urinalysis indicated sterile pyuria, low specific gravity, proteinuria and significant eosinophiluria. The chronic kidney disease workup was negative. Imaging indicated nephromegaly and a normal CT of the chest. Bone marrow and kidney biopsies were obtained. The bone marrow biopsy showed extensive noncaseating granulomatous inflammation. Stains for acid fast bacilli and fungal elements were negative. Kidney biopsy revealed granulomatous interstitial nephritis with focal tubular injury. Patient was started on pulse dose steroids: solumedrol IV daily for three days and then switched to prednisone. He was also started on Bactrim for PCP prophylaxis. He had excellent response to the treatment with improvement in his pancytopenia and creatinine.

DISCUSSION: Renal involvement in sarcoidosis can occur in a variety of ways most common of which include abnormal calcium metabolism, nephrolithiasis and nephrocalcinosis. Glomerular disease, obstructive uropathy, and end-stage renal disease may occur infrequently. It can also present as a rare form of interstitial nephritis with noncaseating granulomas. Typical tubular manifestations include mild proteinuria, sterile pyuria and impaired ability to concentrate urine. Early recognition and initiation of therapy is critical to avoid morbidity and mortality. This particular case presentation had several interesting features viz., absence of overt systemic sarcoidosis, normal serum calcium and angiotensin converting enzyme levels, dramatic response to corticosteroid therapy and most importantly no pulmonary involvement.

A RARE CASE OF OSMOTIC NEPHROPATHY Rishi Kumar; Mrinalini Krishnan. Pinnacle Health, Harrisburg, PA. (Tracking ID #2199170)

LEARNING OBJECTIVE #1: Recognize a rare side effect of a commonly prescribed medication

LEARNING OBJECTIVE #2: Diagnostic approach to renal failure when initial work up is negative

CASE: A 69 year old female with a medical history of diabetes mellitus and hypertension presented to the emergency department with a 1 week history of anuria. She experienced nausea and vomiting that was not relieved by ondansetron. The patient's medications included metformin, losartan-hydrochlorothiazide and amlodipine. Of note, the patient had discontinued saxagliptin therapy for diabetes approximately 2 months prior. Physical examination was unremarkable, and laboratory work revealed blood urea nitrogen level of 58 and creatinine level of 7.88, with normal renal function documented one year prior. Urinalysis showed trace blood and was negative for protein. Fractional excretion of sodium was calculated to be 4.1 %, indicative of acute tubular necrosis. Complement levels, acute hepatitis panel and ANCA serologies were negative. Renal ultrasound revealed kidneys were within normal size limits. Despite aggressive IV fluid therapy, renal function declined and peaked at creatinine level of 8.79. Nephrology was consulted for evaluation; a renal biopsy was scheduled, and the patient was started on hemodialysis for anuria and completed two sessions. Renal biopsy revealed osmotic tubulopathy. Patient began diuresing within a few days, and was discharged home with renal function returning to baseline within a week. At present time, the patient's renal function remains stable without any recurrence of acute renal failure.

DISCUSSION: Osmotic nephropathy is a rare pathological pattern described as proximal tubular cell swelling secondary to vacuolization of the cell cytoplasm. This cause of renal failure has been associated with exogenous substances such as sucrose containing intravenous immunoglobulin (IVIG), dextrans, mannitol, contrast media and hydroxyethyl starch. Literature search revealed one reported case of osmotic nephropathy associated with concurrent use of saxagliptin. This case demonstrates the development of osmotic nephropathy presumably secondary to saxagliptin, despite the discontinuation of this medication 2 months prior to her renal decline. This case is important to highlight this potential side effect of saxagliptin, as renal failure is not a known adverse effect associated with this medication. Further investigation may be required to determine the implications of this medication on renal function.

A RARE CASE OF PERITONITIS CAUSED BY CANDIDA ALBICAN IN AN ALCOHOLIC LIVER CIRRHOSIS PATIENT Steve M. Antoine; Bisma Alam; Varada Nair; Amit Sharma. Upstate Medical University, Syracuse, NY. (Tracking ID #2199939)

LEARNING OBJECTIVE #1: Recognize a less common cause of peritonitis in liver cirrhosis and how to treat it

CASE: A 51 year old male with a past medical history of alcoholic liver cirrhosis, hepatic encephalopathy, abdominal ascites for the past 3 months which had required 2 paracentesis procedures (both were negative for any infectious process) and gastric bypass surgery over 7 years ago, presented to the hospital with worsening abdominal distention and abdominal pain. His pain was diffused and non-radiating, accompanied by subjective fever and chills. The patient denied any recent jaundice, no changes in bowel habits, no skin rashes. On presentation, he had a fever of 101.5 F. Physical examination revealed a cachectic appearing white male with distended abdomen and shifting dullness, diffusely tender to palpation in all quadrants. He did not appear to be jaundiced. Complete blood count revealed a slight leukocytosis of 10.9 with neutrophilic predominance. Patient underwent a diagnostic paracentesis, and was empirically placed on ceftriaxone therapy 2 g IV daily. The preliminary ascitic fluid analysis showed 503 WBC, 68 % PMN, 32 % monocytes. Despite being on antibiotic therapy, patient continued to be febrile over the next few days with complaints of worsening and diffuse abdominal pain. Peritoneal fluid culture after 2 days grew 2 colonies of *Candida albicans*. There was no evidence of candiduria or candidemia. Patient was started on Fluconazole 200 mg IV daily in addition to Ceftriaxone. Infectious disease specialists were consulted at that time and a repeat diagnostic paracentesis was performed. The second set of peritoneal fluid studies revealed a double in the number of WBCs compared to prior sample, and grew 100 colonies of *Candida albicans*, sensitive to Fluconazole. Infectious disease service recommended increasing fluconazole to 400 mg IV daily. Patient improved clinically 2 days after the fluconazole dose was increased. He was discharged on a 3 week course of PO Fluconazole 400 mg daily and follow up with Infectious disease as an outpatient.

DISCUSSION: Fungal peritonitis has been documented in the literature, in the setting of cirrhosis; Cleophas et al. described cases of *Cryptococcus neoformans* peritonitis that was found in patients with advanced hepatitis B associated cirrhosis. This has also been shown in Hepatitis C and H.I.V patients. *Candida albicans* peritonitis have been described in peritoneal dialysis patients. In this case, the patient did not have any of the above

mentioned risk factors. Two paracentesis procedures were done to confirm the diagnosis as *Candida* was initially thought to be a skin contaminant. The gastrointestinal tract is also a reservoir for *Candida*. A study performed by Choi, SH et al. isolated a group of cirrhotic patients with ascitic fluid cultures positive for *Candida* species who was not given any antifungal therapy. The study showed that within 1 year of therapy, all patients in that group had died. Our patient was treated with IV fluconazole as this was shown to have effective penetration into the ascitic fluid but at a higher dose. Other antibiotic regimens may have been considered such as caspofungin, micafungin, echinocandin or amphotericin B in combination with flucytosine. It is therefore imperative to consider *Candida* species when treating SBP in cirrhotic patients, that although, uncommon, can be associated with poor prognosis and poor overall outcome.

A RARE CASE OF SARCOID PRESENTING WITH HYPERCALCEMIC CRISIS Sonia Rajput; Nasser Mikhail. UCLA Olive View Medical Center, Sylmar, OR. (Tracking ID #2197765)

LEARNING OBJECTIVE #1: Hypercalcemia is commonly associated with malignancy and primary hyperparathyroidism, however up to 10 % of cases are seen in sarcoidosis.

CASE: A 54 year-old African American woman with a PMH of hypertension presented to the hospital with 1 month of fatigue, epigastric abdominal pain and ongoing vomiting. These symptoms were in the setting of 1 year of dyspnea, alternating sweats and chills, as well as a 34 lb unintentional weight loss. She denied cough, myalgia/arthritis, rash, recent travel, sick contacts, heavy NSAID or alcohol use or a FH of malignancy. She did not take any medications either. Upon evaluation, VS were normal. She was nontoxic appearing, but had diffuse wheezes and rhonchi bilaterally, inguinal lymphadenopathy, a benign abdomen, and tenderness to palpation along the spine with no step off. Laboratory analysis revealed hypercalcemia to 14.1 with a normal albumin, elevated phosphorus to 4.4, low-normal PTH of 15, low 25-hydroxyvitamin D of 18 and an elevated 1,25-dihydroxyvitamin D of 120. CT CAP showed multiple pulmonary micronodules, diffuse lymphadenopathy and lytic lesions of the thoracic spine. She was admitted to the ICU for hypercalcemic crisis and given IV fluids and pamidronate. Her calcium down-trended to normal. Workup for malignancy vs. infectious causes was negative including CEA, CA-125, LDH, peripheral smear, PTHrP, quantiferon gold and HIV. An inguinal lymph node core biopsy showed non-necrotizing granulomatous lymphadenitis concerning for sarcoidosis. She was started on prednisone with marked improvement of symptoms and sent home days later.

DISCUSSION: The mechanism of hypercalcemia in sarcoidosis is not well understood. Granulomas produce 1-alpha-hydroxyvitamin D, which causes elevated levels of 1,25-dihydroxyvitamin D leading to elevated serum calcium. Hypercalcemia in sarcoidosis has been reported in only 10 % of cases and rarely is it the presenting manifestation. To our knowledge this represents one of the first reported cases of severe hypercalcemia (Ca 14.1) in sarcoidosis. Only a handful of other cases have been reported with moderate elevations in serum calcium (Ca 13.5). While our patient presented with hypercalcemia, she had no other clinical clues to suggest sarcoidosis. Her ubiquitous symptoms coupled with her CT findings, namely lytic bone lesions made malignancy highest on the differential diagnosis. Key clues that separated sarcoidosis from malignancy and hyperparathyroidism included normal tumor markers, specifically a negative PTHrP and suppressed PTH levels, respectively. Widespread lytic bone lesions have been described in sarcoidosis as well. This case demonstrates that the diagnosis of sarcoidosis may be elusive, especially in patients with minor pulmonary symptoms. Internists should have a low threshold for diagnosing sarcoidosis in patients who present with hypercalcemia of unclear etiology.

A RARE CASE OF SEPTIC SHOCK ASSOCIATED WITH A PITUITARY ABSCESS Shoko Ando; Ryuichi Sada; Etsuko Fujisawa; Sandra Moody; Yoichi Kikuchi; Makito Yaegashi. Kameda Medical Center, Kamogawa, Japan. (Tracking ID #2178827)

LEARNING OBJECTIVE #1: Recognize the clinical features of pituitary abscess

CASE: An 83-year-old woman with a history of pituitary adenoma presented with a progressive headache and low-grade fever for 3 weeks and blurry vision for 1 week. Non-contrast computed tomography (CT) revealed a 22 mm thick-walled suprasellar mass. After her clinic visit, a high fever developed; she was hospitalized 2 days later. On admission, she was alert and had mild bitemporal hemianopsia. The following day, however, her consciousness deteriorated drastically with vision to light perception only. A repeat head CT revealed increased size of the suprasellar mass to 24 mm in diameter. She had acute hyponatremia with relatively low serum cortisol. Hydrocortisone 400 mg/day was initiated for secondary adrenal insufficiency. Cerebrospinal fluid revealed pleocytosis, hypoglycorrhachia, and an elevation in protein. The result of the culture was negative, but ceftriaxone and vancomycin were started empirically. Brain MRI showed a high-intensity suprasellar mass with a low-intensity rim on T2-weighted image. Gadolinium enhanced T1-weighted image showed enhancement of the rim and lower aspect of the mass as well as enhancement of the wall of the right sphenoid sinus. On

hospital day three, septic shock and acute renal failure developed, which required norepinephrine and massive fluid resuscitation. Transsphenoidal surgery was performed and yellowish pus was obtained from the pituitary gland, which led to a diagnosis of pituitary abscess. Postoperatively, she was treated with meropenem. The culture showed *Staphylococcus aureus*, *Streptococcus viridans*, *Peptostreptococcus* spp., and anaerobes. The antibiotics were changed to cefepime and metronidazole. Although incomplete bitemporal hemianopsia persisted, her vision recovered significantly. She was discharged 47 days after admission without pituitary insufficiency.

DISCUSSION: In this case, we suspected a pituitary lesion because of progressive bitemporal hemianopsia and signs of adrenal insufficiency. A pituitary abscess is an extremely rare disorder with 250 cases reported worldwide as of this report. In addition, there are few case reports of pituitary abscess with sepsis. To our knowledge, however, this is the first case report of a pituitary abscess that was associated with septic shock. Besides, this is the oldest patient ever in whom a pituitary abscess was diagnosed. In the past, the mortality rate of a pituitary abscess was 50–60 %. In contrast, recently the mortality rate has been as low as 3 %. Physicians need to be aware of this condition, since prompt and timely recognition of the disease may lead to appropriate and early medical and surgical treatment.

A RARE CAUSE OF BALDNESS Brian Dorsey¹; Darlene LeFrancis². ¹Montefiore Medical Center, New York, NY; ²Montefiore Medical Center, Bronx, NY. (Tracking ID #2199245)

LEARNING OBJECTIVE #1: Formulate a differential diagnosis for androgen excess in women

LEARNING OBJECTIVE #2: Diagnose and Manage Ovarian Steroid Cell Tumors and Ovarian Stromal Hyperthecosis

CASE: A 56 year-old woman presented with 1 year of progressive baldness. She also noted 3 months of worsening acne across the chest and upper back as well as excessive hair growth on the face, neck, arms, chest, and back. She underwent hysterectomy at 35 years old for uterine myomas. She had a BMI of 32 with truncal obesity. Hair was thin in the central and temporal regions with the frontal hairline spared. Hair ends were tapered, and pulling the distal end did not cause removal of more than six hairs. Face, chest, back, and arms were shaven. She had scattered closed comedones on the chest. There were no areas of hyperpigmentation or striae, and no signs of virilization on gross examination. Testosterone was 392 ng/dL (5–81) and DHEA-S was 29ug/dL (35–430). FSH was 20miu/ml (21–153), LH was 22miu/ml (11–40), and Sex Hormone Binding Globulin was 27 nmol/L (17–120). Sonography revealed a 3×1×1 cm right ovary and a 3×2×3 cm left ovary with a 2×2×2 cm complex mass. Patient underwent laproscopic bilateral salpingo-oophorectomy. Pathology revealed stromal hyperplasia and hyperthecosis of the right ovary and a 2.2 cm Leydig cell tumor of the left ovary. Following the procedure, testosterone levels fell to less than 3 ng/dL, and her baldness, acne, and hirsutism improved.

DISCUSSION: Progressive baldness is disturbing for patients and is a common complaint encountered by internists. Female baldness in a frontotemporal or vertex distribution associated with acne, male-pattern hair growth, and irregular menses is suggestive of androgen excess. Polycystic Ovarian Syndrome (PCOS), adrenal and ovarian androgen secreting tumors, Cushing's Syndrome, and Ovarian Stromal Hyperthecosis are common etiologies of a hyperandrogen state. While pathology revealed two potential ovarian etiologies for androgen excess—Leydig cell tumor and Ovarian hyperthecosis, the primary driver of the patient's presentation was likely the Leydig cell tumor. Concomitant adrenal origin is unlikely as DHEA-S was not elevated. Leydig cell tumors, which belong to the steroid cell class of ovarian sex cord stromal tumors, are rare, accounting for less than 0.1 % of all ovarian tumors. The incidence of steroid cell tumors is 0.2 cases per 100,000, and Leydig cell tumors comprise only 15 % of this group. Leydig cell tumors present in the sixth or seventh decade of life with symptoms of progressive androgen excess. As the tumors are often less than 4 cm, identification by imaging is challenging. Laboratory evaluation may localize the anomaly to the ovary with elevated testosterone and normal DHEA-S. Diagnosis is made by pathology. Reinke crystals, which are rectangular crystal-like eosinophilic cytoplasmic inclusions, are characteristic and differentiate Leydig cell tumors from other steroid cell tumors. The tumor is typically benign and treatment is not often required following oophorectomy. Steroid cell tumors develop following the luteinization of stromal elements in a process similar to ovarian hyperthecosis. In fact, some members of the steroid cell tumor class are found coincident with ovarian hyperthecosis in both the ipsilateral and contralateral ovary. Ovarian hyperthecosis is a non-neoplastic cause of androgen excess marked by nests or nodules of luteinized theca cells in a proliferated ovarian stroma. Symptoms may vary from mild asymptomatic disease to virilization, which is often more severe than PCOS and may persist beyond menopause. Ovarian hyperthecosis is common, with one autopsy series identifying the process in one third of the specimens examined. The asymptomatic or mild variant predominates. Testosterone levels may be elevated (over 150 ng/dL), and

sonography may reveal enlarged ovaries. Diagnosis is established by biopsy. In the setting of androgen excess, patients with hyperthecosis are at elevated risk for insulin resistance and diabetes, which may be addressed with weight loss and Metformin. Additionally, endometrial carcinoma may be more likely in the setting of increased conversion of testosterone to estrogens. In this case, the patient had an AIC of 5.5 and was post-hysterectomy. Treatment, either with bilateral oophorectomy or GnRH agonist therapy, aims to reduce testosterone levels and thereby improve symptoms of hirsutism and virilization, reduce insulin resistance, and moderate the endometrial carcinoma risk. When addressing progressive female baldness, clinicians should recognize androgen producing tumors and consider ovarian hyperthecosis, when appropriate, as the disease process may be associated with insulin resistance, diabetes, cardiovascular disease, and endometrial carcinoma.

A RARE CAUSE OF HYPERCALCEMIC CRISIS: CHRONIC MYELOGENOUS LEUKEMIA CAN DO THAT? Meeta Desai. Penn State Hershey Medical Center, Hummelstown, PA. (Tracking ID #2196524)

LEARNING OBJECTIVE #1: Recognize an uncommon cause of malignant hypercalcemia.

LEARNING OBJECTIVE #2: Discuss the treatment of chronic myelogenous leukemia in blast crisis.

CASE: A 44-year-old female with a past medical history of chronic myelogenous leukemia (CML) presented to the emergency department after she was found unresponsive at home. Her CML was diagnosed eight years ago, and was stable on imatinib therapy with full hematologic response and partial cytogenetic response. In the emergency department, she was hemodynamically stable but unresponsive and required intubation. Physical examination was unremarkable. Laboratory studies showed calcium level of 23 mg/dL (range 8.4–10.2 mg/dL) and leukocytosis of 44 K/uL (range 4.0–10.4 K/uL). A peripheral blood smear showed 10 % blasts, suggestive of accelerated phase CML. Further workup of the hypercalcemia revealed an intact PTH level that was appropriately suppressed. Serum and urine protein electrophoresis were checked to exclude multiple myeloma and results were unremarkable. PTH-related protein (PTHrP) returned positive, which was suggestive of humoral hypercalcemia of malignancy. A subsequent CT scan of the chest, abdomen, and pelvis did not show any evidence of a mass. Given the presence of blasts on the peripheral smear, flow cytometry was done and showed myeloid blasts. A bone marrow biopsy showed 19 % blasts and FISH was positive for BCR/ABL1 fusion, consistent with a CML blast crisis. The patient was treated acutely for the hypercalcemia with intravenous fluids, zoledronic acid, furosemide, and calcitonin. Following treatment, her calcium level normalized and her encephalopathy resolved. For the CML she was started on dasatinib, an oral tyrosine kinase inhibitor. Unfortunately the patient had a complicated hospital course and ultimately died of acute respiratory failure secondary to extensive tumor burden with a high blast count.

DISCUSSION: Hypercalcemia is a frequently encountered clinical problem by general internists. The most common cause in ambulatory settings is primary hyperparathyroidism, while the most common cause in the hospital setting is malignancy. Clinicians should suspect malignancy in patients who are symptomatic and have very high serum calcium levels, typically greater than 12 mg/dL. Initial workup includes measuring PTH level, followed by PTH-rP and vitamin D metabolites. Additional imaging should be done to identify a primary source if malignancy is suspected. Hypercalcemia in malignancy can occur by one of three major mechanisms: osteolytic metastases, tumor secretion of PTHrP, and tumor production of 1,25-dihydroxyvitamin D. Common tumors that secrete PTHrP include solid tumors (e.g. breast, lung, renal, bladder) and hematologic malignancies (e.g. non-Hodgkin lymphoma). Chronic myeloid leukemia in blast phase has also been implicated, however, there have only been a few cases reported. There are two major forms of blast crisis in patients with CML: myeloid and lymphoid. Our patient had a myeloid blast crisis, which is more common (70 %). Treatment regimens depend on whether the patient developed blast crisis *de novo* or while on an oral tyrosine kinase inhibitor (TKI). For a *de novo* blast crisis, a TKI alone is used. For patients already on a TKI, AML-type induction chemotherapy in addition to a more potent TKI, such as dasatinib, is used. Despite treatment, hypercalcemia is a poor prognostic factor, as illustrated by our patient.

A RARE CAUSE OF MULTIPLE BONE LESIONS: METASTASIS OR NOT? Tatsuya Sato; Junwa Kunimatsu; Eriko Kanehisa; Junko Maeda; Mikiko Arai; Riri Watanabe; On Kato. National Center for Global Health and Medicine Hospital, Tokyo, Japan. (Tracking ID #2166077)

LEARNING OBJECTIVE #1: Recognize hyperplastic hematopoietic bone marrow as a differential diagnosis of metastatic bone tumors.

LEARNING OBJECTIVE #2: Recognize the difference between radioisotopes used in nuclear medicine imaging in order to clarify pathophysiology of multiple bone lesions.

CASE: A 59-year-old Japanese woman presented with 6 months history of tingling sensation in her toes. The patient lost balance while walking and experienced frequent fall. She had no past medical history, and reportedly drank 4 to 5 glasses of Japanese distilled spirit daily. Neurological examination revealed no remarkable muscle weakness, with strength assessed at 5 of 5 bilaterally, and decreased Achilles tendon reflexes. Sensation in her lower extremities was diminished. She showed prominent wide based gait and positive Romberg sign. Laboratory study showed mild liver abnormality and macrocytic change of the red blood cells. Brain MRI revealed multiple focal low intensity areas in the skull and vertebral bones (C3 and C4) on both T1 and T2-weighted images. Multiple, metastatic bone tumors were strongly suspected. Bone scintigraphy using technetium 99 m (99mTc) showed significant uptakes in the skull, spine, and costal bones. However, whole body CT and endoscopic examinations found no evidence of the primary site of malignancy. 18 F FDG-PET/CT indicated low-level accumulation of FDG in the vertebral bones, but it could not point out an origin of the suspected metastatic bone tumors. We conducted CT-guided biopsy of the 12th vertebra, which had the highest accumulation of FDG among the involved vertebral bones. Established tissue diagnosis was hyperplastic hematopoietic bone marrow (HHBM). Encouraging the patient to stop alcohol use led to partial recovery from neurologic symptoms, which was suggestive of alcoholic neuropathy as the cause of her complaints. One year has passed since her first visit and she is well now.

DISCUSSION: HHBM is caused by proliferation of hematopoietic cells, as a result of active response to increased peripheral oxygen demand. In general, bone marrow turns from hematopoietic marrow (red marrow) to fatty marrow (yellow marrow) with aging. However, reversion from yellow marrow to red marrow can occur under certain circumstances. These include chronic anemia, obesity, heavy smoking or drinking, long-distance running, and use of hematopoietic growth factors. HHBM mimics metastatic bone tumors on MRI images, because both the two process usually present with multiple bone lesions that are illustrated as low intensity areas on T1 and T2-weighted images. In our case, it was noteworthy that, although significant uptakes were observed in bone scintigram, 18 F FDG-PET/CT did not elucidate any focal high FDG accumulation. We speculated that this phenomenon resulted from the difference between 99mTc and 18 F-FDG. 99mTc uptake directly reflects a proliferation of hematopoietic cells that leads a high osteoplastic activity. However, the proliferation of hematopoietic cells does not bring abnormal metabolism that provokes accumulation of 18 F-FDG. This mismatch may help us to differentiate HHBM from metastatic bone tumors. In summary, this case illustrates a rare differential diagnosis for metastatic bone tumors. We should recognize the difference between 99mTc and 18 F-FDG in order to clarify pathophysiology of multiple bone lesions by nuclear medicine imaging modalities.

A RARE CAUSE OF PORTAL HYPERTENSION AND AN UPDATE OF TREATMENT STRATEGIES: SPONTANEOUS ARTERIOPORTAL FISTULA. *Katrina DeLeon; Thomas Le; Richard Hu. UCLA- Olive View Medical Center, Sylmar, CA. (Tracking ID #2194993)*

LEARNING OBJECTIVE #1: Identify a rare cause of portal hypertension.

CASE: A 58 year old Armenian male with no significant past medical, surgical, or procedural history presented with a 6 week history of mild abdominal pain and 4 week history of increasing abdominal swelling. He described eating and drinking less for fear of worsening of his abdominal swelling. He does not take any home medications. His social history includes 40 pack-year tobacco smoking and social alcohol use. His family history is noncontributory. On physical exam, vital signs are normal. Abdominal exam is significant for distension with shifting dullness and positive fluid wave with splenomegaly and audible epigastric bruit. Laboratories were unremarkable including normal complete blood count, complete metabolic panel, INR and negative viral hepatitis serologies. Ascites fluid demonstrated no evidence of spontaneous bacterial peritonitis, negative gram stain and cultures, with a total protein 1.6 g/dL, albumin 1.1 g/dL, and serum albumin of 3.7 g/dL with a SAAG of 2.6 consistent with portal hypertension. Abdominal ultrasound with doppler demonstrated an arteriovenous fistula with vascular collateralization, retrograde flow in splenic vein, no evidence of portal thrombus or cirrhosis. On CT angiogram SMA injection demonstrated no hepatic arterial supply, common hepatic arterial injection showed a vascular malformation originating from the left hepatic artery, with an extremely tortuous path into the vascular malformation and terminated in the left portal vein. He subsequently underwent embolization with multiple coils inserted in the vascular malformation arising from the hepatic artery and terminating in an aneurysmal left portal vein. From the time of initial assessment to the time of intervention, the patient required four paracenteses. At three month follow up, the patient's ascites had resolved after coil embolization with no further need for paracentesis.

DISCUSSION: In the United States, cirrhosis is the leading cause of portal hypertension. However, in the absence of cirrhosis, noncirrhotic portal hypertension comprises far fewer of the total cases in America. Worldwide, the most common etiology of noncirrhotic portal hypertension is schistosomiasis. In the Western world, chronic liver diseases including

nonalcoholic steatohepatitis, primary biliary cirrhosis, primary sclerosing cholangitis, and congenital hepatic fibrosis are the leading causes along with extrahepatic causes including portal vein thrombosis and Budd-Chiari syndrome. A rare cause of noncirrhotic portal hypertension to consider is an arterioportal fistula (APF). An APF is defined as any connection between the splanchnic arteries and the portal veins. In a review of 88 case reports, the common causes of APF were penetrating trauma (28 %), iatrogenic causes including biopsies and instrumentation (16 %), congenital causes including hereditary telangiectatic diseases like Osler-Weber-Rendu syndrome and Ehlers-Danlos syndrome (15 %), neoplasm (15 %), and aneurysms (14 %). Spontaneous APF is extremely rare. Recently, it has been proposed that APF's can be further classified into three types by etiology, size, involved vessels, and location. Type 1 includes small, peripheral, asymptomatic APF with minimal physiologic insult, type 2 includes larger, central fistulas causing physiologic insult, and type 3 including congenital fistulas. Small APF's are usually found incidentally and are asymptomatic, however large APF's are usually symptomatic with the most common presenting symptoms of gastrointestinal bleed (33 %), ascites (26 %), heart failure (4.5 %), and diarrhea (4.5 %). A Bruit or thrill can also be appreciated in approximately 33 % of patients and is most likely present when the fistulas are greater than 4 mm. Spontaneous APF in an adult with no history of prior trauma, instrumentation, or liver disease, is an extremely rare condition with the historical treatment being surgical ligation of the artery supplying the APF or resection of the vascular anomaly. Because of the morbidity and mortality associated with surgical intervention and the development of non-invasive endovascular interventions, embolization has progressively become the first line treatment. Embolization with coils, balloons, and n-butyl cyanoacrylate (NBCA) have all been demonstrated as potential therapies. Should the patient continue be symptomatic with ascites or gastrointestinal bleeding, surgical treatment is then pursued. In rare cases with continued complications, liver transplantation may be necessary as the ultimate therapeutic option. In our case of spontaneous APF without prior trauma, instrumentation, or liver disease, a large, symptomatic, APF was treated successfully with coil embolization. This further suggests that non-surgical treatment through interventional radiology is a safe and practical management option although there is no large clinical study available.

A RARE DISEASE (MULTICENTRIC CASTLEMAN'S DISEASE) IN AN IMMUNOCOMPROMISED PATIENT. *Mazyar Malakouti; Jessica B. Polasek. University of Texas Health Science center in San Antonio, Texas, San Antonio, TX. (Tracking ID #2200763)*

LEARNING OBJECTIVE #1: Recognize the clinical features and treatment of multicentric castleman's disease (MCD)

LEARNING OBJECTIVE #2: Recognize the vast differential diagnosis in immunocompromised patients and the relationship between MCD and HHV 8

CASE: A 21-year-old Hispanic male with no past medical history presented to our hospital with worsening abdominal pain for approximately 2 months. He described the pain as intermittent initially, but not associated with eating food. Due to the abdominal pain, associated nausea and vomiting, he had lost approximately 15 lb. He denied any hematochezia, melena, dysphagia or hematemesis. In addition, he also complained of diffuse maculo-papular rash involving the palms and soles. He also had noted that his lower extremities were more swollen than usual. The patient had normal vital signs. His exam was significant for a semi protuberant abdomen, with some mild tenderness to deep palpations in the right and left upper quadrants without guarding or rebound tenderness. A diffuse non-itchy maculo-papular rash, was also noted on his torso and extremities, including his palms and soles. His exam also revealed a 2.6 cm right inguinal slightly tender lymph node in addition to some minimal submandibular lymph nodes. He had two distinct anal warts measuring about 0.5 cm in diameter. His labs were normal except for a normocytic anemia and a positive HIV and RPR. His chest x-ray showed a large right pleural effusion. CT scan of the abdomen and pelvis showed diffuse lymphadenopathy with moderate ascites. A paracentesis performed was consistent with an exudative process and revealed a normal cell count and negative gram stains. The patient was immediately started on highly active antiretroviral therapy (HAART) for his recent diagnosis of AIDs and benzathine penicillin for his underlying syphilis. Two weeks after the treatment was initiated, his rash dramatically improved but his abdominal pain and lymphadenopathy remained present. A biopsy of the inguinal lymph node was subsequently performed with an initial read of Kaposi sarcoma associated with Human herpes virus (HHV) 8. A final read was amended to include multicentric Castleman's disease (MCD). Due to his extensive disease process, rituximab was later added to his therapy. Two doses later, the patient developed multi-organ failure from possible rapid progression of his disease or perhaps due to immune reconstitution syndrome (IRS) and subsequently died a few weeks later.

DISCUSSION: Castleman's disease is a lympho-proliferative disorder also known as angiofollicular lymph node hyperplasia. This disease remains rare and the real incidence is currently unknown. Histologically, Castleman's disease can be classified as either hyaline-

vascular or plasma cell variant with some cases demonstrating mixed features. In HIV associated MCD, all patient are co-infected with HHV-8 and hence malignancies such as Kaposi sarcoma and primary effusion lymphoma; that also share this common pathogen (HHV-8) are frequently encountered. The natural history of MCD is variable but can be fatal in patient with concomitant HIV 2. Usually patient will present with a plethora of symptoms including, fevers, peripheral lymphadenopathy, hepatosplenomegaly, weight loss and edema. Ascites, pleural and pericardial effusion have also been reported. The diagnosis is made via excisional biopsy of an affected lymph node usually showing angiofollicular hyperplasia and interfollicular plasma cell infiltration. Core needle biopsy is preferred to a fine needle aspiration. The treatment of MCD remains controversial and based on a few studies and some case reports. HAART is key in patients with HIV although this does not alleviate symptoms associated with Castleman's disease. Interestingly, initiation of HAART can cause rapid progression of the disease perhaps due to immune reconstitution inflammatory syndrome (IRIS). Glucocorticoids offer short term symptoms management by controlling the inflammatory response, but effects have not been studied in HIV patient with MCD. Multiple chemotherapeutic agents have been used as single agents or in combinations but the data remains limited and non-conclusive. However, the use of rituximab, an anti-CD 20 monoclonal antibody, has shown promising results. Of note, rituximab can often cause a flare up of Kaposi sarcoma in patients with HIV. Anti-herpes virus therapies have also been explored but the studies remain small and the data inconclusive. Patients with AIDs continue to present with wide array of symptoms and opportunistic diseases. This case shed light on a rare lymphoproliferative disorder, multicentric Castleman's disease (MCD), which is often found in patients with HIV. This case also reflects on the challenges that many providers face while taking care of patients with AIDs and HIV.

A RARE DRUG ERUPTION IN A PATIENT WITH AN UNUSUAL MENINGITIS
Teo Soleymani¹; Hannah Bechtold³; Omar Medina³; Francis E. Dailey²; Oragun Rojanapairit¹; David Frishberg²; Robert I. Goodman². ¹Cedars Sinai Medical Center, Glendale, CA; ²Cedars-Sinai Medical Center, Los Angeles, CA; ³UCLA, Los Angeles, CA. (Tracking ID #2197970)

LEARNING OBJECTIVE #1: Recognizing rare adverse cutaneous reactions and understanding the importance of recognition that allows for prompt discontinuation of the offending agent, reducing the morbidity that is associated with such drug reactions.

LEARNING OBJECTIVE #2: Recognizing the importance of early detection and diagnosis of acute bacterial meningitis, particularly in the setting of rare organisms such as *Streptococcus salivarius*.

CASE: A 56-year-old woman with no significant past medical history presented to our emergency department with a chief complaint of headache for 5 days. A week prior to admission, the patient had sought medical attention at an outside emergency department for similar symptoms and was subsequently discharged without intervention. At presentation, the patient complained of severe headache, fever and associated nausea, vomiting, and photophobia. Concerned for meningitis, the patient was admitted to the teaching service. Appropriate laboratory studies were performed including a lumbar puncture, which demonstrated findings consistent with acute bacterial meningitis. Broad-spectrum antibiotics were initiated pending cultures and sensitivities. On hospital day 2, CSF cultures grew *Streptococcus salivarius*. Antibiotics were tailored appropriately based on sensitivity studies. By hospital day 4 the patient had defervesced and improved symptomatically. However, on hospital day 7, the patient was acutely febrile again, with significant leukocytosis and an acute rise in serum creatinine. She complained of severe burning and itching of her face, trunk and extremities. Repeat cultures were negative. Overnight, the patient suddenly developed an acute eruption of widespread non-follicular pustules, 1–2 mm in size and diffusely widespread, overlying areas of generalized erythematous edema. On oral examination, limited involvement of the left buccal mucosa was also seen. A diagnosis of acute generalized exanthematous pustulosis (AGEP) was presumed. A gram stain and culture was performed on the pustules, which demonstrated no bacteria but many neutrophils. A punch biopsy of the abdominal skin demonstrated subcorneal neutrophilic inflammation with spongiform pustules, with the subjacent dermis displaying mild perivascular lymphocytic inflammation, consistent with the diagnosis of AGEP. Over the next few days the patient's pustulosis regressed and was followed by widespread superficial desquamation. She defervesced again and her symptoms of burning and itching subsided. Extensive work-up for the underlying etiology of her *Streptococcus salivarius* meningitis returned inconclusive. By hospital day 12 the patient had completed her appropriate course of antibiotic therapy and was deemed appropriate for discharge with follow-up. Renal function slowly improved in the coming weeks.

DISCUSSION: Acute generalized exanthematous pustulosis (AGEP) is a rare acute cutaneous reaction that is characterized by an eruption of small, superficial, nonfollicular sterile pustules usually 1–2 mm in size that overlie areas of edematous erythema. It has an annual incidence of approximately one to five cases per million. Though AGEP can occur at any age, the average age of onset is 56 years, and women are affected more often than men.

Nearly 90 % of the cases of AGEP are due to drugs, particularly antibiotics. The most commonly implicated antibiotics are beta-lactams, particularly penicillins, and macrolide classes. The spectrum of drugs implicated in AGEP are different than those usually responsible for other skin reactions such as Stevens-Johnson syndrome/toxic epidermal necrolysis. AGEP has also been seen following mercury ingestion or certain viral infections such as Cytomegalovirus, Parvovirus B19, Coxsackievirus, and Mycoplasma pneumoniae. Classically, the cutaneous eruption in AGEP begins within 1 to 2 weeks of starting the offending agent and starts as generalized edematous erythema, which acutely disseminates into widespread small, sterile nonfollicular pustules within a few hours to a few days, followed by brisk desquamation. The rash is characteristically accompanied by fever, leukocytosis, pruritis and burning. Mucous membrane involvement occurs in approximately 20–30 % of patients and is generally mild and limited to the mouth and tongue. Histopathologically, the most relevant features on biopsy are patterns of non-follicular subcorneal and/or intracorneal spongiform pustules that coalesce, with a neutrophilic inflammatory dermal infiltrate. After elimination of the causative drug, pustules spontaneously disappear within a few days with desquamation and the reaction resolves in approximately 2 weeks. Internal organs are not usually involved and no systemic treatment is required. Withdrawal of the culprit drug is mandatory for resolution. Although AGEP itself is a self-limiting disease with a good prognosis, secondary infections are not uncommon complications, particularly in patients with multiple medical co-morbidities. The reported mortality is approximately 3–5 %.

A RARE ISOLATE: DAPTOMYCIN NONSUSCEPTIBLE VANCOMYCIN RESISTANT ENTEROCOCCUS FAECIUM CAUSING ENDOCARDITIS Neal George; Joshan Suri. Conemaugh Memorial Medical Center, Johnstown, PA. (Tracking ID #2198721)

LEARNING OBJECTIVE #1: Diagnosing Daptomycin nonsusceptible vancomycin resistant enterococcus faecium.

LEARNING OBJECTIVE #2: Identify risk factors for the development daptomycin nonsusceptible vancomycin resistant enterococcus.

CASE: A 76-year-old male with history of coronary artery disease and chronic kidney disease stage IIIB developed abdominal pain for 7 days prior to presenting to the emergency room. The patient was afebrile with laboratory studies significant for a WBC of 13.6 thousand/cumm, troponin of 0.04 ng/m, and GFR of 49 mL/min, which was similar to the patient's baseline renal function. Computed tomography of the abdomen and pelvis with contrast revealed a colon mass in proximal transverse colon near the area of the hepatic flexure. Blood cultures drawn 12 h apart revealed vancomycin resistant enterococcus (VRE) faecium. This particular isolate had a non-susceptibility Etest to daptomycin with a mean inhibitory concentration (MIC) of 12 µg/mL, with sensitivity to linezolid. Colonoscopy revealed an ulcerated non-obstructing large mass in the proximal transverse colon which was biopsied. Pathology was negative for any malignancy but revealed acute necro-inflammatory debris and lamina propria hemorrhage. Transesophageal echocardiogram (TEE) revealed small vegetations on the anterior mitral valve leaflet. The patient was treated successfully with intravenous linezolid and gentamicin for a total of 8 weeks with repeat TEE showing resolution of the previously seen vegetation.

DISCUSSION: The first case of VRE endocarditis that met the Duke Criteria was reported in 1996. Native valve endocarditis secondary to enterococci account for 14–17 % of cases among patients over the age of 60. Enterococci are considered to be susceptible if the MIC is less than 4 µg/mL and have intermediate resistance once the MIC are between 8 and 16 µg/mL. VRE colonization has been shown to have a higher incidence amongst renal transplant and hemodialysis patients. There are limited case reports of enterococci faecium causing endocarditis. We report a rare case of daptomycin nonsusceptible vancomycin resistant enterococcus faecium (DNS-VRE) causing endocarditis in a patient with an underlying benign colon mass. It was believed that the source of the isolate was the ulcerated colon mass. The reported patient fulfilled the modified Duke Criteria for endocarditis with 2 major criteria (ie positive blood cultures for enterococci and mitral valve vegetation). DNS-VRE is an extremely rare isolate, however several risk factors for DNS-VRE isolation have been suggested via retrospective analysis including immunosuppression, duration of hospitalization, indwelling devices thought to foster biofilm formation on prosthetic devices, and previous daptomycin exposure. Pfaller MA et al. 2005 found only 0.6 % (10/1560) of isolates among VRE species were DNS-VRE. At the present time, little is known about the emergence or the incidence of DNS isolates. Kelesidis T et al. 2011 report that less than 2 % of enterococci isolates were daptomycin nonsusceptible with MIC of ≥4 µg/mL. The rising reports of DNS-VRE is concerning. We report a case in which the MIC was found to be 12 µg/mL suggesting that this isolate was truly DNS-VRE. Daptomycin is the only antibiotic with in vitro bactericidal activity against VRE that has been approved by the Food and Drug Administration. Based on susceptibility breakpoints approved by the Clinical Laboratory Standards Institute, daptomycin has in vitro activity against >90 % of enterococcal isolates. Dohmen PM et al. 2012 outlines daptomycin for the treatment of infective endocarditis through one of the largest trials involving infective endocarditis and suggests that ≥8 mg/kg dosing of daptomycin has a higher clinical success

rate (90 %) compared to standard dosing (4 mg/kg). At the current time there exists no recommendations from the Infectious Disease Society of America regarding treatment for DNS-VRE infections. Further studies are needed to clarify the mechanism of development of resistance among patients with VRE, and what dose of daptomycin would most be effective in patients found to have DNS-VRE infections.

A RARE YET EMERGING CAUSE OF SEVERE MYOCARDITIS AND CARDIOMYOPATHY Sweny Gulati; Aymara Chang; Amy Vittor; John Petersen; Margaret C. Lo. University of Florida College of Medicine, Gainesville, FL. (Tracking ID #2198964)

LEARNING OBJECTIVE #1: Recognize typical and atypical clinical manifestations of chikungunya infection

LEARNING OBJECTIVE #2: Identify risk factors and poor prognostic indicators for atypical, severe chikungunya infection

CASE: A 40 year-old male presented as a hospital transfer for severe cardiomyopathy after 7-days of high fevers (101.9 °F), cough, sore throat, arthralgias, chest pain, and diarrhea. He required vasopressor support for hypotension. Medical history includes tobacco abuse and herniated lumbar disc but no hypertension, diabetes, or cardiopulmonary diseases. Social history noted recent immigration from Puerto Rico 2 weeks ago, multiple mosquito bites back in Puerto Rico, and girlfriend with recent chikungunya infection in Puerto Rico. Outside lab values revealed leukocytosis (12700/ μ L), thrombocytopenia (85000/ μ L), renal dysfunction (creatinine 1.21 mg/dL), and transaminitis (ALT 206 IU/L, AST 52 IU/L). EKG showed sinus tachycardia with T-wave inversions in V4-V6. Initial troponin-T level was 0.34 ng/mL and peaked to 2.63 ng/mL. Initial BNP value was 236 pg/mL but increased to 1864 pg/mL in 24 h. A transthoracic echocardiogram (TTE) showed severe left ventricular systolic dysfunction, ejection fraction (LVEF) of 25 %. Due to concerns of NSTEMI, the patient was started on heparin drip and transferred to our cardiac care unit for advanced heart failure therapies. Upon transfer, physical exam was remarkable only for diffuse abdominal tenderness. Repeat Troponin-T level was 0.26 ng/mL with normal CK and CK-MB. NT-proBNP level was 37329 pg/mL. CRP level was high at 328 mg/L. TTE again showed low LVEF of 15 %, diffuse hypokinesis and moderate right ventricular systolic dysfunction. Heparin drip was discontinued as troponinemia were felt to be from chikungunya-induced myocarditis. Infectious Disease agreed; chikungunya and dengue serologies were sent. The patient slowly improved with supportive care and was discharged with close outpatient Cardiology follow up. Two weeks later, the diagnosis of chikungunya was confirmed with positive IgM titer of 1:640 and IgG titer of 1:1280. Dengue IgG titer was positive at 14.6 (range<1.64) but IgM titer negative at 1.08 (range<1.64), consistent with prior dengue virus infection.

DISCUSSION: This case illustrates the growing footprint of global medicine in the U.S. and the increasing need for global health training among U.S. clinicians, particularly on emerging infections. Similar to the West Nile and dengue viruses, chikungunya virus (CHIKV) is a mosquito-borne illness endemic to tropical regions. With air travel and rapid spread of *Aedes spp* mosquitoes into Europe and Latin America, case reports are now surfacing in the U.S., all transmitted autochthonously. Typical CHIKV illness presents as high fevers and debilitating polyarthralgias with associated prostration, headaches, backache, rash, and diarrhea. The arthralgia and fatigue can persist for months to even years. Key diagnostic clues include those with acute symptoms unexplained by other medical illnesses and recent travel or residence in endemic or epidemic areas, as true in our patient. Of importance also is the social history in our case of recent mosquito bites and girlfriend with CHIKV infection. Rarely in 0.3 %, CHIKV infections progress to atypical, severe symptoms other than fevers and arthralgias, requiring maintenance of ≥ 1 vital organ. Such severe manifestations include cardiovascular disorders (myocarditis, arrhythmias, heart failure, cardiogenic shock), pre-renal failure, respiratory failure, and neurological disorders (meningoencephalitis, seizures). Hemorrhagic complications are rare, which is a key distinction from dengue fever. Literature cites atypical CHIKV infections occurring commonly (90 %) in those with chronic medical conditions, i.e. hypertension, diabetes, cardiovascular disease, and COPD. Advanced age, i.e. ≥ 60 years-old, has been cited as a significant risk factor for not only atypical, severe infections but also increased mortality. Other poor prognostic indicators include hypertension, underlying respiratory disease, recent NSAID use prior to admission, and pre-existing cardiac disorders. However, the immunocompetent state of our patient should not mislead clinicians. Literature has reported severe CHIKV infections affecting the cardiovascular and neurological systems in healthy young patients. Early recognition of myocarditis and cardiomyopathy as a rare manifestation of CHIKV infection may not alter prognosis but will prevent extensive and costly testing. Lab confirmation of CHIKV infection via virus isolation, viral RNA detection, or detection of IgM antibodies is needed to exclude similar illnesses that may warrant different treatments (e.g. influenza, dengue). Identifying individuals with risk factors and poor prognostic indicators of atypical CHIKV infection is important to expedite inpatient supportive management. Neither effective antiviral treatment nor vaccines are available, though multiple vaccine candidates are under development.

A REAL PAIN IN THE NECK: A BOXER'S BOUT WITH LEMMIRE'S SYNDROME. Ankeet Bhatt²; Shaina Lynch¹. ¹University of Connecticut, Farmington, CT; ²University of Connecticut School of Medicine, Farmington, CT. (Tracking ID #2194066)

LEARNING OBJECTIVE #1: Recognize Lemierre's syndrome as a rare cause of an otherwise healthy person presenting with neck mass and throat pain.

LEARNING OBJECTIVE #2: Understand the clinical consequences of Lemierre's syndrome and the role of oral flora in the disease state.

CASE: HPI: Twenty-one year old college student and competitive boxer with no significant PMH presents with 5 day history of sore throat and headache. Symptoms began with a mild sore throat and 7/10 bi-frontal and right sided pain. The patient initially saw his PCP, rapid strep test and Monospot were negative. The patient had body aches, chills, low grade fevers (99.4–100.6), nausea, and one episode of NBNB emesis. The patient was again brought to his PCP, and CXR was normal. The patient's throat pain worsened, with odynophagia and increasing swelling on the right side, associated with shortness of breath and cough productive of white sputum. A CT chest showed a process consistent with viral/atypical pneumonia. With worsening right sided throat pain and 102.7 fever, the patient was seen in the hospital. CT neck revealed density suspicious for thrombus in the right internal jugular vein, consistent with diagnosis of Lemierre's syndrome. The patient was placed on Ampicillin/sulbactam 3 g Q6hr and azithromycin 250 mg daily, and transferred to a tertiary care facility for further management. The patient's mother did mention he infrequently cleaned his mouthguard for boxing, and would often chew on it, suspected to be a nidus for the infection. Neck CT from OSH was reviewed by radiology confirming thrombus in the right IJV. Blood cultures grew anaerobic Gram negative rods, consistent with *Fusobacterium*. The patient was maintained on Ampicillin/sulbactam and began to improve clinically. Repeat CT showed new interval opacities in the upper lobes bilaterally, consistent with septic emboli. ROS negative for any altered mental status, recent travel, or hemoptysis. PICC line was placed and the patient continued to improve clinically. The patient was discharged with PICC line in place and support services to continue IV antibiotics with anaerobic coverage for a total of 4 weeks. Past Medical, surgical and family history all noncontributory. Up-to-date on all vaccinations. **Allergies:** NKDA **SH:** Exercise physiology student; competitive boxer. Social drinker. Denies smoking or recreational drug use. **PE:** Vitals on admission: Temp 101.5, HR 122, BP 110/74, non-orthostatic, RR 40, O2 sat 97 % on 3 L NC. General: lying in bed, uncomfortable, diaphoretic. HEENT: Decreased neck ROM to right side. + 1cmx2cm tender mass in the right anterior neck. + tender LAD in the right posterior cervical chain. Respiratory: + tachypnea, + nasal flaring, unable to complete a full sentence in one breath. Lungs clear Heart: Tachycardia. Regular rhythm. S1, S2 heard. Neuro: No focal deficits. **Diagnostic Data:** CBC/BMP on admission—WBC 10.2, Hb 13.2, hct 38.4, plt count 79,000. Na 141, K 3.8, Cl 107, HCO3 27, BUN 16, Cr 1.4 (BL unknown), glucose 110. EKG: Sinus tachycardia, rate 118 bpm. Micro: + anaerobic Gram negative rods 4/4 bottles. CT Chest: Small peripheral consolidation in the apices bilaterally, consistent with septic emboli.

DISCUSSION: Lemierre's syndrome is described as a septic thrombophlebitis of the internal jugular vein, caused by the migration of bacterial through the deep tissues of the neck to the lateral pharyngeal space, near the vein. In 80 % of cases, the offending bacteria is *Fusobacterium necrophorum*, an anaerobic gram negative rod, quoted in multiple studies to be responsible to 10 % of acute sore throats and 23 % of peritonsillar abscesses. According to a systemic review of Lemierre's syndrome in 2009, sore throat is the first presentation sign in one third of all cases, followed by neck mass (23 %) and neck pain (20 %). Pooled mortality rates are about 5 %, and the disease usually affects previously healthy young people, as our patient was. From a physiological standpoint, the symptoms of SIRS/sepsis are caused by induction of a cytokine response by lipopolysaccharide endotoxin produced by the bacteria. *Fusobacterium necrophorum* produces *hemagglutinin*, which causes platelet aggregation that leads to thrombophlebitis or DIC. As seen in this case, the thrombophlebitis can spread distantly, most commonly affecting the pulmonary capillaries and leading to pulmonary septic emboli. Other sites include large joint spaces, such as the knee or hip. The mainstay of treatment for the condition in antibiotics, but increasing beta-lactamase resistance has been shown, and therefore beta-lactamase resistant antibiotics with anaerobic coverage are recommended. Perhaps the increasing incidence of the disease is secondary to the movement to avoid antibiotics in the treatment of typical upper respiratory infections. The role of anticoagulation in Lemierre's syndrome remains controversial, with the low incidence of the disease preventing adequate sized control studies to study the question.

A SHEEP IN WOLF'S DISGUISE: THORACIC ACTINOMYCOSIS MASQUERADING AS LUNG CANCER Ming Zhao; Charu Ramchandani; Maher Jafar; Manuel Matos. Rochester Regional Health System, Rochester, NY. (Tracking ID #2192261)

LEARNING OBJECTIVE #1: Recognize the common presentations of actinomycosis

LEARNING OBJECTIVE #2: Distinguishing thoracic actinomycosis from pulmonary malignancy

CASE: Patient is a 52 year old male, who hasn't seen a primary care physician for more than 30 years, was admitted to our hospital due to 2 weeks of dry cough, night sweats, mild chest pain, worsening weakness and more than 30 lb weight loss over 2 months. Patient denies any fever or shortness of breath. Patient denies any significant medical history in the past. No history of tuberculosis or exposure. His social history was remarkable for significant second-hand tobacco exposure and weekly marijuana use. On examination, his vital signs were within the normal range. No lymphadenopathy. Lungs were clear to auscultation bilaterally. Breathing was non-labored. His labs were remarkable for WBC of 12.0 and hemoglobin of 11.6 g/dl. Chest X-ray on admission showed extensive right paratracheal density that was concerning for mass. Chest CT showed large mass in the right upper lobe abutting the right side of the mediastinum measuring up to 5.2 cm, highly suspicious for neoplasm, as well as adjacent ground glass opacities and mild mediastinal and right hilar adenopathy. Given his dry cough, significant rapid weight loss and radiological appearance of lung mass, lung cancer was highly suspected and patient underwent a CT guided biopsy of the mass. While waiting for the pathology result, oncology was consulted, who recommended CT head, CT abdomen/pelvis and nuclear bone scan for metastasis work up as inpatient, due to the patient's lack of primary care physician and difficulty of outpatient follow up. All these imaging came back negative for any metastatic disease. Later, the pathology report came back showing lung parenchyma with areas of necrotizing inflammation, no evidence of malignancy, and stains revealed microorganisms located in the necrotic tissue appear to form thin hyphae-like formations with a beaded appearance. Gram stain highlighted gram positive bacteria, concerning for actinomyces. Upon further questioning, patient recalled a recent history of "bad molar", for which he did not seek any medical attention. Oral exam showed poor oral hygiene, a severe dental caries and surrounding gingivitis. Patient was diagnosed as thoracic actinomycosis and treated with 6 months of antibiotics. Repeat CT scan after treatment showed significant improvement. And the patient's symptoms also resolved.

DISCUSSION: Actinomycosis is a chronic bacterial infection caused by Actinomyces species. Actinomyces are gram-positive anaerobic bacteria that are part of the normal mucosal flora of the oral, gastrointestinal, respiratory, and genital tracts and can cause infection in these systems if the mucosal integrity is compromised. Most of the actinomycosis present as oral-cervicofacial infection. About 15–20 % of actinomycosis involves the thorax, most likely resulted from aspiration of the organism from either the oropharyngeal cavity or gastrointestinal tract. Common signs and symptoms of thoracic actinomycosis include fever, weight loss, cachexia, weakness, chest pain, shortness of breath and cough potentially accompanied by hemoptysis. Masses with pleural involvement are common radiologic findings and may be easily confused with malignancies. The diagnosis of thoracic actinomycosis is always challenging because it is a rare disease, symptoms are non-specific and can mimic a lot of other pulmonary pathologies. It has been described as "the most misdiagnosed disease" and "so often missed by experienced clinicians." The biggest challenge is to have an awareness of the disease presentations and consider the possibility that actinomycosis is present. Thus a comprehensive history and physical exam is always very important. Risk factors such as aspiration, history of dental procedure and poor oral hygiene during oral exam should always raise the suspicions of actinomycosis. However, given the non-specific presentation of thoracic actinomycosis, appropriate microbiologic and pathologic studies are still essential for definitive diagnosis. CT guided biopsy or bronchoscopy can be used to obtain a specimen. A high index of suspicion should be communicated to the microbiology laboratory, along with material from biopsy specimens. The presence of non-acid-fast, gram-positive organisms with filamentous branching is suggestive of the diagnosis. Penicillin G is the drug of choice for treatment of any infection caused by Actinomyces. Alternative antibiotics include tetracycline, erythromycin, cephalexin, oxacillin and clindamycin. Course of therapy should be individualized depends on the initial burden of disease and the clinical and radiologic response. Surgical removal of infected tissue may also be necessary in some cases, if burden of disease is extensive, poor response to antibiotics or malignant disease cannot be excluded.

A SHOCKING CAUSE IN A CASE OF CARDIOGENIC SHOCK. Kavel Visrodia. Mayo Clinic Rochester, Rochester, MN. (Tracking ID #2198116)

LEARNING OBJECTIVE #1: Recognize pericardial effusion as a potential manifestation of primary adrenal insufficiency.

LEARNING OBJECTIVE #2: Question adrenal insufficiency in patients presenting to the clinic with chronic fatigue.

CASE: A 20-year-old woman presented to the emergency room with 3 days of nausea and epigastric pain. Her medical history was remarkable for Hashimoto's thyroiditis requiring levothyroxine replacement, anxiety and depression. For the last 2 years she had been experiencing unexplained debilitating fatigue and weakness rendering her unable to attend school and work. Her vitals were remarkable for blood pressure 77/26, heart rate 119, respiratory rate 30, and oxygen saturation 94 % on 2 L nasal cannula. On physical exam she was notably mentating well, but ill-appearing with dry, warm skin, and a nontender

abdomen. Labs revealed hemoglobin 11.1, leukocytes 13.3, sodium 129, potassium 4.5, creatinine 1.7, bicarbonate 19, lactate 2.8, and thyroid stimulating hormone 5.8. Electrocardiogram revealed diffuse ST and T wave abnormalities and chest x-ray was unremarkable. After failure to respond to 5 L of rapid fluid resuscitation over 90 min (blood pressure 75/39, heart rate 122), pressor support was initiated and she was transferred to the medical intensive care unit. Bedside ultrasound revealed a moderately sized circumferential pericardial effusion with hepatic venous flow consistent with tamponade physiology. Urgent pericardiocentesis led to aspiration of 175 cc of serous fluid with only transient improvement in hypotension so stress-dosed steroids were initiated for possible underlying adrenal insufficiency. Over the next 2 days she was gradually weaned from pressor support with resolution of her symptoms, labs and ECG abnormalities, and therefore was transferred to the medical floor for continued care. Pericardial fluid gram stain and bacterial cultures were negative, as were PCR tests for *M. tuberculosis* and *M. pneumoniae*. Cytology revealed reactive mesothelial cells consistent with an inflammatory process. An exhaustive rheumatologic workup returned negative. A cortisol level was added to blood work obtained on presentation and returned undetectable. Adrenocorticotrophic hormone and 21-hydroxylase antibody levels were markedly elevated at 4055 and 54, confirming primary adrenal insufficiency due to autoimmune adrenalitis. She was evaluated by Endocrinology and transitioned to oral hydrocortisone before discharge with outpatient follow-up.

DISCUSSION: We present a case of a young woman admitted for pericardial effusion and cardiogenic shock potentially secondary to primary adrenal insufficiency. Although up to nearly one half of pericardial effusions have been described as idiopathic, previously published case reports have also described effusions secondary to primary adrenal insufficiency. While it is impossible to know in our case, a workup for adrenal insufficiency should perhaps be considered in the setting of pericardial effusion after a negative exhaustive workup. More importantly, we had low threshold to initiate stress-dosed steroids for possible adrenal crises when her hemodynamic instability only transiently improved following pericardiocentesis. Failure to recognize early adrenal crises and promptly initiate steroids contributes to the high mortality that is associated with this disease. In a young woman with existing autoimmune thyroid disease and presenting with shock and no evidence of infection, primary adrenal insufficiency should be high in the differential. Not uncommonly, autoimmune thyroid and adrenal disease coexist and is recognized as type II polyglandular autoimmune syndrome. Earlier detection of adrenal insufficiency in the outpatient setting may have prevented crises as our patient had 2 years of preceding unexplained fatigue. Delayed recognition of adrenal insufficiency is well recognized as half of patients have been reported to have symptoms longer than 1 year and two-thirds will have sought evaluation by three or more providers before a correct diagnosis. Primary care providers often have the first opportunity to diagnose adrenal insufficiency and not only drastically improve a patients quality of life, but prevent life-threatening adrenal crises.

A STROKE OF POLYCYTHEMIA VERA Jordan D. Becerril; Rachel Oreck; Nina Thomas. Tulane University Health Sciences Center, New Orleans, LA. (Tracking ID #2198740)

LEARNING OBJECTIVE #1: Assess, diagnose, and treat a patient suspected to have polycythemia vera (PV)

LEARNING OBJECTIVE #2: Recognize risk factors for thrombotic events in patients with PV

CASE: A 72 year-old man with history of chronic obstructive pulmonary disease (COPD) presented with focal neurologic deficits including worsening dysarthria, right upper extremity paresthesia, and facial droop for three days. On presentation, neurology was consulted for stroke activation. Head imaging was negative for an acute intracranial event but positive for remote ischemic events as well as diffuse atherosclerotic disease. The patient had partial resolution of his neurological symptoms and was placed on aspirin and rosuvastatin by the primary neurology service. Internal medicine was consulted regarding his reported history of positive purified protein derivative and incidental finding of elevated hemoglobin. Social history was significant for a 50 pack-year history of smoking though he did not have any chronic occupational exposures to carbon monoxide. On physical exam the patient was noted to be hypertensive at 177/95, oxygen saturation was 95 % on room air, and he demonstrated plethoric facies with right-sided facial droop. Complete blood count (CBC) was noted to have a white blood cell count of 17,000/ μ L, hemoglobin count of 20 g/dL, hematocrit of 63 %, platelets of 437,000/ μ L, confirmed with repeat studies. Erythropoietin (EPO) level was found to be low at 2.2 mIU/mL and Janus Associated Kinase (JAK) 2 mutation was positive, meeting diagnostic criteria for polycythemia vera. Chest x-ray and T-SPOT.TB were negative for active or latent tuberculosis infection. The patient was phlebotomized a total of 1.5 L over five days with a reduction of hematocrit to 51.5 %. He was discharged on hydroxyurea 500 mg daily and was scheduled for follow up with hematology, weekly assessment of hemoglobin/hematocrit, phlebotomy as needed with goal hematocrit less than 45 %, and bone marrow biopsy.

DISCUSSION: Polycythemia vera (PV) is a chronic myeloproliferative neoplasm characterized by clonal growth of an aberrant hematopoietic progenitor cell. Common presenting features include nonspecific complaints such as headache and weakness, pruritus, thrombosis, transient visual disturbances, and gastrointestinal symptoms. Often patients have no complaints and are only diagnosed after an incidental finding of elevated hemoglobin on CBC. It is important to exclude other causes of elevated hemoglobin. Physical exam findings include splenomegaly, plethoric facies, and hepatomegaly. Patients with PV have high rates of cardiovascular (CV) events and are also at risk for transformation to myelofibrosis and acute leukemia. In a large cohort study the cumulative rate of CV events was found to be 5.5 events per 100 persons per year, 25 % of which were cerebrovascular-related. Risk factors for thrombotic events include age >65 years and prior history of thrombosis. Diagnosis of PV per the World Health Organization PV Criteria requires two major criteria and one minor criterion or the first major with two minor. Major criteria include a hemoglobin count of greater than 18.5 g/dL in men, 16.5 g/dL in women and the presence of JAK2 mutation. Minor criteria include serum EPO level below normal reference range, bone marrow biopsy showing hypercellularity for age, and endogenous erythroid colony formation in vitro from the aspirate. The primary goal of treatment is to reduce the risk of thrombosis. Phlebotomy remains the mainstay of treatment with a goal hematocrit less than 45 %. Other treatment modalities include low dose aspirin, hydroxyurea, and/or interferon alpha therapy. In addition ruxolitinib, a JAK 1 and 2 inhibitor, was recently named the first FDA-approved drug for PV.

A SURREPTITIOUS DIAGNOSIS: HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS Joyce Alencherril; Maisha Barnes; Leigh Hunter; Asma Khatoun. Methodist Dallas Medical Center, Dallas, TX. (Tracking ID #2158620)

LEARNING OBJECTIVE #1: Hemophagocytic lymphohistiocytosis (HLH) is a disorder of immune dysregulation that can lead to multiorgan failure. A high level of suspicion and prompt diagnosis are essential so that life-saving treatment is not delayed.

CASE: A 63-year-old man presented with a 9-month history of intermittent weakness, progressive fatigue, and abnormal hepatic function punctuated by four hospitalizations. The first presentation occurred after 6 weeks of fatigue, intermittent fever and chills, anorexia, 20-lb weight loss, and jaundice. He was noted to have elevated liver function tests (LFTs) and a liver biopsy was performed and consistent with cholangiopathy thought to be drug-induced secondary to herbal supplements. The patient was told to abstain from these supplements and was prescribed ursodeoxycholic acid and prednisone, with improvement of his symptoms and LFTs. The patient's second hospital admission came after a syncopal episode thought to be due to volume depletion and adrenal insufficiency caused by rapid tapering of the patient's prednisone. Pancytopenia was also noted and bone marrow biopsy was performed which was normal. The patient's LFTs were elevated again and his dose of prednisone was increased. The patient's third hospitalization occurred after outpatient blood work indicated thrombocytopenia. The patient underwent another bone marrow biopsy that was again normal, so he was treated with intravenous immunoglobulin and steroids for presumed idiopathic thrombocytopenic purpura. The patient had another liver biopsy which was concerning for HLH, but he had no other diagnostic criteria at the time. The patient's fourth hospital admission was prompted by another elevation of his LFTs. On presentation, the patient only complained of generalized weakness, although he was also noted to have scleral icterus, oral thrush, and splenomegaly on physical examination. Initially, he was continued on steroid therapy, but then fever ensued. An infectious diseases evaluation was performed and was negative. During this hospitalization, the patient demonstrated worsening anemia, thrombocytopenia, hepatic and renal function. Triglycerides and ferritin were markedly elevated (680 mg/dL and >10,000 ng/mL, respectively) which further supported a diagnosis of HLH. The patient had a third bone marrow biopsy that was consistent with HLH. A treatment plan consisting of IVIG followed by etoposide was initiated, but the patient suffered a cardiac arrest after the first day of treatment.

DISCUSSION: This case illustrates the challenge of making a timely diagnosis of HLH. Patients with HLH often have nonspecific presentations that can be mistaken for primary liver disease, infection, or malignancy among other diagnoses. A positive biopsy is not necessary for diagnosis, nor does a positive biopsy confirm diagnosis without other criteria being met. The complexity of diagnosis and high morbidity and mortality related to untreated HLH underscore the importance of having a high level of suspicion regarding a diagnosis of HLH so that treatment can be promptly initiated.

A UNIQUE CASE OF MULTIDRUG-RESISTANT LATENT TB INFECTION Deepti Chopra; Wendy Wobeser; Jorge Martinez-Cajas. Queen's University, Kingston, ON, Canada. (Tracking ID #2181982)

LEARNING OBJECTIVE #1: Recognize the risk of reactivation TB with Bortezomib-based treatment of multiple myeloma (MM)

LEARNING OBJECTIVE #2: Discuss the treatment options for known or suspected multidrug-resistant latent TB infection (MDR-LTBI)

CASE: A 72 year old retired physician was referred to the Infectious Diseases clinic for assessment and management of a remote positive Mantoux skin test and known exposure to multidrug-resistant tuberculosis (MDR-TB), in the setting of recently initiated chemotherapy for MM. His past medical history is significant for COPD, 40 pack year smoking history, obstructive sleep apnea, previous non-TB mycoplasma pneumonia, hypertension, adult mumps, and peripheral neuropathy. He has had a chronic, minimally productive cough for several years thought to be due to his COPD. He denied hemoptysis, fevers, chills, anorexia or night sweats. He was beginning to regain some of the weight he lost while caring for an ill close relative. His chemotherapy regimen includes Melphalan 18 mg PO OD and Prednisone 125 mg PO OD for 4 days followed by Bortezomib SC weekly for 4 weeks (per cycle). His physical examination only revealed mild bibasilar crackles which have been present for many years. Biochemistry demonstrated anemia and hypercalcemia but normal renal function. Skeletal survey shows lytic lesions in the cranium and left proximal humerus consistent with MM. Chest X-ray revealed a small right middle lobe calcified granuloma, first detected in 1983, prior to the development of a positive Mantoux test in April 1989 with an induration of 23 mm. Dr. X had cared for multiple patients with active pulmonary TB as well as a known case of cavitary pulmonary MDR-TB resistant to isoniazid and rifampin in the winter of 1989. His LTBI was assessed by a physician in 1989 who decided to observe him closely without chemoprophylaxis. The decision regarding current treatment for Dr. X was particularly challenging given that risks of reactivation TB in patients with MM receiving Melphalan/Prednisone/Bortezomib therapy is not well described. Similarly, there is little evidence on optimal management of MDR-LTBI. After a detailed literature search and consultation with experts in the field, the ID team opted to treat Dr. X for MDR-LTBI with Moxifloxacin and Ethambutol for at least 9 months.

DISCUSSION: A decision regarding treatment of LTBI requires an estimate of risk for development of active TB, as well as an understanding of the efficacy of treatments and associated adverse effects of selected therapy. Two retrospective Korean case series described the rate of developing active TB in patients receiving Bortezomib-based chemotherapy for MM. The first included 115 patients on Bortezomib and reported a 7 % rate of developing active TB over 6 years of observation. The second reviewed 285 patients over 8 years and reported a rate of only 1.1 %. The varying rates between trials were postulated to be secondary to different combinations of adjunctive steroids and chemotherapeutic agents used in each regimen. Moreover, these rates are not easily transferable to the Canadian patient population but suggest that the risk of reactivation TB could be significant. One case-control study by Jick et al. described an almost 5 fold increase in risk of developing new TB while receiving high dose steroid treatment. However, there is limited information on the rates of reactivation in patients with latent TB on steroids. Additionally, we found no data on the risk of reactivation TB with Melphalan therapy. In terms of treatment options for MDR-LTBI, the 2013 Canadian Standards suggest 9 months of fluoroquinolone monotherapy. One Italian study from 2006 demonstrates limited serious side effects of moxifloxacin used for an average of 6.3 months; however, this data is derived from a single centre and small sample size. In the US, consensus recommends combination therapy with oral fluoroquinolone and ethambutol for a greater duration of 12 months. A recent prospective study from Micronesia supports the practical feasibility of this approach in which daily moxifloxacin or levofloxacin plus ethambutol for a total of 12 months was well tolerated and effective in treating MDR-LTBI in the setting of contact tracing. Hence, based on review of the literature and consultation with TB experts, a decision was made to use combination therapy in our case. Nonetheless, optimal management of MDR-LTBI remains extremely challenging, particularly in the setting of chemotherapy. Further investigation is required to better estimate the risk of reactivation of LTBI during cancer treatment with novel chemotherapeutic agents, and to gain an understanding of the level of immunosuppression induced by them.

A UNIQUE CASE OF REFUSAL TO SIT Asma Khatoun¹; Leigh K. Hunter². ¹Methodist Dallas Medical Center, Dallas, TX; ²Methodist Hospitals of Dallas, Dallas, TX. (Tracking ID #2171147)

LEARNING OBJECTIVE #1: Fusobacterium is a gram-negative, non-sporeforming bacterium widely known as a human and animal pathogen. Fusobacterium's exceptional ability to adhere to both gram-negative and gram-positive plaque microorganisms in biofilms (specifically in soft tissue) makes it a highly invasive microbe. Primarily given attention for its periodontal implications, strains of Fusobacterium have been identified as pathogen in many parts of the body. We present an unusual case of vertebral osteomyelitis caused by Fusobacterium species with bacteremia and sepsis syndrome.

CASE: A 49 year old Hispanic man with past medical history of alcoholic liver cirrhosis, injection drug abuse, and chronic anemia presented to the emergency department (E.D.) with a two month history of right sided lower back pain just above the iliac bone. The pain was insidious in onset over 2 months and progressively worsened to the point of being constant, non-radiating, stabbing, aggravated by sitting and minimally relieved by walking. This pain was accompanied by intermittent, low-grade subjective fevers. Upon arrival, his vital signs were: T: 99 °F, HR: 104/min, RR: 20/min and BP: 130/85 mmHg, SaO₂: 99 % on room air. Physical examination was remarkable for poor dentition, jaundice, scleral icterus, 2+ pitting, bilateral pedal edema, asterixis, and caput medusae on a visibly distended abdomen with ascites. Straight leg raising test was negative and the patient had full mobility of the spine with no point tenderness noted. Laboratory data was significant for anemia, thrombocytopenia, mild hyponatremia, hyperbilirubinemia and ESR of 10 mm/hr and CRP of 35 mg/L. The patient was admitted for evaluation of persistent low back pain and possible sepsis. Blood cultures drawn on admission were negative. Thoracolumbar spine CT revealed lumbar spondylosis, facet arthropathy and multilevel spinal stenosis. MRI confirmed the CT results, but also revealed a partially destructive pattern involving T9-T10 with decreased T1 brightness and an epidural mass 5.7 mm×3.2 cm×5 mm positioned posterior-dorsal to T9-T10 interspace with the most likely etiologies being metastatic involvement of thoracic spine with epidural extension vs. vertebritis and discitis. The right para-midline spinal canal was narrowed to approximately 4 mm by protrusion of material arising from disk interspace. Neurosurgery was consulted regarding these findings and recommended biopsy of the mass in question. The patient developed fever with associated leukocytosis prompting resubmission of blood cultures and initiation of empiric vancomycin and piperacillin/tazobactam. Anaerobic bottles of both blood culture sets became positive for gram-negative rods at 3 days and subsequently the organism was identified as *Fusobacterium* species. Bone biopsy demonstrated abundant acute inflammation, focal necrosis and scant bone necrosis. No AFB, fungal organisms or malignant cells were identified, but anaerobic cultures ultimately grew *Fusobacterium*. Therapy was switched to Penicillin G 18 million units/day IV for 14 days and metronidazole 500 mg PO QID for a minimum of 42 days while following clinical response and ESR and CRP. Blood cultures cleared quickly and 2 weeks later, inflammatory markers were within normal limits and pain was improved.

DISCUSSION: Upon literature review, it was found that only 14 other cases of *Fusobacterium* vertebral osteomyelitis have been reported to date. In all instances, patients had relatively depressed immunity. Although *Fusobacterium* is a common occupant in human oropharynx and female genital tract, current consensus is that it should always be considered a pathogen. Most notable for its appearance in polymicrobial infections with abscess formation, *Fusobacterium* can be a standalone pathogen with hematogenous spread to regions well beyond head and neck, causing skin ulcers, long bone infections, Lemierre's disease, and is also seen in patients with colon cancer. It produces extracellular toxins that facilitate epithelial barrier breach, host mucosal invasion and immune system evasion. In the patient described above, upper GI endoscopy was within normal limits and patient refused colonoscopy. The presumptive source of infection was his carious teeth. The objective of this abstract is to highlight the virulence of *Fusobacterium* and its significant associated morbidity. Early recognition and aggressive, appropriate therapy may prevent long term sequelae in such patients.

A WOLF IN SHEEP'S CLOTHING Matthew L. Law, Tulane University Health Sciences Center, New Orleans, LA. (Tracking ID #2198623)

LEARNING OBJECTIVE #1: Recognize the importance of *Staphylococcus lugdunensis* infections

LEARNING OBJECTIVE #2: Understand the pathogenesis of *Staphylococcus lugdunensis* endocarditis

CASE: A 51 year-old woman presented with 3 days of persistent vertigo and nausea. She had end-stage renal disease, is on hemodialysis, and had HIV with a recent CD4 count of 105. Physical exam showed a 3/6 systolic murmur noted throughout the precordium, which was new from exam 4 weeks prior. Blood cultures consistently returned coagulase negative staphylococcus with eventual speciation into *Staphylococcus lugdunensis*. Initial transthoracic echocardiogram performed on admission showed no vegetations; repeat transthoracic echocardiogram, after persistently positive blood cultures, revealed a new vegetation on the mitral valve. Based on these findings, she was diagnosed with *S. lugdunensis* native valve endocarditis. A transesophageal echocardiogram was not performed and patient was deemed not to be a surgical candidate. Upon further view of her recent medical history, she revealed that 2 weeks prior she had a revision of her AV fistula due to difficulty with access. After 10 days of antibiotics, blood cultures returned sterile and the patient was discharged home with IV antibiotics and repeat follow-up echocardiogram.

DISCUSSION: Internists often encounter vague complaints, especially when dealing with patients on chronic hemodialysis; infection as a potential cause for these symptoms always needs to be considered. *Staphylococcus lugdunensis* was not formally recognized until 1988 when it was isolated in Lyon, France; however most likely this is not a

new infection. Early studies described it as a skin commensal, but more recently it has been found to preferentially colonize the perineal region and is rarely found in the anterior nares of hemodialysis patients. Frequently, *S. lugdunensis* is misdiagnosed as *Staphylococcus aureus*. Some isolates of *S. lugdunensis* are able to produce a membrane-bound form of the enzyme, clumping factor, which yields a positive result on coagulase testing potentially leading to the misidentification of the organism as *S. aureus*. Misidentification of *S. lugdunensis* as a *S. aureus* infection is not critical to treatment as *S. lugdunensis* virulence is more similar to *S. aureus* than other coagulase negative staphylococcus, and treatment for both is similar. Endocarditis caused by staphylococci accounts for approximately 20 to 35 % of native valve endocarditis with the majority of these infections being caused by *S. aureus*. Most of the coagulase-negative staphylococcus endocarditis are caused by *S. epidermidis* (especially prosthetic valves); however *S. lugdunensis* is emerging as a common cause of native valve endocarditis. Case reports have shown three patients on chronic hemodialysis with *S. lugdunensis* endocarditis. All three patients had AV fistula revision before the infection. This increased virulence of *S. lugdunensis* is attributed to its ability to bind to fibrinogen to extracellular matrix proteins (a typical trait of *S. aureus*), and it seems to have an increased affinity for causing embolism more so than other coagulase negative staphylococcus. Given the increased virulence, *S. lugdunensis* should be aggressively treated with both medical and possibly surgical intervention if necessary. Currently, it remains sensitive to a large number of antimicrobials, including methicillin. Persistently positive blood cultures for coagulase negative staphylococcus should be treated as a potential *S. lugdunensis* infection until speciation occurs to rule out this virulent and potentially deadly infection.

A YOUNG MALE WITH RECURRENT PNEUMONIA- LET'S THINK BEYOND THE BOX Dipti Baral¹; Bhishma Pokhrel²; Dinesh Subedi¹. ¹SUNY Upstate Medical University, Syracuse, NY; ²National Academy of Medical Sciences, Kathmandu, Nepal. (Tracking ID #2196711)

LEARNING OBJECTIVE #1: Consider the possibility of anatomic abnormalities in recurrent pneumonia

CASE: A 24-year-old male presented to the hospital with 2 months history of exertional dyspnea and 4 days history of moderate left sided pleuritic chest pain radiating to the back. He denied fever, chills, cough, hemoptysis, night sweats, weight loss and recent travel. Patient had been treated for two separate episodes of pneumonia in the last 4 months. Past medical history and family history was otherwise non-significant. On examination, he was slightly tachycardic. Rest of the physical exam including respiratory system exam was normal. Labs revealed complete blood counts of $14 \times 10^9/L$ with 75 % neutrophils. Human immunodeficiency virus test was negative. Chest X-ray showed left lower lobe opacity. He was treated on antibiotics for community acquired pneumonia. Review of previous chest X-rays and computed tomography (CT) of the thorax revealed severe consolidation in left lower base. CT angiogram of thorax later during this admission showed 9 cm well-defined area of low attenuation in the left lower lobe with dedicated pulmonary arterial and venous drainage and resolving superimposed infection within the area. A radiologic diagnosis of congenital pulmonary airway malformation (CPAM) was made. He underwent open thoracotomy with left lower lobe lobectomy. Pathologic examination demonstrated a relatively well demarcated lesion characterized by multiple bronchiole-like structures scattered within the alveolated parenchyma and 1.5×1.5 cm thin walled cyst with multiple air filled microcysts at its periphery. The final diagnosis was type 2 CPAM. Patient was doing well at 3 months' follow up.

DISCUSSION: In otherwise healthy individuals presenting with recurrent pneumonia, cause for repeated infections needs to be sought. If the same location is involved repeatedly, then any anatomic abnormality in the area needs to be considered. CPAM, previously known as congenital cystic adenomatoid malformation (CCAM) is a rare cystic lung disease with an estimated incidence of 1:25,000-1:35,000 births. With increasing use of ultrasound in pregnancy, CPAM is more frequently diagnosed prenatally. However occasionally, it may remain asymptomatic or present later in life with recurrent pulmonary infections, hemoptysis or pneumothorax. In adults, CPAMs are most commonly seen in the lower lobes. CPAM are categorized into type 0 to 4 based on where the malformation occurred within the tracheo-bronchial tree and at which stages of lung development. Given the increased risk of malignancy and recurrent infections, surgical resection is recommended in CPAM. Careful review of history and images can reveal congenital lesions like CPAM. Surgical resection prevents potential malignancy and further episodes of pneumonias in CPAM.

ACUTE ALCOHOL WITHDRAWAL-ASSOCIATED TAKOTSUBO CARDIOMYOPATHY Qiyuan Liu; Regina Felkner; John Schultz; Haley Ballard. University of South Alabama, Mobile, AL. (Tracking ID #2195239)

LEARNING OBJECTIVE #1: Recognize and manage acute alcohol withdrawal-associated Takotsubo Cardiomyopathy

CASE: A 60-year old white male with past medical history of alcohol abuse, delirium tremens, and subdural hematoma reported to the Emergency Department because of fall secondary to generalized weakness for 2 days. He did not have loss of consciousness or seizure activity. The patient consumed 1 gal of liquor per day for the past 30 years, with the last consumption being 3 days before admission. Physical examination was unremarkable except for generalized weakness. Tests showed potassium 2.8 mmol/L, bilirubin 3.8 mg/dL, total protein 7.4 g/dL, albumin 2.7 g/dL, ALT 158 units/L, and AST 339 units/L. The alcohol level was undetectable. The hypokalemia was appropriately corrected, and his asthenia improved. However, the patient developed acute alcohol withdrawal symptoms and was given lorazepam. Four days after admission, the patient developed sinus tachycardia with heart rate at 160. The chest x-ray showed bilateral pulmonary edema. The brain natriuretic peptide (BNP) was 4000 pg/ml. Though electrocardiogram showed no ST change, the troponin was moderately elevated to 0.15. Transthoracic echocardiogram (TTE) four days after admission showed a left ventricular ejection fraction (LVEF) at 25–30 % with a large area of mid to apical akinesis to dyskinesis suggestive of apical ballooning. The left heart catheterization (LHC) revealed non-ischemic cardiomyopathy with LVEF of 45 %, anterior apical and inferior apical severe hypokinesis. The patient was treated with the standard heart failure medical regimen including aspirin, furosemide, atenolol and furosemide. His symptoms improved with appropriate diuresis, and the patient was discharged home with the same regimen.

DISCUSSION: This patient presents with clinical features that met the Mayo Clinic diagnostic criteria for Takotsubo cardiomyopathy: 1) Transient hypokinesis, akinesis, or dyskinesis of the left ventricular mid segments with apical involvement; 2) Absence of obstructive coronary disease or angiographic evidence of acute plaque rupture; 3) New ECG abnormalities (either ST-segment elevation and/or T wave inversion) or modest elevation in cardiac troponin; 4) Absence of pheochromocytoma or myocarditis. The LHC four days after TTE showed improved LVEF from 25 to 30 % to 45 %. The patient reported improved tolerance of physical activities back to his baseline in the outpatient follow up 3 weeks later. Hemodynamically stable patients of Takotsubo cardiomyopathy are generally treated with diuretics, angiotensin-converting enzyme inhibitors and beta-blockers. To reduce the risk of thromboembolism, antiplatelet or anticoagulant therapy should be considered in the patients with loss of motion of left ventricular apex until the contractility of the apex is improved. Regarding the long-term management of Takotsubo cardiomyopathy, no data support the continuous use of these drugs for the prevention of Takotsubo cardiomyopathy recurrence or improvement of survival rate. After the left ventricular function normalizes, these drugs may be discontinued if they have no other indications for use. The pathophysiology of Takotsubo Cardiomyopathy has been postulated to involve excess catecholamine release precipitated by an acute emotional or physical stressor, and acute alcohol withdrawal is a well-described state of excessive adrenergic activity. However, Takotsubo cardiomyopathy in the context of acute alcohol withdrawal has been only rarely described. It is important for an internist to recognize this condition and provide the appropriate care to the patient.

ACUTE INFECTIOUS PURPURA FULMINANS, A CAUSE OF PURPLE DIGITS Hyejo Jun. University of Pittsburgh Medical Center, Pittsburgh, PA. (Tracking ID #2188846)

LEARNING OBJECTIVE #1: To describe the differential diagnoses for the purple/black digit

LEARNING OBJECTIVE #2: To review the pathophysiology of acute infectious purpura fulminans

CASE: The patient is a 52-year-old Caucasian male with a history of heavy tobacco use and epidermolysis bullosa simplex (EBS) who was transferred from an outside hospital with persistent black discoloration of the fingers and toes. The patient initially presented to the outside hospital 1 week prior to transfer with painful hands and feet, with rapid progression to purple and black discoloration of the fingers and toes. Vital signs revealed hypotension but no fever. Laboratory examination demonstrated leukocytosis with considerable bandemia, thrombocytopenia, acute kidney injury, and transaminitis. Urine drug screen was negative for illicit substances. Gram stain of the blood showed gram-negative rods but an organism could not be speciated despite multiple blood cultures. Peripheral smear demonstrated profound thrombocytopenia and sudden increase in granulocytes with marked left shift that, in light of the clinical picture, suggested DIC. Coagulation times were not available, but d-dimer was reportedly very elevated. The patient was started on aggressive fluid resuscitation and broad-spectrum antibiotics for septic shock complicated by DIC. No pressor support was initiated but the patient did receive 2 packs of platelets. Further diagnostic work up was notable for a normal ANA, ANCA, cryoglobulins, cold hemagglutinins, HIV, and hepatitis panel. Pan-CT was unremarkable. Lower extremity dopplers and MRA (which reached only up to the level of the ankles) revealed patent vessels. ABIs of the upper and lower extremities were normal but photoplethysmography showed no pulse amplitudes distally in the digits and toes. After

the patient was stabilized and acute kidney injury and thrombocytopenia resolved, the patient was transferred to our hospital for further management of persistent black fingers and toes. Physical examination upon admission to our hospital was remarkable for normal vital signs, necrosis of nearly all fingers and toes to the metatarsophalangeal articulations, bullae around the feet, necrosis of the tip of the nose, and palpable radial and pedal pulses. Repeat blood cultures showed no growth. Our own laboratory obtained the blood cultures from the outside hospital, but again, an organism could not be speciated. An upper extremity angiogram showed sluggish flow in the digital and palmar arteries, and superficial hand biopsy showed no evidence of vasculitis. Culture of the biopsy was unrevealing. Discussion with our consultants in Rheumatology, Dermatology, Vascular Surgery, and Plastics Surgery, yielded the most likely diagnosis being ischemic injury from sepsis, or acute infectious purpura fulminans. The decision was made to allow the areas of necrosis to demarcate and minimize the extent of amputations. The patient was discharged with a 2-week course of piperacillin-tazobactam after consultation with ID. Vascular surgery performed bilateral Choparts and left small finger amputations and he is now following up closely for wound care.

DISCUSSION: This case demonstrates an interesting manifestation of septic shock. Our initial differential diagnoses included Buerger's disease, vessel thrombosis, small-vessel vasculitis, or vessel thrombosis. Buerger's disease was thought to be less likely as it is not known to cause such systemic injury. Acute arterial thrombosis or emboli were less likely as the patient had palpable pulses diffusely. There was no evidence of vasculitis on laboratory or pathologic examination. Urine drug screen was negative for cocaine, which made levamisole-induced vasculitis unlikely. The patient denied a history of trauma or cold related symptoms. Given the clinical history of septic shock with GNRs on gram stain, acute infectious purpura fulminans was thought to be the most likely diagnosis. The presentation was thought not to be a flare of the patient's underlying EBS, though perhaps it made the patient more susceptible to injury. There are idiopathic versions of purpura fulminans, but infectious purpura fulminans is considered the more common. Meningococcus is one of the most common pathogens, and disease occurs due to a disturbance between anticoagulant and procoagulant endothelial cell activity, mediated by bacterial endotoxin and other inflammatory markers. What was surprising was that an organism that caused such systemic injury to the patient was unable to be grown, on multiple cultures, at both hospitals. This subjected the patient to a prolonged course of a broad-spectrum antibiotic without the ability to narrow coverage based on susceptibility. In the end, the patient was fortunately saved from more extensive amputations. This case affords an opportunity to review differential diagnoses for the purple digit and the pathogenesis for acute infectious purpura fulminans.

ACUTE MYOCARDIAL INFARCTION IN A MALE YOUNG PATIENT—IT'S NOT JUST THE SMOKING! Navdeep Kaur. Presence Saint Francis hospital, Evanston, IL. (Tracking ID #2198895)

LEARNING OBJECTIVE #1: Review the non-traditional risk factors for acute myocardial infarction in young patients.

LEARNING OBJECTIVE #2: Recognize the diagnostic criteria and management of antiphospholipid syndrome.

CASE: A 30 year old African American male with no significant past medical history presented with intermittent chest pain, numbness and tingling of his left arm, and diaphoresis for 2 days. Patient had no family history of early onset Coronary Artery Disease (CAD). Patient did have 10 pack year smoking history. Vital signs were stable and physical examination as otherwise unremarkable. Initial EKG showed sinus rhythm with anterolateral ST depression. Laboratory studies revealed elevated serum Troponins (0.14 and 0.19). Urine toxicology screen was negative for cocaine. Patient continued to have chest pain and repeat ECG in 1 h showed frequent premature ventricular complexes in a pattern of bigeminy with anterolateral ST depression. Left heart catheterization was done which showed subtotal ostial LAD stenosis with thrombus. Successful thrombectomy was done with aspiration catheter and residual lesion less than 40 %. Due to proximity of LAD stenosis to left main, no stent was placed. Patient was started on strict medical management with aspirin, clopidogrel, statin and beta blocker. On day 4 of admission, patient again developed chest pain. Repeat EKG showed ST elevation in anterolateral and inferior leads and patient was taken for repeat cardiac catheterization that showed subtotal stenosis of LAD. Successful PCI with placement of bare metal stent was done. Lab work showed positive lupus anticoagulant. Anti cardiolipin and anti beta 2-glycoprotein antibodies were negative. Work up for SLE was negative. He was started on warfarin, bridged with enoxaparin. His homocysteine level was elevated to 40Umol/L, vitamin B12 levels were low (88 pg/ml) with positive intrinsic factor antibodies. He was started on vitamin b12 replacement injections. He was discharged on dual antiplatelet therapy and warfarin. At 6 month follow up, repeat lupus anticoagulant was positive, thus confirming the diagnosis of anti-phospholipid antibody syndrome. Patient was continued on life-long anticoagulation with warfarin.

DISCUSSION: The antiphospholipid syndrome (APS) is an autoimmune disorder, characterized by the presence of venous or arterial thrombotic event and/or thrombotic events related to pregnancy and positive laboratory tests for antiphospholipid antibodies (anticardiolipin, ant-beta 2-glycoprotein or lupus anticoagulant) on two or more occasions at least 12 weeks apart. APS occurs either as a primary condition or in the setting of an underlying disease, particularly systemic lupus erythematosus (SLE). The most common presenting manifestation in APS is deep vein thrombosis of the lower limbs (32 %). Acute Myocardial infarction (MI), like in our patient is the first manifestation of APS in only about 2.8 % of patients. Additional risk factor in our case was hyperhomocysteinemia due to vitamin B12 deficiency with pernicious anemia. Hyperhomocysteinemia appears to be an independent risk factor for CAD but a benefit from lowering the homocysteine concentration on cardiovascular disease remains unproven. A young patient with Acute MI should thus be evaluated for non-traditional risk factors like APS, hyperhomocysteinemia, factor V Leiden mutation, abnormal lipoprotein levels, and protein C or S deficiency. Smoking history and/or other drug use might not always be the culprit. Challenge in treatment of such patients is the need for aggressive life long anticoagulation while considering the risks of bleeding. Our patient was thus continued on life-long anticoagulation with warfarin with close monitoring.

ACUTE RENAL INFARCT CASE SERIES Tariq M. Yousuf¹; Edgar V. Lerma²; Hina Iqbal¹. ¹Advocate Christ Medical Center, Oak Brook, IL; ²University of Illinois at Chicago College of Medicine/ Associates in Nephrology, SC, Berwyn, IL. (Tracking ID #2196836)

LEARNING OBJECTIVE #1: Recognize the clinical features associated with acute renal infarction and the importance of considering this diagnosis in patients presenting with acute kidney injury. Acute Renal Infarction is a commonly under-diagnosed condition. Acute renal infarction usually presents with the constellation of signs and symptoms of abdominal or flank pain, elevation of LDH, elevation of white blood count, hematuria, oliguria or anuria, fever, nausea, vomiting and occasionally elevation of liver enzymes. Differential diagnosis includes acute appendicitis, nephrolithiasis, cholecystitis, urinary tract infection, biliary pathology or even mesenteric Ischemia. This report will hopefully highlight the rarity of acute renal infarction and the importance of considering the diagnosis of acute renal infarction in patients presenting with acute kidney injury. The myriad of findings of 1) acute abdominal pain or flank pain, 2) elevation of LDH and 3) a high risk of thromboembolism in a patient presenting with acute kidney injury should make the astute clinician consider the possibility of acute renal infarction in the differential diagnosis.

CASE: Case 1 is a 55 year old male with a past history of coronary artery disease s/p stent placement, AAA s/p repair and atrial fibrillation who presented to the emergency room with a 2 day history of intractable abdominal discomfort localized to the left flank and right lower quadrant (RLQ) with radiation to the right femoral area. On physical exam, the patient was in moderate distress and had significant tenderness over the RLQ. In addition, he also had notable left sided costovertebral angle tenderness. Pertinent laboratory studies included: WBC of 8.0, creatinine of 1.41mg/dL and INR of 1.2. He was known to be non-compliant with warfarin anticoagulation. CT of abdomen revealed areas of decreased perfusion involving the lower pole of the right kidney with perinephric stranding, new occlusion of the left internal iliac artery and aneurysms involving the right common iliac artery as well as both common femoral arteries. Duplex ultrasonography revealed the presence of aneurysms in both common femoral arteries and increased velocity in the right proximal third of the renal artery. Patient was afforded supportive measures and an adequate analgesic regimen and subsequently showed significant clinical improvement as well as resolution of laboratory abnormalities. Case 2 is that of a 53 year old male who has a past history of chronic kidney disease and atrial fibrillation who presented to the emergency room with an acute onset of abdominal discomfort localized to the left flank with radiation to the back. Physical exam revealed stable vitals and an irregular pulse. On examination, he had left CVA tenderness. Initial labs revealed creatinine of 3.5mg/dL, INR of 1.7 and significantly elevated LDH (1323). CT scan of the abdomen demonstrated the absence of the right kidney. A MAG3 nuclear medicine scan revealed diminished flow to the left kidney. A CT angiogram revealed evidence of thrombus in the left renal artery. He was then started on anticoagulation with heparin and a wire guided thrombolysis with thrombectomy was performed. Although there was brisk urine output production post-procedure, there was no evidence of renal recovery in the ensuing days; therefore, he was subsequently initiated on hemodialysis.

DISCUSSION: Acute renal infarction is a commonly missed phenomenon and it should be high on the list of differential diagnosis if a patient presents with abdominal pain, elevated LDH and predispositions to increased risk of thromboembolism. The mainstay of treatment remains to be appropriate anticoagulation. Our cases demonstrate acute renal infarction likely secondary to atrial fibrillation with and without therapeutic anticoagulation. Atrial fibrillation, as the most common arrhythmia identified in

hospitalized patients, warrants increased awareness of its association with acute renal infarction so that it can be promptly recognized and managed appropriately.

ADEM: ACUTE DISSEMINATED ENCEPHALOMYELITIS OR A DISEASE EASILY MISSED? Naveen Nannapaneni²; Joseph Buensalido²; Jonathan A. Cohn¹. ¹Wayne State University, Detroit, MI; ²Wayne State University, Royal Oak, MI. (Tracking ID #2190168)

LEARNING OBJECTIVE #1: Recognize the clinical features of acute disseminated encephalomyelitis.

CASE: Acute disseminated encephalomyelitis (ADEM) is an inflammatory response in the brain most often seen after a viral infection. It typically manifests with acute onset and rapid in progression encephalopathy, motor, and sensory deficits. It can be overlooked when evaluating patients with acute encephalopathy, as presented in our case. A 65-year-old male with diabetes, hypertension and coronary artery disease was transferred from an outside hospital to the neurology intensive care unit due to concerns for status epilepticus. His family reports that three days prior he was found unarousable from sleep and brought via EMS to the hospital after a 2-day antecedent history of a non-productive cough, nasal congestion and chills which were not improved with trimethoprim-sulfamethoxazole. He travelled to both India and Sri Lanka one month ago and to Florida twice since then, receiving a flu vaccine but no malaria prophylaxis prior to all his travel. His wife, who accompanied him on all trips, reported having similar symptoms and that neither experienced headaches, nuchal rigidity or photophobia. Upon presentation to the outside hospital his vitals were stable but he required intubation as physical exam revealed an inability to protect his own airway. Initial chest and abdominal radiographs were negative for acute processes. CT head/angio, MRI brain and brain perfusion studies were also without acute abnormalities. He received vancomycin, cefepime, ampicillin, doxycycline and acyclovir in addition to dexamethasone empirically for meningitis. Two days later a lumbar puncture revealed a monocyte predominant pleocytosis, WBC 89 cells/mL, protein 73 mg/dL, glucose 97 mg/dL with an unremarkable Gram stain. He was suspected to have generalized seizures when weaned off propofol and was transferred to our facility as a result. Infectious Disease was consulted and recommended replacing cefepime with ceftriaxone for treatment of meningitis pending culture finalization. His extensive microbiologic cultures, serologies and PCRs in both blood and CSF did not reveal a causative pathogenic organism and his antibiotics were discontinued and the differential narrowed to ADEM. Within 48 h he was successfully weaned from propofol and extubated without recurrence of seizures and returned to his neurologic baseline, ultimately being discharged without further complication.

DISCUSSION: While a multitude of confounding variables in this case- antecedent antibiotic use prior to cultures (both at home and in the hospital), recent international and domestic travel, and a history of sick contacts- resulted in a broad initial differential, a systemic evaluation was able to rule out many of the potential causes. His history of a precursor upper respiratory infection, rapidly deteriorating encephalopathy, and swift improvement with dexamethasone all support a diagnosis of ADEM. Further substantiation can be provided with MRI findings of demyelination, but are not compulsory for diagnosis. Treatment relies on immune suppression with glucocorticoids as the first-line therapy as the purported pathogenesis is autoimmune in nature. Our case provides a cautious reminder to the inclusion of ADEM in the differential for causes of acute encephalopathy as its rarity leads many to overlook it as a possible diagnosis.

ADULT INTUSSUSCEPTION CAUSED BY VISCERAL KAPOSI 'S SARCOMA IN A PATIENT WITH CD4 COUNT OVER 200 Emory Hsu¹; Varun Phadke¹; Maria M. Rivera⁴; Schuyler D. Livingston³; Minh Nguyen². ¹Emory University, Atlanta, GA; ²Emory University SOM, Atlanta, GA; ³Emory University School of Medicine, Decatur, GA; ⁴Virginia Commonwealth University, Richmond, VA. (Tracking ID #2199457)

LEARNING OBJECTIVE #1: Recognize Kaposi's sarcoma in HIV infected individuals even in the setting of antiretroviral therapy

LEARNING OBJECTIVE #2: Recognize intussusception as an etiology of abdominal pain in an adult with Kaposi's sarcoma

CASE: A 39 year old Nigerian female presented with several weeks of odynophagia, crampy abdominal pain, fatigue, and decreased oral intake. She had been previously healthy until one year prior to admission, when she began to experience unintentional weight loss. Eight months prior to admission, she developed violaceous plaques on her extremities, face, and trunk. She was subsequently diagnosed with human immunodeficiency virus (HIV) infection with an initial CD4 count of 144 cells/mm³, and initiated on antiretroviral therapy (ART) with a fixed-dose combination of efavirenz, emtricitabine, and tenofovir. After 5 months of therapy, her CD4 count had increased to 240 cells/mm³. One month prior to admission, she developed oropharyngeal and abdominal pain, exacerbated by food intake and associated with nausea, but no diarrhea, hematochezia, or

melen. She also reported bilateral swelling of her lower extremities, as well as severe fatigue. Upon admission, the patient was afebrile, with a heart rate of 100 beats per minute, and a blood pressure of 102/47. Her weight was 54 kg (body mass index of 18.25 kg/m²). A focused physical exam demonstrated cachexia, palpable lymphadenopathy, diffuse abdominal tenderness, moderate pitting edema to the thighs bilaterally, and multiple violaceous papules of variable size on the trunk, face, and extremities. Laboratory testing demonstrated a CD4 count of 274 cells/mm³. Computed tomography of the abdomen and pelvis demonstrated numerous intestinal and peritoneal masses, as well as large bowel intussusception. An exploratory laparotomy with resection of the largest masses and a right hemicolectomy were performed. Pathology confirmed a diagnosis of gastrointestinal Kaposi's sarcoma (KS). Post-operatively, the patient experienced multiple bouts of abdominal pain and distention confirmed with repeat imaging to be due to recurrent intussusception. She was managed non-operatively, but required intensive care support for hypotension. Chemotherapy was initiated with liposomal doxorubicin. Her ART was changed to intravenous zidovudine, subcutaneous enfuvirtide, and oral liquid darunavir and ritonavir to maximize bioavailability given presumed gastrointestinal malabsorption. By post-operative day 30, she had marked symptomatic improvement, and repeat abdominal imaging demonstrated resolution of her obstructive pattern and intussusceptions. On hospital day 50, the patient was discharged to home.

DISCUSSION: Kaposi's sarcoma (KS) is an angioproliferative disorder caused by infection with human herpes virus 8 (HHV-8), whose incidence is greatly increased in individuals with HIV and in particular those with CD4 counts of less than 200 cells/mm³ (Antman 2000). The cutaneous form is the most common manifestation, with widely distributed violaceous plaques and nodules. Visceral KS is less common, and can involve the oral cavity, gastrointestinal tract, and respiratory tract. Symptoms are non-specific and include abdominal pain, weight loss, nausea, vomiting, dyspnea, and hemoptysis. Intussusception is a relatively rare complication of visceral KS, and can affect both children and adults. In children, intussusception is a more commonly encountered diagnosis than in adults, though mortality is still high when KS is the cause (Ramdial 2010). The first reported case of an adult with intussusception due to KS was in 1988 (Hofstetter 1988), prior to the era of combination ART. Visceral KS can occur in patients lacking dermatological findings, such as in a 42 year old HIV positive man who presented with ileocolic intussusception despite having no skin lesions (Nidimusili 2013). In another case, a 31 year old man had presented with abdominal pain, and was found to have ileal intussusception leading to a diagnosis of both visceral KS and HIV/AIDS (Wang 2002). Notably, these patients were not on ART, and had CD4 counts under 200 cells/mm³. However, an increasing number of KS diagnoses are being made in individuals with higher CD4 counts (Crum-Cianflone 2010). Maurer et al. described a small cluster of patients with CD4 counts greater than 300 cells/mm³ who nevertheless presented with KS (Maurer 2007). These nine patients only had limited cutaneous disease, without visceral involvement. Our patient, who was on ART and had a CD4 count of 274 cells/mm³, presented with intussusception secondary to extensive visceral KS requiring cytoreductive surgery. Exacerbation or unmasking of KS in the context of ART initiation has been previously described as attributed to immune reconstitution inflammatory syndrome (IRIS), but symptoms typically manifest within 3 months of ART initiation (Leidner 2005; Weir 1997). Thus, further exploration of the etiology that underlies the clinical heterogeneity of KS in HIV-infected patients is warranted.

AFOP'S TALE Jose Garza; Angela Christensen; Hana Safah. Tulane University Health Sciences Center, New Orleans, LA. (Tracking ID #2198245)

LEARNING OBJECTIVE #1: Recognize the clinical presentation and histology of interstitial pneumonia

LEARNING OBJECTIVE #2: Review etiologies of acute fibrinous and organizing pneumonia

CASE: A 59 year-old man presented with an episode of hemoptysis and mild dyspnea on exertion. Three months prior, he had experienced progressive fatigue and a ten-pound weight loss. He denied night sweats, fever, chills, or sick contacts. The patient had a 40-pack year history of smoking. He had been treated for myelodysplastic syndrome with transformation to acute myelogenous leukemia with azacitidine, pegfilgrastim, and decitabine. His vitals were stable. He had no head, neck, or axillary lymphadenopathy. He had decreased breath sounds throughout all lung fields with no crackles, wheeze, egophony, or dullness to percussion. He was pancytopenic. HIV, serum cryptococcal antigen, urine histoplasma antigen, KOH smear, serum fungitell, and B-galactomanin were negative. Fungal blood cultures and routine blood cultures were negative. Three sets of sputum cultures for AFB were negative. CT scan of the thorax revealed extensive hilar lymphadenopathy, left lung nodular opacities, and a 5.0 by 4.6 by 3.1 cm irregular mass along the lateral right major fissure. Bronchoalveolar lavage was non-diagnostic by cytology. Routine culture results from lavage were no growth and AFB smear and KOH

smear were negative. Histology from transbronchial biopsy revealed acute fibrinous and organizing pneumonitis.

DISCUSSION: Acute Fibrinous and Organizing Pneumonia (AFOP) is an unusual variant of idiopathic interstitial pneumonia. It was first described by Beasley et al. in 2002 as a histological pattern differing from that of diffuse alveolar damage (DAD), bronchiolitis obliterans with organizing pneumonia (OP), and eosinophilic pneumonia (EP). Symptoms are similar to that of other infiltrative lung diseases, including dyspnea, fever, non-productive cough, and hemoptysis. Radiographic findings vary along the spectrum of basilar dependent consolidations and ground glass opacities to focal and diffuse parenchymal abnormality. Diagnosis is made by a distinct histologic pattern characterized by the presence of intra-alveolar fibrin, fibrin deposition in a patchy distribution, lack of hyaline membranes, and the absence of noticeable eosinophils. Due to the patchy distribution, biopsy specimens from bronchoscopy yield lower diagnosis. Surgical lung biopsy has a higher yield and should be preformed if there is high suspicion. The dominant histologic finding in AFOP is organizing intra-alveolar fibrin, which differs from the classical patterns of both DAD and OP. AFOP also lacks the hyaline membranes seen in DAD and has a patchy distribution of fibrin rather than diffuse. AFOP is differentiated from EP on histology by its lack of eosinophils. The etiology of AFOP is unknown and considered idiopathic. Associations with inhalants (coal mining, hairspray, construction), infection (hemophilus influenza, H1N1), connective tissue disease, immune suppression, and drug exposure have been described in literature. Both azacitidine and decitabine are hypomethylating agents used in treatment of myelodysplastic syndrome. Though few in number, reports have noted development of AFOP with administration of both chemotherapeutic agents. Treatment in large part is discontinuation of any offending agent. Steroids, antibiotics, and cyclophosphamide have been used. In cases in which steroids were used, there was not a definitive advantage as it did not change mortality outcome. There has been some success with the combination of prednisone and cyclophosphamide. In this patient's case he presented with symptoms of dyspnea and hemoptysis. A diagnosis was made by histology. He is currently being treated with a 2 week course of methylprednisone followed by taper. He has shown signs of clinical and radiographic improvement.

AIR ON THE MIND, A CASE OF NONTRAUMATIC PNEUMOCEPHALUS Michael Gillette; Philip J. Putnam. Tulane University Health Sciences Center, New Orleans, LA. (Tracking ID #2198804)

LEARNING OBJECTIVE #1: Recognize signs and symptoms of venous air embolisms

LEARNING OBJECTIVE #2: Discuss the treatment of pneumocephalus

CASE: A 63 year old man presents to the hospital for a reversal of an ostomy. Five months earlier, the patient had perforated diverticular disease that required an anterior resection of the rectum and placement of a Hartman's Pouch. The initial attempt to reverse the ostomy could not be completed due to adhesions. A second attempt via an exploratory laparotomy was successful. He was extubated on hospital day 10 and a right internal jugular central line was removed on hospital day 15. On hospital day 16, he got out of bed for the first time and suddenly became non-responsive. On exam, he had a new holosystolic murmur, did not withdraw from pain, but did have papillary, corneal, and gag reflexes. A code blue was called and the patient was intubated. CT scans revealed air within the right ventricle, right internal jugular vein, and air in the right cerebral hemisphere with out any air in the liver or portal circulation. A bedside echocardiogram showed a brisk flow of gas through the right ventricle. An EKG showed a new onset RBBB. Mastisol and a tegaderm patch was then placed over the site of the right IJ and patient was placed in trendelenburg position. No further gas was visualized in the heart and a formal echocardiogram did not reveal a PFO. A FiO2 of 100 % on the ventilator was used to aid in cerebral air resorption. However, he continued to decompensate requiring multiple pressors and a follow-up MRI revealed evolving ischemic strokes in the bilateral cortical, right caudate and left cerebellar regions. Care was withdrawn on hospital day 23 and he expired.

DISCUSSION: Cases of nontraumatic cerebral air embolism are largely iatrogenic in origin and are somewhat rare. However, an air embolus should be considered in individuals with altered mental status after a central line manipulation or removal. Air that enters the venous circulation will usually enter the lungs and cause decreased gas exchange. If a patent foramen ovale is present, the air can cross to the left side of the heart and enter the systemic circulation. In the case of this patient, the air entry was brisk enough to travel retrograde up the internal jugular veins into the sagittal sinuses. Cerebral air in the smaller vessels will block the flow of blood and act as a space-occupying lesion inside the closed cranium. The resulting pathology is quite similar to an acute ischemic stroke with focal deficits, confusion, and seizure activity. Treatment for cerebral air centers on supportive care and oxygen therapy. One hundred percent oxygen treats both potential hypoxia and helps create a pressure gradient favorable for air resorption. The current literature favors leaving the patient flat as the trendelenburg position fails to prevent further air from entering the brain and increases cerebral edema.

AKI FROM UNILATERAL URETERAL OBSTRUCTION: ONE HARD CALCULUS PROBLEM THAT NEEDED TO BE WORKED OUT Randy Chung¹; Andrew Caruso^{2, 1}; Jeffrey T. Bates^{2, 1}. ¹Baylor College of Medicine, Houston, TX; ²Michael E. DeBakey VA Medical Center, Houston, TX. (Tracking ID #2199258)

LEARNING OBJECTIVE #1: Recognize that unilateral ureteral obstruction due to a renal calculus can result in acute kidney injury in the setting of a solitary functional kidney.

LEARNING OBJECTIVE #2: Diagnose ureteral calculus with computed tomography, despite absence on ultrasonography, when acute kidney injury is unexplained.

CASE: A 58-year-old man was admitted for acute kidney injury (AKI). His medical history included prostate cancer status post radiation therapy, hypertension and hyperlipidemia. Two days prior to admission, the patient started having subjective fevers and chills, nausea, vomiting, and decreased oral intake. He denied abdominal pain, flank pain, dysuria, hematuria, or difficulty urinating. Physical examination was remarkable only for mild left costovertebral angle tenderness; he did not have abdominal tenderness, suprapubic fullness or tenderness, or edema. Laboratory studies disclosed a serum creatinine level of 6.1 mg/dL (compared to 1.3 mg/dL 1 week prior) and blood urea nitrogen level of 55 mg/dL (compared to 20 mg/dL 1 week prior). Urinalysis was positive for 14 red blood cells; there were no white blood cells or cellular casts. Renal ultrasound showed very mild bilateral hydronephrosis, left renal hypertrophy, right renal cortical atrophy, and no renal calculi. A noncontrast computed tomography (CT) scan of the abdomen showed an obstructing 5 mm×3 mm calculus at the left ureterovesical junction with mild left hydronephrosis and an atrophic right kidney. In the setting of a solitary functional kidney, urology was consulted for urgent cystoscopy and ureteral stent placement. However, the ureter was unsuccessfully cannulated, so the patient underwent left nephrostomy tube placement. His symptoms resolved and his serum creatinine level improved to 1.8 mg/dL by the time of discharge. Four weeks after discharge, a retrograde ureteroscopy was performed, and the calculus was successfully removed with basket extraction.

DISCUSSION: Acute unilateral ureteral obstruction due to renal calculi is a frequent event, affecting up to 15 % of the population worldwide. Common presenting symptoms include nausea, vomiting, hematuria, and severe abdominal or flank pain radiating to the groin. Serum creatinine level and urine output are usually not affected when the contralateral kidney is functioning normally. In this patient, the compromised function of the right atrophic kidney led to the development of AKI from the left unilateral ureteral obstruction. The presentation was unusual in that the patient did not experience pain from renal colic. Nonetheless, early diagnosis and prompt treatment are of utmost importance in preserving or restoring renal function. While routine imaging studies usually add little to the diagnostic workup of AKI, ultrasound imaging of the urinary tract is indicated when the probability of urinary obstruction is high or the kidney failure is unexplained. In the present case, ultrasound showed evidence of left urinary tract obstruction but failed to show the presence of any calculi. Low sensitivity of about 19 % is reported for sonographic detection of ureteral calculi, as most of the ureter is obscured by shadowing from overlying bowel gas. Unexplained obstruction requires additional imaging with CT, which remains the best method for detection of calculi, with sensitivity and specificity estimated at 96 and 99 %, respectively.

ALL THAT WHEEZES IS NOT ASTHMA Shlomo Kuperman^{2, 1}; Danit Arad^{2, 1}. ¹Albert Einstein College of Medicine, Bronx, NY; ²Montefiore Medical center, Bronx, NY. (Tracking ID #2198082)

LEARNING OBJECTIVE #1: Recognize wheezing has many etiologies

LEARNING OBJECTIVE #2: Differentiate between wheezes and stridor

CASE: A 53 year-old man presented with three days of shortness of breath and productive cough. He reported chest tightness, wheezing, and thick yellow sputum. He had no fevers but did have night sweats. He had a history of asthma and COPD and suffered from intermittent exacerbations with similar presentations; occasionally requiring hospitalization, usually non-responsive to nebulizers and treated with oral steroids. He had diffuse wheezes on exam, remainder of examination was unremarkable. CXR and routine labs were within normal limits. He was initially treated with bronchodilators with a mild response. On hospital day two, he was noted to be in tripod position and breathing was labored with accessory muscle use. Inspiratory and expiratory stridor was heard on auscultation of his neck which was more pronounced with rapid breathing suggesting upper airway involvement. Bedside laryngoscopy did not show any edema or occlusion of upper airway. CT neck revealed diffuse tracheobronchial thickening suggestive of relapsing polychondritis. On further examination, a saddle nose, and dysmorphic helices and scapha of the outer ear were present further supporting the diagnosis.

DISCUSSION: Wheezing is a commonly encountered physical exam finding and often attributed to asthma or COPD. However, there are several other less common etiologies. Wheezes originate in proximal conducting airway of any size and thought to be secondary to oscillation of opposing narrowed airway. The pitch can vary and be either monophonic

or polyphonic. A wheeze can be inspiratory, expiratory, or biphasic. The differential diagnosis for wheezing includes pulmonary edema, carcinoid, sarcoidosis, aspiration, parasitic infections, Bronchiolitis, pulmonary embolism, and many other airway disease processes which cause extrapulmonary or intrapulmonary obstruction. Stridor is a high-pitched, musical sound produced as turbulent flow passes through a narrowed segment of the upper respiratory tract. It can be secondary to trauma, viral or bacterial infection, tracheal collapse or stenosis, vocal chord dysfunction, foreign body ingestion or aspiration, or angioedema. Stridor can be differentiated from wheezing as being a monophonic sound, more prominent during inspiration, and louder over the neck than over the chest. Although usually inspiratory, stridor can also be expiratory, or both. In our patient, the history of poor response to bronchodilators and frequent necessity of steroids should raise suspicion of an alternative diagnosis. It is important for physicians to recognize that wheezes and stridor can be a manifestation of many disease processes that affect the airway. In one review of 95 patients with vocal-cord dysfunction, greater than half were incorrectly diagnosed with asthma for years, majority have been treated with glucocorticoids, averaged six hospital admissions per year, and 28 % were intubated. Relapsing polychondritis is a rare autoimmune disease with inflammation and destruction of cartilaginous structures, it can involve almost any organ and has a high risk of misdiagnosis. Laryngotracheobronchial involvement appears in fifty percent of patients. Tracheal collapse, and secondary pulmonary infections are amongst the leading causes of death among patients with relapsing polychondritis. In the above case, the recognition that the lung sounds were upper airway in origin alerted the team and enabled them to arrive at the correct diagnosis.

ALLERGIC TO CANCER Alanna Wong; Yelena Averbukh; Rebecca Koransky. Montefiore Medical Center, Bronx, NY. (Tracking ID #2199975)

LEARNING OBJECTIVE #1: To recognize the clinical presentation of paraneoplastic neurological syndromes in a patient with lung cancer.

LEARNING OBJECTIVE #2: To distinguish between paraneoplastic syndrome and leptomeningeal carcinomatosis based on the results of diagnostic workup.

CASE: A 70 year-old man with no significant medical history presented after an episode of confusion and lethargy. For the past 2 months, he had been having intermittent headaches, difficulty remaining alert and focused, along with progressive fatigue associated with an unintentional 12-pound weight loss, constant dry mouth, and changes in his taste. He was occasionally repetitious and tangential during his mental status exam, unusual for a highly educated professor. Extensive infectious workup was negative. CT thorax revealed a 6 cm×4 cm left upper lung mass with subsequent biopsy revealing papillary adenocarcinoma. MRI brain with abnormal enhancement of the internal auditory canals and cerebellar folia was concerning for leptomeningeal metastasis versus paraneoplastic syndrome. Serial lumbar punctures demonstrated elevated white blood cells (predominately lymphocytes), elevated protein, and low glucose consistent with leptomeningeal metastasis, though negative for malignant cells. Paraneoplastic panel, including antibodies to neuronal, glial, and Purkinje cells, was negative. However, further evaluation revealed nonspecific autoimmune cells in the cerebral spinal fluid suggestive of paraneoplastic syndrome. Unfortunately, the patient's mental status rapidly declined and his hospital course was complicated by simple partial seizures. His family eventually decided on hospice in accordance with the patient's wishes.

DISCUSSION: Paraneoplastic neurological syndromes are rare, affecting less than 1 % of cancer patients, but found in a disproportionate number of patients with lung cancer (up to 5 %). A variable group of disorders, the pathogenesis is believed to be immune-mediated with antibody and T-cell responses against nervous system antigens that are ectopically expressed by the tumor. Clinical presentation depends on what portion of the nervous system is affected. Symptoms of limbic encephalitis include cognitive impairment and complex-partial seizures versus brainstem encephalitis symptoms, which can include dysphagia, sensorineural deafness, and trigeminal sensory loss. Different types of onconeural antibodies have also been known to cause neuropsychiatric manifestations. It is important to note that in 80 % of patients presenting with paraneoplastic neurological syndromes, the primary malignancy is diagnosed later in the course of the disease. Distinguishing between paraneoplastic neurologic syndromes and leptomeningeal carcinomatosis is difficult as clinical presentation can be similar. In leptomeningeal carcinomatosis, malignant cells spread through the subarachnoid space, resulting in either occluded CSF flow from associated inflammation causing mass effect, nerve dysfunction from direct tumor involvement, or invasion of the brain parenchyma. Patients often present with a broad range of multifocal neurological dysfunctions. In 30–50 % of patients, headache is the most common initial symptom and is due to either increased intracranial pressure or meningeal irritation. Patients may also present with encephalopathy and are lethargic, confused, forgetful, or disoriented. Subtle symptoms caused by cranial neuropathies from invasion of the cranial nerves include diplopia, facial pain, sensorineural hearing loss, dysarthria and dysphagia. In distinguishing between these two conditions, MRI brain is non-specific as abnormal enhancement in periventricular regions

can be seen in both cases. Cerebral spinal fluid cytology is essential in attempting to differentiate between one and the other. The specificity of CSF cytology is high as false-positive results are rare. Malignant cells identified within the CSF definitively diagnose a patient with leptomeningeal carcinomatosis whereas paraneoplastic antibodies confirm paraneoplastic neurologic syndrome. Multiple lumbar puncture samples negative for malignant cytology are required, with each increasing in sensitivity to rule out leptomeningeal carcinomatosis (71, 86, 90, 98 %). The combination of negative cytology and the absence of meningeal enhancement on MRI is more indicative of paraneoplastic syndrome. As a clinician, one must be highly suspicious of paraneoplastic neurological syndromes in a patient with lung cancer who has suggestive signs and symptoms as a positive diagnosis can drastically alter treatment options and overall prognosis. In a patient with paraneoplastic neurological syndrome, immunosuppressants may be offered as treatment, and with improvement, possible curative resection of the primary tumor.

AMI“NO”DARONE WHEN THE RHYTHM IS AGAINST THE LUNGS Marianna Sargsyan¹; Harvey J. Friedman³; Malav P. Parikh²; Karandeep Singh¹. ¹Saint Francis Hospital, Evanston, IL; ²Saint Francis Hospital, Evanston, IL; ³SF Hospital of Evanston, Evanston, IL. (Tracking ID #2198296)

LEARNING OBJECTIVE #1: Amiodarone is a popular drug for treating arrhythmias, but enthusiasm for this agent has been tempered by its major side-effect of amiodarone pulmonary toxicity (APT). It is usually a chronic condition, but rarely acute and sub-acute forms are seen. Diagnosis of acute APT can be very challenging and requires a high index of suspicion.

CASE: A 58-year-old male presented to the hospital with complaints of dyspnea, cough and fever for last ten days. He appeared tachypneic and in moderate respiratory distress. On physical exam, vital signs were: O₂ saturation: 90 %-room air, pulse:98/min, BP: 144/70 mmHg, temperature:100.9.F. The patient had normal S1-S2, crackles in the right-sided lung fields and trace pedal edema. Routine investigations showed leukocytosis, normal troponin levels and brain natriuretic peptide (BNP) of 598 pg/ml. CXR revealed right-sided pulmonary infiltrates and echocardiogram showed ejection fraction of 25 %. He was treated with a combination of antibiotics and diuretics for possible pneumonia and congestive heart failure exacerbation (CHF). However he had a gradual worsening of the clinical status characterized by worsening dyspnea, increasing oxygen requirement and diffuse bilateral infiltrations on CXR, eventually requiring intubation. Review of the medications and past medical history revealed that 9 months before current presentation, patient was started on amiodarone (200 mg/day) after he had suffered from acute myocardial infarction and congestive heart failure, when he underwent CABG and ACID placement. At this stage, amiodarone was stopped and patient was started on prednisone with a probable diagnosis of amiodarone induced acute pulmonary toxicity. He showed remarkable clinical and radiological improvement over next 7-10 days. Eventually he was extubated and discharged to long-term care facility with tapering dose of prednisone.

DISCUSSION: Amiodarone can produce lung damage directly by-cytotoxic effect and indirectly by-immunological reaction. It is usually an indolent illness, however acute APT characterized by rapidly progressing diffuse pneumonitis with acute respiratory distress syndrome (ARDS) is also a possibility. It is diagnosed based on clinical and radiological findings after exclusion of common cardio-pulmonary diseases. Patients with acute APT respond well to steroids and stopping amiodarone, however higher mortality rate are seen in patients with underlying lung disease and reduced EF. Amiodarone toxicity usually co-relates with a total cumulative dose or daily dose of 400 mg or more for more than 2 months. Our case is unusual due to development of APT at relatively low maintenance dose of 200 mg/day. Thus, probably there is no 'safe' dose of amiodarone and acute APT can occur even at 200 mg/day, the dose most commonly used by cardiologists. Hence clinicians should be alert to the possibility of APT regardless of the dose and duration of treatment and patients taking amiodarone should be closely monitored to ensure prompt diagnosis should this toxicity occur.

AMIODARONE INDUCED TOXICITY Xin Cai²; Sujata Bhushan¹. ¹Dallas VA Medical Center, Dallas, TX; ²UT Southwestern Medical Center, Dallas, TX. (Tracking ID #2191494)

LEARNING OBJECTIVE #1: Recognize the clinical features of atrial fibrillation due to amiodarone-induced thyrotoxicosis (AIT).

LEARNING OBJECTIVE #2: Diagnose and manage AIT

CASE: A 77-year-old male with atrial flutter and COPD presented with palpitations, increasing lower extremity edema, 10 lb weight gain and worsening dyspnea on exertion over the past few months. Patient first developed atrial fibrillation (AF) in 2004. Electrophysiology study in 2011 revealed left sided atypical atrial flutter, patient was started on amiodarone 200 mg daily and maintained in normal sinus rhythm until current admission. Relevant exam and lab findings included elevated jugular venous distension, bilateral interstitial infiltrates on chest X-ray, atypical atrial flutter at 110 bpm on ECG, and an

undetectable thyroid stimulating hormone (TSH) with a free thyroxine (T4) of 2.52 (patient's TSH in 05/2014 was 4.48 with a free-T4 of 1.10). Transthoracic echocardiography revealed global hypokinesis with depressed left ventricle (LV) systolic function with an ejection fraction (EF) of 29 %, a significant decline compared to LVEF of 51 % in 02/2012. Thyroid ultrasound revealed no nodules. Amiodarone was stopped and patient was started on furosemide for volume overload, metoprolol and digoxin for rate control, and methimazole 20 mg BID along with prednisone 30 mg daily for management of likely amiodarone induced thyrotoxicosis (AIT). Patient's condition gradually improved with rate control and downward trend of T4. He was discharged with the above medications with outpatient follow-up for atrial flutter ablation and management of AIT.

DISCUSSION: Two major goals in the management of AF are to prevent thromboembolic events and to offer symptomatic relief. Both rate- and rhythm-control strategies have been shown to offer similar mortality and morbidity benefits. Amiodarone is often preferred over other anti-arrhythmics due to its superiority in maintaining sinus rhythm and lower incidence of torsades de pointes. However, its benefits often come at the expense of side effects including chronic interstitial pneumonitis, elevated aminotransferase levels, sinus bradycardia or AV nodal block, and thyroid dysfunction (both hypo- and hyper-thyroidism), which could paradoxically exacerbate AF leading to congestive heart failure (CHF). Amiodarone induced thyroid dysfunction likely results from its high iodine content and direct toxicity to the thyroid gland. Serum T4 levels rise by 20-40 % during the first month of therapy and then gradually return to high normal. Serum T3 levels decrease by up to 30 % in the first few weeks of therapy and remain slightly decreased or low normal. TSH levels usually rise after starting therapy but return to normal in 2-3 months. Clinical reviews and reports suggest the prevalence of amiodarone induced thyroid dysfunction is between 2 and 30 % depending on an individual's baseline thyroid function. Two types of Amiodarone Induced Thyrotoxicity (AIT) have been described. Type 1 usually affects patients with latent or preexisting thyroid disorders and is more common in areas of low iodine intake. It is caused by iodine-induced excess thyroid hormone synthesis and release (Jod-Basedow phenomenon). Type 2 occurs in patients with a previously normal thyroid gland and is caused by a destructive thyroiditis that leads to the release of preformed thyroid hormones. Diagnosis is made by elevated T4, elevated T3, undetectable TSH; T3 levels are increased in hyperthyroidism, while they are decreased in early phases of treatment with amiodarone. Thyroid autoantibodies are generally absent in type 2 AIT but usually positive in type 1 AIT. An ultrasonogram of the thyroid that shows hypoechoic or nodular patterns or increased gland size is more indicative of type 1. Continuation of amiodarone treatment does not alter the medical management of thyrotoxicosis, but it reduces the chances of a successful outcome. Even if amiodarone therapy is stopped, thyrotoxicosis persists for up to 8 months because of the drug's long half-life. Discontinuation of the drug has no immediate benefit. Amiodarone therapy is usually continued unless it is ineffective in treating the arrhythmia or toxicity in other organs is evident. Type 1 AIT is treated with high doses of thionamides (eg, methimazole [40-60 mg/d] or propylthiouracil [600-800 mg/d]). Type 2 Thyrotoxicosis requires a relatively long course of glucocorticoids (start at 40 mg and taper over months, until T4 normalizes). Unknown type 1 vs 2 is treated with a combination of glucocorticoids and thionamides. A rapid response suggests type 2 AIT; thionamides can be tapered. A poor initial response suggests type 1 AIT; the steroids can be tapered. RAIU is not preferred, as the iodine of amiodarone inhibits uptake by the gland. Thyroidectomy can be considered for type 1 thyrotoxicosis, but only after the euthyroid state is established and if there is a need to restart amiodarone. AIT should be considered in a patient on amiodarone with recurrent atrial fibrillation.

AMYLOID FIBRILLATION: UNEXPECTED DIAGNOSIS, UNFORTUNATE PROGNOSIS Paul Leis; Robert E. Graham. Lenox Hill Hospital, New York, NY. (Tracking ID #2199450)

LEARNING OBJECTIVE #1: Discuss cardiac amyloidosis, and identify its key findings seen on electrocardiogram and echocardiogram.

LEARNING OBJECTIVE #2: Recognize cardiac amyloidosis as an etiology of atrial fibrillation.

CASE: A 60 year-old woman with a history of recurrent atrial fibrillation presented for elective radiofrequency ablation (RFA). Her vital signs were within normal limits. She had bilateral lower extremity swelling that ascended up to her knees. Her electrocardiogram showed known atrial fibrillation at a rate of 66 beats per minute with low voltage QRS complexes in the limb leads. The RFA was complicated by an episode of pulseless electrical activity with cardiac arrest and successful resuscitation. An echocardiogram was performed which revealed severe left ventricular concentric hypertrophy with preserved ejection fraction, as well as evidence of inter-atrial septal thickening. At this point, cardiac amyloidosis was suspected. A serum protein electrophoresis highlighted elevated lambda free light chains at a level of 66.4 mg/dL (normal 0.5700-2.63 mg/dL). Bone marrow biopsy confirmed plasma cell myeloma. An endomyocardial biopsy was pursued to further investigate the cardiac abnormalities, and revealed amorphous pale pink material. Congo red and crystal violet stains confirmed the diagnosis of cardiac amyloidosis.

DISCUSSION: Amyloid is an insoluble fibrillar protein that arises from many diverse diseases, most commonly plasma cell dyscrasias. Amyloidosis refers to the infiltration of multiple organs by these insoluble deposits, where myocardial involvement carries one of the worst prognoses. Cardiac amyloidosis is the term for myocardial disease caused by amyloid infiltration that can be found extracellularly throughout the heart. The amyloid deposits occur in both the atria and ventricles, affecting the conduction pathways, coronary vasculature, and contractile function of the heart. The most common cardiac arrhythmia seen in cardiac amyloidosis is atrial fibrillation, occurring in 10–15 % of patients. This is a result of perivascular fibrosis which tends to affect the sinus node leading to atrial arrhythmias. Amyloid deposits lead to other electrocardiogram findings including low-voltage QRS amplitudes defined as ≤ 0.5 mV in all limb leads or ≤ 1 mV in all precordial leads. Pseudoinfarct patterns can also be seen, which are depicted as QS waves in consecutive leads. Echocardiographic findings in cardiac amyloidosis include left ventricular wall and atrial septal thickening, with the latter being more specific for the disease. A thickened heart leads to worsening cardiac relaxation and compliance, leading to elevated filling pressures. The ejection fraction is often preserved and a "granular sparkling" of the myocardium can be seen on echocardiogram. Recognizing specific electrocardiogram and echocardiographic findings suggestive of cardiac amyloidosis is essential in prompting early treatment of the underlying disorder, given the better response to therapy with early diagnosis.

AN ACE INHIBITOR OF SPADES: AN UNSUAL CAUSE OF ENTERITIS Srikar R. Mapakshi; Neelima Reddy; Rajasekhar Katuru; Catalina Negulescu; Brandon Amant. Baton Rouge General-Tulane Internal Medicine Residency program, Baton rouge, LA. (Tracking ID #2199301)

LEARNING OBJECTIVE #1: Recognize an underappreciated cause of abdominal pain in patients on an ACEI.

LEARNING OBJECTIVE #2: Include visceral angioedema in the differential diagnosis of symptomatic patients taking ACEI

CASE: A 37-year-old African-American female was admitted with 2-week history of persistent generalized abdominal pain associated with nausea, emesis and diarrhea. She denied any fever and any relation of pain with food intake. Two weeks prior to this admission, she was discharged from an outside hospital with presumed gastroenteritis for similar complaints with an abdominal ultrasound at that time showing sludge in gall bladder without cholecystitis. Persistent symptoms lead to an outpatient surgical evaluation and a laparoscopic cholecystectomy. Despite surgery, her ongoing symptoms prompted gastroenterology consultation leading to this hospitalization. PMH is significant for newly diagnosed hypertension for which she was started on ACE inhibitor (ACEI) by her PCP. She denied drug allergies and usage of tobacco, alcohol or illicit drugs. On admission, she was afebrile and hemodynamically stable. She only had mild transaminitis on lab work. Stool studies including *Clostridium difficile* were negative. She was started on empiric intravenous antibiotics without significant improvement of symptoms. On further questioning she recalled that she started having abdominal pain, vomiting and diarrhea on the day she was started on ACEI. Contrast-enhanced CT abdomen and pelvis revealed multiple loops of small bowel wall thickening involving distal ileum but sparing terminal ileum with adjacent mesenteric edema and ascites. Given the strong temporal correlation between symptom onset and initiation of ACEI a diagnosis of drug-induced visceral angioedema was made and ACEI was discontinued. Within 24 h of ACEI discontinuation patient reported significant improvement of symptoms.

DISCUSSION: Visceral angioedema poses a diagnostic challenge because it involves internal organs that are not classically affected by ACEI induced angioedema. This condition is more commonly seen in women compared to men, with predominant symptoms being abdominal pain, vomiting, ascites, diarrhea, and leukocytosis¹. Contrast enhanced CT of the abdomen and pelvis is the imaging modality of choice to evaluate for bowel wall thickening and free fluid consistent with visceral angioedema². Bradykinin associated vasodilatation is the most widely accepted theory for the etiology of angioedema³. Symptoms usually resolve within 48 h of ACEI discontinuation⁴. We hope this case will increase awareness of ACEI induced visceral angioedema as an important and under-recognized complication of ACE inhibitor therapy. A correct diagnosis in cases presenting with acute abdominal symptoms and a history of ACEI intake hinges on a high index of suspicion for visceral angioedema. Timely recognition of this entity is essential to prevent undue burden to the patient with unnecessary invasive procedures and bring about quick symptomatic relief. **References:** 1. AN ADULT WITH ATOMOXETINE-INDUCED HEPATITIS: A REPORT OF A RARE CASE Francis E. Dailey¹; Samuel Burstein². ¹Cedars-Sinai Medical Center, Los Angeles, CA; ²VA Greater Los Angeles Healthcare System, Los Angeles, CA. (Tracking ID #2200271)

LEARNING OBJECTIVE #1: Recognize symptoms stemming from adverse reactions associated with atomoxetine therapy

LEARNING OBJECTIVE #2: Diagnose acute hepatitis secondary to a rare adverse reaction from a medication in common use

CASE: A 59 year old Caucasian gentleman with Attention Deficit Hyperactivity Disorder (ADHD) presented to his primary care provider after developing abdominal pain, decreased appetite, fatigue, and jaundice over a 7-day period 3 weeks after beginning atomoxetine. He had no prior history of liver disease, but had been exposed to Hepatitis C with undetectable viral loads and to Hepatitis B with subsequent immunity. The patient was taking hydrochlorothiazide and mirtazapine but was not taking any other medications or herbs. The patient was abusing heroin intravenously several times per week, using clean needles and not sharing. He was currently smoking a half-pack of cigarettes daily without any alcohol use. His vital signs were normal. Examination was significant for generalized jaundice, conjunctival icterus, and mild right upper quadrant tenderness. There was no rash and no hepatosplenomegaly. His initial liver enzymes were significant for a total bilirubin of 14.3 mg/dL (direct 7.1), alanine aminotransferase (ALT) of 3566, aspartate aminotransferase (AST) of 2934, and serum alkaline phosphatase (ALP) of 269 U/L. The patient was instructed to stop taking atomoxetine, and sent to the emergency department for abnormal liver tests. Three days later, the patient presented to the emergency department with the same complaints but stated that the abdominal pain had improved. His vital signs and physical exam were unchanged. Labs were significant for platelets 110 k/uL, prothrombin time 15.3 s, international normalized ratio 1.4, total bilirubin of 13.4 mg/dL (direct 7.5), ALT 2306 U/L, AST 881 U/L, ALP 214 U/L. Urine toxicology demonstrated opiates. Serum acetaminophen and ethanol levels were undetectable. Abdominal ultrasound showed no evidence of hepatic vein thrombosis or ischemic process. Tests for antibodies to Hepatitis A and B confirmed immunity; Hepatitis C RNA was undetectable. Atomoxetine was discontinued and the patient was monitored on supportive measures. He markedly improved over the next several days, with his jaundice and abdominal pain resolved and all of his abnormal labs downtrending during hospital admission. His discharge laboratory values showed a total bilirubin of 5.2 mg/dL, ALT 850 U/L, AST 161 U/L, ALP 199 U/L. A literature search performed for similar cases revealed few cases of acute hepatitis from atomoxetine. Because recurrence with re-exposure has been reported, the patient was instructed to avoid atomoxetine.

DISCUSSION: ADHD is the most common childhood neurobehavioral disorder in the world, with a prevalence of 6–8 %, and often persists into adulthood. Because it is associated with a significant impairment in social, occupational, and academic settings, pharmacotherapy is of the ultimate importance. While stimulants are the most tested and commonly prescribed treatments for ADHD and demonstrate the greatest efficacy, non-stimulants—such as Atomoxetine—are often preferred due to less potential for abuse and a greater overall side effect profile. This medication is considered both safe and effective, and is associated with only a few adverse effects, mostly anti-cholinergic. Very rarely, there have been cases reported of hepatotoxicity, causing a modified label to include severe liver injury among its adverse events. However, a current PubMed literature search demonstrates that since atomoxetine was approved for use in 2002, there are only four reported cases of this medication inducing liver injury. Here, we described a case of acute hepatitis in an adult occurring after initiation of atomoxetine therapy, with a combination of jaundice and high serum aminotransferase levels. Upon discontinuation of this medication, the patient's jaundice resolved and the laboratory levels began to normalize. Two standardized scales, the International Organization of Medical Science Diagnostic Scale and the Adverse Drug Reaction Probability Scale, were applied to assess causality of our patient's acute hepatitis, and both labeled the association of atomoxetine and hepatitis as "probable." While a positive rechallenge would have made this association "definitive," our patient showed a marked improvement after discontinuation of the medication and was instructed to remain off of it. To our knowledge, there are only four other similar cases of atomoxetine-induced hepatitis reported in the literature, mostly in children. While most of the hepatic abnormalities secondary to atomoxetine are transient and do not pose a serious risk, our case demonstrates a serious potential to lead to acute liver failure. Therefore, our case emphasizes the importance of providers and patients recognizing symptoms stemming from adverse reactions associated with atomoxetine therapy.

AN ATYPICAL CASE OF HEMOPTYSIS Ruth W. Wang¹; Theodore Long. Yale University School of Medicine, New Haven, CT. (Tracking ID #2179042)

LEARNING OBJECTIVE #1: Recognize atypical mycoplasma pneumonia as a possible etiology of hemoptysis in patients with underlying sarcoidosis

LEARNING OBJECTIVE #2: Highlight bronchoscopy as an important diagnostic tool in confirming diffuse alveolar hemorrhage in patients with hemoptysis

CASE: Infections are the major cause of hemoptysis, which can result from diffuse alveolar hemorrhage (DAH) or localized pulmonary hemorrhage, in adults. In patients with hemoptysis, thorough infectious work-up should accompany investigations of other possible causes. A 45 year old African American gentleman with hypertension, obstructive sleep apnea, and stage IV pulmonary sarcoidosis with cardiac involvement presented to the Emergency Department (ED) in May 2013 with dyspnea and two episodes of coughing up dime-sized, dark-red blood, in the setting of a 2-month history of dry cough. Upon presentation in the Emergency Department (ED) the patient was dyspneic and afebrile, with oxygen saturation of 84–89 % on room air, decreased from a baseline of 96 % on room air a week prior to admission. Lung fields were clear to auscultation bilaterally. A chest radiograph revealed hyperinflated lungs with large bullae in the right upper lung zone and airspace opacities in the left lung and right middle and lower lung zone. Samples were obtained for blood culture and the patient was started on 1 g intravenous vancomycin and 3.375 g piperacillin/tazobactam. One dose of 400 mg intravenous moxifloxacin was administered for concern of aspiration pneumonia. The patient's oxygen saturation briefly improved to 96–100 % on 4 l of supplemental oxygen via nasal cannula but decreased to 90 % requiring oxygen supplementation of 40 % via a non-rebreather face mask. The patient was admitted to the medical intensive care unit (MICU) for concern of worsening hemorrhage that would require bronchoscopy and the potential for escalating oxygen requirement. In the MICU, the patient's oxygen saturation increased to greater than 96 % on 4 l of supplemental oxygen. The patient's respiratory status remained stable with oxygen saturation of up to 98 % on 3 l of oxygen via nasal cannula, weaned from 4 l. Doxycycline was administered for empiric coverage of atypical pneumonia. The patient remained afebrile, hemodynamically stable, with negative blood cultures, and stable respiratory status. Upon transfer to the medical floor, bronchoscopy was conducted to confirm the diagnosis of suspected diffuse alveolar hemorrhage (DAH) and rule out a large endobronchial lesion, which although not detected on CT, could have been a contributing factor to hemoptysis and hypoxic respiratory distress. A serial aliquot lavage was performed with blood tinged return that increased with each subsequent lavage confirming DAH. Bronchial inspection did not show any evidence of actively bleeding endobronchial lesions. Direct fluorescent antibody testing, subsequent polymerase-chain-reaction (PCR) tests for respiratory viruses, including adenovirus, rhinovirus, influenza A/B, parainfluenza, human metapneumovirus, and RSV were negative. Further work-ups for urine legionella antigen, Streptolysin O antibody, HIV-1/HIV-2 antibodies, and alpha-1 antitrypsin were also negative. Cultures, PCP silver stain, tests for fungal organisms and acid fast bacilli of BAL washings were all negative. Blood cultures were negative. Rheumatoid factor, antibodies against DNase B, beta-2 glycoprotein, cardiolipin, double-stranded DNA, and glomerular basement membrane, obtained to rule out systemic autoimmune diseases, were negative. A urine test for legionella antigen was negative. A *Mycoplasma pneumoniae* IgM antibody test, obtained when the patient initially presented, was positive.

DISCUSSION: This case points to the need to consider atypical mycoplasma pneumonia as a possible etiology of hemoptysis in patients with underlying sarcoidosis. Although *Mycoplasma pneumoniae* is a common cause of respiratory infections in adults it is rarely associated with diffuse alveolar hemorrhage. Recognition of this atypical infection is important for implementation of appropriate antibiotic therapy.

AN AUTOIMMUNE PARADOX OF IMMUNODEFICIENCY Sonia Jarrett¹; Harish Jasti². ¹Icahn School of Medicine at Mount Sinai, New York, NY; ²Mount Sinai, New York, NY. (Tracking ID #2196609)

LEARNING OBJECTIVE #1: Identify the clinical features associated with Common Variable Immunodeficiency (CVID)

LEARNING OBJECTIVE #2: Describe the diagnosis and management of CVID

CASE: A 50-year-old female with a past medical history significant for diabetes mellitus type I, refractory autoimmune hemolytic anemia (AIHA), immune thrombocytopenic purpura (ITP), recently diagnosed interstitial lung disease (ILD) and hypogammaglobulinemia presented with shortness of breath (SOB), fever to 102 °F, and malaise for the past 4 days. She also endorsed night sweats and intermittently productive cough. She denied hemoptysis, nausea, vomiting, or diarrhea. She previously had unlimited exercise tolerance but now experienced SOB after walking 1 block. She had been hospitalized and treated for presumed pneumonia 4 times in the past 12 months. Due to unresolved pulmonary infiltrates at her last hospitalization, she underwent video-assisted thoracoscopic surgery with biopsy findings suggestive of organizing pneumonia with non-caseating granulomas. Medications at the time included insulin and albuterol, budesonide-formoterol, ipratropium, and fluticasone inhalers. Social history was significant for secondhand smoke exposure during childhood, but she never smoked or used recreational drugs. She had no occupational exposures that would induce lung disease.

Physical exam revealed a tired-appearing Caucasian woman in no acute distress. Oxygen saturation was 98 % on room air. Lung exam was remarkable for bronchial breath sounds in all lung fields, with no evidence of accessory muscle use. Cardiac and abdominal exams were unremarkable. Labs were notable for hemoglobin 8.9, platelets 119, and lactate dehydrogenase 155. White blood cell count and electrolytes were within normal limits. ANA, ANCA, SCL, myositis, Sjogrens, and HSP panels were negative. Immunoglobulin levels were: IgG 34 (normal range: 767–1590 mg/dL), IgM 21 (37–286 mg/dL), IgA <1 (61–356 mg/dL). Chest x-ray showed interstitial infiltrates with no evidence of active infection. Given her history of AIHA, ITP, ILD, recurrent pneumonia, and near agammaglobulinemia, CVID was considered the most likely diagnosis.

DISCUSSION: CVID is the most common symptomatic primary immunodeficiency disorder affecting children and adults with a prevalence of 1 in 25,000 people. The disorder involves impaired B cell differentiation which causes defective immunoglobulin production. There is a family history in 20–25 % of cases. The diagnostic criteria are: immune globulin levels 2 standard deviations below the mean for age; absent isohemagglutinins and/or poor response to vaccines; and exclusion of other causes of hypogammaglobulinemia. The clinical presentation of CVID is heterogeneous, often leading to a delay in diagnosis. The majority of patients are diagnosed between ages 20–45, but diagnosis is often delayed by 5–7 years after the onset of symptoms. The clinical manifestations of CVID comprise 6 major categories. 1) Infections: particularly recurrent pneumonia and rhinosinusitis. 2) Chronic lung disease: including bronchiectasis or ILD due to recurrent pulmonary infections. 3) Autoimmune disease: with AIHA, ITP, or Evans syndrome found in 25 % of CVID cases. The diagnosis of autoimmune cytopenia precedes detection of hypogammaglobulinemia in up to 60 % of CVID patients. 4) Granulomatous disease: with non-caseating granuloma formation in lymphoid or solid organs. 5) Gastrointestinal disease: often presenting as chronic diarrhea and malabsorption. 6) Neoplasms: with increased risk of developing non-Hodgkin lymphoma. The first-line treatment of CVID is intravenous immunoglobulin (IVIG) replacement therapy which reduces the number of infections and hospitalizations. Treatment involves monthly IVIG infusions and measurement of IgG trough levels every 6 months. The goal of therapy is to increase IgG levels to normal range. Recurrent infections and chronic conditions associated with CVID result in considerable morbidity and mortality. Given the effective available therapy, early recognition and management of CVID is critical in decreasing morbidity and mortality of this relatively prevalent condition.

AN ITCHY BUEGER Yuto Arai²; Christine Kwan¹. ¹Teine Keijinkai Hospital, Arlington, TX; ²Teine Keijinkai Hospital, Teine-ku, Sapporo, Japan. (Tracking ID #2194396)

LEARNING OBJECTIVE #1: Recognize that Buerger disease can present with itchiness

LEARNING OBJECTIVE #2: Diagnose Buerger disease even during the summer

CASE: A 49 years old Asian woman comes in the summer with 2 months' bilateral fingers' itchiness despite topical steroids for a diagnosis of eczema. In fact, the itchiness has turned to pain that is sharp, 9/10, non-radiating, not improved by anything, and worsened by baths. Negative symptoms include swelling, increased warmth, and extreme temperature exposure; other review of systems is within normal limits (WNL). The patient's past medical history includes adenomyosis; she has no medications or allergies. She smokes 0.5 pack/day for 20 years and drinks 1 beer/day but denies any recreational drug use. Her father has rheumatoid arthritis. On physical exam, vital signs include temperature 36.6°, pulse 70, blood pressure 110/74, respiratory rate 20, and O2 saturation 100 % room air. Generally, the patient has an agonized look due to itchiness and pain. On extremities, the fingertips of her right first, second, and fifth digits and left first and second digits are violaceous, cool, and painful to palpation with no erosions or ulcers. Her bilateral palms show excoriations. Pulses are 2+ except for the right radial, popliteal, and dorsalis pedal pulses, which are 0. The distal interphalangeal joints of the above corresponding digits are tender to palpation but not red or swollen; flexion is decreased to 10°. The rest of the exam is WNL. On labs, the patient's complete blood count, chemistry, coagulation panel, hemoglobin A1C, and autoimmune markers are WNL. Foot Doppler ultrasound and computed tomography angiogram show corkscrew sign. Plethysmography confirms poor blood circulation in her fingers. She is thus clinically diagnosed with Buerger disease and is prescribed a prostacyclin inhibitor, alprostadil, without symptomatic improvement. Two weeks after smoking cessation, however, her symptoms do gradually improve.

DISCUSSION: Buerger disease, or thromboangiitis obliterans, an autoimmune disorder related to long-term smoking, affects small vessels although its pathogenesis remains unclear. Typical ischemic symptoms and signs include pain (81 %), ulcerations (67 %), Raynaud's phenomenon (40 %), and gangrene of the fingers; 13 % of patients have arthralgias. The clinical diagnostic criteria include age <45; current/recent tobacco use; distal extremity ischemia; typical arteriographic findings of Buerger disease, like corkscrew collaterals; and exclusion of autoimmune disease, thrombophilia, diabetes, and

proximal embolic sources. Moreover, most occur in the winter possibly because many also have Raynaud's phenomenon. In the above patient, while she does smoke, her summer symptoms of bilateral fingers' itchiness and pain without ulcerations are not initially consistent with a vascular occlusive disease. In fact, a literature search does not show any reports of itchiness in Buerger disease. Although the pathophysiology of ischemia's causing itchiness is poorly understood, a theory includes the mediators' being released by ischemia, thereby stimulating nerve fibers' transmitting the itchiness. In addition to histamine's transmitting the sense of itch, interleukins and prostaglandins, whose production can be induced by COX-2, whose transcription pathway is activated by oxygenated stress and ischemia, can also stimulate nerve fibers. Itchiness, therefore, can be a symptom of ischemia.

AN OLD ACQUAINTANCE REDISCOVERED AS A NEW EVIL: CANNABIS INDUCED MYOCARDIOPATHY Mohammed A. Bahaa Aldeen¹; Nibras Talibmamy²; Essam Nakhl¹; Omar Nadhem¹; Roger D. Smalligan¹; Rahul Chandra¹. ¹Texas Tech Univ Health Sc Center—Amarillo, Amarillo, TX; ²Kufa, Najaf, Iraq. (Tracking ID #2179809)

LEARNING OBJECTIVE #1: To recognize acute cannabis intoxication as a cause of myocarditis in young patients.

LEARNING OBJECTIVE #2: To learn about the various newer toxic effects of contemporary forms of street cannabis on the human heart.

CASE: A 21-year-old African American woman with no past medical history and on no medications came with nausea and vomiting that started a few hours after smoking marijuana. She was seen in the ER and sent home with pantoprazole. The patient returned 8 h later with severe mid-chest tightness, 10/10 in intensity, which woke her up from sleep. The pain radiated to both shoulders and jaw with some shortness of breath, sweating, nausea and clear vomitus. There were no aggravating or relieving factors. No history of trauma. No history of previous chest pain/heart attacks. No family history of premature MI or CVA. She used occasional alcohol but no binge drinking. She admitted to smoking marijuana for the last 2 years. Physical exam: BP 124/77, heart rate 90, respirations 14, temperature 98.1, 100 % O₂ saturation on room air. Heart was regular rate and rhythm without murmurs, gallops, or rubs. Lung and abdominal exams were normal. She had normal distal pulses, no calf tenderness, no leg edema, and no skin rash. Laboratory: normal WBC and differential, Hgb 13.4. Electrolytes, liver function and lipase were all normal. Troponin was high at 0.78 and 2 h later was 1.56. Urine toxicology was positive for only cannabis. Alcohol level was zero. Pregnancy test: negative. Chest X-ray was normal. The first EKG was normal sinus rhythm but a few hours later she developed diffuse ST depressions and multiple ventricular ectopic beats. Later, she developed runs of nonsustained ventricular tachycardia (NSVT). Hospital Course: The patient was initially treated as acute coronary syndrome with full dose heparin, beta blockers, nitroglycerine and amiodarone drip for her NSVT. Echocardiogram showed normal LV EF of 60 %, mild ventricular enlargement, small pericardial effusion and mild tricuspid regurgitation. Left heart catheterization showed normal coronary circulation. Her HIV, hepatitis, Coxsackie, West Nile virus, Mycoplasma and Chlamydia testing were all negative. In light of acute cannabis abuse with positive troponins, with negative cardiac cath and diffuse ST changes on EKG the patient was finally diagnosed with acute cannabis induced myocarditis. Her condition was stabilized and she was discharged in good condition three days later.

DISCUSSION: *Cannabis sativa* or marijuana has been known to man since 800 A.D, as a substance that alleviates pain and cures insomnia. Over time cannabis developed into one of the most widely misused recreational drugs. It has a dose-dependent acute effect on the autonomic nervous system. At low doses it causes an increase in sympathetic activity and a decrease in parasympathetic activity. This causes tachycardia and increased cardiac output. High doses of cannabis inhibit sympathetic activity and increase parasympathetic activity leading to bradycardia and hypotension. Acute cardiac effects occur commonly in the first 2–72 h of intoxication. Cannabis has also been linked to acute coronary vasospasm manifesting as acute coronary syndrome. Peripheral arteriopathy (cannabis arteritis) has also been reported. Reversible EKG abnormalities including ST-T segment changes with increased ectopy has been seen. There are also case reports of cardiac muscle damage manifesting as myocarditis, myopericarditis and serious cardiac arrhythmias including sudden cardiac death, especially if combined with alcohol. The severity of myocarditis is variable with occasional permanent damage leading to heart failure with one report of a patient requiring a left ventricular assist device. Myocardial biopsy pathology has shown sparse lymphocytic myocardial infiltrates, subendocardial and interstitial fibrosis with normal vasculature. The reason more cardiovascular effects are being reported in the recent times may relate to the increased content of marijuana in each smoked joint (100–150 mg per joint compared to 10 mg/joint in the 1960's). Another concern is that the street cannabis available today is known often contains additives intended to increase the psychotropic effects. These substances may have concomitant cardiac side effects. Typical additives include industrial etchants, solvents, micro glass beads, pesticide derivatives and

chemical sugars. Cannabis has classically not been considered to the medical community as a possible fatal substance of abuse. Hence its association with deaths is often underreported. However, coroner autopsy studies in Ireland and addict surveillance programs in France have raised concerns about cannabis as a lethal agent over the last 8 years. Our case reminds physicians of a rare but potentially serious toxic effect of cannabis use which may be seen more and more as legalization is granted or considered in various states in the US.

AN UNCOMMON CAUSE OF BACK PAIN Nathan Moore. Washington University, Saint Louis, MO. (Tracking ID #2181185)

LEARNING OBJECTIVE #1: Recognize the clinical features of multiple myeloma in the younger population

CASE: HPI: A 44 year old male with history of diabetes, anxiety and hyperlipidemia visited our resident clinic to establish care. Eight months ago the patient started developing intermittent crampy leg pain with movement. He ascribed it to his job as a construction worker. Some time after that also he developed intermittent low back pain that radiated to the backs of his legs, associated with numbness and tingling. Initially the pain was only present when working but progressed to intermittent pain at rest. He visited several chiropractors without relief. Two months prior to presentation, the patient fell onto his L side while working with resulting pain and subjective weakness in his L arm and leg, especially over the past 3 weeks. He feels "clumsy" while walking. He visited an urgent care center 6 weeks ago with these complaints where he was prescribed oxycodone, flexeril and ibuprofen and told to follow up with a primary care physician. **PMH:** Diabetes, anxiety, HLD **Family History:** MI in father, lung cancer in mother **Medications:** None. **Social History:** Worked a desk job for many years before being laid off 2 years ago and starting working in construction. He lost his health insurance at that time and has had difficulty seeing a PCP. He quit working 2 months ago. Tobacco—1 PPD for 25 years; Alcohol—Quit 8 months ago, previously heavy drinker; Drugs—None; Travel—None **Review of Systems:** Pertinent positives—significant weight loss since starting his new job; occasional subjective fevers; progressive fatigue; chronic dry cough; constipation (BM every ~4 days); frequent urination; chronic anxiety; cold intolerance; polydipsia. **Physical Exam:** T 37.1, HR 94, RR 18, BP 138/94, 100 % on room air, BMI 21 Constitutional: Chronically ill appearing white male in a wheelchair. Appears uncomfortable. Cardio: Regular rate and rhythm, no murmurs/rubs/gallops. Lungs: CTAB Abdomen: Soft, nontender, nondistended, + bowel sounds. No organomegaly. Skin: Dry skin Neurologic: A & O x4. CN 2–12 intact to testing. Strength is 5- out of 5 in bilat UE, RLE; 4 out of 5 in LLE. Intact reflexes at bilat triceps and biceps. Decreased reflexes bilateral patellar. **Labs:** WBC 10.1 Hb 8 / Hct 24.1 Plt 229 Na 142 K 5.9 Cl 109 CO2 20 BUN 64 Cr 5.2 Glc 83 Ca 12.7 Plasma protein 8.5 Albumin 5.0 Bilirubin 0.1 Alk phos 74 AST 14 / ALT 12 Phosphorus 6.2 Magnesium 2.3 HIV (–) TSH 2.14 A1c 5.2 % LDH 146 Ionized Ca 6.3 UA: 2+ protein, 1+ glucose, 1+ blood EKG: peaked T waves Kappa/Lambda FLC ratio 7684.21 (0.26–1.65) Kappa FLC 4380.00 (0.33–1.94) Lambda FLC 0.57 (0.57–2.63) 24 h urine protein 9226 (0–150) beta-2-Microglobulin 25.8 (1.1–2.5) MRI: Extensive malignant disease throughout the spine resulting in numerous compression fractures and involving the left iliac wing, left chest wall, left T9 rib, and paraspinal soft tissues. No spinal cord compression. Skeletal Survey: Extensive lytic lesions throughout the entire axial skeleton and the proximal two thirds of the humeri and femora. Multiple pathologic compression fractures throughout the thoracic and lumbar spine and an incomplete pathologic fracture of the left proximal humerus. Bone Marrow Biopsy: Plasma cells are increased (30 %). Flow cytometric analysis shows a monotypic, kappa-restricted plasma cell population (15 %) that is positive for CD56 and negative for CD20 and CD19. **Diagnosis:** Multiple Myeloma **Patient's course:** He was treated for elevated K and Ca emergently. His L humerus was immobilized in a sling. Renal biopsy showed cast nephropathy and he was started on sodium bicarb for acidosis. He received multiple blood transfusions and was started on cyclophosphamide, bortezomib and dexamethasone (CyBorD). He could not afford a SNF so he was discharged home after 4 weeks. As an outpatient, he received 3 more rounds of CyBorD. His creatinine improved to 2, and his kappa FLCs decreased from 4380 to less than 1. He underwent his first round of autologous hematopoietic stem cell transplant in Nov 2014.

DISCUSSION: Only 10 % of cases of multiple myeloma are diagnosed in individuals younger than 50, and only 2 % of cases in those younger than 40. Some of these cases are hereditary. The signs and symptoms of MM—anemia (73 %), bone pain (58 %), elevated creatinine (48 %), and fatigue (32 %)—are nonspecific, so a high index of suspicion is required to diagnosis multiple myeloma in the middle aged population. Most patients with MM initially present to their primary care provider, and delay in testing and diagnosis of MM leads to worse outcomes. Screening tests include SPEP+Immunofixation, UPEP+Immunofixation, serum free light chains, CBC, and CMP. Confirmatory tests include LDH, b2-microglobulin, bone marrow biopsy, and a skeletal survey. Treatment options include watchful waiting, chemotherapy and stem cell transplant. Younger patients with MM have a better prognosis than older patients.

AN UNCOMMON CAUSE OF SCANT PSEUDOHEMOPTYSIS Amy Chen, UCSF, San Francisco, CA. (Tracking ID #2198552)

LEARNING OBJECTIVE #1: Recognize the presenting symptoms of nasopharyngeal carcinoma (NPC).

LEARNING OBJECTIVE #2: Recognize extrapulmonary sources of bleeding when a patient presents with hemoptysis.

CASE: A 53 year-old Chinese woman with a history of hypertension presented to clinic for blood-tinged sputum. She developed a cough and bloody sputum in the setting of an upper respiratory tract infection 3 weeks prior to her visit. She continued to produce a pea-sized amount of bloody sputum every morning despite complete resolution of her cough. She denied fevers, chills, weight loss, hearing changes, nasal congestion, facial pain, dyspnea, chest pain, abdominal pain, changes in stool color. She is a lifetime nonsmoker. She was born in Hong Kong and lived there until she moved to the United States 20 years ago. Her head and neck exam was normal, she had no cervical lymphadenopathy, her lungs were clear to auscultation, and the remainder of her exam was unremarkable. Initial chest imaging was normal. Nasopharyngoscopy by ENT revealed a nasopharyngeal mass. A biopsy confirmed the diagnosis of nasopharyngeal carcinoma and additional imaging confirmed stage I disease.

DISCUSSION: In the US, the estimated incidence NPC is 0.5–2 per 100,000, whereas it is as high as 25 per 100,000 in Southeast Asia. Incidence of nasopharyngeal carcinoma remains high among people from endemic regions like Southern China and Hong Kong even after emigration but decrease with successive generations. The marked geographic and ethnic variation suggests an interplay of genetic, ethnic, and environmental factors. Patients often present with nonspecific head and neck symptoms and unfortunately, the majority of patients are found to have advanced disease at the time of diagnosis due to the propensity for lymphatic spread. A painless palpable neck mass is the most common presenting symptom (55 % in one study) and the diagnosis is then made after biopsy. Aural symptoms such as tinnitus, hearing loss, or recurrent serous otitis media are the second most common class of symptoms. Some patients present with sinus symptoms including epistaxis and recurrent rhinosinusitis. Epistaxis can be an overlooked source of bleeding and can be mistaken for hematemesis or hemoptysis, or in this case, pseudohemoptysis. Pseudohemoptysis is defined as expectorated blood that does not originate from the lungs or bronchial tubes. One study found that 10 % of patients who presented with hemoptysis were ultimately found to have an upper airway source of bleeding. Although a thorough history and physical can help distinguish true hemoptysis from pseudohemoptysis, in some cases, it is prudent to pursue a workup for both pulmonary and extrapulmonary sources of bleeding. NPC is rare in the United States but even in high risk regions, there are no guidelines for if and how to screen for NPC. However, experts recommend nasopharyngoscopy in the workup of new and recurring head and neck symptoms particularly in patients from Southeast Asia. In summary, this case reviews the pseudohemoptysis and other common presenting symptoms of nasopharyngeal carcinoma.

AN UNFORESEEN REACTION: A LESS COMMON CAUSE OF HYPERCALCEMIA Marlene Martin, Noriko Anderson, Sumant Ranji. University of California, San Francisco, San Francisco, CA. (Tracking ID #2195608)

LEARNING OBJECTIVE #1: Diagnose calcitriol-mediated hypercalcemia

LEARNING OBJECTIVE #2: Manage calcitriol-mediated hypercalcemia

CASE: A 52-year-old man with a history of Human Immunodeficiency Virus (HIV) and Hepatitis B (HepB) developed polyuria, polydipsia, nocturia, fatigue, and weight loss over a 2-month period. He attributed his symptoms to a change in his HIV medications and stopped his antiretrovirals (ARVs). He presented to a new primary care physician with acute kidney injury (AKI) to 2.18 mg/dL and hypercalcemia to 14.6 mg/dL, and was admitted for further workup and management. Hypercalcemia and AKI improved with intravenous fluids and pamidronate. Further workup revealed a suppressed parathyroid hormone (PTH) level of 3 ng/L and undetectable PTH related peptide (PTH-rP). 1,25(OH) vitamin D level was elevated at 128 pg/mL, with a normal TSH and cortisol level. There was no evidence of lymphoma or granulomatous disease on chest x-ray or computed tomographic (CT) scan of the chest, abdomen, and pelvis. Out of continued clinical concern for lymphoma, a PET scan was performed, which showed uptake in the patient's bilateral deltoid and buttock muscles. On further history, the patient admitted to injections of polymethyl methacrylate (PMMA) at these locations 5 years and 6 months prior to admission. These injections were performed for cosmetic reasons due to perceived muscle atrophy from HIV medications. Muscle biopsy showed chronic inflammation with histiocytes and a profuse foreign body giant cell reaction. Although frank granulomas were not found, the dense foreign body reaction was felt to explain his calcitriol-mediated hypercalcemia. The patient was treated with a course of prednisone, with resolution of hypercalcemia and improvement in his renal function.

DISCUSSION: Primary hyperparathyroidism and malignancy account for 90 % of the cases of hypercalcemia. While other etiologies are rare, they must be recognized because they can cause life-threatening hypercalcemia. Hypercalcemia greater than 13 mg/dL is usually malignancy associated. As our patient had both marked hypercalcemia and a history of HIV, a lymphoma needed to be ruled out. This led to a biopsy showing a foreign body reaction to PMMA injections. Calcitriol-mediated hypercalcemia is generally associated with granulomatous disorders. The granulomatous macrophage reaction produces PTH-independent calcitriol resulting in increased gut absorption of calcium and increased bone resorption. Although no granulomas were found, the histopathology of inflammation with giant cells has been found in other cases of calcitriol-mediated hypercalcemia due to foreign body reactions. In addition to treating the underlying disorder, treatment of calcitriol-mediated hypercalcemia encompasses reducing calcium intake, eliminating vitamin D supplements, and avoiding the sun. In some cases steroids and bisphosphonates are also warranted. Foreign body reactions to cosmetic injections can present as calcitriol-mediated hypercalcemia. To our knowledge this is the first case of PMMA injections causing such a reaction. Previous cases of calcitriol-mediated hypercalcemia have been reported in cosmetic paraffin oil and silicone injections.

AN UNUSAL CASE OF SATIN-INDUCED MYOPATHY Patrick Fadden²; Susan Wolver¹. ¹VCUHS, Richmond, VA; ²Virginia Commonwealth University, Chesterfield, VA. (Tracking ID #2195037)

LEARNING OBJECTIVE #1: Distinguish between statin induced myopathy and immune-mediated statin induced myopathy.

CASE: A 73 year old female with history of mitral valve stenosis requiring valve replacement presented to primary care clinic in May 2014 with sub-acute, progressive, painless, bilateral thigh weakness. She reported her weakness was first appreciated in 2010 after she suffered an elevated ST segment myocardial infarction (STEMI). Her cardiovascular function improved with rehabilitation but she reported her strength never returned to baseline. Her symptoms never interfered with daily activities and she maintained functionality in walking and using stairs. However, over the past 6 months she noted accelerated progression of thigh weakness so significant she required assistance in standing up and increased supervision while walking. She denied any associated pain or concerns for infection. Her other active medical issues included chronic atrial fibrillation, essential hypertension, and a multinodular goiter with negative FNA biopsy. Her pertinent medications included warfarin, tramadol, Lisinopril, metoprolol and Plavix. Simvastatin was initially added after her STEMI in 2010 but stopped in 2012. On exam, her vitals were within normal limits. She had 4/5 muscle weakness of her bilateral hip flexors with a delayed Timed Up and Go test. No atrophy, asymmetry, fasciculation or sensory deficits were observed. Labs revealed an elevated creatinine kinase (CK) at 709 U/L, normal ESR and TSH, and a negative ANA and anti-Jo. Neurology was consulted for assistance in evaluating her progressive myopathy. Over the next 4 months, her symptoms worsened and she demonstrated a persistent CK elevation of 500-700 U/L. EMG and muscle biopsy were deferred for concerns of bleeding due to mandatory anticoagulation. Screening labs for autoimmune and necrotizing myopathies were completed and all were normal with the exception of the HMG-CoA reductase IgG antibody which was positive at 3900 (reference <2400). In the setting of prior statin exposure and a remarkably negative work up, a positive HMG-CoA reductase antibody suggested evidence of an immune-mediated statin-induced myopathy.

DISCUSSION: Statin induced myopathy is a common adverse effect observed in up to 20 % of patients on statin therapy. Fortunately, symptoms are typically self-limited once the offending medication is discontinued. In contrast, immune-mediated statin-induced myopathy is a rare and serious complication from statin exposure and is characterized as a necrotizing myopathy with autoantibodies to the HMG-CoA reductase (HMGCR) receptor. The incidence of anti-HMGCR myopathy is estimated at 2 per million per year and can occur any time after exposure to statins. Clinical presentation is similar to statin induced myopathy with proximal muscle weakness and pain but often symptoms are more severe with persistent elevation in CK levels even after discontinuation of statin therapy. Distinguishing between these two statin induced myopathies is important as the autoimmune myopathy is treated with immunosuppressive therapy with either prednisone or immunoglobulin with or without methotrexate. This case was enlightening as she presented with progressive myopathy symptoms 2 years after discontinuation of statin therapy which highlights the sporadic nature of disease incidence. Statin use among Americans is at an all time high and likely to increase given the atherosclerotic cardiovascular risk guidelines developed by American College of Cardiology and the American Heart Association in 2013. Internists need to be aware of this rare and disabling autoimmune complication from statin exposure as the treatment differs vastly from general statin induced myopathy. Reference: Mohassel, P. and Mammen, A. L. (2013), Statin-associated autoimmune myopathy and anti-HMGCR autoantibodies. Muscle Nerve, 48: 477–483. doi: 10.1002/mus.23854

AN UNUSUAL ABDOMINAL MASS Migdalia Feliciano; Geeta Varghese. Mount Sinai Beth Israel, New York, NY. (Tracking ID #2193938)

LEARNING OBJECTIVE #1: Recognize unusual causes of abdominal masses

LEARNING OBJECTIVE #2: Recognize atypical features of lipomas and other variants of benign adipose tumors

CASE: A 72 year old female with a 15 year old left lower quadrant mass presents to the office for acute changes in the mass. She never saw a physician for this mass and over the last year, the mass had increased in size, became itchy and started to burn. She also noted a second lesion in the left upper quadrant. Patient denied fever, chills, weight changes, trauma to area, abdominal pain or constipation. Physical exam was remarkable for a left lower quadrant mass that measured 10 cm x 8 cm and a left upper quadrant mass that measured 5 cm x 4 cm. Both masses were warm, non tender, non fluctuant and without erythema. Vital signs and lab results were normal. Patient's weight remained stable within the past year. Ultrasound was done which revealed a 6.1 x 2.0 x 4.5 cm well-circumscribed, fatty mass in the left upper quadrant without demonstrable vascularity at the junction of the subcutaneous fat and rectus muscle consistent with a lipoma. In the left lower quadrant, a 11.3 x 4.3 x 8.7 cm well-circumscribed, subcutaneous, soft tissue mass with an echo pattern characteristic of fatty tissue was found. However unlike most lipomas, this mass had increased vascular flow which corresponded to venous flow on spectral tracings. The left lower quadrant mass was consistent with a giant lipoma with atypical vascularity. Given the atypical vascularity of the left lower quadrant mass in the initial study, magnetic resonance imaging (MRI) abdomen and pelvis was completed, which revealed a 8.4 cm craniocaudal x 5.2 cm AP x 10.1 cm transverse left lower abdominal wall lipoma with mild increased vascularity along its anterior superior aspect and thin peripheral septations consistent with a giant lipoma, and a 4.0 cm craniocaudal x 1.8 cm AP x 5.4 cm transverse left upper anterior abdominal wall lipoma, without suspicious enhancement or nodularity. Surgery was consulted for excision and biopsy. Patient underwent excision of left upper and left lower quadrant lipomas. Pathology was consistent with lipoma. No recurrence to date.

DISCUSSION: Abdominal masses encompass a broad differential diagnosis, including various malignancies, abscesses, abdominal aortic aneurysm, organ enlargement and volvulus. Of these different possibilities, benign adipose tumors in the abdomen are rare. Differentiating the cause of the abdominal mass in our patient was initially difficult given her unusual history and physical. Her stable mass started growing, became pruritic, developed a burning sensation and the mass was warm to touch. These findings suggested vascularity or infection. Lipomas are not typically vascular which warranted further study with MRI and biopsy. There are three different types of benign adipose tumors including lipoma, hibernoma and angiolipoma. Lipomas are the most common benign adipose tumors with an estimated incidence of 10 %. Lipomas can be either superficial or deep tissue. Eighty percent of superficial lipomas are less than 5 cm and located most commonly on the trunk, shoulder, upper arm and neck. Deep lipomas commonly occur in the chest wall and the deep soft tissues of the hands and feet. Rarely do they occur in the retroperitoneum. In comparison to superficial lipomas, deep tissue lipomas are less well defined and are larger in size. Giant lipomas are located in deep body planes and are at least 10 cm in one dimension. Lipomas are typically solitary lesions. The majority of lipomas gradually increase and then remain stable in size. They usually are asymptomatic, although pain, tenderness or compression of peripheral nerves can be present in up to 25 % of patients. Imaging for lipomas in atypical locations include ultrasonography, computed tomography (CT) scan and magnetic resonance imaging (MRI). Lipomas can be treated with nonexcisional techniques such as steroid injection and liposuction, as well as enucleation and excision. Indications for surgical excision of presumed lipomas include a mass greater than 5 cm, a tumor that is growing, a tumor deep to the deep fascia, concerning clinical features such as irregularity, rigidity or pain or a patient's cosmetic concern. Other benign adipose tumors include hibernoma and angiolipoma. Angiolipoma, a lipoma variant, contains mature fat cells, small vessels and capillaries. They are often multiple tumors commonly located in the arms and trunk. The ideal treatment of angiolipoma is surgical resection. Hibernoma is a rare benign, highly vascular adipose tumor composed of brown fat cells. They account for 1.6 % of benign adipose tumors. The most common location is the thigh, followed by the shoulder, back, head and neck. Surgical excision is the treatment of choice for hibernomas. Although, giant lipomas are rare in the abdominal cavity, they should be considered in the differential for abdominal masses.

AN UNUSUAL CASE OF ACUTE PULMONARY EMBOLISM PRESENTING WITH ST ELEVATION AND APICAL BALLOONING SYNDROME Deepthi Sudhakar¹; Jason Pelton¹; Holly Bentz¹; William Posligua¹; Don Pham¹; Mostafa O. El-Refai¹; David Paniagua²; Hani Jneid²; Ali Denktas². ¹Baylor College of Medicine, Houston, TX; ²Michael E. DeBakey VA Medical Center, Houston, TX. (Tracking ID #2195821)

LEARNING OBJECTIVE #1: Recognize acute pulmonary embolism as a cause of apical ballooning syndrome

CASE: Our patient is a 61 year old caucasian female with no significant past medical history who developed acute hypoxic respiratory failure while undergoing prolonged inpatient mental health treatment for suicidal ideation. The hospital's rapid response team was immediately activated. Initial assessment revealed a heart rate of 122 beats per minute, respiratory rate of 30, blood pressure of 141/77 mmHg, and oxygen saturation of 72 % on room air. Physical exam showed an unresponsive female in severe respiratory distress. Cardiopulmonary exam revealed regular tachycardia with no audible murmurs or gallops with clear lungs and absent jugular venous distension. Electrocardiogram showed ST elevation in anteroapical leads and the STEMI pager was activated. Laboratory findings were significant for elevated troponin I (0.05), CK-MB (14.7), CK (2647). The patient was subsequently started on unfractionated heparin and loaded with clopidogrel for treatment of acute coronary syndrome (ACS) and taken urgently for coronary catheterization. On arrival to the catheterization lab she went into cardiac arrest was emergently intubated for airway protection. Return of spontaneous circulation was achieved after 2 min of advanced cardiac life support (ACLS). Subsequent coronary angiography revealed normal coronary anatomy without obstruction; left ventriculogram was also performed and was significant for apical ballooning consistent with apical ballooning syndrome (APS). The mean pulmonary artery pressure was measured at 38 mmHg, consistent with pulmonary arterial hypertension. Transthoracic echocardiogram showed a severely dilated right ventricle and severe right ventricular systolic dysfunction concerning for acute pulmonary embolism. Chest X-ray was unremarkable. Computed tomography confirmed emboli in the left and right main pulmonary arteries with extension into the upper and lower lobe branches. Given hemodynamic instability and high oxygenation requirements, she was given 100 mg of systemic tPA with significant improvement in oxygenation. Troponin I peaked at 9.10 while CKMB and CK peaked at 30.6 and 3847 respectively. Lower extremity venous ultrasound subsequently showed a subacute occlusive thrombus in the left popliteal vein. She was transitioned from unfractionated heparin to low molecular weight heparin and started on warfarin for treatment of DVT/PE. Our patient improved significantly over the next few days and was successfully weaned off ventilator support and extubated. Due to our patient's extensive thrombus burden and risk of recurrent emboli and hemodynamic collapse, the decision was made to place an IVC filter. Repeat transthoracic echo was performed which showed mild improvement in right ventricular function with normal left ventricular ejection fraction. The remainder of her hospital course was unremarkable without any sequelae of heart failure or pulmonary hypertension.

DISCUSSION: Apical ballooning syndrome (APS), also known as Takotsubo cardiomyopathy or Broken Heart Syndrome, is a reversible stress-induced cardiomyopathy characterized by transient left ventricular (LV) apical ballooning and basal hyperkinesis. Predominantly seen in postmenopausal women, it presents with features of an acute myocardial infarction the absence of obstructive coronary artery disease or history of heart failure. Angina and dyspnea are the most common presenting symptoms but APS can also manifest as acute pulmonary edema, cardiogenic shock, ventricular tachyarrhythmias, and sudden cardiac death. APS is clinically indistinguishable from acute myocardial infarction and it is estimated that APS makes up approximately 2 % of acute coronary syndromes. While it is commonly linked to physical or emotional stressors, precipitating factors, particularly physical, remain challenging to identify and are unknown in one-third of cases. Our case is unique in the fact that although acute pulmonary embolism is a recognized cause of APS, there are only isolated case reports in the literature. The pathophysiological mechanism remains unknown, but is thought to be related to a stress-induced catecholamine surge and subsequent increase in sympathetic activity. While there lacks a consensus for diagnostic criteria for APS, guidelines proposed by the Mayo Clinic can provide diagnostic utility. Our patient satisfied all four criteria, including transient apical akinesis, ECG abnormalities, absence of obstructive coronary artery disease, pheochromocytoma, intracranial hemorrhage, and myocarditis. Prognosis for APS is excellent with low in-patient mortality and most patients recovering completely within days to months. In addition, although our patient presented with ST elevation on ECG, her clinical presentation was most consistent with pulmonary embolism. This case highlights the importance of recognizing pulmonary embolism and as a cause for APS with ST elevation.

AN UNUSUAL CAUSE OF DIARRHEA IN A YOUNG ADULT, EOSINOPHILIC COLITIS Andrew W. Hahn¹; Jamie Riney¹; Rebekah Mulligan¹; Kanak Das². ¹The University of Tennessee Health Science Center, Old Hickory, TN; ²The University of Tennessee Health Science Center, Memphis, TN. (Tracking ID #2182630)

LEARNING OBJECTIVE #1: Diagnose eosinophilic colitis based upon the triad of clinical, laboratory, and histological findings.

LEARNING OBJECTIVE #2: Treat eosinophilic colitis by distinguishing among the different etiologies of eosinophilic colitis.

CASE: The patient is a 27 year-old Caucasian male who presented to the ED with a chief complaint of diarrhea of 1-week duration. He had 10-15 watery, non-bloody bowel

movements per day with associated “crampy” RLQ abdominal pain unrelated to food or bowel movements. Upon questioning, he recently traveled to Costa Rica and had no family history of inflammatory bowel disease. Of note, he saw a gastroenterologist 2 days prior where he underwent a colonoscopy with multiple biopsies performed. Initial evaluation revealed a male in mild distress with stable vital signs. He had diffuse tenderness to palpation of his abdomen worst in the RLQ without rebound tenderness, and a rectal exam showed brown stool with a negative stool guaiac. Complete blood count (CBC) was significant for leukocytosis of 10.7 billion cells/L with 26 % eosinophils and 14 % bands, while remaining labs were unremarkable. The patient was admitted for evaluation of his diarrhea in the context of an elevated peripheral eosinophilia. Laboratory tests for parasitic infections and autoimmune conditions were negative. Stool cultures were positive for salmonella. Biopsy results from the colonoscopy revealed right colonic mucosa with preserved crypt architecture, brisk eosinophilic infiltrate in the lamina propria with greater than 100 eosinophils per high-power field (HPF), patchy mild neutrophilic cryptitis, and no parasitic elements. He was diagnosed with eosinophilic colitis. The patient’s salmonella infection was treated with levofloxacin for 7 day. His symptoms completely resolved 1 day after discharge and did not recur in the first month from discharge.

DISCUSSION: Eosinophilic colitis (EC) is one of the eosinophilic gastrointestinal disorders (EGID) along with eosinophilic esophagitis and gastroenteritis. EC is the least common of the EGIDs and has a bimodal distribution affecting infants and young adults. EC can be primary or secondary to numerous causes including parasitic infections, inflammatory bowel disease, and others as listed in Table 1. The disease has three hallmarks in its presentation: peripheral eosinophilia (5–35 %), segmental eosinophilic infiltration of the colon, and clinical symptoms that correlate to the layer of the colon affected. Colonoscopy findings in EC are non-specific, so biopsy is required to demonstrate the presence of eosinophils in a layer of the colon. While no consensus exist, EC is usually diagnosed between 15 and 25 eosinophils/HPF dependent upon the segment of the colon biopsied. The natural course of the disease is undefined, but treatment often begins with discontinuation of contributing medications and treatment of any parasites present. Then, clinicians can treat with a course of either corticosteroids or 5-aminosalicylic acid if needed.

AN UNUSUAL CAUSE OF HEART FAILURE -LEFT VENTRICULAR NON-COMPACTION Diana Purushotham; Nunzio Gaglianelli; Kurt J. Pfeifer. Medical College of Wisconsin, Milwaukee, WI. (Tracking ID #2195223)

LEARNING OBJECTIVE #1: Recognize left ventricular non-compaction(LVNC) as an etiology for new-onset heart failure in young patients

LEARNING OBJECTIVE #2: Review the unique diagnostic treatment options and medical complications associated with LVNC

CASE: A 29-year-old male with a history of severe systolic dysfunction presented with clinical symptoms of heart failure. At the age of 22 he was admitted for a gunshot wound and incidentally found to have severe systolic dysfunction with a left ventricular ejection fraction of 20 %. He underwent a left heart catheterization that revealed normal coronary arteries. He did have a history of substance abuse (a bottle of wine twice a month for “many years”, and occasional cocaine use). The patient subsequently had an implantable cardiac defibrillator (ICD) placed, but the etiology of his heart disease remained unknown. During this hospital admission he was diagnosed and treated for congestive heart failure exacerbation secondary to medication and diet non-compliance. He had a repeat transthoracic echocardiogram that showed trabeculations and a larger region of non-compacted myocardium compared to compacted myocardium consistent with a diagnosis of left ventricular non-compaction (LVNC). The echocardiogram also noted possible thrombus within the trabeculations, which is a known complication of this disease. He was aggressively diuresed and was continued on atorvastatin, carvedilol, lisinopril, spironolactone and lasix. Given the possible ventricular thrombus he was started on lifelong warfarin.

DISCUSSION: LVNC is a disease thought to be caused by early cessation of the compaction process during the 12th to 18th week of embryogenesis. As a result individuals with LVNC have a larger proportion of non-compacted to compacted myocardium, which increases the risk for development of severe left ventricle dilatation. As a result, they are more prone to heart failure, arrhythmias, sudden cardiac death, strokes, and limb ischemia. The diagnosis of this disease is made by either transthoracic echocardiogram or cardiac MRI. LVNC has an autosomal dominant mode of inheritance although sporadic cases have been reported. Patients should be managed according to the current guidelines for heart failure. This includes being treated with a beta blockers, statin therapy, renin-angiotensin blockade and aldosterone antagonists. The unique medical management for this disease includes consideration for anticoagulation given the higher risk for thromboembolism, as well as genetic testing for family members. LVNC is a rare disease, and should be considered in young patients with heart failure. The prognosis of this disease is poor, with many patients requiring heart transplantation.

AN UNUSUAL CAUSE OF UNILATERAL VISION LOSS IN A YOUNG FEMALE Kymberly E. McDonald^{1, 2}; John Vischio². ¹University of Connecticut, Wethersfield, CT; ²Hartford Hospital, Hartford, CT. (Tracking ID #2198088)

LEARNING OBJECTIVE #1: To keep a broad differential of etiologies causing sudden unilateral blindness in patients with seemingly negative initial work up.

LEARNING OBJECTIVE #2: Early diagnoses and recognition of disease etiology decreases morbidity by allowing targeted pharmacotherapy.

CASE: A 19 year old African-American female with no significant past medical history presented to the Emergency Department complaining of sudden onset left sided blindness. She had noted some blurred vision associated with a left sided headache the week prior to presentation, however, denied any focal weakness, changes in speech, or diplopia. She also noted some photosensitivity and eye pain over the same time period. Her vital signs were within normal limits. Review of systems was pertinent for reports of chronic dry eyes. Physical exam was only notable for decreased vision at one to two feet, however the remainder of the neurological exam was unremarkable. Initial laboratory data showed a white blood cell count of 7.1, normal chemistry panel, ESR 6, and a moderately elevated CRP at 4.3. Vitamin B12 and folate levels were WNL. Patient underwent an MRI of the orbits which showed enlargement and diffuse enhancement of the optic nerve from the left globe to the level of the optic chiasm consistent with acute left optic neuritis. Further work up included a lumbar puncture; cerebral spinal fluid was negative for Lyme antibody and HSV. There were no CSF oligoclonal bands, and cell count, protein, and glucose were all within normal limits. Neuromyelitis Optica testing was also found to be negative. She was initially treated as a new onset multiple sclerosis flare with high dose corticosteroids and discharged to home after some improvement in her vision. Further outpatient work up included a negative ANA, negative ANCA serologies, negative SCL-70, and negative rheumatoid factor. A PET scan was performed which showed increased uptake in her bilateral parotid and sublingual glands. She was then referred to Rheumatology where further work up revealed negative Ro (SSA), however positive La (SSB) antibodies at a level of 58. Due to the paucity of other symptoms or laboratory markers consistent with rheumatologic disorders, she then underwent a lip biopsy which showed >4 foci of >50 lymphocytes consistent with sialadenitis. A diagnosis of Sjögren’s Syndrome was made based on the positive La antibody and the lip biopsy results.

DISCUSSION: Sjögren’s syndrome (SS) is a chronic autoimmune inflammatory disorder characterized by diminished lacrimal and salivary gland function. Several established criteria are in place in order to diagnose SS, however caution must be taken in patients who test positive only for SSA or SSB antibodies; in those cases, a lip biopsy is warranted to confirm diagnoses and start appropriate pharmacotherapy. Central nervous system manifestations are rare and may mimic other autoimmune or neurologic diseases including multiple sclerosis and therefore proper diagnosis is key. Treatment typically includes corticosteroid treatment, however if the disease consists of continued progressive CNS destruction, monthly intravenous Cyclophosphamide for six to twelve months, or until stabilization or improvement is seen, has been recommended.

AN UNUSUAL PRESENTATION OF GOUT Saki Miwa. Baystate Medical Center, Springfield, MA. (Tracking ID #2196807)

LEARNING OBJECTIVE #1: Recognize cervical gout as a possible cause of severe neck pain.

LEARNING OBJECTIVE #2: Recognize the importance of history-taking in patients with severe neck pain.

CASE: A 74 year-old woman with history of coronary artery disease, diabetes, hypertension, hyperlipidemia, and bilateral breast cancer for which patient did not complete full chemotherapy regimen, presented to the Emergency Department (ED) with one month history of worsening posterior neck pain. She described the pain as radiating from her left jaw to left temple, constant but worse with movement of the neck, and associated with dizziness. She had visited the ED a month prior, where she underwent a CT of the spine w/o contrast which did not reveal any significant abnormalities, and she was discharged home. The neck pain initially improved but returned with more intensity several days prior to her second visit. Patient appeared to be in severe pain. Full neurological was exam normal, including strength and reflexes. Labs showed iron-deficiency anemia and elevated sedimentation rate (>130 mm/hr) but otherwise unremarkable. A routine chest x-ray revealed new 19 mm opacity in the left upper lung and a chest CT confirmed the presence of an irregular, spiculated mass in left upper lobe with lymphadenopathy, highly concerning for malignancy. An extensive work up was performed including: MRA of head and neck which was negative for stroke or arterial dissection; and MRI of cervical spine (with and w/o contrast) which was negative for metastatic lesion. However, the latter showed T1 and T2 hypointense soft tissue associated with the dens as well as craniocervical and C1-C2 articulations, which correlates with hyperdense and mineralized soft tissue related to the dens with multiple bony erosions, overall strongly suggestive of

gout. Further review of the patient's medical history revealed a prior history of gout, although never confirmed with joint aspirate, of her wrist 10 years prior. A uric acid level checked 1 year ago was 7.2 mg/dL. She was not on any long-standing gout treatment. Patient was treated symptomatically colchicine and oxycodone. With this treatment, her symptoms improved and her pain had nearly resolved 2 weeks later. Outpatient biopsy of the lung nodule showed features consistent with metastatic breast cancer, and patient has refused chemotherapy, electing for watchful waiting. Over the next 6 months, patient has had another episode of cervical gout (diagnosed based on symptoms) as well as gout in her wrist.

DISCUSSION: This case illustrates that although unusual, gout may be considered in the differential diagnosis of neck pain and the importance of a detailed history for diagnosis. In this case, the finding of a possible lung malignancy made bony metastases a major concern requiring extensive work-up. The lack of any recent gouty attacks and a relatively normal uric acid level made gout seem unlikely. However, studies suggest that cervical gout may be more common than expected. Although it would be unreasonable to expect cervical gout in all cases of severe neck pain, consideration should be given in light of past medical history. In addition, this case also touches upon the possible relationship that has been observed between gout and malignancy.

AN UNUSUAL SITE OF AVASCULAR NECROSIS IN A PATIENT WITH SICKLE CELL PAINFUL CRISIS Adnann Polani; Faran Polani; Pradeep Joseph, marshfield clinic, Marshfield, WI. (*Tracking ID #2153253*)

LEARNING OBJECTIVE #1: Patients with sickle cell painful crisis may present with musculoskeletal complications like avascular necrosis and osteomyelitis.

LEARNING OBJECTIVE #2: Although the areas most frequently affected are cortical bone of the acetabulum, the head of the femur, and the head of the humerus, occasionally unusual skeletal sites can be involved. In the setting of skeletal pain, a thorough and detailed musculoskeletal exam with high index of suspicion for these potential complications is hence recommended.

CASE: A 24 years old African American inmate with known history of sickle cell disease presented with back pain and generalized weakness that was consistent with his prior episodes of painful sickle cell crisis. However this time he also had an unusual pain over his collar bone. No fevers or chills were reported. There was no history of trauma. His physical exam except for the musculoskeletal system was unremarkable. There was fullness and exquisite tenderness over the medial aspect of right supraclavicular fossa. There was also significant tenderness over the right sternoclavicular joint and the medial aspect of the right clavicle, however there was no redness or warmth. Laboratory studies revealed a hemoglobin level of 9 g/dl which was close to patient's known baseline. Reticulocyte count, renal functional studies and venous lactate levels were normal. Mild leukocytosis and moderate elevation of inflammatory markers were noted. X-ray showed no fractures. The patient was treated with Intravenous fluid hydration, narcotics and empiric antibiotics for suspicion of avascular necrosis and possible osteomyelitis or septic arthritis. MRI within 24 h showed prominent bone marrow edema, periostitis, and surrounding soft tissue edema of the medial right clavicle, without discrete fracture or definitive evidence of osteomyelitis. In the proper clinical context the findings were suggestive of avascular necrosis. Subsequent blood cultures were negative. Antibiotics were discontinued and patient continued to improve with conservative therapy of Intravenous fluid hydration and pain control.

DISCUSSION: Avascular necrosis of bone is a common problem in patients with sickle cell disease however the areas most frequently affected are cortical bone of the acetabulum, the head of the femur, and the head of the humerus. There are case reports of avascular necrosis affecting other bony structures or joints, including the mandibular condyle and temporomandibular joint and the elbow, though the incidence and prevalence of involvement of these sites is unknown. Our survey of the literature however did not identify any reported case of avascular necrosis of the sternal end of clavicle secondary to sickle cell crisis. Given the early decrease in splenic function in sickle cell disease, bacterial super infection especially in the setting of osteonecrosis is not uncommon. Moreover it can be challenging to differentiate osteomyelitis and septic arthritis from osteonecrosis/avascular necrosis based on imaging and clinical features alone. Early diagnosis and high level of suspicion for musculoskeletal complications in a patient with sickle cell crisis is hence crucial.

AN UNUSUAL TUBERCULOSIS CASE Binyue Chang, Berkshire Medical Center, Pittsfield, MA. (*Tracking ID #2159575*)

LEARNING OBJECTIVE #1: Utilize proper diagnostic method in patient with unusual presentation of tuberculosis

CASE: A 62-year-old Caucasian male presented to emergency room (ER) for shortness of breath and nonproductive cough for a month. He smokes half a pack of cigarettes per day

for 40+ years. He works as a painter and repairman for nursing homes in recent years, during which he has negative tuberculin skin test (TSTs) to date. He is a regular blood donor with negative HIV infection. He was born and raised in the United States (US) and has never traveled abroad. At ER, patient's chest x ray showed bilateral predominantly right lung infiltrate and right middle lung nodule. He was discharged to home with 5-day Azithromycin. Despite antibiotic treatment, he started to have purulent sputum production. His follow-up CT chest ordered by primary care provider (PCP) in 1 month revealed irregular outlined well-circumscribed nodules with a cavitary lesion of right upper lobe. His PCP ordered TST and referred him to lung nodule clinic to be evaluated by thoracic surgery. TST turned out to be negative. After reviewing his CT imaging, pulmonary recommended QuantiFERON assay (an interferon- γ release assay used in tuberculosis diagnosis). When the QuantiFERON assay was positive, patient was admitted and bronchoscopy was performed. Bronchoscopy washings were sent for acid-fast bacillus (AFB) smear and culture. Initially, AFB smear did not detect mycobacteria. However, nuclear acid amplification test (NAAT) performed at the state lab was positive, confirming TB infection. Subsequently, sputum culture and bronchial washings culture turned out to be positive and this confirmed that he has active *Mycobacterium tuberculosis* (TB).

DISCUSSION: TB is one of the most debilitating diseases in the world. With more than two billion people infected by TB, it creates a huge economic and healthcare burden worldwide. In US, the rate of TB has declined to 3.0 cases per 100,000 inhabitants in 2013. Since there is a less alarming rate of TB infection in US, physicians may be less vigilant, especially when encountering US-born patients with negative TST. Interferon- γ release assay (IGRAs) are blood test that measures T cell release of Interferon-gamma followed by TB stimulation in vitro. The United States Centers for Disease Control and Prevention (CDC) 2010 guidelines indicate that IGRAs can be used in place of TST for diagnosis of TB. NAAT can reliably detect *Mycobacterium tuberculosis* bacteria in specimens 1 or more weeks earlier than culture and confirms rapidly the presence of *M. tuberculosis* in 50–80 % of AFB smear-negative, culture-positive specimens. When physicians are suspecting TB infection in TST negative patients, IGRAs and NAAT are reliable tests to order.

ANCA-ASSOCIATED RENAL-LIMITED VASCULITIS PRESENTING ATYPICALLY AS NONOBSTRUCTIVE HYDRONEPHROSIS Sarah Chuzy¹; Courtney Tuegel²; Bijal Jain^{3, 1}. ¹Northwestern University, Chicago, IL; ²Feinberg School of Medicine, Northwestern University, Chicago, IL; ³Jesse Brown VA, Chicago, IL. (*Tracking ID #2196728*)

LEARNING OBJECTIVE #1: Identify the different ANCA-associated vasculitides and the challenges in classification and diagnosis

LEARNING OBJECTIVE #2: Recognize nonobstructive hydronephrosis as an atypical presenting sign of ANCA-associated vasculitis

CASE: A previously healthy 68-year-old male presented to his primary doctor with 2 months of diffuse abdominal pain, fatigue, and a 30-lb weight loss. Workup revealed significant acute kidney injury (AKI), prompting admission. He had no urinary complaints and reported normal urine appearance and output. The rest of his history and examination was unremarkable. Serum creatinine (Cr) was 5.2 mg/dl, up from 1 mg/dl 2 months prior. Urinalysis revealed microscopic hematuria, sterile pyuria, proteinuria, and no casts. An abdominal CT-scan showed bilateral hydronephrosis with retroperitoneal lymphadenopathy along the right ureter, but no clear source of obstruction. Bilateral ureteral stents were placed without improvement in the Cr. Percutaneous nephrostomy tubes were subsequently placed with only modest improvement in the kidney function. Meanwhile, workup sent for weight loss and constitutional symptoms revealed a negative anti-nuclear antibody, mildly elevated rheumatoid factor, unremarkable workup for multiple myeloma, a markedly elevated erythrocyte sedimentation rate (108 mm/hr), and a positive cytoplasmic antineutrophil cytoplasmic antibody (c-ANCA). Given these findings, a renal biopsy was obtained, which showed crescentic glomerulonephritis, interstitial nephritis, and tubulitis, all consistent with a diagnosis of pauci-immune ANCA-associated vasculitis. The patient received 7 days of plasmapheresis, 3 days of pulse methylprednisone, and was started on maintenance cyclophosphamide and prednisone.

DISCUSSION: The diagnosis and classification of the ANCA-associated vasculitides (AAVs), which include granulomatosis with polyangiitis (GPA), microscopic polyangiitis (MPA), eosinophilic granulomatosis with polyangiitis (EGPA), and renal-limited vasculitis (RLV), is challenging as there are no well-validated classification schemes. Further, there is substantial overlap in clinical features among the AAVs and patients often fall on a continuum. Likewise, renal histopathology is quite variable within the AAVs and there is similar overlap among the vasculitides. For example, while pauci-immune crescentic necrotizing glomerulonephritis is the hallmark histologic lesion, glomerulosclerosis, interstitial fibrosis, tubular atrophy, and interstitial nephritis have all been described in the literature. No lesion, however, is shown to be specific for any diagnostic subgroup. Our patient had a positive c-ANCA and renal biopsy consistent with ANCA glomerulonephritis. However, he lacked the classic extrarenal manifestations of GPA, MPA, or EGPA. Thus, based on current

classification schemes, our diagnosis is renal-limited vasculitis. There are, however, case reports describing patients who initially presented with isolated pauci-immune glomerulonephritis but developed diagnostic extrarenal lesions later in their courses. In light of this, our patient's diagnosis remains subject to change. Importantly, this case represents an atypical presentation of renal vasculitis as hydronephrosis. There are case reports of GPA presenting as obstructive hydronephrosis from granulomatous inflammation of the peri-ureteral vessels or involvement of the ureter. Our patient did have narrowing of the right ureter at the level of the iliac vessels. However, since there was no improvement in kidney function after decompression, the hydronephrosis was nonobstructive. Lillaz and colleagues described a similar case in 2011 of GPA presenting with hydronephrosis on imaging. As in our case, the patient's Cr failed to improve with decompression, prompting kidney biopsy and subsequent discovery of AAV. In both cases, the underlying vasculitis caused the AKI, not obstruction. Physicians, thus, should be aware of hydronephrosis as an atypical presenting feature of AAVs and consider ANCA testing and renal biopsy in patients with AKI and hydronephrosis, particularly if decompression fails.

ANOTHER TYPE OF SICKLE CELL PAIN CRISIS Claire A. Evans²; Madeline E. Petty²; Thomas Montgomery¹. ¹Carolinas Healthcare System, Charlotte, NC; ²Carolinas Medical Center, Charlotte, NC. (Tracking ID #2200151)

LEARNING OBJECTIVE #1: Recognize hepatic sequestration crisis and acute sickle hepatic crisis as sequelae of sickle cell disease which are distinguished by clinical and laboratory findings.

LEARNING OBJECTIVE #2: Treat sickle cell patients with preoperative transfusions to prevent postoperative sickle cell crises, including hepatic sequestration crisis and acute sickle hepatic crisis.

CASE: A 19-year-old African American man with history of homozygous sickle cell (SS) disease underwent removal of an obstructed common bile duct stent and elective laparoscopic cholecystectomy at an outside hospital. Postoperatively, he developed severe right upper quadrant pain, anorexia, and fever to 103 °F. Serologic testing revealed a total bilirubin of 13.1 mg/dL, alkaline phosphatase of 98 IU/L, alanine aminotransferase (ALT) of 815 IU/L, aspartate aminotransferase (AST) of 697 IU/L, reticulocyte count of 23,000/microL, and lipase of 13 IU/L. His hemoglobin dropped from 8.2 g/dL to 7.0, then to 5.4. Given his continued severe pain, laboratory abnormalities, and dropping hemoglobin, he was transferred to our hospital for further treatment. On admission, patient was tachycardic and febrile with leukocytosis of 32,000/microL. His liver edge was palpable 1 cm below the right costal margin. Differential diagnosis included retained common bile duct stone, cholangitis, necrotizing pancreatitis, hepatic sequestration crisis, acute sickle hepatic crisis, or shock liver. Given his critical condition and rapidly dropping hematocrit consistent with hepatic sequestration crisis, exchange transfusion was deemed necessary and he was transfused 12 units packed red blood cells. His hemoglobin increased from 5.0 to 9.5. His percentage of hemoglobin S decreased from 60 to 14.9 %. For the remainder of his hospitalization, his pain improved substantially, vital signs stabilized, and hemoglobin was stable at 9.4.

DISCUSSION: As is true in other organ systems, the liver is susceptible to damage due to the sickling process. Two conditions associated with acute sickling are acute sickle hepatic crisis and hepatic sequestration crisis. The pathogenesis of acute sickle hepatic crisis is hypothesized to involve ischemia caused by sinusoidal obstruction. On the other hand, hepatic sequestration crisis is thought to be due to large numbers of sickled red blood cells acutely sequestered in the liver, similar to splenic or pulmonary vascular sequestration crises. Both of the described liver conditions can present with jaundice, right upper quadrant pain, and hepatomegaly. The key to determining the difference between the two is evaluating specific clinical and laboratory findings. Acute sickle hepatic crisis physical exam findings include nausea and low grade fever. Important laboratory values include increased concentrations of ALT and AST. Although there are some cases of levels over 1000 IU/L, aminotransferase levels rarely exceed 300 IU/L. Additionally, the serum total bilirubin concentration is usually elevated but not by more than 15 mg/dL. Conversely, hepatic sequestration crisis is associated with rapidly increasing hepatomegaly. Laboratory tests reveal falling hematocrit, often inversely related to the increase in liver size. Liver function tests are usually not affected. Eventually, continued sequestration can lead to shock and death. Treatment differs for the two conditions. While acute sickle hepatic crisis can be treated with intravenous fluids and analgesia, hepatic sequestration treatment can be more involved. Sometimes, simple transfusion therapy is sufficient to decrease the symptoms of anemia. One unit of blood may be enough to release blood that was previously sequestered in the liver back into circulation and thus cause autotransfusion. However, in extreme cases such our patient with acutely dropping hemoglobin, exchange transfusion may be necessary. The perioperative period is associated with increased risk of complications for patients with sickle cell disease. The current standard of care for patients with SS disease undergoing general anesthesia and surgery is to preoperatively be transfused to a hemoglobin level of 10 g/L to prevent precipitating a crisis. Importantly, however, there is ongoing debate in the literature regarding this issue. Some small nonrandomized studies of sickle cell patients undergoing laparoscopic

cholecystectomy showed no clinical benefit from preoperative transfusion. Conversely, the TAPS randomized controlled trial of patients undergoing medium-risk surgery ($n=343$) showed that preoperative transfusions were associated with decreased risk of clinically important and severe complications. Also, in another study of 364 sickle cell patients undergoing cholecystectomy, the incidence of sickle cell events was lower in patients who were transfused preoperatively. For our patient, it is worth wondering if his hepatic sequestration crisis may have been avoided had he been pre-transfused prior to his cholecystectomy.

ANTI-ERYTHROPOIETIN ANTIBODY ASSOCIATED PURE RED CELL APLASIA RESOLVED AFTER LIVER TRANSPLANTATION: A CASE REPORT Annie K. Hung; Jennifer Guy; Caroline Behler; Eugene Lee. California Pacific Medical Center, San Francisco, CA. (Tracking ID #2194743)

LEARNING OBJECTIVE #1: Patients undergoing antiviral therapy for chronic hepatitis C often develop anemia secondary to ribavirin, which causes dose dependent hemolysis, and interferon, which causes bone marrow suppression. Dose reductions of antivirals secondary to anemia are common and have been shown to be associated with decreased rates of sustained virological response. To improve anemia associated with antiviral therapy and to minimize dose reductions, erythropoiesis stimulating agents have been used. Rarely, patients can develop anti-erythropoietin antibodies which also have neutralizing capacity for endogenous erythropoietin. It is important to consider this complication in patients undergoing antiviral therapy when they develop severe anemia refractory to erythropoiesis stimulating agents.

LEARNING OBJECTIVE #2: Because of the rarity of this anemia, there have been no randomized controlled trials to date and there are only limited treatment recommendations which are immediate cessation of erythropoiesis stimulating agents and initiation of immunosuppression. Reports have documented full clinical recovery in patients treated with various immunosuppressive therapies including corticosteroids, cyclophosphamide, intravenous gamma globulin, cyclosporine, mycophenolate mofetil, and rituximab. In chronic kidney disease patients who received recombinant erythropoietin for anemia support and then developed anti-erythropoietin antibody associated pure red cell aplasia, there have been good outcomes associated with renal transplant and subsequent immunosuppression.

CASE: This report describes a 66 year old African American man with chronic hepatitis C and associated hepatocellular carcinoma who underwent treatment with ribavirin, pegylated interferon, and telaprevir while awaiting liver transplantation for the indication of hepatocellular carcinoma. Shortly after initiation of treatment, he developed anemia and was started on epoetin alfa. After 5 months, he continued to be anemic despite an increased dose of epoetin alfa and started requiring blood transfusions of two to three units of packed red cells every three to four weeks to keep hemoglobin above 7.0 g/dL. After dose reduction and then subsequent discontinuation of all antiviral therapy, his anemia did not improve. He underwent a thorough work up of his anemia and was found to have pure red cell aplasia from high titer neutralizing anti-erythropoietin antibodies at 21.4 mcg/mL. Bone marrow biopsy showed hypocellularity with trilineage hematopoiesis, without increase in blasts. Four weekly treatments of rituximab 375 mg per m² did not improve his transfusion dependent anemia. Subsequently, the patient underwent orthotopic liver transplantation for hepatocellular carcinoma without any complications. Chronic immunosuppression was initiated with prednisone, mycophenolate mofetil, and tacrolimus. In 10 weeks, he achieved hemoglobin greater than 10.0 g/dL. He has not required any more blood products with his last transfusion being 2 weeks post transplant. He was started on iron chelation therapy for iron overload, likely secondary to chronic transfusions.

DISCUSSION: Most of the research on anti-erythropoietin antibody associated pure red cell aplasia has focused on patients with chronic renal disease. The immunological mechanism behind this severe and often transfusion dependent anemia has yet to be elucidated and warrants further exploration. There is also limited data regarding outcomes of this entity in the setting of liver disease and liver transplant. In this case, a chronic liver disease patient developed anti-erythropoietin antibody associated pure red cell aplasia, and recovered after liver transplantation and three drug immunosuppression. It is unclear whether it is the transplanted organ, the subsequent immunosuppression, or a combination of both that contributed to the hematological response. In conclusion, anti-erythropoietin antibody associated pure red cell aplasia is a serious complication of recombinant erythropoietin therapy that necessitates prompt recognition and treatment, but this entity should not be considered a contraindication for solid organ transplantation.

ANTIBODIES IN ACUTE HEPATITIS: FRIEND OR FOE? Jonathan T. Cheah^{1,2}; Julie Kanevsky^{1,2}. ¹Montefiore Medical Center, Bronx, NY; ²Albert Einstein College of Medicine, Bronx, NY. (Tracking ID #2193973)

LEARNING OBJECTIVE #1: Describe the serologic profile of acute hepatitis B, including antibodies more commonly associated with other liver pathologies

LEARNING OBJECTIVE #2: Describe ways to differentiate between viral and autoimmune hepatitis when there is serological evidence of both

CASE: A 53-year-old man with no significant past medical history presented with a 3 month history of fatigue, nausea and weight loss of 25 lb. There was no vomiting, abdominal pain or change in bowel habits. Furthermore, there had been no recent medication changes and no reported use of over the counter supplements, illicit drugs or new sexual partners. Vital signs were stable. Examination was notable for scleral icterus, a soft, non-tender abdomen and no signs of chronic liver disease. Hemoglobin was 11.4 g/dL, white cell count 4.1 k/uL, platelet count 189 k/uL, total bilirubin 17.6 mg/dL, direct bilirubin 10.9 g/dL, alkaline phosphatase (ALP) 131 u/L, aspartate aminotransferase 1508 u/L, alanine aminotransferase (ALT) 1431 u/L and international normalized ratio 1.3. Liver tests when last checked 6 months earlier were all within the reference range. Cross-sectional imaging revealed a liver normal in size and signal intensity with no biliary tree dilatation. As the patient was hospitalized, a serological work up for the causes of an acute hepatitis was sent concurrently. This initially revealed a positive smooth muscle antibody (SMA) so a diagnosis of auto-immune hepatitis was entertained. However, this was then followed by positive hepatitis B surface antigen (HBsAg), IgM hepatitis B core antibody (IgM anti-HBc), hepatitis B e antigen (HBeAg) and a hepatitis B viral load of 1031,664 iu/mL. Additionally, anti-nuclear antibody (ANA) titer was <1:40 and anti-liver kidney microsomal (LKM) antibody was negative. The only potential cause of transmission identified was a clean shave at a barber shop and overall, the presentation felt consistent with acute hepatitis B infection.

DISCUSSION: The internist in both the outpatient and inpatient settings will encounter the discovery of markedly raised liver tests. While the differential can initially be broad, acute hepatitis occurs over 2–24 weeks when values of ALT rise to at least 800 u/L and there is an accompanying ALP rise to less than three times the upper limit of normal. This has a much narrower differential including viral, ischemic, auto-immune and toxin-mediated (for example, medications including acetaminophen) causes. Viral causes of an acute hepatitis are comprised of the hepatotropic viruses: hepatitis A, B, C, D, E as well as reactivation of hepatitis B. In the United States, acute hepatitis A, B and C are most common with hepatitis B comprising 2890 reported and 18,800 estimated cases in 2011. In adults, 70 % of acute hepatitis B infection results in a subclinical or anicteric hepatitis, 30 % have icteric hepatitis while less than 1 % progress to fulminant hepatitis. The diagnosis of hepatitis B depends on a number of serologic markers. Acute hepatitis B is defined by positive HBsAg, HBeAg (detectable at start of infection) and IgM anti-HBc (detectable 1–2 weeks after the appearance of HBsAg and at the time of rise in aminotransferase concentrations). However, other serologic markers can additionally be detected. These include auto-antibodies more commonly associated with auto-immune disease such as ANA and SMA. Classically, SMA are found in conjunction with the diagnosis of auto-immune hepatitis, which may lead to uncertainty in the diagnosis of an acute hepatitis in the early course of disease. In a range of studies, SMA was present in between 27 and 71 % of patients with acute hepatitis B infection. Furthermore, some studies have suggested that the presence of SMA, especially of the IgG sub-group, in acute hepatitis B infection may be a marker of increased likelihood of progression to chronic hepatitis B infection. However, the reason for the development of SMA in hepatitis B infection has not been well defined. If serological features of both viral and auto-immune hepatitis are present, a number of suggested differences between the two can be used to distinguish the two entities. Phenotypically, those with auto-immune hepatitis tend to be female and generally present with chronic hepatitis, while serologically, those with auto-immune hepatitis have titers of auto-antibodies (ANA, SMA or LKM) at least >1:40 and a selective elevation of IgG with levels of IgA and IgM within the reference range. Furthermore, both have distinctive appearances on liver biopsy. Additionally, there are a subset of patients who have both auto-immune and viral hepatitis concurrently, however, it is more likely to be in the setting of chronic disease and with hepatitis C infection. In conclusion, acute hepatitis B should be considered in the differential of markedly elevated ALT and can induce the development of circulating auto-antibodies which may lead to confusion regarding initial diagnosis.

AOSD MASQUERADING AS SEPSIS: A CASE REPORT Djamshed Samiev; Daniel Goldsmith; Michael S. Beede; Olga Tarasova. Capital Health Regional Medical Center, Trenton, NJ. (Tracking ID #2197535)

LEARNING OBJECTIVE #1: Recognize AOSD when it presents with symptoms characteristic of sepsis

CASE: AOSD is an inflammatory disorder of unknown etiology that is characterized by daily fevers, an evanescent rash, and arthritis. In rare cases, a patient with AOSD may present with symptoms characteristic of sepsis. Because the treatments for AOSD and sepsis are different, it is very important to correctly distinguish between the two, as early recognition of AOSD masquerading as sepsis will allow for earlier implementation of steroid treatment and better treatment outcomes. A 32 year old African American female with a known history of AOSD and rheumatoid arthritis who was being treated with

azathioprine and naproxen presented to the ER with a complaint of daily fevers, sore throat, arthralgia, and skin rash for five days. On examination, her initial vital signs were 103.20, heart rate 145, blood pressure 121/76, respiratory rate 22, saturation 97 % on room air. She had pharyngeal erythema and a salmon-pink rash on her upper extremities. Electrolytes were normal, lactic acid 1.3, WBC 8.1, bands 56, ESR 84, CRP 16.8, CXR clear, UA 6–10 WBCs. The patient was given Tylenol and aggressively hydrated in the ER. After the first liter, her heart rate went down to 125, but her systolic blood pressure dropped to the 70s. Sepsis was suspected and aggressive hydration was continued. The patient was also started on vancomycin and maxipime. The patient was transferred to the ICU, at which point her ferritin level was reported to be 4558. At this juncture, the possibility was entertained that the patient's sepsis-like presentation could be triggered by hyperferritinemic syndrome, especially considering her established history of AOSD, and the patient was started on IV steroids, which resulted in rapid improvement in her condition. On the second day, antibiotics were discontinued, and by the fourth day she was released in stable condition.

DISCUSSION: This case illustrates the potential for AOSD to present with symptoms characteristic of sepsis due to hyperferritinemic syndrome. Especially in patients with an established history of AOSD, clinicians should be aware of this possibility in order to enable earlier introduction of corticosteroids into the treatment regimen, thus achieving speedier recovery and decreased length of stay in acute care settings.

APICAL HYPERTROPHIC CARDIOMYOPATHY: A “GIANT-NEGATIVE” DIAGNOSIS Patrick J. Nolan¹; Courtney M. Moore¹; Sajith Matthews^{1, 2}; ¹WSUSOM, Northville, MI; ²Detroit Medical Center, Detroit, MI. (Tracking ID #2191707)

LEARNING OBJECTIVE #1: Recognize the distinctive ECG and TTE findings in Apical Hypertrophic Cardiomyopathy, especially in patients presenting with dyspnea, palpitations, and displaced PMI.

CASE: A 61-year old African American gentleman with past medical history of intermittent atrial fibrillation, hypertension, and COPD presented to the emergency department (ED) in an extremely somnolent state with chief complaints of shortness of breath and a “pounding heart”. On physical exam he was malnourished, dehydrated, and tachycardic at 100 beats per minute with a 5/6 holosystolic murmur heard best at the left sternal border. PMI was visible and displaced infero-laterally. There was decreased air movement globally and a prolonged expiratory phase. Arterial Blood Gas drawn in the ED showed pH=7.39, CO₂=76, HCO₃=36 and O₂=86 with no wheezing, likely reflecting compensated COPD; not an acute exacerbation. Chest radiograph showed emphysematous changes without pulmonary infiltrates. His clinical condition limited the history of present illness, leading to an EMR review exposing several ED visits. On admission 8-months prior, an ECG was performed showing apical left ventricular hypertrophy evidenced by R-waves ranging 2.0 to 3.0 mV and deeply inverted (“Giant-Negative”) T-waves (>1.0 mV) in leads V4–6. However, it was not until a later, separate, admission that a Transthoracic Echocardiogram (TTE) was ordered in response to an indeterminate troponin. TTE revealed a morphologic appearance consistent with apical variant hypertrophic cardiomyopathy including disproportionate apical segment hypertrophy, visually estimated ejection fraction >80 % with impaired relaxation pattern, and near cavity obliteration at the apex in systole. The abnormal ECG and TTE findings were combined with our patient's presentation and physical exam to, at last, establish a diagnosis of Apical-HCM. Normal saline at 100 ml/hr. and 2 L/hr. of oxygen via nasal cannula were started. Our patient became increasingly more alert and less dyspneic. He was counseled on the importance of adequate hydration, as his cardiovascular morphology is fluid dependent, and adherence to Metoprolol for increased ventricular filling time.

DISCUSSION: Apical Hypertrophic Cardiomyopathy (A-HCM), a variant in which the hypertrophied myocardium is located in the most distal portion of the Left Ventricle (LV), was first described in Japan in 1976. Prevalence of this variant represents only 1–3 % in the non-Japanese population. Symptoms may include dyspnea and palpitations, reflecting the reported arrhythmias associated with this condition. Since our patient had not received an appropriate and conclusive diagnosis of A-HCM, it is likely his COPD (resulting in recurrent ED visits with only slight improvement) and its rare occurrence in the non-Japanese population actually masked the true underlying cause as A-HCM. Therefore, abnormal cardiovascular findings on physical exam, as evident in our patient, should strongly alter the workup to pursue an alternative diagnosis. Thus, recognition of the distinctive ECG and TTE findings are vital in diagnosing A-HCM; especially in patients presenting with dyspnea, palpitations, and displaced PMI.

ARE OUR PATIENTS SAFE DURING IN-HOSPITAL TRANSPORT ??? Chandramohan Meenakshisundaram¹; Nanditha N. Malakkla¹; Dima Dandachi¹; Venu Pararath Gopalakrishnan¹; Venu M. Ganipiseti². ¹Saint Francis Hospital, Evanston, IL; ²presence saint francis, Evanston, IL. (Tracking ID #2199633)

LEARNING OBJECTIVE #1: Importance of administering incremental doses of sedatives in high risk individuals who are prone to develop respiratory depression.

LEARNING OBJECTIVE #2: To emphasize the importance of essential monitoring during in-hospital transport of patients. Discuss the basic strategies to decrease the adverse events and ensure safe transport.

CASE: Fifty-two year old obese AA female was brought by her sister to ED as she sounded confused and her speech was slurring over phone. Her past medical history included hypertension, DM, HLD, Sleep apnea and hypothyroidism. Her medications were metformin, amlodipine, Lisinopril, metoprolol, synthroid and fluoxetine. Vitals revealed tachycardia and SpO₂ of 91 %. On physical examination she appeared confused, agitated, had slurring speech but no significant neurological deficit. Basic labs were significant for leukocytosis, blood glucose of 685 mg/dl, ABG showed severe respiratory and metabolic acidosis, negative serum and urine acetone. She received ativan for agitation and placed on BiPAP support. She was given fluid boluses and started on insulin infusion. During CT imaging of brain as she remained agitated she received additional doses of ativan. Then she was transferred to ICU with only cardiac monitor. On arrival to ICU, she was found to have shallow respirations and saturated 60 % with BiPAP. She had massive emesis twice during intubation and was started on mechanical ventilatory support. Next day her CXR showed increasing infiltrates in both lung fields and her oxygen requirements were also increasing. ARDS protocol was initiated. Over the next few days she also developed AKI and eventually became oliguric. She also needed Hemodialysis for few weeks. Her TSH was elevated (30 mIU/ml) and started on IV levothyroxine. She was successfully extubated and her renal function returned to baseline in about a week. As she was deconditioned by the complicated hospital stay of 48 days she was discharged to sub-acute rehabilitation facility.

DISCUSSION: Our patient had a prolonged and complicated hospital stay that was not related to her presenting complaints but due to insufficient monitoring during imaging that was least necessary and during transport to intensive care unit after multiple doses of benzodiazepine which is well known to cause respiratory depression. The intra-hospital transport of patients is often performed by unlicensed hospital personnel who encounter patient condition changes that require immediate intervention. Risk reduction strategies include development of an intra-hospital transport team, handoff communication using a specific tool including written information facilitating clear communication before, during and immediately following transport from the patient care unit to the destination point and back. Also the transport personnel should have robust educational and competency program including CPR certification to ensure safe patient transport. All hospitals should develop a transport team model with clear outline of specific responsibilities for each team member. Every patient should be assessed for the basic level of monitoring needed, the required equipment and the expected level of intervention if there is any change in patient condition. Intra-hospital transport exposes patients to potential periods of instability and increases the risk for complications, morbidity and mortality. Physicians must evaluate the risk benefit ratio of each transport, the need of urgency of diagnostic imaging or the therapeutic procedures, and accurate information exchange will decrease the number of adverse events.

ASCITES IN A CASE OF MONOCLONAL GAMMOPATHY OF UNDETERMINED SIGNIFICANCE (MGUS). Venu Pararath Gopalakrishnan³, Sreelakshmi Panginikkod², Malav P. Parikh⁴, Chandramohan Meenakshisundaram³, Mashooque Dahar², Ubaid Sherwani¹. ¹Presence Saint Francis Hospital, Evanston, IL; ²Presence saint Francis hospital, Evanston, IL; ³Saint Francis Hospital, Evanston, IL; ⁴Saint Francis Hospital, Evanston, IL; ⁵Calicut Medical College, Calicut, India. (Tracking ID #2199428)

LEARNING OBJECTIVE #1: Recognize the clinical manifestations of POEMS syndrome. (Polyradiculoneuropathy, Organomegaly, Endocrinopathy, Monoclonal plasma cell neoplasm, Skin changes).

LEARNING OBJECTIVE #2: Recognize the role of SAAG (Serum Ascites-Albumin Gradient) in the differential diagnosis of ascites.

CASE: A 52 year old male presented with complaints of abdominal distention associated with discomfort, fatigue and decreased appetite for past 2 months. His past medical history was significant for a diagnosis of hypothyroidism, polyneuropathy and Monoclonal Gammopathy of Undetermined Significance (MGUS). Clinical examination revealed an emaciated male with large tense ascites, pedal edema, small muscle wasting of hands and tight skin of fingers. Routine laboratory studies were unremarkable with normal Liver Function tests (LFT) including albumin. Ascitic fluid analysis revealed SAAG of 0.9 and ascitic fluid protein of 3.2. The ascitic fluid cytology was negative for malignant cells. Hepatitis serology and HIV were non reactive. CEA and CA 19-9 levels were normal. Serum protien electrophoresis was positive for an M spike. Serum immunofixation was consistent with IgA monoclonal gammopathy. The serum VEGF (Vascular Endothelial Growth Factor) and IL-6 (Interleukin—6) levels were also found to be elevated. Chest X Ray showed mild right pleural effusion. Transthoracic echocardiography showed normal ejection fraction. Computerized Tomography scan of the abdomen revealed massive ascites, normal liver, mildly enlarged spleen and retroperitoneal lymphadenopathy. Bone scan did not show any sclerotic lesions. Based on the overall clinical picture of

polyneuropathy, monoclonal gammopathy associated with splenomegaly, lymphadenopathy, hypothyroidism, sclerodermoid skin changes, features of extravascular volume overload and supporting lab results, the patient was diagnosed with POEMS syndrome and started on Melphalan and Decadron therapy. He showed significant improvement in the follow up.

DISCUSSION: POEMS syndrome is a rare paraneoplastic syndrome which is caused by an underlying plasma cell disorder. The acronym PEOMS stands for Polyradiculoneuropathy, Organomegaly, Endocrinopathy, Monoclonal plasma cell neoplasm and the Skin changes. The diagnosis of POEMS syndrome requires the presence of at least one of the three major criteria, one minor criteria and both the polyradiculoneuropathy and the monoclonal plasma cell disorder. Major criteria include Castleman disease, sclerotic bone lesions and elevated VEGF. Minor criteria include organomegaly, endocrinopathy, characteristic skin changes, papilledema, extravascular volume overload and thrombocytosis. Extravascular fluid overload most commonly manifests as peripheral edema, effusions and ascites. Only those patients with peripheral neuropathy and a plasma cell clone should be classified as having classic POEMS syndrome. Diagnosis is often delayed because the syndrome is rare and can be mistaken for other neurologic disorders, most commonly chronic inflammatory demyelinating polyradiculoneuropathy. Early recognition is important to reduce morbidity. Systemic chemotherapy with the use of melphalan plus dexamethasone has demonstrated good response rates with an acceptable toxicity profile. Median survival in patients of POEMS syndrome with extravascular fluid overload was determined to be 6.6 years as compared to overall median survival of 13.7 years.

ASYMMETRIC PLEURAL EFFUSION AS AN INITIAL PRESENTATION OF RHEUMATOID ARTHRITIS Neal George; Samer Makhoul. Conemaugh Memorial Medical Center, Johnstown, PA. (Tracking ID #2198762)

LEARNING OBJECTIVE #1: Diagnose pleural effusions associated with rheumatoid arthritis.

LEARNING OBJECTIVE #2: Diagnose atypical presentations of rheumatoid arthritis.

CASE: A 56-year-old caucasian male with no significant past medical history except for 3 month history of mild diffuse arthralgias presented to the emergency room with shortness of breath for the last 7 days. On physical exam, there was decreased air movement on the left side. Upon interview of the patient he admitted to intermittent arthralgic pain in both bilateral hands and bilateral feet that he controlled with over the counter non-steroidal anti-inflammatory medications. Laboratory studies revealed a leukocytosis of 21.1 thousand/cumm. Chest x-ray showed moderate-sized left pleural effusion and associated airspace opacity. Blood cultures remained negative after 5 days. Pulmonary medicine was consulted for thoracentesis of what was initially thought to be a parapneumonic effusion. Thoracentesis was successfully performed with 1000 mL of yellowish cloudy fluid removed from the left chest. Pleural fluid was negative for any acid-fast organisms, exhibited no growth on culture, and cytology revealed abundant mixed inflammatory cells and macrophages, and was negative for malignant cells. The pleural fluid contained RBCs of 100/cumm, WBCs of 15,000/cumm, 83 % segs, 4 % lymph's, 11 % macrophages, 2 % eosinophils, protein of 5.7gm/dL, LD 5005 IU/L, glucose was <5 mg/dL, and pH was 7.10. Lyme serology was negative. Rheumatoid factor was positive with a titer of 320 IU/mL and an elevated erythrocyte sedimentation rate of 32 mm/hr. Pt was treated with methylprednisolone intravenously and subsequently discharged on oral prednisone with significant improvement of his arthralgias and shortness of breath. Pt is currently undergoing rheumatologic evaluation and treatment for his rheumatoid arthritis.

DISCUSSION: Rheumatoid arthritis (RA) is a systemic inflammatory destructive process that characteristically attacks joints. RA can contribute to increased mortality through its extra-articular pulmonary, cardiac, and vascular manifestations. Pulmonary manifestations contribute to 10 to 20 % of all mortality amongst patients with RA and tend to occur within 5 years after initial diagnosis. Pleural effusions tend to occur in approximately 5 % of patients and tend to be small and asymmetric, and occur more frequently in males than females. Patients who develop RA associated pleural effusions tend to have high titers of rheumatoid factor that may precede joint involvement. Avnon LS et al. 2007 conducted a literature review and found that 95 % of patients with RA-associated pleural effusions had high titers of rheumatoid factor. RA associated effusions account for only 0.6 % of all exudative pleural effusions. Pleural fluid associated with this type of effusion typically shows a low glucose level (<50 mg/dL), high lactate dehydrogenase (>1000 IU/L), and low pH (<7.30). No consensus exists of how RA associated effusions appear upon cytological evaluation. Further studies are needed to elucidate if cytology plays a role in distinguishing these exudative effusions from other causes for exudative effusions. Treatment with systemic steroids and intra-pleural steroids are effective in most cases. The above case illustrates that the initial presentation for RA can manifest atypically as an exudative pleural effusion and is therefore often overlooked by clinicians.

AXITINIB INDUCED CARDIOMYOPATHY Christopher A. D'Avella; Rahul Parikh. University of Pittsburgh Medical Center, Pittsburgh, PA. (Tracking ID #2195102)

LEARNING OBJECTIVE #1: Recognize the existence of cardiovascular complications associated with Vascular Endothelial Growth Factor (VEGF) tyrosine kinase inhibitors (TKI) including axitinib

LEARNING OBJECTIVE #2: Emphasize the importance of monitoring subjects on Vascular Endothelial Growth Factor (VEGF) tyrosine kinase inhibitors (TKI) for cardiomyopathy

CASE: Sixty year old male with history of hypertrophic cardiomyopathy, coronary artery bypass surgery and septal myectomy 6 years prior to presentation was started on axitinib for metastatic renal cell carcinoma. His co-morbidities included obstructive sleep apnea, chronic renal insufficiency and hypertension. He started axitinib in June 2013 after progression on sunitinib (VEGF tyrosine kinase inhibitor) and everolimus (mammalian target of Rapamycin (mTOR) inhibitor). A baseline echocardiogram prior to starting axitinib showed an ejection fraction of 40–45 % with no wall-motion abnormalities. Six weeks after initiation of axitinib, the patient developed increased fatigue and dyspnea on exertion. His examination revealed bilateral lower extremity edema, normal S1 and S2, no murmurs nor elevated JVP. Repeat echocardiography demonstrated acute worsening in his ejection fraction to 25–30 % with mild dilation of the left ventricle. His EKG showed no acute changes and no acute coronary syndrome. His laboratory findings including a CBC and BMP were within normal limits. Though not previously reported, his clinical course suggested possible axitinib induced cardiomyopathy; axitinib was held and enalapril, carvedilol, and furosemide were initiated. The patient's symptoms improved off axitinib and a repeat echocardiogram 6 weeks later showed an improvement in his ejection fraction to 35–40 %. Subsequently, a case report of axitinib-induced Takotsubo like syndrome was published.¹

DISCUSSION: Myocardial toxicity is a known side effect of many cancer treatments. The anthracyclines doxorubicin, daunorubicin, epirubicin and mitoxantrone have known cardiotoxicity; additionally, myocardial injury has also been associated with tyrosine kinase inhibitors, alkylating agents, anti-metabolites, proteasome inhibitors and anti-microtubule agents.² Recently, a number of VEGF-R directed targeted therapies have been approved for the treatment of metastatic renal cancer. In this case, a patient with metastatic renal cell carcinoma and pre-existing cardiac disease developed a reversible cardiomyopathy while taking axitinib. Axitinib targets the vascular endothelial growth receptors 1, 2 and 3 and is approved as a second line therapy for metastatic renal cell carcinoma based on results of a Phase III AXIS study.³ Four additional VEGF inhibitors-sunitinib, pazopanib, sorafenib and bevacizumab- are also approved for the treatment of metastatic renal cell carcinoma. Traditionally, fatigue and hypertension have been the most commonly reported side effects with this class of targeted therapies. Cardiomyopathy has been associated with the use of sunitinib, bevacizumab, and sorafenib. An association between pazopanib or axitinib and cardiotoxicity has not been well described.⁴ Phase III clinical trials for axitinib showed a small incidence of cardiomyopathy.³ Compared to anthracyclines, cardiotoxicity associated with tyrosine kinase inhibitors appears to be less profound but more acute in presentation and is not dose-dependent. Treatment of VEGF inhibitor associated cardiomyopathy includes cessation of therapy with close follow up to monitor for recovery of systolic function. The reversibility of this cardiomyopathy is unknown, although limited literature with sunitinib induced cardiotoxicity suggests improvement in ejection LV function and symptoms after cessation of the drug.⁵ In our subject, cardiac function improved dramatically after discontinuing axitinib. Targeted therapies have an ever-expanding role in modern medicine, and likewise, VEGF inhibitors are commonly utilized for treatment of metastatic kidney cancer. Adverse effects of these new agents are continuing to be evaluated; further studies are needed to delineate their cardiovascular side effects. Generalists and subspecialists alike should be aware of possible cardiotoxicity in association with targeted therapies, especially in patients with cardiac comorbidities, and should monitor patients accordingly. 1. BACK PAIN MADE WORSE Madeline E. Petty²; Claire A. Evans²; Thomas Montgomery¹. ¹Carolinas Healthcare System, Charlotte, NC; ²Carolinas Medical Center, Charlotte, NC. (Tracking ID #2200140)

LEARNING OBJECTIVE #1: Recognize that the clinical signs of spinal epidural abscess (SEA) are localized back pain, fever and neurological changes, and that intramuscular injections for analgesia are a predisposing risk factor.

LEARNING OBJECTIVE #2: Treat SEAs with prolonged antibiotic therapy for at least 8 weeks and surgical drainage when appropriate to avoid complications.

CASE: The patient is a 60 year old woman with a past medical history of mild low back pain who developed severe right-sided lumbar back pain after twisting her back while playing with her grandchildren. She received an intramuscular injection containing 10 mg of dexamethasone, 60 mg of orphenadrine, and 60 mg of ketorolac to her right gluteus muscle for possible sciatica 12 days before presentation. Six days later she continued to have pain, so she saw her primary care physician who performed a magnetic resonance imaging scan (MRI). This showed mild degenerative changes with a minimal annular bulge at L5-S1. Six days later, she presented to the hospital for weakness, severe back pain, hypotension, tachycardia, fever, and leukocytosis to 35,000/microL. Her lumbar paraspinal muscles on the right side were exquisitely tender to palpation. The pain radiated down her right leg and she was unwilling to move that leg. She was neurologically intact but she was having some episodes of urinary incontinence. She underwent a repeat MRI of her lumbar spine which revealed an L3-S1 epidural abscess, several paraspinal abscesses and right sacroiliitis (images included). The infection was thought to have originated in the right sacroiliac (SI) joint. A computed tomography-guided aspiration was performed, but all cultures were negative for growth. A transesophageal echocardiogram was performed which showed no evidence of valvular vegetations or endocarditis. Two sets of blood cultures were performed which revealed no growth. She was treated with 8 weeks of intravenous (IV) vancomycin and cefepime. Her infection, as well as her pain, completely resolved.

DISCUSSION: A spinal epidural abscess (SEA) is a collection of pus between the dura mater and the ligamentum flavum. The development of these abscesses is relatively rare. However, if they are not diagnosed and treated, they can lead to septic shock, spinal cord impingement and irreversible paralysis. The clinical signs of SEA are localized back pain, fever and neurological changes. The incidence of SEAs has increased recently, possibly due to an increase in the number of spinal procedures and IV drug use. The organism responsible for SEAs in 50–90 % of cases is *Staphylococcus aureus*. The incidence of Methicillin-resistant *S. aureus* (MRSA) is increasing, especially in IV drug users and those with a history of spinal surgery. Other organisms that can cause SEA include *Streptococci*, gram negative bacilli, *Nocardia* species, *Mycobacterium tuberculosis* and fungi. In this case, the patient's paraspinal and epidural abscesses were thought to be secondary to right-sided pyogenic sacroiliitis. The sacroiliitis itself was secondary to a right gluteal injection that she received. Epidural abscesses are usually caused by hematogenous dissemination. However, her blood cultures were negative and no evidence of endocarditis was found. In her case, the infection was undoubtedly spread by direct dissemination from adjacent structures. Our patient did not have any of the other usual risk factors for SEA, such as diabetes mellitus, blunt spinal trauma, or a history of back surgery, alcohol abuse, or IV drug use. No organisms were identified on culture of aspirated pus from her largest paraspinal abscess. Therefore she was treated with broad-spectrum first-line coverage for MRSA and aerobic gram negative bacilli. She did not require surgical drainage as she improved with antibiotics alone. Our case demonstrates that intramuscular injections for analgesia should be considered a predisposing risk factor for spinal epidural abscess. If these patients present with localized pain and fever, they should receive a prompt MRI with contrast enhancement. Prolonged antibiotic use for at least 8 weeks and surgical drainage depending on the situation are the appropriate treatment choices to avoid spinal cord compression and sepsis.

BACTERIAL MENINGITIS WITHOUT CEREBROSPINAL FLUID PLEOCYTOSIS Dipti Baral¹; Bhishma Pokhrel²; Bhaskara Madhira¹. ¹SUNY Upstate Medical University, Syracuse, NY; ²National Academy of Medical Sciences, Kathmandu, Nepal. (Tracking ID #2196644)

LEARNING OBJECTIVE #1: Manage suspected bacterial meningitis in the absence of cerebrospinal fluid changes

CASE: A 46-year-old African American woman with history of migraine, systemic lupus erythematosus (SLE) and lupus cerebritis in the past came in with 3 days history of headache, lethargy, photophobia and 1 day history of fever and nausea. Two weeks ago, she had increased pain in her back and left shoulder and had started taking prednisone 10 mg regularly, which she was taking inconsistently in the last 2 years. On examination, she was alert, oriented but febrile with a temperature of 102 F. She had neck tenderness; Kernig's and Brudzinski's signs were negative. Labs showed $14 \times 10^9/L$ white cell counts (WBC) with 81 % neutrophils. Lumbar puncture (LP) in lateral recumbent position revealed an opening pressure of 39 cc of water. Cerebro-spinal fluid (CSF) analysis showed 6 WBCs/microliter (μL) with 54 % polymorphs, glucose of 4.2 mmol/L, and protein of 0.29 g/L with no organisms in gram stain. Chest X-ray and urine analysis didn't suggest infection. She was human immunodeficiency virus negative. She was started on empiric antibiotics for possible meningitis. Rheumatologic work up including antinuclear antibody, lupus anticoagulant, C3- C4 complement level was negative; erythrocyte sedimentation rate and C-reactive protein were elevated at 89 mm/hr and 146 mg/L respectively.

MRI brain showed chronic progressive small vessel ischemic changes. She was determined not to be in lupus cerebritis. Both blood culture and CSF culture sent at admission came out positive for *Streptococcus pneumoniae*. Transesophageal echocardiogram showed less than 1 cm vegetation in the aortic valve and moderate aortic insufficiency. She is waiting for aortic valve replacement after the completion of 6 weeks of ceftriaxone.

DISCUSSION: Bacterial meningitis is a life-threatening neurological infection and requires immediate intervention. LP and CSF analysis are the initial diagnostic work-up that help to confirm the diagnosis and guide treatment. Upto 5 red blood cells and/or 5 WBCs/ μ L of CSF are considered normal. Bacterial meningitis without CSF pleocytosis can occur in pediatric population but is rarely seen in adults. A Low CSF cell count has been described in immune-compromised people and very early stages of meningitis, without enough inflammatory process. Literature has advocated a repeat LP the following day if first LP is negative. A falsely low CSF white count is possible due to the settling of the cells in the CSF or due to the adherence of cells to plastic tubes if CSF is analyzed more than 60 min after lumbar puncture. If bacterial meningitis is a clinical suspicion, empirical antibiotics should be promptly instituted to avoid potential neurological complications. Normal appearing CSF counts, glucose and protein don't exclude bacterial meningitis and hence, shouldn't delay treatment; treatment should be completed unless meningitis is confidently ruled out.

BENIGN T WAVE INVERSION WITH ACUTE BELLY DILLI R. POUDEL¹; Paras Karmacharya¹; Ranjan Pathak¹; Sushil Ghimire¹; Raju Khanal¹; Ana Salvatierra¹; Madan R. Aryal². ¹Reading Health System, West Reading, PA; ²The Reading Hospital and Medical Center, Wyomissing, PA. (Tracking ID #2198992)

LEARNING OBJECTIVE #1: Consider acute abdomen (eg. cholecystitis, colitis) as a cause of T wave inversion in EKG in a person without cardiac comorbidity.

CASE: A 76-year-old non-smoker without significant cardiac history presented with sudden onset lower abdominal pain, diaphoresis, nausea and multiple episodes of bloody diarrhea of one day. He denied any history of sick contacts, fever, chills or vomiting. Physical exam was positive for left lower quadrant tenderness without guarding or rigidity. Laboratory evaluation revealed leukocytosis without left shift. Computed tomography showed inflammation of the left descending colon. Patient was diagnosed with ischemic colitis and was managed conservatively with gradual improvement in symptoms. Interestingly, patient was also noted to have new T wave inversion in the infer-lateral leads at the time of admission. Patient denied any cardiac complaints and serial troponins were negative. Echocardiographic evaluation showed normal ejection fraction without any regional wall motion abnormalities. Repeat EKG on day 5, after the resolution on colitis, showed improvement in T wave inversion.

DISCUSSION: T wave changes are generally cardiac in origin but can be associated with benign non-cardiac causes. Acute abdominal pathology such as acute cholecystitis, acute pancreatitis are well recognized cause of T wave inversions but our case suggests that even acute colitis can also lead to such EKG changes. Knowledge of this association might help clinicians avoid unnecessary invasive interventions in patients with acute colitis and low cardiovascular risk factors.

BETWEEN A ROCK AND A HARD PLACE: A PATIENT WITH HEPARIN-INDUCED THROMBOCYTOPENIA AND CONCURRENT BLEEDING Shreevinaya Menon; Jessica Zuleta. University of Miami, Miami, FL. (Tracking ID #2198032)

LEARNING OBJECTIVE #1: Manage heparin-induced thrombocytopenia in the setting of clinically significant bleeding

LEARNING OBJECTIVE #2: Review presentation, diagnosis and treatment of type II heparin-induced thrombocytopenia

CASE: An 82-year old male with symptomatic, severe aortic stenosis (aortic valve area 0.7 cm²) was electively admitted for hemodynamic assessment of his valve by cardiac catheterization via right radial artery and right brachial vein. His medical history was also notable for obstructive sleep apnea, heart failure, hypertension and diabetes. The patient's recovery was complicated by post-procedure atrial fibrillation requiring therapeutic anticoagulation with unfractionated heparin (UFH) drip protocol. Subsequently, the patient underwent balloon aortic valvuloplasty with hemodynamic assessment via right femoral artery and vein approach as a bridge therapy for eventual Transcatheter Aortic Valve Replacement (TAVR). The second catheterization was complicated by post-procedure hypercapnic respiratory failure requiring intubation. Once the patient was hemodynamically stabilized and successfully extubated, he was transferred to a medical telemetry bed. Due to a CHADS₂ score of four, bridging anticoagulation to an oral vitamin K antagonist (VKA) was initiated. During his protracted hospital stay after the cardiac interventions, the patient complained of right groin pain with a visible hematoma. Hematologic evaluation revealed a platelet count of 75,000/ μ L compared to an admission

level of 130,000/ μ L. Diagnostic imaging demonstrated a 6.5×6.2×9.2 cm right psoas muscle hematoma. In light of the recent cardiac interventions and thrombocytopenia, all anticoagulation was discontinued. Platelet count continued to drop to 42,000/ μ L in the context of a large, symptomatic psoas hematoma necessitating an urgent platelet transfusion. Subsequent testing showed an anti-platelet factor 4 (PF4) antibody level of 3.088 optical density (optical density >2 considered positive) and confirmatory serotonin release assay (SRA) showing 99 % serotonin release with low-dose UFH (>20 % serotonin release considered positive). This indicated a diagnosis of heparin-induced thrombocytopenia (HIT). In light of this treatment dilemma, Hematology was consulted to assist with the management of HIT in the context of a significant bleed. Since the patient's hemoglobin remained stable, the initial recommendation was to avoid further anticoagulants with continued surveillance of the platelet count and hematoma size. Radiographic follow-up of the hematoma showed no change in size but did demonstrate increasing high-density material suggesting interval additional bleed while the platelet count continued to decrease to 17,000/ μ L. Due to worsening thrombocytopenia and bleeding, Hematology suggested immediate intravenous immunoglobulin (IVIG) infusion. From that day forth the platelet count increased, stabilizing around 130,000/ μ L. TAVR workup was resumed and, per protocol, a computed tomography scan of the chest was performed for pre-procedural planning of aortic valve implant size and suitable access route. This scan incidentally found bilateral pulmonary emboli. Subsequent lower extremity ultrasound demonstrated bilateral deep vein thromboses. Inferior vena cava filter was placed as a temporizing measure until anticoagulation could be initiated. Once the platelet count was uptrending with IVIG treatment, the patient was started on an argatroban drip bridging to VKA. Psoas hematoma size was unchanged on repeat imaging done 2 weeks later. Platelet count remained stable at a follow-up ambulatory visit 5 months later.

DISCUSSION: HIT is a common hematologic problem encountered by internists. There are two types of HIT with Type 2 being the immune-mediated, clinically significant phenomenon requiring intervention. Heparin exposure leads to autoantibody production directed against a complex of PF4 with heparin. This manifests as thrombocytopenia with arterial and venous thromboses. Enzyme-linked immunoassay testing (anti-PF4 antibody) with an optical density >2 corresponds to a high likelihood of SRA positivity. SRA is considered the gold standard test for diagnosis. Treatment involves discontinuation of heparin and initiation of alternative, non-heparin anticoagulants to prevent and treat thromboses. Bleeding is not a known complication of HIT and there are no guidelines on how to manage HIT in the setting of a clinically significant bleed. Published guidelines on the use of IVIG do not recommend it as a therapy for HIT. However, a literature search yielded a limited number of case reports demonstrating successful treatment of HIT with IVIG. Our case highlights the unique situation of HIT with concurrent bleeding in which IVIG may be the most feasible treatment choice when guideline-recommended, non-heparin anticoagulants are contraindicated.

BIOPSY, BIOPSY, AND BIOPSY AGAIN: AN UNEXPECTED CAUSE OF SPONTANEOUS PNEUMOTHORAX IN AN HIV-INFECTED WOMAN Deep Shah; Abeer Memon; Varun Phadke; Minh Nguyen; Anandi Sheth. Emory University School of Medicine, Atlanta, GA. (Tracking ID #2193570)

LEARNING OBJECTIVE #1: Evaluate for non-infectious causes of pneumothorax in HIV patients with reconstituted immunity

LEARNING OBJECTIVE #2: Recognize the clinical and histopathologic challenges in distinguishing uterine sarcoma, specifically endometrial stromal sarcoma, from benign uterine leiomyoma and the survival benefit of early diagnosis

CASE: A 41-year-old Mexican woman with HIV/AIDS (CD4=439 cells/mm³ on antiretroviral therapy, CD4 nadir=79 cells/mm³) presented to her primary care clinic with cough, pleuritic chest pain, and shortness of breath at the time of menses. Her past medical history was notable for latent Tuberculosis. Two years earlier, she underwent removal of a uterine mass diagnosed as benign uterine leiomyoma. On examination, her temperature was 36.9 °C, pulse 101 beats per minute, and blood pressure 150/81 mmHg. She was in mild respiratory distress with respiratory rate 18 breaths per minute and oxygen saturation 99 % on supplemental oxygen at 2 l per minute. Pulmonary exam was significant for decreased breath sounds at the left lung base. Abdominal exam was unremarkable. Chest x-ray showed bilateral pneumothoraces. The patient was admitted, and chest tubes were placed. Computed tomography (CT) with intravenous contrast demonstrated bilateral pneumothoraces, scattered cavitary pulmonary nodules, hilar lymphadenopathy, and heterogeneously enlarged uterus and bilateral adnexa. Laboratory and microbiologic work-up was non-diagnostic, notable only for an elevated CA-125 (41.5 U/mL, normal 0–20 U/mL). Percutaneous biopsy of the pulmonary nodules and transbronchial biopsy of a left hilar lymph node were unrevealing. A video-assisted thoracoscopic biopsy of several left-sided pulmonary nodules established a diagnosis of metastatic (stage IV) endometrial stromal sarcoma. The patient was started on hormonal therapy and eventually underwent total abdominal hysterectomy with bilateral salpingectomy.

DISCUSSION: Spontaneous pneumothorax is an uncommon but potentially serious cause of respiratory distress, particularly in HIV patients. In significantly immunosuppressed patients ($CD4 < 200$ cells/mm³), infection is the predominant etiology. Pneumocystis jirovecii and Mycobacterium tuberculosis are the most frequently implicated pathogens. In this case, negative microbiologic evaluation and reconstituted immunity ($CD4 > 400$ cells/mm³) prompted consideration of alternate processes, such as parenchymal lung disease, catamenial pneumothorax, or malignancy. Most impressive, though, was her history of uterine mass in the setting of an enlarged uterus and bilateral adnexa as well as an elevated CA-125. These findings were suggestive of a gynecologic cancer. Excisional lung biopsy ultimately served as both a diagnostic and staging procedure, yielding a diagnosis of metastatic endometrial stromal sarcoma (ESS). Distinguishing between benign uterine leiomyoma and uterine sarcoma is difficult, particularly the subtype ESS which accounts for 15 % of all uterine sarcomas. Both benign and malignant pelvic tumors present with similar symptoms, including vaginal bleeding and pelvic discomfort. Imaging is typically inconclusive. Pathology is required to diagnose ESS, but false negatives are common due to sampling error and overlapping cytopathologic profiles between fibroids and ESS. A retrospective analysis of 15 ESS cases showed that 40 % were initially misdiagnosed as benign lesions, resulting in a mean delay in diagnosis of 143 months (Amant 2003). Early detection is key as the 5-year survival rate for metastatic ESS is 50 % (Chang 1990). Lung is the most common site of spread. General internists may glean several diagnostic and management pearls from our case of metastatic ESS presenting with spontaneous pneumothoraces in a HIV-infected patient. First, while respiratory infections are frequently associated with pneumothorax in HIV patients, evaluation in individuals with reconstituted immune systems should extend beyond infectious processes. Our patient's history of uterine mass, abnormal imaging, and elevated CA-125 were concerning for metastatic disease. Second, benign uterine leiomyoma and ESS, a subtype of uterine sarcoma, are difficult to distinguish clinically and histopathologically. Physicians may need to reconsider a patient's prior diagnosis of fibroids to identify a missed cancer. Finally, early recognition of ESS has a significant impact on overall prognosis. If suspicion of uterine sarcoma, physicians should involve a pathologist with expertise in gynecologic cancers.

BISPHOSPHONATES CAUSES OSTEOMYELITIS IN ADDITION TO OSTEONECROSIS OF JAW Ravi Thimmisetty; Syed Javeria; Renuga Vivekanandan. Creighton University Medical Center, Omaha, NE. (Tracking ID #2200203)

LEARNING OBJECTIVE #1: Recognize that definition of osteonecrosis of jaw from bisphosphonates also includes infection.

LEARNING OBJECTIVE #2: Distinguishing the bisphosphonates related Osteomyelitis & Osteonecrosis of Jaw is very difficult.

CASE: Sixty-six year old man came to clinic c/o right jaw pain and foul smelling greenish discharge from 4 weeks. Past medical history includes hypertension, edentulous, history of mandibular fistula, Multiple myeloma diagnosed in 10/2012, chronic Hepatitis C infection, autologous bone marrow transplant, pathologic fracture of vertebrae, pancytopenia, nephrolithiasis, neurogenic bladder s/p intermittent suprapubic catheterization, tooth extractions. Medications includes monthly zoledronic acid, norvasc, gabapentin, folic acid, trimethoprim/sulfamethoxazole twice weekly. Patient was on pamidronate for 18 months and then monthly zoledronic acid for 5 months so far. Social history includes one pack per day for almost 35 years, minimal alcohol use and no illicit drugs. His vitals are completely normal and on exam there is sub-mental fistula on right side of jaw with greenish foul smelling discharge and area is very tender to palpation. Rest of exam reveals normal findings. We suspected osteomyelitis of jaw and as his vitals and laboratory results are normal and also there is no SIRS criteria, planned to treat as an outpatient. Discontinued zoledronic acid and ordered wound swab and blood cultures and then started clindamycin. CT scan of mandible showed circumscribed osseous lesion involved in right mandible at the site of presumed prior dental extraction, may represent chronic osteomyelitis or osteonecrosis of right jaw, but there is no distinct abscess or fluid collection. No fistula or sinus tract identified. Patient improved symptomatically within 3 weeks and on exam the right mandible appears clean, there is no discharge and is non-tender. We continued clindamycin for another 3 weeks. Final wound swab cultures showed mixed organisms and blood cultures were negative.

DISCUSSION: This case illustrates that bisphosphonates are having potential to cause osteomyelitis. There were few case reports published after the first case of bisphosphonate-related osteonecrosis of the jaw (BRONJ). Both of them have similar pathogenesis and causes confusion about the diagnosis and treatment. The estimated incidence of bisphosphonates related osteomyelitis of jaw among patients with cancer receiving intravenous bisphosphonate therapy the incidence is between 0.5 and 4 %, depending on the dose, frequency, and duration of therapy (on average, approximately 2 %). Osteomyelitis of the jaw in long-term survivors of multiple myeloma who are receiving chronic bisphosphonate therapy may be a new clinical entity. Although it is not possible to prove beyond doubt an etiologic link between bisphosphonate therapy and the

occurrence of osteomyelitis of the jaw, the association of multiple myeloma with severe immunosuppression, the prolonged bisphosphonate therapy, and the localization to the jaw all point to a relationship. Our patient have risk factors for developing osteomyelitis of jaw which includes intravenous bisphosphonate therapy, immunosuppression, dentures, and periodontal surgeries. All bony exposures in oral cavity is not always caused by avascular necrosis of jaw from bisphosphonates. All health care providers should be aware of 4 stages in defining osteonecrosis of jaw and from stage 2 and above includes infection and raise of concept of osteomyelitis of jaw and therefore have low threshold of starting antibiotics and referral to surgery at the same time.

BLACK HOLE AND A REVELATION John O'Reilly; Naomi Karlen. Tulane University Health Sciences Center, New Orleans, LA. (Tracking ID #2198608)

LEARNING OBJECTIVE #1: Discuss the clinical presentation and radiographic findings of pulmonary mucormycosis in the immunocompromised patient.

LEARNING OBJECTIVE #2: Review the clinical utility of bronchiolar lavage and CT-guided lung biopsy.

CASE: A 34 year-old woman presented with right axillary pain and fevers for 2 weeks. The pain was worse with movement and inspiration. She also reported having hemoptysis and increasing shortness of breath over this period. She had a history of chronic myelogenous leukemia, which had progressed into a blast crisis, and recently completed her first round of induction chemotherapy. Physical exam revealed tachycardia, a normal respiratory rate and blood pressure, and decreased breath sounds with dullness to percussion over the left upper lung field. Laboratory studies demonstrated pancytopenia with an absolute neutrophil count of 60 cells/microliter. CT imaging of the lung showed a 6.0 by 5.8 cm peripheral left upper lobe cavitary lesion with a reversed halo sign. The initial work-up, including bacterial and fungal blood cultures, AFB sputum stains, viral serologies and PCR, galactomannan, and (1→3)-beta-D-glucan assay was negative. Broad-spectrum antibiotics, acyclovir, and voriconazole were started. A bronchiolar lavage showed no evidence of bacteria, hyphae, or malignant cells. She remained febrile despite treatment and her lung lesion expanded on repeat imaging. CT-guided lung biopsy was performed. Pathology revealed broad, non-septate hyphae, branched at right angles. Silver staining confirmed mucormycosis. She was treated with amphotericin but was not a candidate for surgery given her medical comorbidities.

DISCUSSION: Internists often in the inpatient setting encounter fever in the neutropenic patient. It can present a diagnostic challenge due to a broad differential diagnosis. While fungal causes are typically considered, especially in a cavitary lung lesion, it is important to remember that not all fungi are alike. Galactomannan and (1→3)-beta-D-glucan tests are useful for diagnosing *Aspergillus*, *Candida*, *Histoplasma*, and *Coccidioides*. However, they do not detect any of the mucormycosis, *Blastomyces*, or *Cryptococcus*. In addition, mucormycosis does not grow in blood cultures or on routine culture media, so a high index of clinical suspicion is needed. Imaging may be helpful in making the diagnosis. The reversed halo sign seen on CT represents a central area of ground glass opacity surrounded by a ring of consolidation. In the non-immunocompromised host, this finding has classically been associated with cryptogenic organizing pneumonia. However, in the immunocompromised patient, it may be highly indicative of pulmonary mucormycosis. Bronchiolar lavage (BAL) may be helpful in making the diagnosis for fungal infections. However, when evaluating a peripheral lung lesion, particularly an abscess, the BAL may only reveal colonizing organisms of the respiratory tract. An indeterminate result on BAL with a strong suspicion for mucormycosis should be followed up with a CT-guided biopsy for definitive diagnosis. If mucormycosis is suspected, amphotericin should be added to the treatment regimen, as monotherapy with fluconazole or voriconazole is not effective. For stable patients without significant co-morbidities, surgical debridement of lung lesions is recommended.

BOCHDALEK HERNIA PRESENTING AS FLANK PAIN IN A PREGNANT WOMAN Naoki Takamatsu²; Christine Kwan¹. ¹Teine Keijinkai Hospital, Arlington, TX; ²Teine Keijinkai Hospital, Sapporo-shi, Japan. (Tracking ID #2193592)

LEARNING OBJECTIVE #1: Recognize that Bochdalek hernias can occur in adults and present with vague gastrointestinal (GI) symptoms

LEARNING OBJECTIVE #2: Treat Bochdalek hernias in pregnant women with emergent surgery

CASE: A G₃P₁ 29 years old Asian woman in her 29th weeks' gestation presents with 1 day's sudden-onset, worsening left flank pain that is dull, constant, 6/10, radiating to her left shoulder, not improved by anything, worsened by lying supine, and associated with nausea. Other review of systems is within normal limits (WNL). The patient's medical history includes treated Kawasaki disease, asthma on salmeterol/fluticasone, and a previous Cesarean (C-) section at 40 weeks' gestation. She does not use tobacco, alcohol, or recreational drugs. Prenatal checkups have shown no abnormalities. Family history is not

significant. On exam, vital signs include temperature 37 C, heart rate 108, blood pressure 108/81, respiratory rate 24, and O₂ saturation 97 % room air. She appears calm, alert/oriented x3, and non-obese. Lung sounds are decreased in the left base. GI exam shows a 10 cm, well-healed vertical incisional scar in the lower abdomen, normal percussion, and diffuse left flank tenderness without guarding, rebound, rigidity, or CVA tenderness; bowel sounds are decreased. Uterine fundus is normal for date. Otherwise, her exam is WNL. Labs/imaging show complete blood counts, chemistries, cardiac markers, D-dimer, urinalysis, and abdominal/transvaginal ultrasound (U/S) WNL. Chest x-ray reveals radio-opaque blunting of the left costophrenic angle, possibly from a pleural effusion. Just prior to the U/S-guided thoracentesis, the U/S reveals a solid echogenic mass, likely bowel loops, in the left thoracic cavity, which is corroborated on a chest/abdominal computed tomography. Emergent surgery is thus performed, which confirms a Bochdalek hernia. The postoperative period is uneventful, and her pregnancy is allowed to continue until 38 weeks' gestation at which time elective C-section will be performed.

DISCUSSION: Bochdalek hernia, the most common congenital diaphragmatic hernia (DH), is mostly found in the neonatal period, rarely carrying over into adulthood. Only ~150 cases of delayed presentation of DH in adults are described in literature. Symptomatic maternal DH during pregnancy is a surgical emergency and may lead to life-threatening complications, such as intestinal obstruction/strangulation, hemothorax, shock, and even sudden death; it has led to maternal deaths in 10 % and fetal deaths in 13 % of reviewed cases. While a reluctance to expose an unborn child to radiation exists, a literature review reveals an alarming number of misdiagnoses in 50 % due to misreading chest radiographs and atypical symptoms. Although appropriate treatment depends on the gestational age, once identified, the hernia should be repaired with prompt surgery. The patient's acute onset of flank pain occurs without any preceding trauma or strenuous activity, which suggests a hernia of congenital origin. The clinical presentation of hernias during pregnancy varies widely, and the vague symptoms, most commonly being vomiting, abdominal pain, and dyspnea, may mimic other thoraco-abdominal diseases. Adult Bochdalek hernias rarely occur but do represent a well-recognized clinical entity. This case underscores the importance to be aware of its existence, as misdiagnoses and management delays result in lethal complications if left untreated.

BOTH LOW VOLTAGE ON ECG IN SPITE OF HYPERTROPHY ON ECHOCARDIOGRAM MAY SUGGEST CARDIAC INFILTRATION RATHER THAN TRUE MYOCARDIAL HYPERTROPHY Takafumi Takase¹; Takehiko Takeda¹; Kazumasa Suga²; Mitsunori Iwase^{1, 2}. ¹TOYOTA memorial hospital, Aichi, Japan; ²TOYOTA memorial hospital, Toyota, Japan. (Tracking ID #2191121)

LEARNING OBJECTIVE #1: Recognize the importance of sequential comparisons of echocardiography and ECG to diagnose infiltrative cardiac disease.

LEARNING OBJECTIVE #2: Distinguish patients with unexplained heart failure and various symptoms.

CASE: The patient is a 67 year-old female. She was well until she was diagnosed hypertension 4 months ago. Over the last 2 months prior to admission, exertional dyspnea and leg edema have gradually developed. Besides of these symptoms, she had various symptoms including skin rash, headache, nausea, constipation and abdominal pain. On examination, she appeared to be in mild respiratory distress. Her vital signs were as following, blood pressure: 142/54 mmHg, pulse: 69 beats per minute, respiratory rate: 18 per minute and oxygen saturation: 96 % on room air. Holosystolic murmur at the left sternal border was auscultated. Pitting edema was noted in bilateral lower legs. The BNP level was 982.2 pg/mL, the troponin level 0.18 ng/mL, creatine kinase (CK) 1875 U/L, CK-MB 11.1 ng/mL, and creatinine 0.61 mg/dL. Chest radiography showed cardiomegaly and bilateral pleural effusions. ECG showed low voltage and flat T wave. Echocardiography showed and left ventricular ejection fraction (EF) 77.2 %, E/E' 23.62, estimated RV pressure up to 60 mmHg, moderate tricuspid regurgitation, and mild LVH (IVST 11.6 mm). These findings indicated diastolic LV dysfunction with mild LVH. There was no sign of granular sparkling appearance. Contrast-enhanced computed tomography (CT) did not reveal acute pulmonary embolism or deep-vein thrombosis. Right and left heart catheterization revealed pulmonary capillary wedge pressure (PCWP) was 10 mmHg and cardiac index was 3.43 l/min/m². Coronary angiography revealed minimal luminal irregularities with no evidence of plaque rupture or thrombus. Because the burden of disease appears more likely in the heart rather than in the lung, RV endomyocardial biopsy was performed. The final diagnosis was cardiac amyloidosis secondary to be primary AL amyloidosis because of the serum kappa free light-chain level as well as the findings of bone marrow biopsy. On the second day after the biopsy, monitoring ECG showed intermittent ventricular tachycardia and torsades de pointes. Then, an implantable cardioverter-defibrillator was placed on the 8th day. Importantly subsequent echocardiography revealed the rapid development of LVH (IVST 14 mm). Although the therapy with the regimen of dexamethasone and melphalan was initiated, her condition gradually worsened. One month after the admission, she died from multiple organ failure.

DISCUSSION: Cardiac amyloidosis should be considered in any patient with an unexplained heart failure. The typical echocardiographic findings include increased LV wall thickness without dilation of left ventricular cavity. Importantly, the echocardiographic findings of LVH in patients with amyloidosis essentially are due to abnormal infiltration of amyloid rather than cardiomyocyte hypertrophy itself. Accordingly, the typical features of ECG in this disease include not "high voltage" but "low voltage". Importantly, cardiac infiltration diseases including Fabry disease, Gaucher disease, and sarcoidosis etc. These diseases should be taken into account in patients with unexplained heart failure. The key element in the diagnosis of cardiac amyloidosis includes increased wall thickness in echocardiogram and low voltage on an ECG. When cardiac amyloidosis is suspected, a biopsy of selected cardiac or noncardiac tissue should be performed because that is the only way to define the diagnosis of amyloidosis. This case had a sign of heart failure but the its cause could not be explained at first. We performed contrast-enhanced CT and right and left heart catheterization to rule out myocardial infarction and pulmonary embolism. For further investigation, additional immunology blood test and myocardial biopsy were performed, which led to the diagnosis of cardiac amyloidosis. After that, bone marrow biopsy was performed and did confirm the diagnosis of AL amyloidosis. Most importantly, subsequent echocardiography revealed the progressive progression of LVH, which seems to reflect the rapid development of LVH. Once congestive heart failure occurs, the median survival term is 6 months in untreated patients. But the deterioration in this case developed much faster than that of typical cases. The management of cardiac amyloidosis is difficult. However, with the recent advancement in chemotherapy and autologous stem cell transplantation, the median survival term has been extended substantially. For these reasons, the diagnosis should be made as soon as possible in order to start the proper treatment before worsening of the patient's quality of daily life.

BRINGING CNS LYME INTO FOCUS: A CASE OF DECREASED VISION Hyejo Jun; Cristina Merkhofer. University of Pittsburgh Medical Center, Pittsburgh, PA. (Tracking ID #2188784)

LEARNING OBJECTIVE #1: To describe the differential diagnoses for decreased vision and papillitis

LEARNING OBJECTIVE #2: To review diagnostic criteria for peripheral and CNS Lyme and options for therapy

CASE: A 60 year-old Caucasian male with hypertension and right eye blindness secondary to retinal detachment, vitreous hemorrhage, and amblyopia in childhood presented with decreased vision in his left eye. He first noted blurry vision and difficulty focusing in the left eye 3 weeks prior, associated with mild frontotemporal headaches. He denied fatigue, eye pain, floaters, neck stiffness, jaw claudication, swollen joints, or rash. Persistent symptoms caused him to be seen by several optometrists and retinal specialists. CRP and ESR were mildly elevated, and MRI of the orbits was normal. His ophthalmic exam was thought consistent with bilateral anterior ischemic optic neuropathy possibly due to GCA, and he started high-dose prednisone. One dose of prednisone yielded no improvement in symptoms and he presented to the hospital for further management. Physical exam was notable for normal vitals, mild left temporal tenderness, bilateral blurred disc margins, and 20/40 visual acuity in the left. Initial labs including CBC, CMP, TSH, ANA, RF, and urine drug screen were within normal limits. CRP and ESR had normalized. A lumbar puncture showed normal opening pressure, glucose, and protein, and 2 WBC's. After consultation with Neurology, Ophthalmology and Rheumatology, the etiology of his vision loss was thought most likely atypical GCA versus infection, and high-dose prednisone was continued. An MRI head/neck/orbits and CTV head were negative for any abnormalities. Additional labs were notable for non-reactive RPR, negative PPD, negative Bartonella serologies, elevated toxoplasma IgG but negative IgM, negative antibodies for neuromyelitis optica, and negative ACE. However, serum Lyme screen returned positive and due to concern for neuroborreliosis, IV ceftriaxone was started empirically after consultation with ID. Bilateral temporal artery biopsies were eventually negative for GCA. The patient was discharged on a rapid steroid taper and a 3-week course of IV ceftriaxone. Post-discharge, the Lyme Western blot returned with 9/10 IgG and 1/3 IgM bands. CSF Lyme PCR was negative, but CSF B. burgdorferi IgG and IgM were positive. He demonstrated marginal improvement at 3-week follow-up with ID, and so another week of IV ceftriaxone was added with the understanding that it might take months for his vision to improve. Of note, at that appointment, he did recall a large red rash over his inner thigh 2-3 months prior to presentation during the summer.

DISCUSSION: This case encourages the physician to consider a broad differential for vision loss in cases that do not fit the classical picture for GCA, paying particular attention to Lyme neuroborreliosis in endemic or prevalent areas. While ocular neuroborreliosis is very rare, optic neuritis is a more common manifestation among affected patients. In this case, GCA was deemed less likely given duration of symptoms and lack of significant vision loss. Factors more consistent with an infectious etiology included blurred disc margins on ophthalmic exam without evidence of increased intracranial pressure, suggesting papillitis rather than papilledema, and the wooded location of the patient's home.

Interestingly, the thigh rash that the patient recalled after hospitalization may have been erythema chronicum migrans of Lyme disease. To review, this patient met criteria for peripheral Lyme disease with a Western Blot positive for at least 5/10 IgG bands. Although 2/3 IgM bands are needed to be considered positive, Lyme disease can be confirmed by IgG alone. A Western Blot only positive for IgM suggests either early Lyme disease or a false-positive test, for which a repeat Western Blot in 30 days is recommended. While his CSF Lyme PCR was negative, the positive CSF Lyme serologies are thought to be a more sensitive test and clinched the diagnosis of neuroborreliosis. However, such positive CSF serologies must be interpreted with caution, as they may simply reflect a diffusion of serum antibodies into the CSF. The patient was treated with IV ceftriaxone given concern for CNS penetration, though general review of the literature reveals IV and oral regimens are equally effective. One multicenter, non-inferiority, blinded, and randomized trial by Ljstad et al. in Norway demonstrated no difference in subjective symptom improvement or post-treatment CSF cell counts for patients treated with IV ceftriaxone versus oral doxycycline. The generalizability of this study may be limited, as the strains of *B. burgdorferi* endemic to Norway are different from that seen in the United States. Additional randomized studies are sparse, and there are no clear guidelines regarding duration of antibiotics. This case represents an interesting presentation of CNS involvement of Lyme disease, as well as an excellent chance to review the options for therapy.

BROADENING THE DIFFERENTIAL DIAGNOSIS OF ABDOMINAL PAIN TO INCLUDE SUMP-THING UNUSUAL Richard H. Zou¹, Thomas R. Radomski¹, Anna K. Donovan². ¹University of Pittsburgh, Pittsburgh, PA; ²University of Pittsburgh School of Medicine, Pittsburgh, PA. (Tracking ID #2194000)

LEARNING OBJECTIVE #1: Identify the differential diagnosis of right upper quadrant abdominal pain in patients who have undergone choledochoduodenostomy

LEARNING OBJECTIVE #2: Describe the diagnosis and management of biliary sump syndrome

CASE: A 42 year-old female with a history of choledocholithiasis status post cholecystectomy complicated by common bile duct injury requiring a side-to-side choledochoduodenostomy presented with a chief complaint of right upper quadrant abdominal pain for 1 day. The pain was colicky in nature, radiated to her back and right shoulder, lasted approximately 15–20 min, and was aggravated by oral intake. She first experienced similar symptoms 2 years earlier and then 3 additional times since then, with each instance lasting no longer than 30 min. During a prior admission, she was diagnosed with reflux cholangitis after undergoing an ERCP that demonstrated a widely patent choledochoduodenostomy, and was managed with a 10-day course of amoxicillin-clavulanic acid. On review of systems, she denied fevers, chills, nausea, vomiting, jaundice, pruritis, or chest pain. She noted a maternal family history of gallbladder disease. The patient's physical examination revealed a middle-aged appearing female in no acute distress. She was afebrile with stable vital signs. She had normoactive bowel sounds and a soft abdomen. Her abdominal exam was remarkable for moderate tenderness to palpation of the right upper quadrant and epigastrium. No rebound tenderness, guarding, fluid wave, or masses were appreciated. Murphy's sign was negative. The remainder of her examination was unremarkable. Labs revealed AST 321 IU/L, ALT 197 IU/L, Alk Phos 64 IU/L, gGTP 72 IU/L, and TBili 0.9 mg/dL. Amylase and lipase levels were within normal limits. A basic metabolic panel and complete blood count were unremarkable. Serologic testing for hepatitis A, B, and C; anti-smooth muscle antibodies; anti-mitochondrial antibodies; and total immunoglobulins was negative. MRCP showed no evidence of biliary ductal dilatation or choledocholithiasis. She was given bowel rest with fluid resuscitation and analgesia. Gastrointestinal medicine was consulted, and the patient was diagnosed with an acute flare of biliary sump syndrome as a result of her mild transaminitis, unremarkable MRCP, and surgical history. She was started on an empiric 5-day course of amoxicillin-clavulanic acid given her history of reflux cholangitis. Her abdominal pain improved after intravenous fluids and bowel rest, followed by slow advancement to a low-fat diet. She was discharged on hospital day 2.

DISCUSSION: Right upper quadrant abdominal pain is a common clinical presentation; however, a history of choledochoduodenostomy warrants special consideration when developing the differential diagnosis. Choledochoduodenostomy is a surgical procedure in which a passage is created between the common bile duct and duodenum, with the formation of a "blind sac" between the anastomosis and the ampulla of Vater. This procedure is indicated for the definitive correction and treatment of recurrent choledocholithiasis, common bile duct injury during cholecystectomy, and obstructing pancreatic head carcinoma, among others. Complications of choledochoduodenostomy that present as right upper quadrant abdominal pain include biliary sump syndrome, reflux cholangitis, ascending cholangitis, and alkaline reflux gastritis. Biliary sump syndrome is a late complication of side-to-side choledochoduodenostomy, resulting in the accumulation of food and debris in the distal common bile duct between the anastomosis and the ampulla of Vater as this "blind sac" becomes excluded from physiologic drainage of bile. Obstruction of the sphincter of Oddi with food, cholesterol stones, or static bile serves as a nidus

for bacterial proliferation leading to complications such as ascending cholangitis, recurrent pancreatitis, and liver abscesses. Clinical signs and symptoms include intermittent pain and tenderness of the right upper quadrant most pronounced after meals, recurrent cholangitis, fevers, chills, nausea, vomiting, and jaundice. In rare cases, steatorrhea secondary to absent intestinal bile salt secretion may be the initial presentation. Diagnosis is made with a high index of clinical suspicion, and can be confirmed with imaging modalities such as plain film, sonography, upper GI series, high-resolution CT scan, and/or hepatobiliary scintigraphy. In most cases, ERCP is required for definitive diagnosis. Current guidelines recommend ERCP with removal of debris and concomitant endoscopic sphincterectomy in the distal common bile duct as the gold standard for the treatment of biliary sump syndrome. Alternatively, percutaneous transhepatic cholangiography or EUS-guided choledochoduodenostomy have been utilized with success in cases refractory to ERCP treatment. Postoperative re-stenosis has been reported in up to 19 % of patients, requiring repeat papillotomy.

CALCIPHYLAXIS: CLINICAL MANIFESTATION AND MANAGEMENT Shenelle-Marie Wise, Marlowe Maylin. Tulane University Health Sciences Center, New Orleans, LA. (Tracking ID #2198349)

LEARNING OBJECTIVE #1: Recognize the clinical manifestations of and risk factors for calciphylaxis

LEARNING OBJECTIVE #2: Identify the differential diagnosis for calciphylaxis and its appropriate diagnostic evaluation and treatment.

CASE: A 51-year-old man presented with 1 month of progressively painful eschars on his toes, fingers, and penis. He first noticed ulcers at the tip of his penis, his right second and third fingers and his right second toe. Within a month it became necrotic and 3 days prior to admission it was painful. On presentation, his vital signs were normal and physical exam revealed 1–2 cm necrotic eschars on the tips of his penis, his second toe of his right foot and the second and third finger of his right hand. The patient has a history of end stage renal disease and coronary artery disease and receives dialysis twice weekly. His phosphorus level was 9.6 mg/dL, calcium was 8.9 mg/dL, and parathyroid hormone level was 100 pg/mL. X ray of his right foot and hand revealed extensive soft tissue vascular calcifications. Given his history of end stage renal disease with elevated calcium and phosphorus product and worsening pain and necrosis of his extremities, he was diagnosed with calciphylaxis. He was treated with daily hemodialysis and phosphate binders to decrease his calcium and phosphorus levels.

DISCUSSION: Calciphylaxis is a rare disorder characterized by systemic calcification of the arterioles leading to ischemia and subcutaneous necrosis. It affects 1–4 % of the population with end stage renal disease (ESRD) and has a mortality rate of 60–80 %. Given its rarity but high mortality, internists should consider this diagnosis in patients with chronic renal failure who develop a sudden onset of painful necrotic ulcers. Limited data is available regarding the incidence of calciphylaxis in those without ESRD. Patients with nonuremic calciphylaxis frequently have a history of primary hyperparathyroidism, malignancy, alcoholic liver disease, underlying connective-tissue disease or pro-inflammatory conditions that lead to vascular calcification. Lesions of calciphylaxis typically develop suddenly and progress rapidly. They are often violaceous subcutaneous nodules that progress to ischemic ulcers with eschars that can become super-infected. They generally occur on the lower extremities; however lesions may also develop on the hands and torso. Intense pain is a common finding. There are no specific laboratory findings to diagnose calciphylaxis. Laboratory values often show a trend of increasing calcium x phosphate (Ca x P) product and parathyroid hormone (PTH) levels. Plain radiography uniformly demonstrates vascular calcification within the dermis and the subcutaneous tissue, which is not specific for calciphylaxis. Bone scintigraphy may be used as a noninvasive diagnostic tool to show the extent of calciphylaxis lesions. Calciphylaxis can be definitively diagnosed by a skin biopsy. An incisional cutaneous biopsy is usually diagnostic, as ample subcutaneous tissue is needed for diagnosis. Once diagnosed all patients should undergo an aggressive program of wound care, adequate pain control, and avoidance of local tissue trauma. Underlying abnormalities in plasma calcium and phosphorus concentrations in patients should be corrected, with lowering of the calcium x phosphate (Ca x P) product below 55 mg/dL. For ESRD patients, daily dialysis for seven days followed by five to six times per week is recommended until resolution of symptoms.

CAN'T CANDY CRUSH IT: A CRYPTIC PRESENTATION OF A DEMYELINATING DISORDER Lello Tesema, Priyank Jain, Rachel Nardin, Shruti Sonni. Cambridge Health Alliance, Cambridge, MA. (Tracking ID #2199728)

LEARNING OBJECTIVE #1: Describe a systematic approach to differentiating demyelinating conditions.

LEARNING OBJECTIVE #2: Highlight the distinction between acute disseminated encephalomyelitis (ADEM) and multiple sclerosis (MS).

CASE: A previously healthy 32 year old woman presented to her PCP in late April with difficulty concentrating. She worked as a federal air marshal. She first noted her symptoms on a flight home from London during which she experienced difficulty with color recognition of the characters of the online game "Candy Crush Saga." She reported feeling overwhelmed with stress, which she attributed to sleep deprivation. Review of systems was remarkable for subjective fever at the airport prior to her flight. PMH was notable for migraine with aura, shift phase sleep disruption and a prior rugby related concussion. On examination, she was anxious and distressed, but answered questions appropriately. Visual examination revealed intact acuity but impaired peripheral vision. Her neurological examination was benign. She was referred to Ophthalmology and Psychiatry. In the interval period, she had trouble recalling her passwords for work. She presented to the ED for evaluation of these mental status changes. Head CT was unremarkable. She was diagnosed with migraine with aura and referred to a neurologist. Neurological evaluation demonstrated poor attention (difficulty with serial 7's), but normal short-term recall. Visual field, sensory, motor and coordination testing were entirely normal. Brain MRI with contrast revealed multiple mass-like hyperintense lesions in both cerebral hemispheres, subcortical white matter of both hemispheres (frontal and parietal) as well as temporal and occipital lobes (gray and white matter) measuring up to 3 cm. Cervical spine MRI showed multiple T2 weighted signal intensity foci within the spinal cord at C2, C4 and C6 measuring up to 3.4 mm. Infectious and inflammatory etiologies, including HIV, PML, sarcoid and Lyme, were excluded with negative laboratory and CSF studies (no pleocytosis, negative oligoclonal bands, positive myelin basic protein). Given the subacute course, in the setting of a possible viral prodrome and disseminated demyelination on MRI, and exclusion of other infectious process, the patient was diagnosed with ADEM. She received a course of IV corticosteroids and IVIG therapy with good effect. Four months later, she was re-admitted for new onset gait instability and facial sensory deficits. Repeat MRI showed new enhancing lesions and expansion of old lesions. CSF at this time revealed oligoclonal bands. She was diagnosed with MS and subsequently started on disease modifying therapy.

DISCUSSION: This patient presented with subacute encephalopathy, which has a wide differential diagnosis. The patient described was found to have multiple demyelinating lesions on brain and cervical spinal cord MRI. With demyelinating lesions, it is useful to classify them according to their pathogenesis: primary vs secondary (infectious, toxic, ischemic). Further differentiating between primary demyelinating disorders, which include ADEM, MS, neuromyelitis optica and transverse myelitis, requires careful consideration of the course of disease, presence of an antecedent infection or optic neuritis and the features of the demyelinating lesions. ADEM is an acute, widespread demyelinating condition that affects the brain and spinal cord. The challenge in this case was differentiating ADEM from a first occurrence of MS. ADEM is more common in children, and often presents after a viral prodrome. Associated fever and impairment of consciousness are more common in ADEM. In terms of neuroimaging, it is widely believed that distinguishing MS from ADEM based on a single MRI scan is virtually impossible[1], although seeing lesions of different ages may suggest MS. Although ADEM can progress in the acute phase, the appearance of new lesions on follow-up imaging suggests MS. CSF in ADEM may be normal or reveal pleocytosis, in contrast to cases of MS which rarely have pleocytosis. While detection of oligoclonal bands may be helpful in predicting a subsequent diagnosis of MS, the true utility is unknown since as many as 58 % of adults cases with ADEM have oligoclonal bands. The largest follow-up series of adult patients with ADEM found 35 % of patients developed clinically definite MS within the 12 months of initial presentation[2]. This fact should alert internists to closely monitor patients who carry a diagnosis of ADEM for new neurological symptoms that would trigger an evaluation for MS. 1. Singh S, Prabhakar S, Korah IP, et al. Acute disseminated encephalomyelitis and multiple sclerosis: magnetic resonance imaging differentiation. *Australas Radiol*2000; 44:404–11 2. Schwarz S, Mohr A, Knauth M, et al. Acute disseminated encephalomyelitis: a follow-up study of 40 adult patients. *Neurology*2001; 56:1313–18

CAN'T DECIDE, BUT REFUSING TO COMPLY Naomi Karlen; Kevin Attenhofer; Catherine Jones. Tulane University Health Sciences Center, New Orleans, LA. (*Tracking ID #2198781*)

LEARNING OBJECTIVE #1: Recognize that patients without capacity have the right to refuse

LEARNING OBJECTIVE #2: Understand the importance of adequately addressing challenging ethical cases

CASE: A 30 year-old woman presented with febrile neutropenia. She had multiple comorbidities including end-stage AIDS, end-stage renal disease, HIV encephalopathy, depression, and stage IV sacral decubitus ulcers. She required frequent admission for infections, altered mental status, and emergent dialysis, was formally evaluated by psychiatry on multiple occasions and was found to lack decision-making capacity. Her mother, who possessed power of attorney, continued to desire full treatment and declined

hospice care despite numerous discussions regarding the topic. The patient was again found to lack capacity but adamantly refused most medications, imaging procedures, and other diagnostic procedures. She slowly declined and died secondary to septicemia resulting from multi-drug resistant *Acinetobacter* from an unclear source.

DISCUSSION: Physicians are often tasked with caring for patients with psychological illness that may impede care and require psychiatric assessment. The terms "competence" and "capacity" are learned early in medical school and usually coincide with education about medical ethics. Those lessons cannot prepare clinicians for all of the variations of situations that they will encounter during practice. This case illustrates an interesting moral dilemma when posed with the question, "How do you approach a patient without capacity whose power of attorney requests treatment while the patient refuses treatment?" While many of the interventions requested by the power of attorney would aid in prolonging life, the diagnostic work-up and treatment would have been against the will of a combative patient, causing far greater risk to achieve the desired result. For example, a desired CT exam would have necessitated sedation in a patient with end stage renal failure and encephalopathy as the patient continued to refuse the imaging. Lack of decision-making capacity does not necessitate the pursuit of all interventions by physicians. The internist confronts the dilemma of "what is right" and "what is right for this patient." Moreover, the internist must keep in mind the principles of assent and consent. When patients do not have the capacity to consent (because they are children or adults who lack capacity), they must still assent to procedures. It is the physician's duty to secure that assent before proceeding. Acknowledging that there are no clearly correct answers in moral dilemmas is an important step in furthering our ability to deal with difficult situations as they arise. They are complicated and require an interdisciplinary team. A psychiatrist and an ethics committee as well as patient and family involvement can aid in making the right decisions in these difficult situations.

CANNABIS-INDUCED HYPERSENSITIVITY PNEUMONITIS: A CASE REPORT Matthew J. Miles; Andres Zirlinger. Lehigh Valley Health Network, Allentown, PA. (*Tracking ID #2185559*)

LEARNING OBJECTIVE #1: Recognize smoking cannabis as a risk factor for hypersensitivity pneumonitis.

CASE: A 64 year old male presented with worsening dyspnea, five pound weight loss, night sweats and dry cough for 2 weeks. He denied chest pain, fever or sick contacts. The patient was a former tobacco smoker, quitting 50 years prior to admission. He had a history of asthma with a recent admission for presumed asthma exacerbation which responded well to a short course of oral steroids. On admission his oxygen saturation was 92 % while breathing room air; physical exam was essentially normal except for bibasilar crackles. White cell count, liver and kidney function were normal. The initial chest X-ray showed bibasilar interstitial infiltrates so he was started on Vancomycin and Cefepime for presumed hospital acquired pneumonia. One day after admission he developed hypoxic respiratory failure secondary to acute respiratory distress syndrome which required invasive mechanical ventilation. A CT scan of the chest revealed bilateral ground-glass opacities. A bronchoscopy did not reveal any abnormalities of the airways. A bronchoalveolar lavage revealed primarily neutrophils without organisms. Bacterial blood cultures were negative, as were *Pneumocystis jirovecii*, respiratory viruses PCRs and HIV testing. Thus, he underwent a video-assisted thoracoscopic biopsy of the lung. The cultures and stains from the biopsy were negative for organisms; pathology revealed patchy areas of consolidation presented by a pattern non-caseating granulomas consistent with hypersensitivity pneumonitis. The patient was started on oral corticosteroids daily and was extubated two days after treatment. After extubation, the patient's daughter mentioned that the patient had been regularly smoking a significant amount of cannabis, but did not want anyone to find out. The patient's symptoms completely resolved after 8 weeks of corticosteroid therapy and cannabis cessation. A confirmation CT scan showed resolution of bilateral ground-glass opacities after 10 weeks of medical therapy. The patient continued to be asymptomatic 22 weeks after cessation of steroids and cannabis use.

DISCUSSION: Hypersensitivity pneumonitis is a complex syndrome caused by inflammatory mediated reaction in the lungs due to an external antigen. The more common antigens include molds, fungal spores, bacteria and yeasts. Diagnosing hypersensitivity pneumonitis relies several clinic features including: patient's history (cough, wheezing, weight loss, smoking history), physical exam (fever, crackles on pulmonary exam and digital clubbing) identifying microbiologic and environment exposures, bronchoalveolar lavage (lymphocytosis), CT scan (ground-glass opacifications), histopathology (non-caseating granulomas). Hypersensitivity pneumonitis can be treated with systemic corticosteroids and removal of the offending antigen. However, even with treatment, patient with hypersensitivity pneumonitis can develop chronic lung conditions such as pulmonary fibrosis and emphysema. The patient's history, physical exam findings, CT scan and biopsy are all supportive of the diagnosis hypersensitivity pneumonitis. The clinical improvement and the resolution of CT findings after 8 week of oral steroids and cannabis use cessation led us to conclude the diagnosis was hypersensitivity pneumonitis secondary

to cannabis smoking. The patient lives in a suburban area and denied any other exposures known to cause hypersensitivity pneumonitis. It is important to recognize hypersensitivity pneumonitis in urban and suburban patients that may have smoked cannabis and present with similar symptoms. There are multiple studies citing that cannabis can be contaminated with fungus that are known triggers of hypersensitivity pneumonitis. Bacteria linked to hypersensitivity pneumonitis have also been recovered from cannabis samples.

CAPNOCYTOPHAGA SEPSIS: A RARE DISEASE Muhammad Sarfraz Nawaz¹; Toufik Mahfood Haddad¹; Saraschandra Vallabhajosyula¹; Nikhil Jagan¹; Sunil K. Jagadesh^{1, 2}. ¹Creighton University School of Medicine, Omaha, NE; ²CHI Health Creighton University Medical Center, Omaha, NE. (Tracking ID #2199025)

LEARNING OBJECTIVE #1: Recognize *Capnocytophaga* as potential source of sepsis in appropriate clinical settings

LEARNING OBJECTIVE #2: Highlight management of sepsis related to *Capnocytophaga* infection

CASE: A 57-year old Caucasian male with history of stage IV non-small cell lung cancer, presented with lethargy and weakness over a period of 2 weeks, which was progressive and associated with anorexia and pain around his lips, side of the tongue and gums. He was unable to tolerate oral intake. His medications included vinorelbine, with last dose given 1 week before admission. Physical Examination revealed blood pressure 94/57 mm Hg, pulse 121/minute, a fatigued and cachectic male with poor dentition, disrupted oral mucosa, uninfected port site and generalized weakness without any apparent rash. Laboratory data revealed hemoglobin 6.3 Gm/dl, white cell count of 0.5/mm³, and absolute neutrophil count (ANC) of zero. He developed fever, hypotension and tachycardia during transfusion of the second unit of packed red cells requiring intravenous fluid resuscitation. Blood cultures were drawn and he was started on cefepime, vancomycin and filgrastim for febrile neutropenia with mucosal lesions. Being afebrile afterwards, vancomycin was discontinued on day three and filgrastim on day six once ANC was >500. Port site blood cultures grew gram-negative rods on day six, so infectious disease service recommended switching from cefepime to piperacillin-tazobactam empirically. Further identification revealed it to be *Capnocytophaga* species, related to his close exposure to dogs and cats at home. His dog used to lick his chest port and face. Repeat blood cultures showed no growth. On hospital discharge, he was switched to oral amoxicillin-clavulanate for a total of 3 weeks of antibiotics from the date of his bacteremic clearance. He remained afebrile on outpatient follow up.

DISCUSSION: The *Capnocytophaga* genus has nine species, with all being common to human and canine flora. However, only *Capnocytophaga canimorsus* causes severe infections in human beings, ranging from cellulitis to meningitis and endocarditis, and potentially septic shock, multiorgan failure and death.^{1,2} However, severe sepsis caused by *C. canimorsus* is extremely rare.² Risk factors include an underlying immune disorder, including splenectomy, chronic alcohol use, or cirrhosis.² However, 40 % of cases had no identifiable risk factor.^{1,3} Most infections occur in individuals older than 40 years.² Pathogenicity is not fully understood, but a substance inhibiting neutrophil motility has been identified, and may be associated with moderate resistance to phagocytosis.² Almost 80 % of patients report canine exposure, with 58 % being a bite, and 20 % report exposure without a bite or scratch (such as licking of broken skin).¹ Mortality from sepsis ranges from 25 to 30 %, but reaches up to 60 % in cases of septic shock. Patients with septic shock have a 30-day mortality of 60 %.^{1,2} Clinical features, depending on severity, include fever, chills, myalgia, vomiting, diarrhea, abdominal pain, dyspnea, mental confusion, and headache. After an incubation period of 1–7 days, patients can experience an abrupt onset of malaise, abdominal pain, confusion and shortness of breath, and can progress rapidly to severe septic shock. Physical examination might reveal a petechial rash on the trunk, lower extremities, and mucous membranes which can evolve from purpuric lesions to gangrene.² Since bacteria are extremely difficult to grow and up to 14 days of incubation might be necessary to detect growth on typical media; diagnosis is usually clinical based on history and physical findings.^{2,4,5} Abundant intra-cytoplasmic fusiform rods within neutrophils on peripheral blood smear may allow for a presumptive diagnosis in the appropriate setting.^{4,5} *Capnocytophaga* species infection responds well to penicillin and β -lactam- β -lactamase inhibitor combinations.⁵ Because of the relatively aggressive nature of *C. canimorsus* and the difficulty in obtaining a laboratory diagnosis, therapy should be started as early as possible.⁵ **References:** 1. CARDIOVASCULAR IMPLICATIONS OF MULTIPLE SCLEROSIS

Rekha Thammana. Emory University, Atlanta, GA. (Tracking ID #2195158)

LEARNING OBJECTIVE #1: Recognize inflammatory diseases as risk factors for cardiovascular disease.

LEARNING OBJECTIVE #2: Diagnose coronary artery disease syndromes in patients with characteristic electrocardiographic changes and negative biomarkers.

CASE: A 45 year old African-American man presents with episodes of new onset chest pain, shortness of breath, and sweating on exertion. These symptoms developed while mowing his girlfriend's lawn on a recent trip to Seattle, and similar symptoms occurred while pulling his suitcase through the airport on his trip home. His symptoms resolve with rest. He also notes that over the last few weeks, when he flexes his neck, he feels electric twinges in his legs bilaterally. He has started to develop bilateral leg weakness and his legs "give out" occasionally. His right thorax and forehead have suddenly become numb as well. Other than a childhood history of Bell's palsy with persistent R lower face weakness, he has no known medical problems. His sister was recently diagnosed with multiple sclerosis, and his father is deceased but had a stroke late in life. He is not a tobacco, drug, or alcohol user. He has no other significant medical history, medications, or complaints. His physical exam is significant for normal vital signs and unremarkable cardiovascular and pulmonary examinations. He has decreased sensation to light touch and pinprick along his right forehead and T10-T12 dermatomes on the right thorax, as well as decreased right lower facial strength. Initial lab work shows troponin-I peaking at 0.04 ng/mL and is otherwise unremarkable. An electrocardiogram (ECG) shows biphasic T-waves in V1 and V2 with t wave inversions in V3 and V4. Cardiac catheterization reveals a 100 % proximal left anterior descending coronary artery (LAD) occlusion with a 70 % ulcerated right coronary artery lesion and a 40 % left circumflex coronary artery lesion; other smaller lesions are present as well. MRI brain shows nonenhancing lesions in the right centrum semiovale, left corpus callosum, and cervical and thoracic cord most compatible with multiple sclerosis. Cerebrospinal fluid analysis reveals oligoclonal bands. He undergoes coronary artery bypass surgery and does well after surgery. No treatment is started for the diagnosis of multiple sclerosis during this hospitalization.

DISCUSSION: This case represents a seemingly unexpected combination of a first diagnosis of multiple sclerosis (MS) and coronary artery disease. Few studies are available to quantify the risk of cardiovascular disease (CVD) in patients with multiple sclerosis. Yet, multiple cross-sectional studies support the hypothesis that patients with MS have an increased risk of vascular disease within the first years of diagnosis, as is seen in our case. Autoimmune and other inflammatory diseases are also associated with enhanced atherosclerosis, believed to be due to immune-mediated processes. Several inflammatory pathways lead to the development of atherosclerosis, including macrophage and T cell activation. Activation of specific leukotriene pathways implicated in myocardial infarction (MI) are associated with genetic polymorphisms seen in multiple sclerosis. Investigation of the association between inflammatory diseases and CVD represents an area of growing research that has yet to be fully realized. Our case also demonstrates important features of cardiovascular medicine. Our patient's presentation of classic exertional angina is accompanied by negative biomarkers, but he does have characteristic electrocardiogram features suggesting coronary artery disease. Wellens and colleagues first described anterior T-wave changes suggestive of LAD occlusion in 1982, and later studies showed that these findings correlate with extensive anterior wall MI within several days of presentation. Wellens' syndrome includes a history of chest pain, normal or minimally elevated cardiac enzymes, and little or no ST segment changes and no Q waves. The key findings in Wellens' syndrome are deep T-wave inversions or biphasic T-waves in leads V1–V4, as seen in our patient. Wellens' syndrome illustrates an important warning in an era of overreliance on biochemical testing. These patients are very high risk for adverse events, but they do not usually have elevations of cardiac enzymes. While this patient had the characteristic findings of Wellens' syndrome, he fortuitously also had collateral vessel development from other coronary arteries that would have likely prevented an anterior wall MI. His symptoms on presentation were most likely associated with an occlusion of his right coronary artery. Above is a case of advanced atherosclerosis at a relatively young age (45) without classic risk factors of hypertension, diabetes mellitus, tobacco use, or significant family history of myocardial infarction. It illustrates the importance of recognizing non-classical risk factors for cardiovascular disease. These patients may require closer clinical scrutiny in order to evaluate them appropriately.

CARE FOR THE CAREGIVER: A CASE OF VTE AT THE BEDSIDE Jillian Roper; Jillian S. Catalanotti. The George Washington University, Washington, DC. (Tracking ID #2194028)

LEARNING OBJECTIVE #1: Recognize the heightened VTE risk in patients with IBD

LEARNING OBJECTIVE #2: Describe health risks associated with the caregiver role, and the role of providers in encouraging self-care to mitigate these risks

CASE: A 38-year-old woman with Crohn's disease presented to the emergency department with one day of severe persistent left thigh pain and swelling. She denied back pain, trauma or neurologic symptoms. She denied recent travel, surgeries or hospitalizations. She had no chest pain, dyspnea or cough; review of systems was otherwise unremarkable. She did not use alcohol, tobacco or drugs. Current medications included Canasa 1000 mg rectal suppository nightly and Apriro 0.375 g PO daily for Crohn's disease. Due to a change in her insurance formulary, she was recently changed from Delzicol to Apriro and noted increasing abdominal pain since time of medication change. Past medical history was otherwise unremarkable. Family history included inflammatory bowel disease (IBD) in her mother and son. There was no known family history of hypercoagulability disorders. On physical exam, vital signs were unremarkable; she was in no acute distress but appeared mildly anxious. Heart, lung, abdominal and neurologic examinations were normal. Her left thigh was mildly edematous without erythema. No cords were palpated. Labs were significant only for leukocytosis ($15.6 \times 10^9/L$) and thrombocytosis ($509 \times 10^9/L$). Venous ultrasound of the extremity confirmed unilateral deep venous thrombosis. INR, Factor V Leiden, protein C, protein S and Lupus anticoagulant were within normal limits. She was treated with enoxaparin 50 mg subcutaneously twice daily and warfarin 5 mg daily, and was discharged. On follow-up with her primary care physician, more detailed social history revealed that her son had a recent 9-week hospitalization for Crohn's flare. She reported remaining in his hospital bed to comfort him for days at a time while her husband brought food to the bedside.

DISCUSSION: Patients with IBD have a significantly increased risk of venous thromboembolic events (VTE). Recent meta-analysis of VTE in IBD patients suggests a two-fold increased risk as compared to the general population. While the greatest number of events occurs in patients older than 60, the relative increase in risk was greatest for patients less than 40 years. VTE in IBD patients tend to be unprovoked and in the outpatient setting. Although the mechanism of VTE in patients with IBD remains unknown, many speculate that it is due in part to the underlying inflammatory state inherent in the disease. Patients with IBD have high rates of VTE during flares, as in our patient. Traditional hereditary causes of hypercoagulability such as Factor V Leiden and protein C and S deficiencies do not occur in greater percentages in the IBD population, nor do valvular incompetency or venous obstruction. Patients with IBD and VTE often have additional risk factors beyond their baseline inflammatory risk, such as our patient's prolonged immobility. For this reason, providers should maintain a heightened awareness of VTE risk when patients with IBD develop additional VTE risk factors or are in an active IBD flare. This case also highlights the importance of caregiver health. In this case, our patient's baseline propensity towards VTE was augmented by her prolonged immobilization to comfort her hospitalized son. For parents of chronically ill children, highlighting the importance of parental well-being in connection to improved child health outcomes has been shown to motivate parents to seek personal help. Many caregivers experience a range of emotions including blame, anger, emotional stress and feeling selfish when they think to care for themselves. Caregivers may require validation and permission from health care providers to seek self-care. Who is responsible for care of the caregiver? Caregivers may have frequent contact with the health care system as advocates, but their own health needs may go unnoticed by providers who do not view them in the patient role. Greater attention to caregivers may be advantageous to optimize their health outcomes. Methods may include screening with validated questionnaires, referring to focus and support groups, and educating health care professionals regarding caregiver needs.

CATASTROPHIC COAGULOPATHY WITH THROMBOCYTOPENIA AFTER ENOXAPARIN—IT'S NOT ALWAYS HEPARIN INDUCED THROMBOCYTOPENIA *Garen J. DeCaro²; Rex Wilford¹. ¹Summa Health System, Akron, OH; ²Summa, Akron City Hospital, Brunswick, OH. (Tracking ID #2155874)*

LEARNING OBJECTIVE #1: Diagnoses other than heparin induced thrombocytopenia should be considered in patients who develop thrombocytopenia after receiving low molecular weight heparin.

CASE: Coagulopathy in cancer is relatively common. The standard treatment of venous thromboembolism in patients with cancer is low molecular weight heparin. However, heparin induced thrombocytopenia (HIT) is a known side effect of low molecular weight heparins and it should always be considered in any patient on a heparin product who develops new onset thrombocytopenia and thrombosis. The diagnosis should be confirmed using HIT antibody testing. We present a patient with clinically suspected HIT who suffered catastrophic hypercoagulable state due to underlying malignancy. A fifty one year old female recently diagnosed with metastatic lung adenocarcinoma and deep venous thrombosis (DVT) of the lower extremity presented with nausea, vomiting, bilateral flank pain and worsening cognition. Therapy for the malignancy had not been started yet, she had been started on enoxaparin 6 days prior to presentation in order to treat the DVT. The patient's platelet count had dropped from 313 thou/cmm at the time enoxaparin was started to 87 thou/cmm on the day of admission for the DVT. Her physical exam was without focal neurological deficits, but positive for bilateral flank pain to percussion and general

confusion. The abdominal CT showed multiple bilateral renal infarctions, splenic infarction and right hepatic artery embolus. MRI of the brain revealed innumerable areas of acute infarction throughout both cerebral and cerebellar hemispheres. HIT was tentatively diagnosed. Enoxaparin was discontinued and argatroban drip was started immediately with a rapid therapeutic PTT level reached. Review of peripheral smear by a hematologist revealed thrombocytopenia and no evidence of microangiopathic hemolysis. On day 3 of hospitalization the patient developed right sided hemiplegia and aphasia. CTA of the head and neck revealed no hemorrhage, multiple ischemic changes, and a filling defect in the superior vena cava thought to represent thrombus. Echocardiography suggested a right atrial mass concerning for thrombus. The patient developed seizures and respiratory failure and the family opted for comfort care. The patient died on day 7 of hospitalization. Pending workup revealed both anti-platelet factor 4 antibody and serotonin release assay to be negative, but a positive lupus anticoagulant test (LA-HexPhospholipid Neut).

DISCUSSION: This case illustrates ongoing, catastrophic, diffuse coagulopathy in a patient being treated presumptively for HIT. It is critical to determine the underlying pathological process in patients with thrombosis to best guide treatment. Lupus anticoagulant has been found more frequently in malignancy and is associated with increased thrombotic risk. Catastrophic hypercoagulable state of malignancy or antiphospholipid syndrome should be considered in patients with suspected HIT who continue to have thrombosis despite recommended therapy.

CAVITARY LUNG LESION: PRESENTATION OF HODGKIN LYMPHOMA

<div id="__IF72RU4RKJAHUIYI_ONCE" style="display:none;"></div>

<div id="__IF72RU4RKJAHUIYI_ONCE" style="display:none;"></div>

<div id="__IF72RU4RKJAHUIYI_ONCE" style="display:none;"></div>

<div id="__IF72RU4RKJAHUIYI_ONCE" style="display:none;"></div> Oluwaseun Shogbesan; Opeyemi Fadahunsi; Anene Ukaigwe; Adetokunbo Oluwasanjo. Reading Health System, West Reading, PA. (Tracking ID #2197676)

LEARNING OBJECTIVE #1: Recognize cavitory lung lesions as a presentation of Hodgkin lymphoma <div id="__if72ru4rkjahuiyi_once" style="display:none;"></div> <div id="__if72ru4rkjahuiyi_once" style="display:none;"></div> <div id="__if72ru4rkjahuiyi_once" style="display:none;"></div>

LEARNING OBJECTIVE #2: <div id="__if72ru4rkjahuiyi_once" style="display:none;"></div> <div id="__if72ru4rkjahuiyi_once" style="display:none;"></div> <div id="__if72ru4rkjahuiyi_once" style="display:none;"></div>

CASE: Thirty-three year-old-male presented to the ED with productive cough, hemoptysis and intermittent low grade fever for 7 months. There was associated night sweats and a 10 lb weight loss. He had no history of recent travels outside of the United States, HIV infection or tuberculosis exposure. He had a 10-pack-year smoking history but denied alcohol use. He had been treated for pneumonia with four different courses of antibiotics outpatient. He reported marginal improvement in symptoms on antibiotics, but no complete resolution at any time. On physical examination, he was febrile, tachycardic and tachypneic but with normal oxygen saturation. A left non-tender 1 cm supraclavicular lymph node was found. Coarse breath sounds were noted in the left lung field. The rest of the physical examination was normal. Chest x-ray showed a mass like opacity in the left upper lobe and left perihilar region. Chest computed tomography (CT) scan revealed a large mass like consolidation in the left upper lobe with cavitation, bilateral pulmonary nodules and extensive mediastinal adenopathy. Laboratory data were remarkable for a white blood count of 32,000/microliter (normal: 4000 to 11,000/microliter) with lymphopenia and eosinophilia, microcytic hypochromic anemia, thrombocytosis and C-reactive protein of 13.26 mg/dl (normal: 0.00–0.70 mg/dl). Other laboratory tests including HIV, anti-neutrophilic cytoplasmic antibody, angiotensin converting enzyme assay, lactate dehydrogenase, and sputum for acid fast bacillus and culture were negative. Pathology of mediastinal biopsy obtained from a video mediastinoscopy confirmed classical Hodgkin lymphoma (HL), nodular sclerosing type. PET scan revealed extensive extralymphatic involvement and was categorized as stage IV. Despite receiving 8 cycles of ABVD (adriamycin, bleomycin, vinblastine, and dacarbazine) chemotherapy, the cavitory lung mass persisted. Consequently, a video assisted thoracic surgery wedge resection of the lung mass was done, which also confirmed HL. He is presently undergoing salvage chemotherapy with ifosfamide, carboplatin and etoposide, and he is being evaluated for autologous bone marrow transplantation. <div id="__if72ru4rkjahuiyi_once" style="display:none;"></div> <div id="__if72ru4rkjahuiyi_once" style="display:none;"></div> <div id="__if72ru4rkjahuiyi_once" style="display:none;"></div>

DISCUSSION: Pulmonary involvement in HL is not uncommon, about a fifth of cases involve the lungs at diagnosis. Most cases of lung involvement usually involve mediastinal adenopathy before progressing to the lung parenchyma as nodules, mass-like consolidations and rarely, cavities. Cavitory lung lesion has a broad differential, including tuberculosis, abscess, bronchial carcinoma, metastatic lung nodules, fungal infections,

bronchiectasis, pulmonary infarction, Wegener's granulomatosis, and pulmonary sequestration. Lymphadenopathy as seen in HL is a common feature in most of these differentials. Hence, can be a diagnostic dilemma. Our patient was treated over a 7-month period with antibiotics for pneumonia with little to no response. However, the persistence of respiratory symptoms, fever, and lung mass resulted in further evaluation and eventual diagnosis of HL. Poor response to appropriate antibiotics with persistence of cavitary lung mass should prompt exploration of viable differential diagnosis, guided by clinical data. Our index case highlights HL presenting as recurrent pneumonia-like symptoms, persistent cavitary lung lesion despite appropriate antimicrobials, and radiologically significant lymphadenopathy in a chemotherapy-naïve patient. Biopsy of lymph node or lung lesion might be required for final diagnosis. <div id="__if72ru4rkjahiuyi_once" style="display:none;"></div><div id="__if72ru4rkjahiuyi_once" style="display:none;"></div><div id="__if72ru4rkjahiuyi_once" style="display:none;"></div>

CEFEPIME INDUCED NEUROTOXICITY IN A PATIENT WITH RENAL DISEASE Victoria Forbes; Hamid Habibi; Roy Sittig. University of Connecticut Health Center, Farmington, CT. (Tracking ID #2194613)

LEARNING OBJECTIVE #1: Recognize the neurotoxic effects of cefepime especially in the background of renal impairment

CASE: Our patient is a 79-year-old female with extensive past medical history who presents with progressive and persistent left eye swelling and pain. Her past history includes congenital albinism, autoimmune retinitis on IVIG, chronic kidney disease, Sjogren's syndrome, Non-Hodgkin lymphoma, and chemotherapy-related myeloid neoplasm. Recently, she was seen by her Oncologist for right lower extremity swelling and treated with Keflex. At this time, she also complained of left eye swelling and edema. She was referred to her Ophthalmologist who diagnosed her with cellulitis of the left eye and initiated treatment. Swab cultures from the eye grew *Pseudomonas aeruginosa*. Her pain and swelling worsened despite treatment, prompting her to seek care in the ER. A CT scan revealed left orbit soft tissue inflammation compatible with orbital cellulitis. She was treated with IV vancomycin and cefepime. A subsequent MRI of the brain demonstrated left orbital cellulitis affecting all three compartments without a drainable abscess. Thus, she was maintained on the same antibiotic regimen. Her left eye began to improve on Ophthalmoscopic evaluation. However, she developed low to high-grade fevers. Given the clinical improvement of her original source of infection, other possible causes of her fevers were entertained. Cultures from the blood, eye, and urine were sent as well as a chest x-ray and ultrasound to evaluate for DVT. All proved to be negative. Her renal function remained significantly impaired. She was found to be acutely lethargic with altered mental status. An MRI and MRA of the head, EEG, and a lumbar puncture were pursued. Scans showed marked improvement of her left eye edema. When exploration into potential causes of her encephalopathy was unrevealing, her cefepime was discontinued. After discontinuation of cefepime, her mentation began to improve. Fortunately, her orbital cellulitis gradually resolved and her mental status returned to her baseline prior to her discharge from the hospital.

DISCUSSION: Cefepime, a fourth generation parenteral cephalosporin, is a commonly prescribed antibiotic with an expanded spectrum of activity against gram-positive and gram-negative microbes. The drug is eliminated primarily by the kidneys with ~85 % of the dose excreted in the urine. Drug accumulation can occur in patients with renal impairment. Neurotoxicity from cefepime has been reported to manifest as encephalopathy with or without myoclonus, seizures, hallucinations, coma, or nonconvulsive status epilepticus. The ensuing metabolic-toxic encephalopathy that can occur can be fatal with many reported cases resulting in death. Studies have estimated that it takes ~5 days from the time of administration of the drug to the onset of symptoms. Diagnosis can be especially challenging given the myriad of confounding factors causing encephalopathy such as infection, pain, age, comorbidities, electrolyte abnormalities, administration of multiple medications, and hospitalization. Our patient developed altered mental status in the setting of all the aforementioned confounders. During investigation into alternate causes, antibiotic-induced neurotoxicity was researched and considered. After discontinuation of cefepime, her mentation began to improve and eventually returned to baseline. Although recognized in the literature, cefepime induced neurotoxicity is a widely underappreciated and underdiagnosed phenomenon that can lead to encephalopathy, myoclonus, seizures, and death. The toxicity is especially prevalent in patients with impaired renal function, but has been reported to occur in patients with normal renal function. Discontinuation of cefepime should occur in encephalopathic patients if investigation into alternate diagnoses proves unfruitful. In addition, patients with impaired renal function require a dose adjustment to minimize the risk of neurotoxic sequelae. In conclusion, we must be aware of the propensity of cefepime to produce acute, severe neurotoxicity that can lead to significant morbidity and mortality.

CEREBRAL MYCOTIC ANEURYSM AND SPONTANEOUS SUBDURAL HEMATOMA IN A PATIENT WITH SUBACUTE VIRIDANS STREPTOCOCCI ENDOCARDITIS Shalina Mirza; Jessamyn Blau; Albert Ackil. University of Washington, Seattle, WA. (Tracking ID #2200958)

LEARNING OBJECTIVE #1: Recognize that the development of a cerebral mycotic aneurysm resulting in spontaneous subdural hematoma is a known, but rare, complication of endocarditis.

LEARNING OBJECTIVE #2: Identify key features of a history that raise suspicion for endocarditis, even in the absence of typical clinical signs and symptoms.

CASE: A 66-year-old African-American male with hypertension, mitral regurgitation, and GERD was admitted from the emergency department for severe anemia. He did not have any signs of active bleeding, but was hypotensive to 84/47 with a 10-point hematocrit drop from baseline. He reported that over the previous 3–4 months, he had developed nonspecific symptoms of fatigue, anorexia, early satiety, and a 30-lb weight loss. He denied fevers, chills, rashes, cough, night sweats, melena, or hematochezia. He denied IVDU. He had an episode the previous week of non-traumatic right ankle pain and swelling for which he presented to the emergency department. Radiographs of the ankle were normal, and he was told it was a soft tissue injury. At that time, he had no other localizing signs or symptoms concerning for endocarditis. At the time of presentation, he was afebrile and hypotensive but not tachycardic. He was thin and ill-appearing. His lungs were clear, and he had a grade 4/6 holosystolic murmur appreciated best at the apex with radiation to the axilla. There were no signs of heart failure. He had no palpable lymphadenopathy. His right ankle was diffusely swollen, tender, and warm to touch. His nail beds were pale, but there was no documentation of the presence of either splinter hemorrhages or Janeway lesions. His neurologic exam was normal, and the rest of the exam was unrevealing. Laboratory studies were significant for a leukocytosis of 15.8 with a left shift, microcytic anemia of 21.6 with an MCV of 65.3, and a thrombocytosis of 493. After IV fluids, his blood pressure normalized. At this point, there was suspicion for occult GI blood loss and malignancy. An EGD and colonoscopy were scheduled and the patient began colonoscopy prep on hospital day 1. Meanwhile, blood cultures from admission were positive in less than 24 h with 2 of 2 bottles growing Gram-positive cocci. He was started on IV vancomycin for bacteremia of an unknown source. Transthoracic echocardiogram revealed severe mitral regurgitation similar to his previous study, but no vegetations were visualized. Further chart review revealed he had dental work completed one year prior to presentation, but he appropriately received bacterial prophylaxis given his known valvular heart disease. In the evening of hospital day 1, he remained hemodynamically stable and afebrile, with a normal neurologic exam. Early on hospital day 2, the patient was found unresponsive and tachypneic lying in bed. His neurological exam was significant for minimal response to painful stimuli and sluggish pupils. This progressed quickly to decorticate posturing with fixed and dilated pupils. CT head revealed a large left-sided, acute subdural hematoma with 2 cm midline shift and descending transtentorial herniation. After discussion with his wife, no surgical intervention was taken. He was placed on comfort measures and died later that day. Autopsy determined the cause of death was a ruptured mycotic aneurysm, which developed secondary to high-grade bacteremia from subacute *Viridans Streptococci* endocarditis.

DISCUSSION: This patient's cause of death was unknown until the autopsy, and endocarditis was not suspected at the time of presentation. Subacute bacterial endocarditis can present insidiously with non-specific constitutional symptoms. Misdiagnosis can be life threatening. Therefore, it is important to have a high clinical suspicion for this disease especially in patients with known valvular pathology even in the absence of vegetations on echocardiogram. *Viridans Streptococci* is a known cause of endocarditis, and it has propensity to affect the native, mitral valve. Neurologic sequelae are a rare complication of endocarditis with ischemic stroke being most common. By contrast, there are very few reports of mycotic aneurysm rupture and subdural hematoma as a consequence of endocarditis. This case illustrates the need for high clinical suspicion for subacute endocarditis, and specifically for the devastating and heterogeneous presentation of neurologic sequelae.

CERTAINLY SIRS, BUT SEPSIS MISSES THE SWEET SPOT Christian Ngo; Oanh K. Nguyen. UT Southwestern Medical Center, Dallas, TX. (Tracking ID #2196664)

LEARNING OBJECTIVE #1: Recognize the systemic inflammatory response syndrome (SIRS) as a manifestation of non-infectious illness in the ICU.

LEARNING OBJECTIVE #2: Recognize the role of cognitive biases in diagnostic errors.

CASE: A 55 year-old man with a history of hypertension and hypothyroidism presented with 2 weeks of progressive malaise, weakness, and anorexia culminating in an acute episode of dyspnea and lightheadedness. Review of systems was notable for unintentional weight loss of 20 lbs. and acute on chronic shoulder, knee, and elbow pain. Family history

was significant for type 2 diabetes mellitus in his mother. Social history was notable for limited English proficiency and occupation as a roofer, though he had been recently unable to work due to joint pain. Initial vitals were temperature 34.7 °C, blood pressure 101/59 mmHg, pulse 87 beats/min, respiratory rate 20 breaths/min, and oxygen saturation 98 %. Initial physical exam documented normal sensorium and right upper extremity weakness; musculoskeletal exam was deferred. Initial laboratory evaluation showed serum glucose 983 mg/dL, anion gap 23, creatinine 3.34 mg/dL, white blood cell count 7.65, thyroid stimulating hormone 1.11 mIU/mL. A diagnosis of diabetic ketoacidosis (DKA) was made, with concern for infection as a precipitating factor. The patient was transferred to the intensive care unit, started on an insulin drip, intravenous fluids, and broad spectrum antibiotics. The patient subsequently became febrile to 39.4 °C with tachycardia to 104 beats/min and intermittent episodes of hypotension as low as 87/55 mmHg. Hypotension spontaneously resolved within 24 h, but fevers, tachycardia and weakness persisted. Further evaluation for an infectious source, including blood, urine, and stool cultures, chest radiograph, transthoracic echocardiogram, lumbar puncture, and computerized tomography of the chest, abdomen, and pelvis were unrevealing. Antibiotics were nonetheless further broadened to empirically treat presumed occult infection. Nerve conduction studies showed axonal sensorimotor polyneuropathy consistent with mild diabetic neuropathy. On hospital day six, the patient was transferred to the floor with a diagnosis of 'fever of unknown origin and generalized weakness.' On further questioning, the patient clarified that his 'weakness' entailed difficulty walking and lifting his arms due to pain in the upper extremities and left knee. Subsequent exam revealed warmth, erythema, and swelling of bilateral shoulders, elbows, wrists, left 2nd MCP, right 2nd and 3rd PIPs, 4th and 5th MCPs. Firm 1.5 cm irregular nodules were noted over the left 2nd and right 4th MCPs. Arthrocentesis of the right 2nd MCP showed negatively birefringent crystals consistent with gout. Prednisone, colchicine, and allopurinol were initiated for acute gouty arthritis with resolution of fevers and weakness.

DISCUSSION: Though infection is a common precipitant of DKA, patients with DKA can also present with signs of SIRS (including hypothermia, tachycardia and hypotension) in the absence of infection, due to peripheral vasodilation, volume depletion, and acidosis. Fevers in the context of polyarthralgias may portend septic arthritis but should also raise the possibility of inflammatory and crystal arthropathies. While it is prudent to empirically treat for infection in the setting of DKA without known precipitants, the lack of leukocytosis, localizing signs of infection, or response to antimicrobials, and the presence of important additional clues in the history and physical should have raised the possibility of alternative, non-infectious etiologies for SIRS in this patient. Several cognitive biases led to a diagnostic delay in this case: premature closure, anchoring, and framing effect. Premature closure is the acceptance of a diagnosis before it is fully verified. Here, the presumed diagnosis was sepsis and there was a failure to evaluate additional findings inconsistent with this diagnosis. Anchoring is the tendency to rely too heavily on the first piece of information offered. Here, anchoring to the diagnosis of sepsis led to a subsequent evaluation narrowly focused only on identifying an occult source of infection, rather than broadly evaluating for alternate etiologies of SIRS. Finally, framing of SIRS as an infectious issue and weakness as a neurologic rather than a musculoskeletal issue led to unnecessary testing, prolonged hospitalization, and a near miss in the diagnosis of a common and treatable condition, acute gouty arthritis. In conclusion, internists should recognize that manifestations of SIRS can occur in the setting of non-infectious illnesses, such as DKA and unrecognized acute gouty arthritis. This case specifically illustrates the need to recognize non-infectious causes of abnormal vital signs to guard against potential diagnostic errors arising from premature closure, anchoring, and framing effects.

CHANGE OF HEART Stephanie Hon. Tufts Medical Center, Boston, MA. (*Tracking ID #2199187*)

LEARNING OBJECTIVE #1: Illustrate the importance of recognizing a rare condition (cardiac amyloidosis) that requires prompt treatment to minimize the risk of morbidity and death.

LEARNING OBJECTIVE #2: Differentiate key clinical and diagnostic features between ischemic cardiac disease and cardiac amyloidosis in heart failure

CASE: A 65-year-old man with PMH of CAD status post drug-eluting stent to the distal left circumflex artery a year ago, presented to the ED with 5 days of progressive dyspnea on exertion associated with chest pressure that resolved with rest and sublingual nitroglycerin. Physical examination revealed tachycardia (110 s), orthostatic hypotension and hypoxia (91 % on room air). The patient appeared volume overloaded with bibasilar rales and bilateral pitting edema. Laboratory data was notable for troponin 0.04 and pro-BNP 5613. Chest x-ray showed mild pulmonary vascular congestion and EKG revealed low voltage, normal anteroposterior Q waves and lateral ST depressions. Echocardiography noted severe concentric biventricular hypertrophy with EF 35 %. Given the high suspicion for CAD, LHC was performed and revealed a 50 % ostial lesion and questionable proximal LAD lesion. P-MIBI NM stress test confirmed no new ischemic territories. Given the severe concentric biventricular hypertrophy on echocardiography, he underwent RHC and

3 endomyocardial biopsies. Tissue stained with congo red revealed characteristic apple-green birefringence under polarization microscopy, consistent with amyloidosis. SPEP and UPEP demonstrated moderate hypoalbuminemia and a restricted band located in the gamma region consistent with a monoclonal immunoglobulin as well as presence of Bence-Jones protein, respectively. Immunofixation electrophoresis revealed a monoclonal IgA type lambda gammopathy, confirmed with liquid chromatography tandem mass spectrometry for the diagnosis of light chain (AL) amyloidosis.

DISCUSSION: AL amyloidosis is a systemic disease characterized by extracellular accumulation of insoluble protein fibrils produced from clonal plasma cells in the bone marrow. Without treatment, cardiac involvement portends a median survival of 6 months. The progression of diastolic dysfunction caused by diffuse infiltration of myocardium with resultant stiffening and impaired relaxation leads to systolic dysfunction as functional myocardial tissue is replaced with amyloid protein. Amyloid infiltration can affect the conduction system leading to arrhythmias or sudden death. EKG typically shows low voltage, pseudoinfarct patterns and arrhythmia, while TTE reveals concentric biventricular hypertrophy, valvular thickening and biatrial enlargement. Troponin and BNP provide diagnostic and prognostic information as both are elevated in cardiac AL amyloidosis, often to a degree that appears disproportionate to CHF symptoms. Studies suggest that elevated troponins may surpass symptomatic CHF and TTE findings as predictors for survival and reflect treatment progress(1). Heart transplantation with adjunctive chemotherapy has shown some survival benefit and sequential heart and stem cell transplantation has shown significant survival benefit in certain patient populations(2,3). This case exemplifies the potential for anchoring bias, described as the tendency to rely too heavily on the first piece of information offered. Although CAD has a high pre-test probability as the etiology of this patient's CHF given his prior history, the nuances in EKG and TTE were suggestive of infiltrative disease. Astute observations prompted for timely pursuit of a diagnosis of cardiac amyloidosis. This case demonstrates a classic clinical presentation of congestive heart failure of amyloidosis, and should serve as a reminder to pursue alternative diagnoses when evidence does not support the original theory. Change of heart regarding this patient's change in his heart gave him the opportunity for better survival. 1. CHIKUNGUNYA FEVER IN A RETURNING TRAVELER: A NEW CHALLENGE FOR PRIMARY CARE IN THE WESTERN HEMISPHERE Camelo J, Blanquicett¹; James H. Willig^{1, 2}; Mukesh Patel². ¹University of Alabama at Birmingham, Birmingham, AL; ²Baptist Health System, Birmingham, AL. (*Tracking ID #2198620*)

LEARNING OBJECTIVE #1: Recognize the clinical presentation of Chikungunya fever, an emerging infection in the Western Hemisphere

CASE: A previously-healthy 36 year-old man presented with fever of 101 °F, malaise, headache and joint pain, four days after returning from a week-long vacation in the Caribbean. On day 1, he reported vague, right elbow discomfort and fever. Hours later, he described polyarthralgias, particularly in the hands and feet, limiting his ability to walk and hold objects. On day 2, he noticed a faint erythematous rash on his trunk and extremities. Associated symptoms included blurry vision, fatigue, headache and difficulty sleeping. He denied cough, dyspnea, GI symptoms, bleeding or blood in urine or stool. The patient is married and has a 3 year-old child. He denied sick contacts, new sexual partners or tick bites. He reports numerous mosquito bites to exposed skin during vacation. By day 4, the rash was more pronounced and involved his palms and soles. He described noticeable swelling in his fingers and ankles and was unable to ambulate independently due to pain in the joints of his feet, ankles, knees, and hips. Past medical history included a sports-related, left shoulder injury with subsequent labrum repair and seasonal allergies. On day 2 of illness, his temperature was 100.1 °F, BP 130/73 mmHg, pulse 85 bpm, respiration rate 14. On exam, a morbilliform rash on the trunk and upper and lower extremities was visualized. Conjunctiva were slightly hyperemic, sclera anicteric. Tenderness to passive movement of the ankles and fingers was noted, in addition to tenderness over the lower cervical spine, lumbar spine and paraspinal muscles. No joint effusions or synovitis were detected, edema in bilateral ankles and all fingers was noted. By day 4 of illness, the rash was more erythematous, confluent and lesions were visible on the palms and soles. Laboratory included WBC 4.6/mm³ (56 % neutrophils, 24 % lymphocytes, 20 % monocytes). Hematocrit was 40 %. Electrolytes, coagulation studies and hepatic function tests were normal. Serologic studies for acute viral hepatitis, acute EBV, HIV, syphilis, and dengue were negative. HIV RNA was undetectable and blood cultures were negative. Blood PCR for Chikungunya was positive on day 2 of illness, confirming diagnosis. While treatment with NSAIDs led to some improvement over the subsequent 2 weeks, significant hand and ankle pain continued. Imaging was noncontributory. We

prescribed hydroxychloroquine which subjectively improved arthralgias. He was able to return to normal physical activity 4 months after infection.

DISCUSSION: A little more than a year after its introduction to the Caribbean, Chikungunya virus has caused hundreds of thousands of infections, become endemic in many countries, and has established itself in Southern Florida. Previously, only endemic regions in Africa and Asia were considered at risk for Chikungunya with occasional outbreaks noted as the virus spread to nonimmune populations. Infection may be asymptomatic and is rarely fatal. The Caribbean is one of the most popular international destinations for North Americans and most travelers are unaware of the new risk for Chikungunya transmitted via *Aedes* species mosquitoes, a vector shared with dengue viruses, which may be clinically indistinguishable. Unlike dengue fever, persistent debilitating fatigue and arthralgias may persist for months to years after acute Chikungunya infection. Internists should be aware of the presence of Chikungunya in our hemisphere and its presentation. Pre-travel counseling in methods to prevent mosquito bites is important for travelers to Chikungunya endemic regions, and in those who develop a febrile illness with rash and arthralgias, Chikungunya fever should be considered in the differential. We should also be aware of the potential for long-term musculoskeletal symptoms that can complicate recovery in some patients.

CHIKUNGUNYA INFECTION PRESENTING AS ACUTE PSYCHOSIS Kiruba Vembu¹; Pinky Jha²; Hari Paudel¹. ¹Medical College of Wisconsin, Milwaukee, WI; ²medical college of wisconsin, Milwaukee, WI. (Tracking ID #2199314)

LEARNING OBJECTIVE #1: Recognize the wide differential diagnosis for altered mental status and acute psychosis, including rare infectious causes

LEARNING OBJECTIVE #2: Identify the clinical presentation and rare neurologic complications of Chikungunya infection

CASE: A 53 year old female with recently diagnosed schizophrenia reported to the ED for continued hallucinations. Her husband stated that she reported shadows of a person intending to cut off her arms and legs; she also threatened to physically assault him. Urinalysis returned positive; she was started on nitrofurantoin and admitted to an inpatient mental health facility. Four days later, she reported to the ED again with a chief complaint of altered mental status. She continued to have symptoms, including sexually inappropriate behavior and significant agitation, despite a full course of nitrofurantoin and treatment with lorazepam and olanzapine. Vitals in the ED were as follows: blood pressure 129/65, pulse 90, temperature 37.1 °C, respiratory rate of 18 and oxygen saturation of 100 %. CT scan was negative for acute abnormalities. Patient was admitted for further workup. Additional history was obtained: she had taken a trip to Puerto Rico 2 months prior, and contracted Chikungunya infection. Five days after she initially reported symptoms, she reported significant paranoia, visual and auditory hallucinations, and persecutory delusions. She was treated with supportive care at that time. On admission, urine drug screen was negative. MRI was obtained and showed non specific attenuated nulling of CSF in the sulci. EEG was performed and showed no epileptiform discharges. She was continued on her antipsychotic medication regimen, and a lumbar puncture was performed due to concern for meningoencephalitis. Results were positive for both Chikungunya IgG and IgM; IgM titer returned at a level of 1:160.

DISCUSSION: The differential diagnosis for altered mental status, including acute psychosis, is wide and includes not only primary psychiatric illness but also metabolic disturbances, structural brain defects or lesions, endocrine and liver disease. Infectious causes must also be considered. We present a rare case of Chikungunya infection presenting with acute psychosis; this patient's symptoms were interpreted to be secondary to primary psychiatric illness before the differential diagnosis was expanded to consider rare causes of infection given her recent travel history to Puerto Rico. Chikungunya virus, an arbovirus endemic to west Africa and transmitted by the *Aedes* mosquito, has spread globally since 2004. Three types, based on geographical origin, have been identified to date. Typical symptoms of infection include fevers over 38.9 °C, severe arthritis, and a maculopapular rash. Diagnosis is obtained through detection of viral RNA or antibodies. Virus isolation can also be used when detected in the first 7 days of illness. IgM anti chikungunya bodies typically develop within 1 week, and as in our patient, stay elevated for up to 3 months. IgG antibodies can persist for years after initial infection. Neurologic symptoms of Chikungunya are rare. In early epidemics, meningoencephalitis had been reported, but more recent outbreaks have shown that palsies, acute flaccid paralysis, and Guillan Barre can occur with chikungunya infection. In adults, encephalopathy is most frequent, and is associated with IgM antibodies in CSF. However, literature search shows that psychosis associated with chikungunya is rare; previously, six cases were reported in a 1964 outbreak in southern India. Chikungunya infection was traditionally thought to have only significant morbidity. However, a Reunion island outbreak showed that mortality could be attributed to this infection as well, which had previously not been reported. Thus, further understanding of neurologic complications is essential. Treatment is mainly supportive; anti-inflammatory and antipyretic agents should be provided, along with appropriate pain control measures. To date, no antiviral agents have been proven to be effective.

CHIKUNGUNYA: A MICROBE ON THE MOVE Daniel C. Rogan¹; Jason A. Korcak. Montefiore Medical Center, Bronx, NY. (Tracking ID #2199082)

LEARNING OBJECTIVE #1: Recognize chikungunya fever as an emerging disease.

LEARNING OBJECTIVE #2: Describe the clinical presentation and diagnosis of chikungunya fever.

CASE: A 52-year-old man presented with generalized muscle and joint pain, headache, and subjective fevers for 1 day. The pain was most severe in the elbows and knees. The patient also reported one episode of non-bloody emesis, but denied rash, neck stiffness, sore throat, and abdominal pain. Three days prior to presentation, the patient returned from a trip to Puerto Rico. He visited only urban areas and reported a mosquito bite on his right ankle. The patient's past medical history was significant for HIV on ART with a recent CD4 count of 769 cells/μL and an undetectable viral load. The patient was afebrile with normal vital signs. Range of motion of bilateral elbows and knees was limited secondary to pain. There was no joint swelling or erythema. There was a lesion consistent with a mosquito bite over the medial right ankle, but no petechiae, purpura or other rashes. White blood cell count was 6.4 k/μL, and platelets were 209 k/μL. Blood cultures were negative. Dengue IgG was elevated, but IgM was normal. Chikungunya viral RNA was detected by RT-PCR.

DISCUSSION: From 2006 to 2013, an average of 28 people annually in the United States tested positive for the chikungunya virus. All were travelers from endemic areas, mostly in Southeast Asia, the Indian subcontinent, and sub-Saharan Africa. The first transmission of the chikungunya virus in the Western Hemisphere was reported during an outbreak in the Caribbean in December 2013. Just 4 months later, more than 31,000 cases of chikungunya were reported across the Caribbean. While the actual number is difficult to estimate as chikungunya is not a nationally reportable disease in the United States, a total of 2021 chikungunya virus disease cases have been reported in the United States during 2014. Eleven of these cases were locally transmitted in Florida. All other cases occurred in travelers returning from affected areas in the Americas. Chikungunya virus is transmitted to humans by the *Aedes aegypti* and *Aedes albopictus* mosquito. These mosquitoes are found throughout much of the Americas, including the United States, and also transmit Dengue virus, which shares several key clinical features with chikungunya. Testing serum by immunoassay and PCR can help differentiate between dengue and chikungunya. In this case, a positive dengue IgG in the absence of a positive dengue IgM is consistent with past infection. The diagnosis of chikungunya is usually based on the clinical presentation and travel history. In addition, there are plasma or serum assays for the chikungunya virus itself, viral nucleic acid, or virus-specific immunoglobulin (IgM) and neutralizing antibodies. After an incubation period from 2 to 12 days, chikungunya infections typically present with fever, malaise, headache, myalgia, and arthralgia or arthritis. There is involvement of both large and small joints, usually symmetric and often involving the hands and feet. Chikungunya is rarely fatal. Symptoms are generally self-limiting. Some patients may have persistent joint pains for months to years, and rarely, there may be ophthalmologic, neurologic, gastrointestinal, and cardiologic complications. Neonates and older adults typically experience more severe forms of the disease. Given its rapid emergence in the United States and the Caribbean, clinicians must consider chikungunya in the differential diagnosis for a broad range of patient presentations. Chikungunya is truly a microbe on the move.

CHIKUNGUNYA: A PREVIOUSLY UNCOMMON DIAGNOSIS IN THE AMERICAS Reece Doughty. David Geffen School of Medicine at University of California Los Angeles, Los Angeles, CA. (Tracking ID #2195848)

LEARNING OBJECTIVE #1: Recognize the clinical features of chikungunya virus infection

CASE: We present the case of a 33 year old female seen in the emergency room who developed fever, arthralgias and swelling in both wrists and ankles, and malaise 1 day after returning from Puerto Rico. She subsequently developed a rash as well as persistent mild nausea. She was previously healthy with no active medical conditions and no current medication use. She worked as a nanny and reported no recent sexual partners. She did not have a primary care physician and was not evaluated prior to her travel. She went to Puerto Rico for 8 days for vacation and spent most of her time at a resort condominium complex. She did not use insect repellent or take malaria prophylaxis and denied known insect bites or contact with animals while there. No one else in her travel group became ill. The patient was evaluated by our team after approximately 1 week of symptoms. The patient was afebrile during our initial exam, but was borderline tachycardic to the 90s. She was tender to palpation in both wrists and ankles and had enlarged tender posterior cervical lymph nodes as well as a diffuse, erythematous, blanching maculopapular rash over her trunk and extremities. Initial laboratory studies were significant for a mildly decreased WBC at 3.08 and mildly decreased bicarbonate at 19; otherwise, CBC, BMP, and LFTs were within normal limits. Bicarb improved with IV fluids. Subsequent investigation for HIV, dengue,

malaria, EBV, CMV, Rickettsial disease, and leptospira were negative. Patient had ongoing wrist and ankle pain, but otherwise did well during her admission and was discharged from the hospital on after 48 h with clinic appointment later in week to follow-up. Prior to this clinic appointment, chikungunya antibody studies returned positive with IgM 1:640 (nml <1:10) and IgG 1:20 (nml <1:10). She had ongoing wrist and ankle pain moderately controlled with tylenol, but otherwise felt at her baseline. Interestingly, she had mildly elevated measles antibodies that we suspect was due to cross-reactivity from chikungunya infection as the patient had been vaccinated in the past and had none of the characteristic symptoms suggestive of acute measles infection. We instructed her to follow-up with a new PMD closer to where she lives in and be re-evaluated in 1–2 weeks.

DISCUSSION: Chikungunya virus is a mosquito-borne viral disease which characteristically causes high fever and arthralgias, and may also cause rash, headache, myalgias, and GI complaints. After initial symptom onset, diagnosis can be made by PCR; after about 4–5 days, serum antibodies (IgM/IgG) can be detected. For health care providers in the Americas, chikungunya was previously a rarely seen travel related illness, but in the last 18 months has become an endemic disease in the western hemisphere with reports of autochthonous cases ranging from Florida through upper South America. As of mid-December 2014, there have been about 25,000 confirmed cases in the Americas as well as over 1,000,000 suspected additional cases. Although the disease course is self-limited in the vast majority of cases, and treatment is symptomatic, given the ongoing epidemic, it is important to differentiate this from other diagnoses such as dengue fever which can present similarly but can have severe complications such as bleeding and shock that are worsened by NSAID use.

CHRONIC, CUTANEOUS, AND CALCIFIED: NOT YOUR EVERYDAY ULCER

Brian J. Wentworth¹; Qasim Salimi¹; Julia Grimes². ¹Rutgers Robert Wood Johnson Medical School, Piscataway, NJ; ²Rutgers Robert Wood Johnson Medical School, New Brunswick, NJ. (*Tracking ID #2153249*)

LEARNING OBJECTIVE #1: Recognize and treat calcinosis cutis in a patient with an autoimmune connective tissue disease (ACTD).

LEARNING OBJECTIVE #2: Recognize when biopsy is warranted for cutaneous ulcers.

CASE: A 37 year-old Indian woman with SLE/RA overlap syndrome and GERD presented with non-healing left lower extremity ulcers of 4 months duration unresponsive to cephalexin and levofloxacin. The ulcers began as raised, erythematous, and painful lesions that initially drained a thick, whitish fluid. Of note, the patient reported a five year history of similar slow-healing ulcers. Extensive rheumatologic workup prior to admission revealed positive or elevated levels of the following: ANA (speckled pattern), anti-Sm, RF, anti-CCP, SS-A, ACE, anti-RNP. A lower-extremity x-ray one year prior revealed subcutaneous calcifications. ROS revealed intermittent fevers, fatigue, dysphagia, arthralgia, morning stiffness, painful bilateral extremity subcutaneous nodules, and Raynaud's phenomenon. Her medications included omeprazole, sulfasalazine, methotrexate, hydroxychloroquine, prednisone, folic acid, tramadol, and levofloxacin. Family history was significant for maternal RA. On admission, the patient was tachycardic and physical examination revealed a thin, anxious woman. Neurologic, ophthalmic, cardiac, pulmonary, and abdominal examinations were unremarkable. Musculoskeletal exam was significant for symmetric MCP and PIP joint swelling and ulnar deviation. Dermatologic examination revealed a malar rash, left lower-extremity 2×2 and 1.5×1 cm ulcerations to subcutaneous tissue, multiple healed bilateral lower extremity ulcerations, and multiple bilateral extremity <1 cm subcutaneous nodules. No oral ulcers, sclerodactyly, telangiectasias, heliotrope rash, or Gottron's papules were noted. Labs revealed mild leukopenia without neutropenia, anemia of chronic disease, and elevated ESR. The initial differential diagnosis included rheumatoid vasculitis, infection, and pyoderma gangrenosum. Wound and tissue cultures confirmed pan-susceptible *Pseudomonas aeruginosa*. A punch biopsy was performed but results were not immediately available. The patient was continued on levofloxacin, sulfasalazine, hydroxychloroquine, and tramadol. After multiple days, granulation tissue began to form within the ulcers and the patient was discharged with close follow-up. Final biopsy review after discharge by a board-certified dermatopathologist revealed calcinosis cutis with multibacterial infection and lipodermatosclerosis.

DISCUSSION: Calcinosis cutis involves the deposition of calcium and phosphorus within the skin, causing a chronic inflammatory state that damages tissue and interferes with calcification inhibitors, facilitating mineralization. Additionally, the deposits may ulcerate, extrude calcium salts, or become secondarily infected. Classically seen 8–10 years after initial diagnosis in dermatomyositis and systemic sclerosis, calcinosis cutis may present in other autoimmune connective tissue diseases (ACTDs) and can be difficult to diagnose given its variable clinical latency (2–312 months). Although calcinosis cutis is a rare complication of SLE/RA overlap syndrome, it should be suspected in patients with subcutaneous nodules that present with chronic ulcers. The delay in the patient's diagnosis

highlights the importance of a thorough work-up for chronic, slow-healing ulcers in all patients, especially those with ACTDs. While bacterial superinfection may occur, poor response to antibiotics should alert the internist that further investigation with biopsy is indicated, as it provides excellent diagnostic and prognostic information. Furthermore, a tendency towards earlier biopsy may avoid unnecessarily subjecting patients to extended courses of antibiotics, particularly if suboptimal responses are documented. Clinical improvement of calcinosis cutis in ACTDs is dependent upon successful treatment of the three main contributing factors: 1) **Controlling the underlying inflammatory state**—appropriate use of DMARDs and biologic agents. 2) **Eradicating any infectious pathogen(s)**—judicious use of antibiotics tailored to bacterial sensitivities. 3) **Reducing calcific burden**—medically (diltiazem, minocycline, warfarin, aluminum hydroxide, etc.) vs. procedurally (surgical excision, extracorporeal shock wave lithotripsy, carbon dioxide laser). While small studies and anecdotal evidence support each of the aforementioned therapies, a recent dermatologic review concluded that surgical intervention was the first-line therapy for idiopathic calcinosis cutis and effective in SLE patients. Despite these encouraging results, reduction of calcific burden has primarily been studied in patients with either a single rheumatologic diagnosis or idiopathic calcinosis cutis. Thus, the effectiveness of the various treatments is unknown in overlap disorders and patient preference and side effect profiles should guide therapy. Additional literature and experience are needed to develop an appropriate treatment algorithm.

CLASSIC HYPERTENSIVE EMERGENCY? AN UNUSUAL CASE OF LABILE HYPERTENSION Kanapa Kornswad¹; Alfredo Camero². ¹University of Texas Health Science Center, San Antonio, TX; ²University of Texas Health Science Center at San Antonio, San Antonio, TX. (*Tracking ID #2168599*)

LEARNING OBJECTIVE #1: To recognize an atypical variant of Guillain Barre Syndrome

LEARNING OBJECTIVE #2: To identify the role of autonomic dysfunction in GBS.

CASE: A 65 year old man presented with 1 day of headaches and dizziness. He denied vision changes, chest pain, or weakness. His past medical history was significant for hypertension, chronic kidney disease stage III, and type 2 diabetes mellitus. His blood pressure was noted to be 216/122 with otherwise normal vital signs. His physical exam demonstrated no neurologic abnormalities and his optic disc showed no papilledema. His serum creatinine was 3.7 mg/dL with a baseline serum creatinine of 1.6 mg/dL. A computed tomographic (CT) scan of his head was normal. He was started on a nicardipine drip for aggressive blood pressure control. His blood pressure was labile and corrected quickly over 1 h to 140/80, and thus the drip was stopped. His blood pressure remained labile throughout the subsequent days requiring either extra anti-hypertensive medication or intravenous fluids for hypotension. On his third hospital day, he developed altered mental status with hypercapnea that required intubation for airway protection. It was noted that he could not move his extremities but did open and close his eyes on command. His physical exam at that time showed areflexia. A magnetic resonance image (MRI) of the brain showed a small acute lacunar infarct involving the left lateral thalamus, which did not explain his neurologic deficits. Lumbar puncture was performed due to a concern for GBS. Cerebrospinal fluid (CSF) studies showed a protein level of 144 mg/dL (elevated), no white blood cells, and a negative infectious workup for multiple viruses and bacteria. Electromyography (EMG) and nerve conduction studies were performed that showed evidence of primarily axonal sensory/motor peripheral polyneuropathy. An autoimmune workup was also performed, which was significant for a positive antibody to ganglioside GM1. His diagnostic studies were consistent with a diagnosis of acute motor and sensory axonal neuropathy (AMSAN). He was treated with IVIG therapy for 5 days with remarkable improvement over several weeks with eventual full motor strength recovery on all four of his extremities.

DISCUSSION: Dysautonomia is a common feature of GBS (reported as high as 70 % of cases). Typical cardiovascular findings of dysautonomia in GBS include tachycardia, persistent hypertension, labile blood pressure, and arrhythmias. Our patient exhibited signs of very labile blood pressure that was very sensitive to different medications. Although this was a clue to dysautonomia, he wasn't experiencing neurologic symptoms yet, and thus GBS, or AMSAN specifically, was not one of our differential diagnoses. AMSAN is a variant of GBS typically seen in non-US countries. This variant of GBS is typically differentiated via EMG and antibody tests anti-gangliosides and is associated with higher rates of respiratory failure. His recovery with IVIG is also unusual since cases of AMSAN typically do not have such quick recoveries. Our case highlights a very unusual clinical presentation to an atypical variant of GBS. Hypertensive crises that are overly sensitive to medication should raise the suspicion to a general internist of the possibility of dysautonomia playing a pathophysiological role and thereby adjusting their differential diagnoses accordingly.

CLINICAL ETHICAL DILEMMAS AND THE PRINCIPLE OF PRIMUM NON NOCERE Sagger Mawri²; Jainil Shah²; Joseph Gibbs²; Jessie Tan²; Heidi Alvey¹; Najia Huda². ¹Henry Ford Health System, Southgate, MI; ²Henry Ford Hospital, Detroit, MI. (Tracking ID #2199035)

LEARNING OBJECTIVE #1: Describe a clinical case that illustrates an ethical dilemma and explore different approaches that may be used to facilitate the clinical decision making process

LEARNING OBJECTIVE #2: Explore the risks and potential unintended harms of routine medical interventions and revisit the principle of “First, Do No Harm” (Primum Non Nocere) to ensure safe and ethical patient care

CASE: A 60 year-old man with history of hypertension and diabetes mellitus type 2 was admitted to the hospital for progressive proximal muscle weakness. He was undergoing neurological work-up for suspected amyotrophic lateral sclerosis (ALS). In the general medical floor, he was noted to have gradual increased work of breathing and arrangements were made to transfer him to the medical intensive care unit to receive bilevel positive airway pressure (BPAP). However, his transfer was delayed for several hours due to shortage of ICU beds. Upon arrival to the ICU, he was started on non-invasive ventilation, but did not tolerate it well. Due to impending acute respiratory failure, he was intubated and mechanically ventilated. Following intubation, he developed aspiration pneumonia and was started on Vancomycin and Piperacillin/Tazobactam. Unfortunately, he developed antibiotic-induced acute interstitial nephropathy. He was switched to Moxifloxacin, but subsequently acquired clostridium difficile colitis. His ventilator settings escalated and neurology team determined that his ALS was rapidly progressive. He was fully informed of his prognosis and slim chances of being weaned successfully off the ventilator. His renal failure progressed rapidly and he became oliguric, volume overloaded and developed electrolyte derangements. Urgent hemodialysis was needed; however, at this point the patient refused any further medical interventions. After 3 weeks on the ventilator and subsequent tracheostomy placement with continued clinical decline, the patient finally expressed that life had become too burdensome to bear living. In writing, he thanked the physicians for their efforts to help him and decided to spend his final moments with his younger siblings. Per his wishes, he was weaned off the ventilator and, shortly thereafter, he passed away.

DISCUSSION: In an era of great medical advancements, today's physician is armed and trained with a powerful arsenal of diagnostic and therapeutic tools used to combat diseases and thereby heal patients. However, modern medicine's emphasis on intervention creates a risk for causing inadvertent harm to the patient, as a consequence of medical actions. The above case highlights this point. Each medical intervention used to treat and benefit the patient resulted in an unintended harm to him. Moreover, the case illustrates an example of the tension between a patient's autonomy and medical paternalism, and the difficult medical decision making that arises with this ethical conundrum. The patient was determined to have a rapidly progressive form of ALS. He chose life support and underwent tracheostomy tube placement, despite worsening respiratory status that did not appear to have good chances of improvement, and which may have only prolonged his suffering. Therefore, a greater degree of medical paternalism may have been used to establish a balance with the patient's autonomy. Perhaps it should have been discussed with the patient that a limited trial on the ventilator be attempted, after which the focus should be on comfort care only. Furthermore, in accordance with guidelines from the society of critical care medicine (SCCM) and agency for healthcare research and quality (AHRQ), early multidisciplinary conversations at 72–96 h of ICU stay may have been arranged to help facilitate the decision-making process, and limit the burden of advanced supportive technology when it was deemed ineffective. In addition, adopting an ethical-reasoning tool may have allowed for a structured framework to guide formulation of an informed, morally justified decision. An example is applying the Jonsen's “four boxes” approach, which consists of four broad topics —medical indications, patient preferences, quality of life, and contextual features—within which lie more specific questions to be considered in working through the case. This case serves as a reminder that any medical intervention we perform carries with it the potential risk for unintended harm. It echoes the importance of the most humanistic and enduring pillar of our medical profession: “First, Do No Harm.” The case also illustrates the ethical dilemmas that physicians often confront when making clinical decisions, and the importance of reflecting upon and appraising our management decisions to ensure the delivery of safe and ethical patient care.

CNS LYME WITH CRANIAL NERVE VI Palsy AND CHARLES BONNET SYNDROME Paul X. Fu²; Lorenzo Falchi²; Vincent Lau²; Hajime Tokuno²; Anne Hyson^{1, 2}. ¹West Haven VA, Cos Cob, CT; ²Yale School Of Medicine, New Haven, CT. (Tracking ID #2193722)

LEARNING OBJECTIVE #1: Diagnose CNS Lyme in the setting of isolated cranial nerve VI palsy and visual hallucinations

LEARNING OBJECTIVE #2: Recognize association of CNS Lyme Disease with Charles Bonnet Syndrome

CASE: An 87 year old male with no significant past medical history presented with gradually worsening horizontal diplopia for 1 week. He denied other systemic or neurological symptoms but does report spending much of his time in the woods, often removing ticks from his skin in the past 2 months. On physical exam, patient was found to have left cranial nerve VI palsy. The remaining neurological exam was unremarkable. Notably, patient has noticed visual images that occur unilaterally in his left eye when he closes that eye. These images are fully formed and stimulating, including scenes from the Battle of Little Big Horn, or children playing. He was aware that these images were not real, and they only appeared in the left eye. Initial workup for diplopia included testing for myasthenia gravis, MRI brain, and Lyme disease studies. MRI brain showed no acute intracranial process. Tensilon test and antibodies for myasthenia gravis were negative, however, screening for Lyme was positive. Serum testing by Western blot demonstrated positive Lyme IgM, and negative IgG. Lumbar puncture was obtained with CSF analysis showing protein of 163 mg/dL, glucose of 61 mmol/L, and nucleated cells of 153 per mm³, with 96 % lymphocytic predominance. CSF Lyme index was positive for IgM (>1:16) and negative for IgG (<1:4). A diagnosis of early disseminated Lyme disease was made, and planned treatment was ceftriaxone IV 2 g daily for 21 days. After 14 days of antibiotics, patient continued to notice visual images whenever he closed his left eye. These images were again fully formed scenes, and only occurred in his left eye when closed, or when he wore an eye patch over the effected eye. Lumbar puncture and MRI were repeated at this time. CSF studies showed improvement in the CSF with protein of 94.7 mg/dL, glucose of 60 mmol/L, and nucleated cells of 32 per mm³ with 96 % lymphocytic predominance. Repeat MRI showed bilateral cranial nerve enhancement of nerves III, VI, and VII consistent with persistent CSF Lyme disease. Decision was made to treat patient with IV ceftriaxone for extended 28 days. Patient's final diagnosis was early disseminated Lyme disease associated with Charles Bonnet Syndrome of the left eye.

DISCUSSION: In the United States, Lyme disease is caused by the bacteria *Borrelia burgdorferi*, which is transmitted via the vector *Ixodes* tick. Presentation of Lyme disease can be generally distinguished into three categories: early (1–2 weeks after transmission), disseminated (1–2 months), and late (months to years). Erythema migrans is the classic presenting sign of early Lyme disease, and is found in 80 % of patients in combination with constitutional symptoms. Disseminated disease occurs weeks to months after initial transmission and include neurological and cardiac manifestations. Lyme disease affects the CNS in 10–15 % of cases. Signs of CNS spread of Lyme disease include lymphocytic meningitis, cranial nerve involvement (commonly facial nerve) and painful radiculopathy. Isolated cranial nerve VI palsy as the presenting sign of Lyme disease has been rarely described. Charles Bonnet Syndrome is defined by the appearance of complex visual hallucinations in a patient with impaired eyesight. A diagnosis of Charles Bonnet Syndrome requires that the patient recognizes these images are not real, in addition to the absence of an underlying psychiatric illness. To the best of our knowledge, this is the first report of early disseminated Lyme disease causing cranial nerve VI palsy and Charles Bonnet Syndrome.

COGNITIVE DYSFUNCTION CAUSE BY HYPOGLYCEMIC ENCEPHALOPATHY Taihei Ishikawa; Naoki Matsuura; SATOSHI MATSUNAGA; Hiroyuki Oda; Takashi Akaiwa; Hiroshi Imura; Mitsuo Kozuru. Aso Iizuka Hospital, Iizuka, Japan. (Tracking ID #2197226)

LEARNING OBJECTIVE #1: Include hypoglycemic encephalopathy in the differential diagnosis of any individual with cognitive dysfunctions following a comatose status.

LEARNING OBJECTIVE #2: Recognize the importance of a cerebral MRI at an early stage to diagnose hypoglycemic encephalopathy.

CASE: A 52 year-old Japanese man with no a history of diabetes or cognitive impairment was transferred to our hospital in a comatose status. The patient had excessive alcohol consumption the previous night and his wife found him unconscious in the morning of admission. His initial Glasgow Coma Scale (GCS) score was 6 (eye opening: 1; verbal: 1; motor: 4), and his blood glucose level was 1.6 mmol/L. After an intravenous bolus shot of 50 % glucose by a paramedic, he was transferred to our emergency department. On arrival at our hospital, his GCS score was elevated to 9 (eye opening: 4; verbal: 1; motor: 4). Otherwise he had no significant neurological signs. His arterial blood gas revealed metabolic acidosis with a lactate level of 2.8 mmol/L. A urine test showed positive ketone body. Although his level of consciousness gradually recovered after fluid replacement with thiamine, he still had cognitive dysfunctions. A cerebral MRI was performed on Day 2, which revealed several high intensity lesions in the bilateral hippocampi and the splenium of the corpus callosum. These lesions disappeared on Day 16. His Mini-Mental State Examination score gradually improved to 9 (out of 30) on Day 7, 11 on Day 16, and 15 on Day 25. Based on his history of prolonged hypoglycemic state and the

MRI findings, we made a diagnosis of hypoglycemic encephalopathy as the cause of his cognitive dysfunctions. He was transferred to a local clinic for further rehabilitation on Day 25.

DISCUSSION: Hypoglycemic encephalopathy is a metabolic brain disorder caused by critically low levels of blood glucose. Common causes are 1) overdose of insulin or an oral agent for diabetes mellitus, 2) insulin-secreting tumor, and 3) depletion of liver glycogen storage due to prolonged starvation, alcohol consumption, or liver failure. Prolonged and severe hypoglycemia can cause irreversible brain damage in some vulnerable brain regions, such as in the cerebral cortex and the hippocampus. Neuronal death in the hippocampus results in permanent cognitive impairment. A number of cases report that diffusion weighted imaging often shows hyperintense lesions in the hippocampi and the cerebral cortex, which might either remain or disappear over time. In our case, we considered that the cause of his cognitive dysfunctions was due to hypoglycemic encephalopathy since his history strongly suggested that he had a prolonged hypoglycemic state prior to admission. His MRI findings were also compatible with this diagnosis. Based on his MRI and EEG findings, other causes of cognitive dysfunctions, such as hypoxemia, Wernicke's encephalopathy, and epilepsy are less likely. In conclusion, hypoglycemic encephalopathy should be in the differential diagnosis of any individual with cognitive dysfunctions following a comatose status, and a cerebral MRI should be performed for accurate diagnosis.

COMPLICATION OF INFERIOR MYOCARDIAL INFARCTION; WHEN PHYSICAL EXAMINATION BECOMES UNRELIABLE Naoki Misumida¹; Akihiro Kobayashi. Beth Israel Medical Center, New York, NY. (Tracking ID #2196330)

LEARNING OBJECTIVE #1: Recognize the importance of thorough workup for a mechanical complication following myocardial infarction, even when a cardiac murmur is not present.

LEARNING OBJECTIVE #2: Review the typical clinical course of the complication following inferior myocardial infarction

CASE: A 74-year-old woman with morbid obesity presented with chest pain lasting for 3 h. Chest pain was constant, pressure sensation, located in her left chest. Blood pressure was 106/91 mmHg, pulse rate was 71 /min, respiratory rate was 28 /min, and oxygen saturation was 78 % on 15 L of oxygen through non-rebreather mask. Body mass index was 45 kg/m². Physical examination showed bilateral crackles without cardiac murmur. EKG revealed sinus rhythm and ST-segment elevation in inferior leads without Q-wave. Chest X-ray revealed bilateral pulmonary vascular congestion. Patient was in respiratory distress and subsequently intubated. Patient was diagnosed with inferior ST-segment elevation myocardial infarction and taken to an emergent cardiac catheterization, which showed a total occlusion of right coronary artery. Patient successfully underwent percutaneous coronary intervention. Initial troponin I value was 2.4 µg/ml and troponin was further elevated to 208 µg/ml. Patient became hypotensive and required high-dose catecholamine and intra-aortic balloon pump support. Transthoracic echocardiography showed preserved ejection fraction with regional wall motion abnormality in inferior wall, but an evaluation of mitral valve was limited due to morbid obesity. No cardiac murmur was appreciated on serial physical examinations. Patient remained hypotensive and heart failure was not controlled. On day 3, trans-esophageal echocardiography was performed, which revealed papillary muscle rupture and severe mitral regurgitation. Her condition failed to improve despite intensive medical treatment, and she underwent mitral valve replacement on day 5. After a prolonged duration of hospital stay, the patient was discharged to sub-acute rehabilitation facility.

DISCUSSION: The present case highlighted the importance of thorough workup for a mechanical complication following myocardial infarction and the limitation of physical examination. Acute mitral regurgitation caused by papillary muscle rupture is a rare life-threatening complication of myocardial infarction. Papillary muscle rupture usually occurs in patients with an inferior infarction 2 to 7 days after the infarction, as in the present case. The initial clue to recognize this rare complication is usually physical examination findings since severe mitral regurgitation usually causes easily appreciable loud cardiac murmur. The present case was, however, atypical in terms of the physical exam findings. Mechanical noise due to intra-aortic balloon pump and patient body habitus made it impossible to detect cardiac murmur, and only trans-esophageal echocardiography was able to reveal severe mitral regurgitation. Our study suggested that mechanical complication should be investigated when a patient with inferior myocardial infarction develops persistent hypotension and heart failure, even when a cardiac murmur is not present. Urgent surgical intervention is the treatment of choice of this complication, as the mortality rate of medically managed patient is high. Papillary muscle rupture can happen after a patient is transferred to general medicine floor, and therefore recognizing this rare complication is important for internists to provide appropriate care to patients with recent myocardial infarction.

COMPRESSION, CLOT FORMATION, AND CHRONIC PAIN: A CASE OF MAY-THURNER SYNDROME Christopher Lin-Brand¹; Anna Platovsky². ¹Albert Einstein College of Medicine, Bronx, NY; ²Montefiore Medical Center, Bronx, NY. (Tracking ID #2198405)

LEARNING OBJECTIVE #1: Recognize and diagnose anatomic variants that cause deep vein thrombosis (DVT)

LEARNING OBJECTIVE #2: Manage DVTs caused by venous compression syndromes

CASE: A 69 year-old woman presented with progressive left lower extremity (LLE) pain and swelling with difficulty ambulating for 2 weeks. The symptoms developed 1 day after a period of prolonged sitting. Duplex ultrasound revealed extensive deep vein thrombosis (DVT) of the entire LLE venous system. The patient was started on warfarin 5 mg daily and discharged home after bridging. One week later, she returned with worsening symptoms of pain and swelling, most notably in the left posterior knee and calf. The LLE had diffuse non-pitting edema, warmth, erythema, and tenderness to palpation from the toes to the upper thigh. She had difficulty bearing weight and could not walk, but she had palpable dorsalis pedis pulses, intact sensation, and full strength bilaterally with no evidence of skin breakdown. Serum studies were significant for an INR of 4.2. Despite the supratherapeutic INR, repeat ultrasound revealed a common femoral DVT extending into the left external and common iliac veins. The patient denied any predisposing factors for hypercoagulability such as known malignancy, estrogen supplements, or personal or family history of thromboembolism. Due to the extent of the clot and her significant symptoms, interventional radiology was consulted for catheter-directed thrombolysis. Venography incidentally revealed filling defects consistent with May-Thurner syndrome. As a result, tissue plasminogen activator (tPA) was administered to dissolve the thrombus and a left common iliac vein stent was placed to maintain patency of the vessel.

DISCUSSION: May-Thurner Syndrome (MTS) is a vascular anomaly caused by compression of the left common iliac vein (LCIV) between the right common iliac artery and lumbar vertebrae. This anomaly can lead to venous spur formation, obstruction, and extensive DVT. MTS is found in 2–5 % of lower extremity venous disorders, but given rates of LCIV compression of 20–30 % in some autopsy studies, the prevalence of MTS is likely underestimated. The syndrome typically presents as an extensive left-sided DVT in young women ages 20–40, which can lead to serious consequences such as pulmonary embolism (PE), death, and post-thrombotic syndrome (PTS). The leg symptoms and skin changes of PTS are found in about 20–50 % of patients post-DVT and are a significant source of morbidity. Patients with MTS may be asymptomatic until they present with acute DVT (often left-sided and proximal), chronic PTS changes (persistent pain, swelling, paresthesias, pruritus, skin pigmentation, recurrent ulcers), or PE. Imaging confirms the clinical findings, but duplex ultrasound (US) typically used in DVT diagnosis cannot visualize the compressed LCIV in the pelvis, especially if the patient is obese. X-ray, CT, and MR venography are invasive and expensive procedures; however, they are the gold standard for diagnosis and endovascular treatment of MTS and should be performed if there is strong suspicion of venous compression, especially if initial US reveals an extensive proximal thrombus. Intravenous ultrasound (IVUS) is often a useful adjunct for direct visualization of the vessel. Alternatively, non-invasive imaging with CT and MRI of the pelvis may provide evidence of compression without the need for a procedure initially. Standard therapy for DVT, including cases of MTS, consists of systemic anticoagulation with low molecular weight heparin (LMWH) and warfarin. Further treatment of MTS centers on two major goals: reducing the severity of PTS and preventing compression of the vein. Endovascular interventions such as catheter-directed thrombolysis (CDT) and mechanical thrombectomy have increasingly supplanted surgical procedures to enhance long-term iliofemoral patency and decrease morbidity from PTS. The regular daytime use of elastic compression stockings for 2 years after DVT further decreases the incidence of PTS by 50 %. Additionally in MTS, stents are essential for maintaining patency of the vessel and have been shown to reduce rates of rethrombosis. Early recognition of MTS with appropriate imaging and treatment is critical to prevent morbidity and mortality, especially since standard therapy alone will almost invariably result in PTS. Typical cases involve young women with extensive left-sided proximal DVT, but clinicians must be aware that non-compressive and compressive forms of DVT are often indistinguishable and that the latter are likely underdiagnosed. Patient demographics and presentation as well as invasiveness and cost of the procedure are all important factors in selecting the imaging modality. Further research must be done to determine whether non-invasive CT and MRI have utility over venography when MTS is suspected. Once the diagnosis is made, however, anticoagulation, thrombolysis, and stenting must all be used in concert to prevent the long-term sequelae of MTS.

CONFUSION THE MIDST OF LUPUS Rebecca E. Virata¹; Yelena Averbukh². ¹Albert Einstein College of Medicine, Bronx, NY; ²Montefiore Medical Center, Bronx, NY. (Tracking ID #2155934)

LEARNING OBJECTIVE #1: Recognize delirium as a presentation of neuropsychiatric lupus in the absence of systemic disease.

LEARNING OBJECTIVE #2: Understand the complexities of the diagnostic work-up of neuropsychiatric lupus.

CASE: A 24-year-old female with systemic lupus erythematosus (SLE) and a recent hospitalization for SLE flare which was treated with steroids, presents with increasing social withdrawal, decrease oral intake, and headaches for 1 month since last admission. On physical exam, patient had no rashes or arthropathy. Patient was found to have flat affect and poverty of speech with no sensory or motor defects noted on neurologic evaluation. Laboratory studies revealed the patient had normal complement (C3 120, C4 22) and non-elevated anti-dsDNA (47.2) which were not consistent with a lupus flare. MRI of the brain did not show microhemorrhagic findings that could be consistent with SLE cerebritis. She was started on antipsychotic medications with no clinical improvement. Given lack of response, the patient was started on steroid therapy with rapid improvement of her psychiatric symptoms including increased appetite and ability to engage in social interactions. After 3 days of high dose pulse steroid therapy, the patient was discharged on prednisone and antipsychotic medication with close follow-up with rheumatology and psychiatry services.

DISCUSSION: SLE is an autoimmune disease caused by inflammatory cytokines, autoantibodies, and immune complexes causing systemic inflammation and organ damage. Neuropsychiatric lupus (NPSLE) is thought to affect anywhere between 15 and 80 % of adults with SLE. Clinical manifestations vary from headache, anxiety, depression, and cognitive dysfunction to psychosis and seizures with a total of 19 specific neuropsychiatric syndromes being defined by the American College of Rheumatology. Interestingly, these syndromes can develop outside of active systemic disease and serologic activity and even precede other systemic manifestations. While the pathophysiology is not fully elucidated in NPSLE, it is thought that the inflammatory process involved in the cytokine, autoantibody, and immune complex damage in other organs also affect neurons and the vessels supplying them. SLE also disrupts the blood-brain barrier resulting in the entry of autoantibodies and other molecules that lead to neuronal damage. Some of these autoantibodies may aid the diagnosis, however, none are highly specific or sensitive. Imaging may also assist in the diagnosis. While MRI's may find focal abnormalities, such as cortical atrophy, ventricular dilation and infarcts, functional MR and SPECT can also sense perfusion or metabolic changes in NPSLE in patients with an otherwise normal MRI. Mainstay treatments of NPSLE are glucocorticoids, aspirin, and hydroxychloroquine as well as other immunomodulators. However, treatment must also be tailored to the disease, whether its addressing the presence of antiphospholipid antibodies that increase the risk of stroke or using psychiatric medicines to symptomatically treat mood disorders. In severe NPSLE, more aggressive immunosuppressive agents such as cyclophosphamide have been found effective. Intravenous immunoglobulins, rituximab, plasmapheresis, azathioprine and methotrexate have been used with some success in steroid unresponsive cases. As in the case of our patient with known SLE presenting with psychiatric symptoms, it is important to have a high degree of clinical suspicions for NPSLE, especially given a high prevalence of that syndrome in SLE patient populations. Given both primary psychiatric conditions and NPSLE are diagnoses of exclusion, the right diagnosis for SLE patients with neuropsychiatric findings is challenging. This case has shown that patients who fail to respond to antipsychotic medications, delirium in SLE patients can be treated with immunosuppressive therapy.

CONSEQUENCES OF INCIDENTAL RADIOGRAPHIC FINDINGS. Linh T. Nguyen; Chris Sullivan; Anil N. Makam. UT Southwestern, Dallas, TX. (Tracking ID #2195040)

LEARNING OBJECTIVE #1: Recognize that investigation of incidental radiographic findings can lead to unnecessary hospitalization and iatrogenic injury.

LEARNING OBJECTIVE #2: Engage patients in shared decision making earlier in the course before an extensive work up is conducted or plan of care is developed.

CASE: Mrs. C is a frail 76 year old woman from Mexico with stage IV COPD and history of tuberculosis (TB). One year ago an asymptomatic right carotid body tumor was incidentally discovered during CT angiography to evaluate a possible stroke. Her biochemical workup was nonrevealing, consistent with a benign nonsecretory paraganglioma of her neck. The 1-year surveillance CT scan of her neck showed no significant increase in tumor size, but did show new right upper lobe lung nodules. Mrs. C was admitted to the hospital for workup of this incidental finding. Aside from a cough slightly worsened from baseline, Mrs. C was in her normal state of health. Testing for infectious and neoplastic etiologies were negative, except for 1

of 3 sputum cultures growing an acid-fast bacilli (AFB) without growth from a bronchoalveolar lavage. Mrs. C was discharged with anti-TB therapy while awaiting final identification of the organism. Three days later, she returned to the emergency department with vomiting and abdominal pain. Her transaminases were elevated and she was re-hospitalized for drug induced liver injury. Her anti-TB therapy was discontinued and she subsequently recovered after 8 more days in the hospital. The single sputum culture that initially grew an AFB was ultimately negative for TB. A later conversation with the patient revealed that given lack of symptoms, older age, frailty, and severe COPD, she would have declined any surgery to excise the carotid body tumor were it offered.

DISCUSSION: Surgical excision for benign nonsecretory paragangliomas of the neck presents a significant risk of cranial nerve injury or stroke (35 %) or death (1 %) [1]. In this elderly, frail patient with severe COPD, surgery would have presented a greater than usual risk of adverse outcome. Given Mrs. C's lack of symptoms and aversion to surgery, annual surveillance CT was unnecessary, as it would not have changed management even if the tumor had increased in size. Incidental findings on a CT scan in an asymptomatic patient can be non-specific and often lead to unnecessary clinical work up. In a retrospective cohort study of 1426 imaging studies, 40 % of imaging examinations had at least 1 incidental finding, the incidence of which increased with age [2]. The majority of incidental findings that were investigated further did not result in a clear benefit to the patient. A meta-analysis evaluating incidental findings discovered during cardiac CT showed a similar rate of incidental abnormalities (44 %) and of these only 0.7 % were subsequently found to be malignancies [3]. This case illustrates how further investigation of incidental radiographic findings, especially without engaging the patient in shared decision making to elicit the patient's wishes for care, can result in unnecessary hospitalizations and iatrogenic injury to patients. Ideally, a more careful discussion about the patient's general prognosis due to severe COPD and advanced age, as well as her desire to forgo any invasive surgery, should have been held before an extensive workup for asymptomatic incidental findings was conducted. 1. COOMBS NEGATIVE EVANS SYNDROME Apama Basu; Dhruvan Patel; Rajiv Bhattarai. Mercy Catholic Medical Center, Philadelphia, PA. (Tracking ID #2200332)

LEARNING OBJECTIVE #1: A negative Coombs test does not exclude the diagnosis of Evans syndrome

CASE: A 26 year old Caucasian female presented to the hospital with petechial rash on her extremities for 7 days. She had no complaints of bleeding. Her exam was only notable for petechiae on her arms and legs. There was no pallor, lymphadenopathy or organomegaly. Initials labs included a platelet count of 4000 cells/mm³ and hemoglobin of 11.9 gm/dL. During hospitalization her hemoglobin fell to 9.8 gm/dL without signs of bleeding. Further labs included reticulocyte count of 5.9 %, haptoglobin <10 U/L, and LDH 519 U/L. A review of the peripheral smear revealed no schistocytes. Her ANA, APLA, hepatitis panel, HIV, Direct (IgG) and Indirect (IgM) Coombs test were negative. A diagnosis of coombs negative Evans syndrome was made. She was treated with high dose prednisone and IV Immunoglobulins with improvement of hemoglobin (to 15 gm/dL) but not platelet count. Steroids were discontinued and rituximab was initiated with resolution of thrombocytopenia.

DISCUSSION: Evans syndrome is a chronic, relapsing condition with autoimmune hemolytic anemia and thrombocytopenia that does not have a clear etiology. The pathogenesis of autoimmune hemolytic anemia is believed to be due to IgG antibodies that react with protein antigens on the red blood cell surface at body temperature leading to hemolysis. The pathogenesis of thrombocytopenia is similar but with different antibodies binding to platelets. Direct Coombs test is used to detect presence of antibodies bound on red blood cell surface antigen. In Evans syndrome, the direct Coombs test is usually positive. But as highlighted in our case a negative Coombs test does not exclude the diagnosis of Evans Syndrome. The Coombs test can false negative sometimes because of low levels of IgG that falls below the detection threshold. In such cases a diagnosis of Coombs negative Evans syndrome can be if a patient is found to have autoimmune hemolytic anemia and thrombocytopenia without any other diagnosis explaining the findings. Treatment options include corticosteroids, IVIG, rituximab, splenectomy with

varying results. Existing data shows promising results with Rituximab. Further studies are needed on this subject to compare with other treatment modalities.

COPYCAT PANCREATITIS: A CASE OF AUTOIMMUNE PANCREATITIS AND THE IMPORTANCE OF EARLY DIAGNOSIS Adil S. Zahiruddin¹; Andrew Caruso^{2,1}. ¹Baylor College of Medicine, Houston, TX; ²Michael E. DeBakey VA Medical Center, Houston, TX. (Tracking ID #2199996)

LEARNING OBJECTIVE #1: Autoimmune pancreatitis (AIP) is an IgG4 associated disease (systemic fibroinflammatory disorder) that has pancreatic and extrapancreatic manifestations. The similarity in clinical presentation to pancreatic cancer makes for a significant diagnostic challenge and significantly alters therapy.

CASE: A 67 year old African American male presented with two weeks of painless jaundice, darkening urine, and light-colored stools. Patient denied abdominal pain, fevers, chills, night sweats, or significant weight loss. Laboratory studies revealed a total bilirubin of 12.6 mg/dl, elevated alkaline phosphatase (435 IU/L), normal serum transaminases, elevated IgG levels (2990 mg/dl). Abdominal CT revealed a soft tissue mass in the proximal common bile duct causing intrahepatic biliary ductal dilatation concerning for cholangiocarcinoma. The pancreas was not diffusely enlarged. ERCP revealed diffusely dilated intrahepatic bile ducts without beading, a tight stricture within the distal common hepatic duct, and midcommon bile duct approximately 1 cm in length. Biliary sphincterotomy was performed with common bile duct biopsies and a plastic biliary stent placed with prompt drainage of bile and contrast. An EUS revealed heterogeneous and edematous pancreatic head parenchyma with no discrete mass. There was heterogeneous and hypoechoic circumferential thickening of the mid and distal common bile duct. Several core needle biopsies of the pancreatic head revealed a dense lymphoblastic infiltrate organized in a storiform pattern with obliterative phlebitis and negative for malignant cells. Prednisone therapy was initiated (40 mg/day for six weeks with a subsequent slow taper). At discharge, the total bilirubin decreased to 3.6 mg/dl with improvement in symptoms. Biliary stent is to be exchanged in 4 months with repeat CT abdomen with pancreatic protocol at that time. Serum IgG4 subclass antibodies were not elevated.

DISCUSSION: AIP was first recognized as a distinct form of chronic pancreatitis in 1995. Obstructive jaundice is the most common presenting symptoms. For physicians, it is crucial to recognize this disease as the presentation is very similar to that of malignancy. In contrast to malignancy, AIP responds dramatically to steroids. Studies have shown that about one third of patients undergoing pancreatic resection for possible cancer were ultimately found to have benign disease with the characteristic lymphoplasmacytic infiltrate of AIP. Furthermore, about 30 % of patients with autoimmune pancreatitis relapse. Recognition of autoimmune pancreatitis is crucial in both prognosis and defining therapeutic options.

COUGH COUGH: AN CASE OF MDR TB IN CT Bashir A. Geer; Nandini Nair. Yale New Haven Hospital, New Haven, CT. (Tracking ID #2197695)

LEARNING OBJECTIVE #1: To understand the presentation of primary and recurrent Tuberculosis and to understand how to differentiate TB vs. MDR TB vs. XDR TB and the treatment challenges involved with each.

CASE: This is a 33 yo Filipino woman w/ no significant PMH except a prior+PPD in the Philippines in '99 s/p INH, rifampin and Ethionamide who presented w/ F/C, SOB and DOE after doing a marathon in Kentucky and enjoying some cave exploration. She was found to have bibasilar infiltrates w/ a cavitary mass and positive sputum for TB. She was empirically started on INH PZA EMB AMIK Cyclo Avelox but later found to be resistant to all first line drugs and eventually discharged on a regimen of PAS, Cycloserine, Ethionamide, Linezolid, Avelox and Amikacin after 3 months. Her sputum sample was sent to the CDC and National Jewish where she was further found to be resistant to Avelox and Ethionamide. In collaboration with the CDC she was eventually started on Bedaquiline as she was taken off the Amikacin after 6 months of therapy because of hearing loss and at this time is doing well as an outpatient w/ clearance of her sputum. She is doing well and will continue on a treatment regimen for 2 years from original sputum clearance.

DISCUSSION: Per the WHO in 2012, 8.6 million people fell ill with TB and 1.3 million died from TB. In 2013 Connecticut reported 62 cases of TB and only one patient who had MDR TB because of her resistance to first line agents rifampin and INH as well as ethambutol, pyrazinamide, isoniazid, and rifampin, plus any fluoroquinolone and at least one of three injectable second-line drugs (i.e., amikacin, kanamycin, or capreomycin). MDR is a growing problem in the developing world with 450,000 cases reported in 2012 w/ 9.6 % having XDR TB. The risk of MDR TB is rapidly increasing as

in 2011 there were only 310,000 cases of MDR TB reported and this will present new challenges for future management of TB as more antibiotics become ineffective. Newer medications are being developed such as Bedaquiline to combat this growing threat of MDR TB with more in the pipeline as well. However as MDR and XDR TB become more prevalent here in the United States, we will need more effective regimens and protocols to deal with them.

COUGHING UP BLOOD Matthew L. Law. Tulane University Health Sciences Center, New Orleans, LA. (Tracking ID #2198372)

LEARNING OBJECTIVE #1: Recognize the clinical criteria and "classic triad" for diagnosing a diffuse alveolar hemorrhage

LEARNING OBJECTIVE #2: Describe the need for early diagnosis and treatment of diffuse alveolar hemorrhage

CASE: A 50 year-old man presented with 2 months of progressively worsening shortness of breath along with a productive cough of dark red sputum, which had been occurring for the past two weeks. During the initial interview, he coughed up approximately 30 mls of bloody sputum. In the past 2 months, he had lost 30 lbs. His past medical history was significant for recurrent bouts of anemia, biopsy-proven membranous nephropathy and factor XII deficiency. On physical exam, a 2/6 systolic ejection murmur was noted along with skin examination showing a purplish rash on the face that spared the nasolabial folds. Hemoglobin was 5.1 g/dL with a baseline level around 9 g/dL. Platelet count was 467,000/mcL, and a prolonged PPT of 61 sec was noted with normal INR. ANA was 1:640 with a homogenous pattern; anti-Smith and anti-DS DNA antibody were negative. Bilateral patchy infiltrates were seen on chest x-ray with subsequent CT scan showing diffuse ground glass opacities. A diagnostic bronchoalveolar lavage was performed the following day confirming the diagnosis of diffuse alveolar hemorrhage. He was also diagnosed with systemic lupus erythematosus, which caused diffuse alveolar hemorrhage. He initially improved with high-dose steroids and cyclophosphamide. However, eventually his condition worsened with maximum medical therapy requiring mechanical ventilation, and shortly thereafter he died.

DISCUSSION: Shortness of breath along with new-onset hemoptysis is a common presentation that is encountered by internists. A very large differential exists for shortness of breath with broad categories including cardiac, respiratory and hematologic causes. In addition, new onset hemoptysis has a large differential, which includes bronchiectasis, TB, tumor, lung abscess, emboli and mitral stenosis. Diffuse alveolar hemorrhage is one of the most devastating complications of lupus with an estimated prevalence of approximately 5.4 % with reported mortality as high as 50 %. The "classical triad" of diffuse alveolar hemorrhage consists of hemoptysis, abrupt fall in hemoglobin level, and new onset pulmonary infiltrates. This patient presented with all the classical findings of diffuse alveolar hemorrhage. In evaluating any patient with suspected diffuse alveolar hemorrhage an infection must be ruled out. It is imperative to attempt to perform an early bronchoscopy with BAL to confirm the findings. The return of lavaged fluid should become progressively bloody from aliquot to aliquot to confirm the diagnosis of diffuse alveolar hemorrhage. Additionally, a BAL will allow the clinician to rule-out concomitant infections causing diffuse alveolar hemorrhage. The treatment for diffuse alveolar hemorrhage revolves around treating the autoimmune destruction of the alveolar capillary membrane. In patients with diffuse alveolar hemorrhage due to lupus, corticosteroids with the concomitant use of cyclophosphamide have been linked to better survival. A triad of hemoptysis, abrupt fall in hemoglobin and new pulmonary infiltrates should raise a high suspicion for diffuse alveolar hemorrhage. Due to the high mortality of the disease and need for immediate treatment with immunosuppression, a diagnostic BAL should be immediately performed to confirm the diagnosis and rule-out infections as another possible cause.

COUNTLESS CAUSES OF CONFUSION Jillian Edmunds; Raquel Belforti; William House. Baystate Medical Center, Springfield, MA. (Tracking ID #2196494)

LEARNING OBJECTIVE #1: Identify seizure as an important differential in altered mental status even in the elderly

LEARNING OBJECTIVE #2: List the limitations in the diagnosis for seizure

CASE: The patient is a 70-year-old female with a past medical history of hypertension and hyperlipidemia presenting to the emergency department with acute change in mental status. The husband of this patient states that on the day of admission she seemed off, unaware of the current year and asking nonsensical questions. She was noted to have slurred speech but denies focal weakness or paresthesias. In the days prior she admits to increased stress and fatigue but denies other complaints. She had a similar episode of confusion 2 months prior, which resolved spontaneously and a diagnostic work up in the emergency department did not reveal a cause. At baseline she has no neurological deficits and volunteers at

the hospital. Physical exam revealed a temperature of 100.2 F with other vital signs stable. Exam was unremarkable with no new focal deficits. Mental status was at her baseline, alert and oriented and speech was fluent and clear. Laboratory work-up showed WBC 11.6, creatinine 1.4, potassium 5.8, bicarbonate 20, AST 40, Lipase 83. Free T₄, lactate, ammonia, and RPR were within normal limits. A head CT and brain MRI showed no acute changes, in particular, no mass, hemorrhage, or infarct. She was empirically treated with vancomycin, ceftriaxone, ampicillin and acyclovir for possible bacterial meningitis or HSV encephalitis. Lumbar puncture was traumatic however the culture did not grow bacteria and HSV PCR was negative. She had two more episodes of confusion during the admission where she was speaking nonsense and unable to read. She was not able to remember these episodes. Given these recurrences occurred after electrolytes were corrected and infectious sources were treated, these were considered less likely causes. The clinical picture was thought most consistent with complex partial seizure. An outpatient EEG did not reveal epileptiform changes. She was started on Keppra for seizure prophylaxis. In the following 4 months she has not had recurrent episodes.

DISCUSSION: Altered mental status (AMS) is a common complaint comprising up to 10 % of visits to the ED.² The differential for AMS is broad and should include seizure, which in itself has a varied presentation creating a diagnostic dilemma. A seizure can present with motor manifestations, as in clonic or tonic seizures. It could also be sensory with paresthesia or autonomic sensations like diaphoresis. Seizure can include no loss of consciousness, as in simple partial seizures, or complete loss of consciousness, as in complex partial seizure, or a range of mental status changes in between, which can include distortions of time or partial amnesia. Highest incidence of epilepsy occurs at the extremes of life. A cohort study of 1195 patients with epileptic seizures found that 24 % of patients were older than 60 and the proportion of identifiable causes was greater in older patients (60 % compared to 38 %) with vascular disease being the identified cause in 49 % of older patients.⁵ Similarly Osvaldo finds that stroke accounts for 30 % of newly diagnosed seizure in patients over 60 years old. The diagnosis of seizure is challenging, as a routine EEG is only able to demonstrate epileptiform abnormalities in 25–50 % of patients. Thus a normal EEG does not rule out epilepsy. A retrospective study reviewed EEGs done within 12 h of patients presenting to the ED with altered mental status and found that only 44.8 % of patients with clinical epileptic seizures had epileptiform discharges and 54 % of patients with stroke related seizure had pathologic changes on their EEG including paroxysmal abnormalities and background slowing.² Another retrospective study analyzed 94 EEGs done on patients with AMS and found pathologic changes on 44.7 % of EEGs.⁴ Seizure has been shown to have a correlation with stroke as ischemia can cause gliosis and the development of menigocerebral cicatrix, which can change excitability and neuronal synchrony.³ A group of 4709 patients with idiopathic epilepsy occurring after age 60 with no history of stroke were matched with controls without history of stroke or seizure and found that in the epilepsy group 10 % of patients later developed a stroke compared to 5.6 % in the control group, which gives a hazard ratio of 2.89.¹ New onset of seizure is relatively common in the elderly and should be considered as part of the differential for altered mental status. Both the varied presentation and the limitations in diagnostic studies make this a challenging diagnosis. However a new seizure may suggest underlying cerebrovascular disease and the patient may benefit from risk factor reduction.

CRISIS OF BLEEDING OR CLOTTING? ADRENAL MANIFESTATIONS OF ANTIPHOSPHOLIPID SYNDROME Sean Townsend; Oanh K. Nguyen. UT Southwestern Medical Center, Dallas, TX. (*Tracking ID #2199262*)

LEARNING OBJECTIVE #1: Recognize acute adrenal crisis due to adrenal vein thrombosis as a serious complication of antiphospholipid syndrome (APS).

LEARNING OBJECTIVE #2: Manage anticoagulation therapy in APS-associated thrombocytopenia.

CASE: A 63 year old man with a 15-year history of APS presented with worsening generalized weakness for 10 days, associated with moderately severe diffuse, colicky abdominal pain and one day of nausea and lightheadedness. Review of systems was negative for fever, weight changes, bleeding, bruising, or focal neurologic symptoms. Of note, warfarin was discontinued seven days prior to hospitalization due to concern for occult bleeding in the setting of symptomatic hypotension. However, he had no documented bleeding or anemia and his international normalized ratio (INR) ranged from 1.5–2.4 in the 2 months preceding hospitalization. Past medical history was otherwise unremarkable. Vitals were notable for heart rate 105 bpm, blood pressure (BP) 122/75 mmHg recumbent, and drop in systolic BP >20 mmHg with standing. Physical examination revealed dry mucous membranes, flat neck veins, soft and nontender abdomen, and no rash, hyperpigmentation, or petechiae. Laboratory evaluation was notable for serum sodium 116 mEq/L, potassium 6.2 mEq/L, chloride 87 mEq/L, bicarbonate 17 mEq/L, blood urea nitrogen 19 mg/dL, creatinine 1.82 mg/dL, INR 1.6, partial thromboplastin time 79 s, hematocrit $41 \times 10^3/\mu\text{L}$, and platelets $84 \times 10^9/\mu\text{L}$ (baseline 2 months prior, $163 \times 10^9/\mu\text{L}$). Random cortisol level was 1.0 mcg/dL. Adrenocorticotropin

hormone level was 1416 pg/mL. Magnetic resonance imaging of the abdomen showed symmetric bilateral adrenal gland enlargement. He was admitted to the intensive care unit with a diagnosis of acute adrenal crisis secondary to bilateral adrenal hemorrhagic infarction. His symptoms and metabolic derangements resolved with corticosteroid replacement. He was restarted on warfarin indefinitely for treatment of APS.

DISCUSSION: Acute adrenal crisis secondary to bilateral adrenal hemorrhagic infarction is a rare but serious manifestation of APS. Though the pathophysiology is poorly understood, adrenal hemorrhagic infarction is thought to be secondary to adrenal vein thrombosis due to hypercoagulability rather than primary hemorrhage. Pro-thrombotic states such as trauma, sepsis, heparin-induced thrombocytopenia (HIT), and APS are well-described causes of adrenal hemorrhage.¹ Anticoagulation therapy has rarely been associated as well.² However, thrombocytopenia outside of HIT has not been described in association with adrenal hemorrhage and the presence of thrombocytopenia in APS is not known to increase the risk of hemorrhagic complications. This patient most likely had adrenal vein thrombosis due to subtherapeutic INR leading to hemorrhagic infarction and adrenal crisis, and exacerbation of symptoms with cessation of warfarin. Five-year survival among APS patients with adrenal crisis who survive the acute setting is >90 %. Most patients will require corticosteroid supplementation indefinitely, though up to 6 % will have full recovery of adrenal function.³ Although APS-associated thrombocytopenia alone does not necessarily increase the risk of bleeding, the optimal approach to anticoagulation in these patients remains unknown. By consensus, indefinite anticoagulation with warfarin is the mainstay of treatment for APS even with associated thrombocytopenia, given the overall propensity for thrombosis. Even so, treatment should be tailored according to individual bleeding risk. Those with mild or moderate thrombocytopenia generally do not require therapy for the thrombocytopenia itself, though patients with severe thrombocytopenia at high risk for bleeding may be treated similarly to those with chronic immune thrombocytopenia.⁴ In conclusion, internists should recognize adrenal crisis as a potentially life-threatening complication of APS, and be able to manage anticoagulation therapy in APS even with associated thrombocytopenia. CROSS-DISCIPLINARY APPROACH TO A COMPLICATED CASE OF TYPE-I CRYOGLOBULINEMIA Anne Liu; Luming Li; Mark Youngblood; Randy Luciano. Yale, New Haven, CT. (*Tracking ID #2198896*)

LEARNING OBJECTIVE #1: Recognize a unique clinical presentation of cryoglobulinemia type I

LEARNING OBJECTIVE #2: Address the clinical approach of involving a multidisciplinary team including: rheumatology, hematology, oncology, and dermatology

CASE: A 69 year old gentleman with a history of granulomatosis with polyangiitis (GPA) with secondary renal failure on peritoneal dialysis was originally admitted with complaints of lethargy and acral purpura in the bilateral ear helices, toes, and nose with central necrosis. Two months prior, the patient had received steroid treatment for a whole body pruritic, maculopapular rash and significant eosinophilia (50 %). During his current admission, lab work revealed anemia (Hct 30 %), thrombocytopenia (49 k/uL), elevated cryocrit (0.1–0.4 %), leukocytosis (WBC 16.5), elevated ESR (39 mm/hr), CRP (42.5 mg/L), polyclonal gammopathy (IgM 271 mg/dL, IgA 176 mg/dL, IgG 2860 mg/dL), hypocomplementemia (C3 69 mg/dL, C4 <10 mg/dL), and elevated lupus anticoagulant. Bone-marrow biopsy and flow cytometry provided no evidence of myelodysplasia or monoclonal B-cell lymphoproliferative disease. A skin biopsy revealed multiple, occlusive, small-vessel thrombi consistent with cryoglobulinemia type I. Rituximab therapy was initially considered for treatment of cryoglobulinemia, however concern for an underlying malignancy prompted an inpatient positron emission tomography-computed tomography (PET-CT), which showed extensive hypermetabolic lymph nodes. A lymph-node biopsy and plasmapheresis were planned; however the patient developed worsening shortness of breath and passed away from severe septic shock due to gram negative pneumonia. At autopsy, internal examination revealed atypical lymphohistiocytic hyperplasia in multiple lymph nodes with effaced nodal architecture and red cell extravasation, which may be associated with steroid effects. Also of note is the possibility of GPA associated lymphadenopathy (1). Both lungs were heavy (left 1150 g, right 700 g); with a right lower lobe focal lymphoplasmacytic infiltrate. Staining revealed lambda positive plasma cells, consistent with the patient's known history of GPA (2).

DISCUSSION: We describe a patient with GPA presenting with acrocyanosis and found to be positive for cryoglobulinemia type I. Cryoglobulins are composed of immunoglobulins and complement that become insoluble at reduced temperatures. Cryoglobulinemia is considered a small to medium vessel vasculitis. Clinically this manifests as Meltzer's triad with palpable purpura, arthralgia and myalgia. Cryoglobulinemia is broken down into three types. Type I is an isolated monoclonal IgG or IgM, associated with plasma cell dyscrasias including multiple myeloma or Waldenström macroglobulinemia. Type II is a mixture of polyclonal IgG plus monoclonal IgM or IgA with rheumatoid factor function. This is typically from viral infections such as HIV, HCV, HBV, CMV, EBV, or parvovirus. Type III is polyclonal IgM and IgG molecules strongly associated with connective tissue disease such as systemic lupus erythematosus and rheumatoid arthritis. This patient was serologically positive and biopsy-specific for Type I. His presentation included hyperviscosity, thrombosis, digital ischemia, livedo reticularis, and purpura that became necrotic. Often the necrosis in cryoglobulinemia is cutaneous, as seen in this patient. It is unclear from the literature the co-occurrence between GPA and cryoglobulinemia type-I, and also unclear the best sequence for treating a case of complex vasculitides with multiple end-organ sequelae. The consultant teams recommended different initial treatment options that often focused on a single system of interest. In addition, most teams would exam and round on the patient separately, write a daily progress note, and state their organ-specific recommendations. This type of 'siloed' approach led to increasingly disparate hypotheses and treatment goals by consulting teams. In order to clarify and unify our hypotheses, the primary medicine team decided to call together a multi-team clinical conference with hematology, oncology, rheumatology, and dermatology to have face-to-face communication about the case. We reached a consensus diagnostic and treatment approach that was agreed upon by all teams. However, before we were able to complete the necessary testing, the patient expired. We realized from this complex case that early, clear communication among different treatment providers can be paramount for minimizing delay in diagnostic testing, especially in a rapidly progressive disease state. 1. IgG4 Plasma Cell Infiltration in Granulomatosis with Polyangiitis (Formerly Wegener's) Lung Biopsies. Arthritis and Rheumatism. 2012 64 Suppl 10:1534.

CULTURE-NEGATIVE ENDOCARDITIS CAUSED BY BARTONELLA QUINTANA Koji Koji²; Christine Kwan¹. ¹Teine Keijinkai Hospital, Arlington, TX; ²Teine Keijinkai Hospital, Sapporo, Japan. (Tracking ID #2199712)

LEARNING OBJECTIVE #1: Diagnose endocarditis despite negative blood cultures

LEARNING OBJECTIVE #2: Diagnose Bartonella quintana endocarditis with prolonged blood cultures, antibodies, or polymerase chain reaction (PCR)

CASE: A 77 years old Japanese woman presents with 2 months of continued fever up to 39 °C despite multiple antibiotics. For the past month while being hospitalized, she has had multiple diagnostic work-up including 6 sets of blood cultures, urinalysis, and chest x-ray, which have all been negative. She does not report any other symptoms and has no recent travel. Past medical history includes untreated hypertension and cerebellar infarction (5 months ago) with no residual deficits. The patient's home medication includes aspirin; she has no known drug or food allergies. She does not use tobacco, alcohol, or recreational drugs. She is a housewife. Physical exam shows vital signs of temperature 37.5 °C, heart rate 84, blood pressure 160/80, respiratory rate 12, and O₂ saturation 97 % room air. Generally, the patient is alert/oriented x3. Heart exam reveals a IV/VI systolic ejection murmur at the apex and radiating to the right carotid and II/VI diastolic murmur at the apex. The rest of her exam shows no abnormalities. Labs, including complete blood count, coagulation panel, and chemistries, are within normal limits except for hemoglobin 10.7 g/dL, hematocrit 29.6 %, platelet 5.9 × 10⁴ /μL, albumin 2.6 g/dL, lactate dehydrogenase 332 IU/L, and alkaline phosphatase 271 IU/L. More blood cultures are drawn, and the patient's antibiotic is switched to ceftriaxone and gentamicin. Transesophageal echocardiogram reveals aortic and tricuspid vegetations and abscesses with severe regurgitation. All blood cultures, however, continue to show no growth. She undergoes valve replacement surgery, which confirms vegetations and abscesses at the right and left coronary cusps. Cultures of aortic valve tissue show no bacterial or fungal growth. Sections of the aortic valve stained with hematoxylin-eosin show a dense eosinophilic fibrinoid matrix. PCR of the aortic valve abscesses reveals *Bartonella quintana*; serum bartonella antibodies are also positive. Following surgery, her temperature returns to 37 °C, and her ceftriaxone is changed to doxycycline for a 6 weeks course.

DISCUSSION: The Duke criteria have two major criterion: positive blood cultures or evidence of endocardial involvement, such as exacerbation of valvular disease, abscesses, or vegetations, which the above patient has. The minor criteria present in this patient include fever and a history of arterial embolization, possibly her previous stroke. While bartonella species, an important cause of culture-negative endocarditis, can be identified by cultures (~100 % if cultured for 4 weeks), serologic studies (17.3 %), or molecular

biology techniques (~100 %), culture-negative endocarditis remains a diagnostic and therapeutic problem, accounting for 5–30 % of endocarditis. Three major reasons why cultures can be negative in endocarditis include previous administration of antimicrobial agents, inadequate microbiological techniques, and infection with highly fastidious bacteria or nonbacterial pathogens. Cultures of *Bartonella quintana* usually require 4 weeks to grow, in comparison to the usual 2 weeks. Fortunately, while the above patient's multiple blood cultures show no growth, PCR of the aortic valve abscess reveals *Bartonella quintana*, and serum antibodies are positive.

DEBILITATING JOINT PAIN FOLLOWING EXOTIC TRAVEL Benjamin Monson; Shana M. Peper; Christopher J. Smith. University of Nebraska Medical Center, Omaha, NE. (Tracking ID #2191714)

LEARNING OBJECTIVE #1: Recognize the epidemiology, transmission cycle, and societal impact of chikungunya virus globally and within the United States.

LEARNING OBJECTIVE #2: Identify the clinical presentation, differential diagnosis, and treatment of patients infected with chikungunya virus.

CASE: A 39 year-old African-American woman presented with 3 days of debilitating generalized myalgia and arthralgias. The affected joints included her hips, knees, ankles, hands, wrists, and neck. The patient also noted headache, fevers, chills, pruritus, nausea, and loose stools over the same duration. She did not endorse vision changes, cough, oral ulcers, gingival bleeding, facial rash, shortness of breath, abdominal pain, or urinary changes. Non-steroidal anti-inflammatory drugs failed to relieve her pain. Her past medical history included hypothyroidism for which she did not take medication. She was employed as a home health nurse, but denied ever suffering a needle-stick injury. She quit smoking tobacco 1 year ago and never used recreational drugs. Her vital signs were within normal limits. She exhibited photophobia, dry oral mucosa, and tender anterior and posterior cervical lymphadenopathy. She had no aphthous ulcers. She had diffuse arthralgias without synovitis. Her complete blood count with differential, complete metabolic panel, thyroid stimulating hormone, chest x-ray, urinalysis, and electrocardiogram were within normal limits. Upon further questioning, the patient revealed that she had returned 1 week ago from vacationing in Saint Lucia in the Caribbean. Her travel partner was experiencing similar symptoms. Both recall being bit by mosquitoes throughout the trip. They only consumed bottled water, and neither had eaten undercooked shellfish. The patient received intravenous fluids, analgesics, and anti-emetics with prompt resolution of her nausea, diarrhea, and fatigue. However, her myalgia and polyarthralgia persisted. On the fourth day of hospitalization, she received methylprednisolone 40 mg intravenously with significant improvement in her joint pain. She was discharged on hospital day 6 with an oral prednisone taper. Several weeks after discharge, the serum enzyme-linked immunosorbent assay for chikungunya virus (CHIKV) returned positive. Testing for dengue virus (DENV) was negative.

DISCUSSION: CHIKV is a rapidly spreading contagion that will increasingly be encountered by general internists. The mosquito-borne alphavirus arrived in the Caribbean in December 2013 and to date has infected 576,000 people in the Western Hemisphere. As of August 2014, there have been 484 laboratory-confirmed cases of CHIKV in the United States, including 4 locally transmitted cases in the state of Florida. The virus's vectors, *Aedes aegypti* and *Aedes albopictus*, are aggressive daytime-biting mosquitoes well-established in the Caribbean and southeastern United States. The hallmarks of presentation are acute onset of fever and polyarthralgia. The joint pain is usually diffuse, symmetric, and can be severe and debilitating. Additional symptoms may include myalgia, headache, nausea, and a maculopapular rash. Eliciting a travel history is crucial to make a diagnosis. DENV causes similar symptoms and is also transmitted by *Aedes aegypti* and *Aedes albopictus*. Differentiating between CHIKV and DENV can be difficult so if either is suspected, serology should be sent for both. Treatment is supportive and includes rest, fluids, and analgesics. Recovery typically takes 7–10 days; however, joint symptoms can persist for months. Over 20 % of those infected will have joint pain 1 year after infection. While there are antiviral agents and monoclonal antibodies in early stages of testing, the best defense against CHIKV remains prevention. Primary care physicians should advise patients traveling to endemic areas to use insect repellent, wear protective clothing, and make sure window and door screens are closed.

DEEP VEIN THROMBOSIS IN A BODYBUILDER Danielle Pannebaker; Robin Ivester. Tulane University Health Sciences Center, New Orleans, LA. (Tracking ID #2198393)

LEARNING OBJECTIVE #1: Identify risk factors for deep vein thrombosis

LEARNING OBJECTIVE #2: Recognize abuse of anabolic-androgenic steroids as a risk factor for thrombotic events.

CASE: A 39 year-old man was referred to the emergency department from a local community clinic for painful swelling of his right calf that developed over the previous

week. He did not report any fever, shortness of breath, cough, chest pain, or recent injury or surgical procedures. He had no prior history of similar events. His family history was unknown, as he was adopted as a young child. He was otherwise healthy, and had arrived in town only recently after spending several months traveling in Southeast Asia while participating in amateur bodybuilding competitions. He reported a long plane flight from Bangkok to New Orleans 1 month prior to presentation. He denied smoking or drug use, and endorsed heavy drinking intermittently over the past year and a half. He did not take any prescription medications. On further questioning, he endorsed a 4-year history of using non-prescribed anabolic-androgenic steroids, which were readily available in Thailand. Doppler ultrasound of the leg revealed thrombosis of the right popliteal vein. The patient was bridged to warfarin therapy with low-molecular weight heparin.

DISCUSSION: Deep vein thrombosis and other thrombotic events are problems commonly encountered by the internist. A careful history is important to identify risk factors that could have contributed to the development of a deep vein thrombosis, and in particular to identify modifiable risk factors such that a patient can make changes to reduce their risk of future events. Virchow's triad describes the categories of factors that contribute to thrombotic risk - vascular endothelial injury, stasis, and hypercoagulability. In this case, the patient's did not have any history of trauma, surgery, or other cause of endothelial injury. He did have the classic risk factor of a long plane flight (stasis). His family history was unavailable, so his likelihood of a hereditary hypercoagulable state is unknown. His use of anabolic-androgenic steroids, however, would lead to a hypercoagulable state through a variety of hormonal effects. Previous articles have noted that use of anabolic-androgenic steroids is correlated with consistent increases in blood cell mass, red blood cell count and increasing clotting factors, which would lead to increased thrombotic risk. One of the steroids this patient used regularly, nandrolone, is a synthetic Class A anabolic-androgenic steroid with an unsaturated C4-C5 double bond which can be aromatized back into testosterone and subsequently into estradiol. Given the importance of counseling patients with deep vein thrombosis to minimize any modifiable risk factors and decrease their risk of recurrence, it is important to inquire about the use of anabolic steroids in addition to other hormones such as estradiol (including oral contraceptive use in women) and testosterone supplementation.

DELIRIUM & DECISIONS Margaret P. Huntwork. Tulane University Health Sciences Center, New Orleans, LA. (Tracking ID #2198382)

LEARNING OBJECTIVE #1: Review the Appelbaum and Grisso criteria for decisional capacity.

LEARNING OBJECTIVE #2: Familiarize practitioners with the state hierarchy for surrogate decision-makers.

CASE: A 64 year-old man with known peripheral vascular disease was brought in by ambulance to the ED for bilateral lower leg pain progressive over 8 weeks. Pain progressed to the point where he could no longer ambulate. He denied fevers, chills, or sick contacts. He had no chest pain or shortness of breath. He had a recent vascular evaluation that revealed occlusions in his right and left superficial femoral arteries. Amputation was offered to him at that time, but he and his family opted to wait and see if he improved over the next few weeks. Physical exam was notable for malodorous lower extremities with dry gangrene in multiple phalanges, extensive necrotic ulcerations on both anteromedial shins, and no palpable peripheral pulses. Feet were cool to touch. Initial labs were significant for leukocytosis and an elevated troponin without accompanying angina or changes in his ECG. He was admitted for concern for systemic infection from his lower extremity vascular disease and an evolving heart strain from this infection. The surgical team evaluated the patient and again recommended amputation. The patient refused, saying he thought his legs would heal on their own, and he would only want the surgery if there were no other options. On hospital day two, he became tachycardic. His leukocytosis worsened, and his troponin increased. His mental status deteriorated. The cardiologists determined the patient was suffering a non-ST-elevation myocardial infarction caused by ischemic demand due to sepsis, with his necrotic legs as the nidus of infection. Psychiatry evaluated the patient for decision-making capacity. Initially, psychiatry deemed the patient to retain decision capacity, and he continued to decline the amputation. However, each day thereafter, psychiatry determined the patient to be delirious and without capacity to make medical decisions. The patient's sepsis persisted despite an aggressive antibiotic regimen. His mental status was reassessed twice daily and showed no improvement. With the patient urgently needing surgery, but unable to consent for the amputation, three of five of his adult children assented for the operation on his behalf. The remaining two children were estranged from the family and could not be reached by any family members after multiple attempts.

DISCUSSION: Decisional capacity is the ability to consent for or refuse care. Appelbaum and Grisso describe four elements of decisional capacity: 1. The ability to

communicate a choice. 2. The ability to understand the relevant information. 3. The ability to appreciate a situation and its consequences. 4. The ability to reason rationally. Psychiatrists generally believe that clinicians overestimate patients' decisional capacity. Increased age and cognitive impairment are two risk factors for lack of capacity. Hospitalized patients with delirium should not be evaluated for decisional capacity, as, by nature of their delirium, they do not meet the Appelbaum and Grisso criteria. If a patient lacks decisional capacity and does not have a medical power of attorney, the clinician should then turn to the hierarchy of surrogate decision-makers defined by the state. In Louisiana, the spouse is next in line, followed by any adult children (all must be contacted and in agreement), and lastly, parents of the patient. This patient exemplifies how complex decisional capacity can be. Ultimately, the patient received what could have been a life-saving surgery, despite the fact that it was not in accordance with his original wishes. We recommend that clinicians familiarize themselves with the Appelbaum and Grisso criteria to better evaluate decision-making capacity.

DEXMEDETOMIDINE: A PERPLEXING PYROGEN Margaret Lowenstein; Alexander Yoo; Marcia Glass. University of California San Francisco, San Francisco, CA. (Tracking ID #2194093)

LEARNING OBJECTIVE #1: Recognize drug fever as an important non-infectious cause of fever in hospitalized patients.

LEARNING OBJECTIVE #2: Identify fever as an unusual side effect of dexmedetomidine.

CASE: A 60-year-old woman with history of heart, liver, and kidney transplants secondary to hemochromatosis, quadriplegia, and a stage IV decubitus ulcer was admitted to the intensive care unit for hypoxemic respiratory failure after an aspiration event. She initially improved with mechanical ventilation and broad-spectrum antibiotics, which were narrowed to levofloxacin on hospital day three. The patient remained intubated because of poor respiratory mechanics, so her sedation was changed to dexmedetomidine with the hope of decreasing respiratory depression. On hospital day five, the patient developed daily fevers up to 40 ° C with low-grade tachycardia but otherwise stable hemodynamics and ventilator requirements. She had no localizing signs of infection on exam. Although the patient had a leukocytosis on admission, white blood cell count was 8 g/dL with normal differential; electrolytes and liver function tests were also within normal limits. Urine culture and two sets of repeat cultures of peripheral and central blood remained negative. Chest x-ray and secretions were unchanged. The decubitus ulcer was re-evaluated by surgery without evidence of infection. Four-extremity Doppler revealed no deep vein thrombosis. Careful review of the patient's medications revealed a correlation between initiation of dexmedetomidine and her fevers. Sedation was changed to fentanyl and the patient's temperature decreased within hours, defervescing entirely after 12 h. By identifying drug fever as a possible source, we were able to avoid further invasive and costly testing and treatment. She was successfully extubated three days later and discharged on hospital day 18.

DISCUSSION: Fever is a common finding among critically ill patients and is usually equated with infection. However, there are a number of important non-infectious causes to consider, including venous thromboemboli, transfusion reactions, acalculous cholecystitis, endocrinologic disturbances, alcohol withdrawal and febrile drug reactions. Drug fever is generally defined as a fever coinciding with the administration of a drug and disappearing after the drug is discontinued, after other causes of fever are excluded. Fever is the sole manifestation of drug hypersensitivity reaction in 3–5 % of cases, and most cases of drug fever are not accompanied by rash or eosinophilia. Reactions generally occur within days to weeks of exposure to the drug and resolve within 72 h of discontinuation, although the time course can be idiosyncratic. Common culprits include antimicrobials (particularly beta lactams, sulfa drugs, vancomycin), anti-epileptics (particularly phenytoin), and anti-arrhythmics (particularly procainamide and quinidines), but many other drugs have been implicated. Drug fever is a diagnosis of exclusion, requiring evaluation for infectious and other life-threatening causes of elevated temperature. However, failure to consider drug culprits in a febrile patient can lead to unnecessary testing, therapies, and prolonged hospital stays. Dexmedetomidine is a central alpha-2 receptor agonist with anxiolytic, sedative and analgesic effects that is used for sedation in the intensive-care unit. Benefits include minimal respiratory depression and possibly shortened duration of mechanical and decreased delirium as compared to other sedatives. Common side effects include hypotension, bradycardia, hypertension, atrial fibrillation and other cardiovascular instability. Although rare, dexmedetomidine-induced drug fever has also been reported. Similar to these reports, our patient developed a fever quickly on dexmedetomidine, which rapidly decreased within a day of cessation of the drug.

DIABETIC AMYOTROPHY WITH ABDOMINAL PSEUDO-HERNIATION AND PAIN: CASE REPORT AND REVIEW OF LITERATURE

Paras Karmacharya²; Ranjan Pathak²; Sailu Ghimire¹; Pragya Shrestha⁴; Sushil Ghimire²; DILLI R. POUDEL²; Madan R. Aryal³; Shikha Doornra²; Shawn Potteiger²; Richard Alweis². ¹College of Medical Sciences, Chitwan, Nepal; ²Reading Health System, West Reading, PA; ³The Reading Hospital and Medical Center, Wyomissing, PA; ⁴Nanjing Medical College, Nanjing, China. (Tracking ID #2199210)

LEARNING OBJECTIVE #1: Recognize diabetic amyotrophy (DA) as a cause of recurrent abdominal pain and unilateral which may prevent unnecessary extensive work up

LEARNING OBJECTIVE #2: Treat DA with analgesics and tricyclic antidepressants.

CASE: A 58-year-old Caucasian male with a history of DM II (HA1C: 8.7) for the past 7 years on glipizide presented with a 3 month history of left sided abdominal pain. It was associated with a 25 lb weight loss and bulging of the left flank region. He did not have any history of fever, nausea, vomiting, constipation, bowel/bladder incontinence, trauma, toxin exposure, tick bite, rash or recent travel. On examination, he had marked bulging of the abdominal muscle in the left flank region with decreased sensation and local allodynia at T6-10 dermatomal region. He had undergone extensive evaluations in the past including magnetic resonance imaging of the abdomen and back, upper endoscopy and colonoscopy which were all unremarkable. Basic metabolic profile, liver function tests, Lyme ELISA test, rapid plasma reagin test, thyroid stimulating hormone, vitamin B12, folate, and antinuclear antibody titers were all within normal limits. Electromyography (EMG) showed evidence of denervation of the external oblique and thoracic paraspinal muscles and nerve conduction studies revealed evidence of mixed polyneuropathy compatible with demyelinating diabetic polyneuropathy. Patient was started on analgesics and gabapentin. At 6 weeks follow up, patient's pain and swelling was reduced.

DISCUSSION: DA with pseudo-herniation is a rare entity with only 16 cases reported in literature. In our review, average age at presentation was 62.38 years; exclusively males with DM II for a duration of 7±4.36 years. The most common site was at or below the T5 level. Common complaints include abdominal pain (87.5 %), weight loss (83.3 %) and peripheral neuropathy. Average hemoglobin A1C was 8.39 % at the time of diagnosis. Electromyography showing denervation of muscle is the diagnostic test of choice. Tricyclic antidepressants are effective for symptomatic relief. The role of other neuroleptics commonly used for diabetic neuropathy such as gabapentin is unclear. It has a good prognosis and usually resolves after 3 to 12 months. Although rare, it should be considered in the differential diagnosis for patients presenting with abdominal pain and unilateral herniation with longstanding DM. If considered early, it may prevent unnecessary investigations and proper treatment of this potentially reversible condition.

DIAGNOSING GANGRENOUS CHOLECYSTITIS—PHYSICAL EXAM VERSUS RADIOGRAPHIC IMAGING Ruchir Patel²; Nena S. Auraha²; Herman Dyal²; Sean Drake¹. ¹Henry Ford Hospital, Detroit, MI; ²Henry Ford Hospital, Dearborn, MI. (Tracking ID #2196329)

LEARNING OBJECTIVE #1: Diagnosing acute cholecystitis despite multiple normal radiologic studies.

LEARNING OBJECTIVE #2: Understanding when “premature closure” may inhibit the clinicians ability to make a correct diagnosis.

CASE: A 69 year old Arabic female with a past medical history significant for obesity and type two diabetes mellitus presented to our Emergency Department with new onset right upper quadrant abdominal pain that began after eating a high fat meal six hours prior to presentation. The pain was described as dull, non-positional and colicky with radiation to her back. She denied fevers, chills, nausea, emesis, malodorous urine, changes in skin color or pruritis. On initial evaluation the patient was laying supine, clenching her abdomen in distress. Objectively, she was afebrile, tachycardic and did not appear jaundiced. Her abdominal exam was significant for a soft abdomen with a positive Murphy's sign. The patient's laboratory values showed a mild leukocytosis of 11.8 K/uL. Liver function tests and lipase were normal. Ultrasound of the gallbladder showed a distended gallbladder without evidence cholecystitis. Computed tomography (CT) of the abdomen was performed to rule out pancreatitis and revealed a normal appearance of the gallbladder and pancreas. Due to a high suspicion for cholecystitis, cholescintigraphy was performed, which was also determined to be negative. In light of the discordance between her physical exam findings and radiologic findings the patient was managed conservatively on an inpatient basis opposed to discharge with close outpatient follow-up as there was still a strong clinical suspicion for cholestatic disease. On day three of her admission the patient spiked a fever to 38.3 °C. Her abdominal exam progressed, and was significant for generalized guarding and severe tenderness to palpation of the right hypochondriac region. An urgent abdominal CT scan with contrast was performed and imaging revealed a hydropic gallbladder with wall thickening, hyperemia of the mucosa and pericholecystic

inflammatory changes consistent with gangrenous cholecystitis. The patient was urgently prepared for surgery and underwent laparoscopic cholecystectomy without complication.

DISCUSSION: Acute cholecystitis is characterized by inflammation of the mucosal wall of the gallbladder, most commonly due to cystic duct obstruction. Clinical suspicion for acute cholecystitis is usually confirmed by highly sensitive radiographic evaluation. The accuracy of radiologic imaging modalities in diagnosing acute gangrenous cholecystitis has been well documented with studies showing sensitivities of abdominal ultrasound and cholescintigraphy at 88 and 97 %, respectively. The combined likelihood ratio of physical exam findings, laboratory values and radiographic findings ranges between 25 and 30, thus the total number of false negatives is expected to be minute. However in the rare event of multiple negative laboratory and radiographic studies the clinical exam should take precedence in correctly diagnosing acute cholecystitis in an effort to prevent premature closure.

DIALING DOWN CHEST PAIN: A CASE OF “ATYPICAL” CHEST PAIN AND SHORTNESS OF BREATH David Roofeh; Giovana Uzelac; John Donnelly. Christiana Care Health System, Newark, DE. (Tracking ID #2193933)

LEARNING OBJECTIVE #1: Recognize the clinical complications of interscalene nerve blocks, which include Horner's syndrome and hemidiaphragm paralysis.

LEARNING OBJECTIVE #2: Avoid algorithmic work-up of chest pain and shortness of breath when pre-test probability is low or other causes are more likely to account for presenting symptoms.

CASE: A 58 year-old male with a past history of coronary artery disease (CAD) with prior stent placement and a remote history of pulmonary embolism (PE) following elective knee surgery presented with acute-onset shortness of breath associated with chest pain, 2 days following his elective right rotator cuff shoulder surgery. The patient received an interscalene bupivacaine pump with patient-controlled dosing for post surgical anesthesia. He noted that his pain was well managed, but woke up with paroxysms of shortness of breath and chest pain, which remitted with reducing the dose of his anesthesia. On exam he was tachypneic to 25 breaths per minute, saturating 90 % on room air. He had a mild right Horner's syndrome and his lower right lung fields were diminished half way up through his back which did not change with change in position. His chest X-ray was interpreted as showing a right-sided pleural effusion with basilar atelectasis. A right thoracic ultrasound showed no fluid collection at the base of the lung. His EKG showed non-specific T-wave inversions, but no ST elevations or depressions. His troponin markers were trended and never elevated above 0.01 ng/mL. His D-dimer was 199 ng/mL. The patient was reexamined several hours following the removal of the interscalene block. He no longer complained of chest pain or shortness of breath. His lung expansion improved, with resolution of his tachypnea and relative oxygen desaturation. His ptosis and miosis completely resolved. He was discharged home in less than 24 h.

DISCUSSION: Interscalene nerve blocks have been used effectively to reduce post-surgical pain following shoulder surgeries. These peripheral nerve blocks include anesthetic solutions such as lidocaine, mepivacaine, or bupivacaine. This anesthetic procedure is generally safe, but may present with temporary paresis of thoracic structures and cause symptoms concerning for serious pathology of the respiratory and cardiovascular systems. Horner's syndrome and hemidiaphragm paralysis is a well-known complication of interscalene nerve blocks. This case illustrates how these complications, presenting in a patient with known CAD and history of PE, may cause diagnostic concern for recurrence of acute coronary syndrome or PE following his surgical procedure. Ultimately, the patient suffered no long-term negative sequelae; a thorough history and recognition of this complication prevented the patient from receiving unnecessary diagnostic tests.

DIARRHEA WITH CLOSTRIDIUM DIFFICILE POSITIVE STOOL: TO TREAT OR NOT TO TREAT

SIMRANKAUR B MATTA, M.D.; ALAN GREENBERG, M.D.

DEPARTMENT OF INTERNAL MEDICINE, UNIVERSITY OF NEVADA SCHOOL OF MEDICINE, LAS VEGAS Simran Kaur B. Matta; Alan Greenberg. University of Nevada School of Medicine, Las Vegas, NV. (Tracking ID #2199509)

LEARNING OBJECTIVE #1: Recognizing the importance of good history taking and clinical judgment in decision making

LEARNING OBJECTIVE #2: Recognizing the limitations of Clostridium difficile stool tests while treating patients with diarrhea

CASE: A 70-year-old female with past medical history of metastatic renal cell carcinoma presented with non-bloody, watery diarrhea. She complained of 12–15 bowel movements per day and lower abdominal cramps. She was afebrile and her WBCs were 13.7/mm³.

Her stool *Clostridium difficile* (C. difficile) toxin assay (tcdB real time PCR) was positive. This was her third hospital admission within 1 year due to diarrhea with positive C. difficile assay. The patient had been diagnosed previously with C. difficile infection (CDI) in the context of diarrhea and C. difficile positive stool and was treated unsuccessfully for CDI both in inpatient and outpatient settings. Of note, the patient had not been on any other antibiotics during this period except for vancomycin and metronidazole which was prescribed to her for CDI. Stool cultures obtained in the past visits were negative and CT abdomen was significant for mild colitis. During this admission, we started the patient on vancomycin and metronidazole. At day 6, her diarrhea was unchanged. At this point, we carefully reviewed other potential causes of her diarrhea including her medications. The patient was on Axitinib for renal cancer. We discontinued her Axitinib based on its association with diarrhea and stopped the antibiotics as well. The patient showed dramatic improvement in her symptoms and her bowel movements decreased to 3 per day over the next 2–3 days.

DISCUSSION: Our patient was started on Axitinib 2 years ago and had chronic diarrhea starting 6 months later. Her diarrhea was treated as CDI on multiple occasions subjecting her to a cumulative 70 days of antibiotic exposure and a total of 15 days of hospitalization in one year with no/minimal resolution of her symptoms. She had improved dramatically this time just by discontinuation of her Axitinib. Diarrhea is one of the most common side effects of Axitinib. On retrospective discussion we realized that Axitinib was responsible for her diarrhea while C. difficile was only a colonizer. This case reminds us that the routine diagnostic tests for C. difficile do not distinguish between active disease and colonization. Perhaps the most important point to be learnt is that mere presence of diarrhea and C. difficile positive stools does not always imply CDI. The issue is to consider, when appropriate, other potential causes of diarrhea in a particular patient, both infectious and non-infectious, especially when the patient has failed to respond to an appropriate treatment for CDI. Also to be noted that in the absence of C. difficile associated diarrhea (CDAD), the antibiotics did not eradicate C. difficile colonization/fecal excretion. Our patient continued to test positive for C. difficile despite being treated with vancomycin and metronidazole on multiple occasions. It has been observed that asymptomatic colonization actually can be protective against subsequent CDI. Treating these patients may not only abolish the protective effect but may also allow for a new, more virulent strain to be introduced^{1,2}. It is thus pertinent to take a good history, interpret lab results in an appropriate clinical context as well as consider other etiologies in patients presenting with diarrhea and C. difficile positive stools because the ramifications of our decisions can be harmful, wasteful and costly. 1. Shim, et al., Primary symptomless colonization by *Clostridium difficile* and decreased risk of subsequent diarrhea. *Lancet* 1998;351:633–6 2. Johnson S, et al. Treatment of asymptomatic *Clostridium difficile* carriers (fecal excretors) with vancomycin or metronidazole. A randomized, placebo-controlled

DISSEMINATED HERPES ZOSTER IN SOLID ORGAN TRANSPLANT (SOT) PATIENT PRESENTING WITH ABDOMINAL PAIN AND PULMONARY NODULES Jeremiah Stromich; Soumya Rangarajan; Dr. Mark Barash. Medical College of Wisconsin, Waukesha, WI. (Tracking ID #2198656)

LEARNING OBJECTIVE #1: Review Varicella Zoster Virus (VZV) clinical manifestations

LEARNING OBJECTIVE #2: Increase awareness and diagnostic challenge in disseminated VZV in immunocompromised patients

CASE: A 67 year old female with a past history of ESRD secondary to diabetic nephropathy status post renal transplant 7/2014, coronary artery disease, heart failure with preserved ejection fraction and irritable bowel syndrome presented with 1 week of severe cramping lower abdominal pain. Associated symptoms included nausea, emesis and fluctuating diarrhea and constipation. She also complained of increased dyspnea on exertion for the past 3–4 weeks, and her outside provider had increased her bumex dose for presumed heart failure exacerbation. On physical exam, the patient was in no apparent distress, but her lungs had bibasilar rales and a new 2 L O₂ requirement, her heart was regular rhythm with no murmurs, abdomen was tender to palpation diffusely but worse in both lower quadrants, and she had 1+ lower extremity edema. Labs were notable for slightly elevated creatinine and AST. A CT abdomen/pelvis without contrast ordered in the ED did not identify an etiology for the patient's abdominal pain, but did reveal numerous pulmonary nodules in both lower lung fields. A dedicated CT chest confirmed diffuse pulmonary nodules with surrounding ground glass halos in a random distribution. On the second day of hospitalization the patient complained of a pruritic rash that had been present for past week and was evaluated by dermatology on day three of hospitalization. The rash was scattered diffusely over her body including her labia, with numerous punched-out erosions with hemorrhagic crust, and intact vesicles with an erythematous base. Our differential was broad, including fungal infection, but dermatology confirmed these skin lesions were concerning for Herpes Simplex Virus or VZV. The vesicle was opened and biopsied, and was positive for VZV. On the 4th day of hospitalization, the

patient's O₂ requirements increased to 3 L, but the patient remained comfortable. However, in the early morning of hospital day #5, the patient suffered from cardiopulmonary arrest while ambulating to the restroom. The patient was resuscitated with ROSC and transferred to the medical intensive care unit. She suffered two more episodes of cardiac arrest and expired about 7 h after initial resuscitation. Preliminary autopsy report revealed hemorrhagic pneumonia with acute lung injury and viral cytopathic effect.

DISCUSSION: Here we report a case of disseminated VZV in a renal transplant patient who initially presented with abdominal pain, worsening dyspnea on exertion and a pruritic vesicular rash in numerous dermatomes positive for VZV. Initial infection with VZV usually begins in childhood, and by adulthood 90–95 % of Americans have been seroconverted. The primary infection, "chicken pox", is characterized by fever, malaise and a rash with maculopapules, vesicular and scabs in various stages diffusely over the trunk and extremities. Reactivation of the latent virus occurs later in life and is characterized by unilateral, dermatomal vesicular eruption with severe pain. Mortality is rare in the immunocompetent patient. However, in the immunocompromised, dissemination of reactivated VZV includes distribution over 3 or more dermatomes with visceral involvement. Visceral involvement carries significant mortality, up to 35 %, without anti-viral therapy. Visceral involvement in VZV can present as fever, abdominal pain, disseminated intravascular coagulation and hepatitis. Pulmonary involvement is described as interstitial pneumonitis with scattered necrotic and hemorrhagic foci with intranuclear inclusions on microscopy. Chest x-ray may demonstrate pulmonary nodules that will coalesce into extensive infiltrates bilaterally. Visceral involvement can occur prior to cutaneous involvement in immunocompromised patients, making clinical diagnosis a challenge in providers who do not have a high suspicion for VZV. Therefore, unexplained hepatitis, pancreatitis, complaints of abdominal pain or pulmonary nodules in immunocompromised patients should prompt a high degree of suspicion for VZV and empiric treatment with intravenous acyclovir while further diagnostic work-up is pursued.

DISSEMINATED MYCOBACTERIUM AVIUM-INTRACELLULAR INFECTION IN A PATIENT WITH ALCOHOLIC CIRRHOSIS David Ellenberg²; David Kudlowitz²; Joshua Cohen¹; James Park¹. ¹NYU, New York, NY; ²NYU, New York, NY. (Tracking ID #2179799)

LEARNING OBJECTIVE #1: Recognize the clinical features of *Mycobacterium avium-intracellulare* in patient without AIDS who is immunosuppressed from alcoholic cirrhosis.

CASE: A 27-year-old Mexican-born, homosexual male with a history of alcoholic cirrhosis and treatment-naïve latent tuberculosis presented to our hospital with diffuse abdominal pain and worsening distention for 5 days. The patient admitted to consuming one pint of vodka per day for the past 10 years. Six months prior to presentation at our institution, the patient presented to an outside hospital with a complaint of hematemesis and bright red blood per rectum. A subsequent colonoscopy revealed an ulcer at the transverse colon. Over the course of the next several months, he had several other hospitalizations for alcoholic hepatitis and pancreatitis. He denied prior episodes of ascites. On further review of systems at this latest presentation, the patient admitted to a 20-pound weight loss and productive cough with blood-tinged sputum over the preceding 2 months. He denied fevers, chills, and night sweats. Physical exam was notable for scleral icterus, lower extremity edema and a large amount of tense ascites. There was no asterixis, encephalopathy, or skin lesion. Labs were significant for AST 65, ALT 29, Alkaline Phosphatase 179, Total bilirubin 2.1 INR 1.6, and Creatinine 1.3. HIV ELISA and PCR were negative. Ascites was negative for bacterial peritonitis, but did demonstrate 10,000 red blood cells and 1828 nucleated cells (11 % neutrophils, 77 % lymphocytes). Imaging was notable for omental thickening with a subsequent biopsy of his omentum showing multiple caseating granulomas. Given the patient's history of a positive PPD and the biopsy findings, the patient was initially placed on isolation and treated for tuberculosis. His regimen included rifampin, isoniazid, pyrazinamide, and ethambutol. However, due to hepatotoxicity secondary to these antibiotics, treatment was held. The patient's ascitic fluid and sputum cultures subsequently grew *Mycobacterium intracellulare*. The patient was started on a 2-month long, liver-sparing regimen of moxifloxacin, ethambutol, azithromycin, and amikacin. A liver biopsy confirmed cirrhosis secondary to alcoholic injury with concomitant drug related hepatotoxicity (likely secondary to the initial tuberculosis antibiotics). The patient's condition stabilized on this regimen and he was discharged with close follow up.

DISCUSSION: *M. intracellulare* is one of the non-tuberculous mycobacteria that comprises the MAC organisms. Classically, it causes a localized pulmonary infection in immune-competent hosts, typically disseminating only in immune-compromised patients. While patients with underlying lung pathology have a significantly increased risk for developing a MAC infection, approximately half of cases are identified in patients without known lung disease. The infection is characterized by relatively non-specific URI symptoms, with almost all patients describing a productive cough, one-third of whom develop

hemoptysis. Constitutional symptoms including fevers, night sweats and weight loss occur in up to one-third of immune-competent patients. By contrast, disseminated MAC infections in patients with an immunodeficiency (such as AIDS) or with steroid-induced immunosuppression do not usually affect the lung. Constitutional symptoms, gastrointestinal involvement and infiltration of reticuloendothelial organs are more common. Risk factors include CD4 counts below 100, hypertriglyceridemia, interruption of HAART regimens, anemia and iron metabolism disturbances. Further, and similar to other mycobacterial infections, HIV replication is thought to be potentiated by MAC. Whether the host is immunocompetent or immunocompromised, diagnosis is secured with culture growth of the organism in a patient with an accompanying clinical picture suggestive of infection. Given the abundance of the organism in our environment, colonization alone is not enough to warrant treatment. Disseminated infections in patients who are not otherwise immunocompromised are rare. A review of the literature demonstrates five reported cases of disseminated MAC infections in patients with alcoholic cirrhosis, of which our patient had biopsy proven confirmation. Potential mechanisms increasing patients' susceptibility in this context are deactivation of T cells, which may be directly related to alcohol intake as opposed to liver dysfunction; further, cytokine inhibitor pentoxifylline, used to treat alcoholic hepatitis, has been shown to promote MAC in vitro. Decreased immunomodulating proteins in ascitic fluid, particularly complement, may also be implicated in the development of MAC peritonitis, characterized by a lymphocytic predominance in ascitic fluid, of which the patients described in the literature (and ours) showed evidence. Concomitantly, his alcoholic cirrhosis may independently increase his risk, as anecdotally evidenced by other cases seen in literature review.

DIVERTICULITIS POSING AS A "COMPLICATED" URINARY TRACT INFECTION Nathalie Regalado. UCSF, San Francisco, CA. (Tracking ID #2197668)

LEARNING OBJECTIVE #1: Recognize the atypical presentations of diverticulitis

LEARNING OBJECTIVE #2: Select the appropriate antibiotics for acute uncomplicated diverticulitis

CASE: An 81 year old man with well controlled human immunodeficiency virus (HIV) presented to the emergency room with acute onset chills and dysuria. Per medical records, he had been hospitalized 4 months prior with Klebsiella bacteremia and an Enterococcus urinary tract infection (UTI). He recovered having had completed a total of 14 days of antibiotics with ceftriaxone and then cephalexin. At the current presentation, he had burning with urination, which was much worse than on his prior admission. He endorsed mild abdominal discomfort and loose stools for 2 days, which he attributed to taking laxatives. His past medical history included HIV (CD4 count 454 cells/mm3 with an undetectable viral load 4 months prior), stage IIb chronic kidney disease, indirect hyperbilirubinemia likely secondary to protease inhibitors and hypertension. His medications included Metoprolol 25 mg twice daily, Emtricitabine 200 mg/Tenofovir 300 mg daily, Atazanavir 300 mg daily, and Ritonavir 100 mg daily. He had allergies to sulfa, penicillin and levofloxacin. He was not sexually active but used to have sex with men. He never smoked, used alcohol in excess or any illicit drugs. His temperature was 102 F, pulse 83 beats per minute, blood pressure 145/75 mmHg, respiratory rate 24 breaths per minute and O2 sat 96 % on room air. He was in no acute distress. Bowel sounds were normal, and there was no abdominal distension or organomegaly. He was tender to deep palpation in the suprapubic area with no rebound or guarding. There was no costo-vertebral angle tenderness. His prostate was mildly enlarged and nontender. His white blood cell count was $10.9 \times 10^3/\mu\text{L}$, serum creatinine 1.4 mg/dL (baseline) and bilirubin 3.3 mg/dL (baseline). His urinalysis (UA) had trace leukocyte esterase, trace bacteria and <2 WBC/HPF. He was started on ceftriaxone for presumed urosepsis given weekly positive UA, suprapubic tenderness, dysuria and recent UTI. Given his advanced age, co-morbidity with HIV, known bilirubinemia, prior Klebsiella bacteremia and enterococcus UTI, and now a suspected recurrent UTI, a non-contrast abdomen/pelvis CT was obtained to gather more information. This showed diverticulitis of the sigmoid colon with modest inflammation of the adjacent bladder. Patient then recalled a previous episode of diverticulitis at age 60, where he presented with left lower quadrant pain and tolerated metronidazole poorly. He was started on moxifloxacin 400 mg daily for 10 days, which lead to symptom resolution. His urine culture grew <1000 colonies of enterococcus species and his blood cultures were negative.

DISCUSSION: In this case, an HIV positive elderly man with dysuria and vague abdominal symptoms was found to have acute uncomplicated diverticulitis. As tends to be the case with other intra-abdominal processes, diverticulitis is more likely to present with atypical symptoms in elderly patients. Our patient did not have the classic left lower quadrant pain that could be expected with sigmoid diverticulitis. However, there is extensive literature to support including diverticulitis in the differential diagnoses for patients presenting with concomitant abdominal and lower urinary tract symptoms, regardless of age. Close anatomical proximity to the inflamed colon can lead to bladder irritation in men (or women who have had a hysterectomy). Subsequently, patients can develop dysuria, frequency and sterile pyuria. In his case, the enterococcus bacteriuria was

probably not a true infection, but his symptoms were difficult to interpret before the diagnosis of diverticulitis was known. Referred pain via the sacral plexus can also present with pain affecting the suprapubic area, the groin, the scrotum or the penis. Once diverticulitis is complicated by fistula formation, symptoms can also include pneumaturia, fecaluria or true UTIs. Before the realization that genitourinary symptoms can present in up to 35 % of patients with diverticulitis, we had questioned the relevance of this patient's HIV status. Review of the literature did not reveal data to suggest that patients with HIV and diverticulitis present any different or that they are more likely to suffer complications. In general, diverticulitis is caused by a bacterial infection with gram negative rods (GNRs) or anaerobes (or a combination). Since this patient had an allergy to levofloxacin and tolerated metronidazole poorly in the past, he was not a candidate for ciprofloxacin plus metronidazole (a typical regimen for uncomplicated diverticulitis). There are other recommended antibiotic regimens, but the literature does not support one regimen over another. Given this, moxifloxacin was chosen since it covers both GNRs and anaerobes, leading to a full recovery in this patient.

DOC, MY HEART IS IN MY STOMACH Rachel Vanderberg¹; Jen Rusiecki²; Deborah DiNardo³. ¹UPMC, Pittsburgh, PA; ²University of Pittsburgh, Pittsburgh, PA; ³University of Pittsburgh School of Medicine, Pittsburgh, PA. (Tracking ID #2196765)

LEARNING OBJECTIVE #1: Recognize the role of physical exam (PE) in evaluating asymptomatic abdominal aortic aneurysm (AAA)

LEARNING OBJECTIVE #2: Manage a patient with an asymptomatic AAA

CASE: A 65 year old male with diabetes mellitus type II, hyperlipidemia, and a 50 pack year smoking history presented to primary care clinic with a complaint of a palpable abdominal pulse in the setting of a recent intentional 15 lb weight loss. Exam revealed a periumbilical pulsatile mass approximately 7 cm in diameter. Abdominal ultrasound (US) revealed a 5.9 cm aneurysmal dilation of the infrarenal abdominal aorta. The patient was immediately referred to vascular surgery. CTA demonstrated a fusiform infrarenal abdominal aortic aneurysm 5.6 cm transverse. The patient is currently scheduled for endovascular repair.

DISCUSSION: The estimated prevalence of AAA among men aged 65 to 79 years is 5–10 %. Approximately 12,000–15,000 patients/year in the U.S. will suffer a ruptured AAA. AAA screening has been demonstrated to reduce AAA related mortality making it an important aspect of preventative care. The primary care physician should understand the role of physical exam in diagnosing an AAA, identify appropriate patients for AAA screening, and manage patients with known asymptomatic AAAs. Asymptomatic AAAs include unruptured AAAs found on imaging or exam. The United States Preventive Services Task Force (USPSTF) recommends that men ages 65 to 75 who have ever smoked should have a onetime AAA screening with US (Grade B).¹ Some experts recommend yearly AAA screening through focused PE in all men older than 60; however, this recommendation is not shared by many other organizations.² A meta-analysis of 15 studies assessing PE as a screening method for AAA found the sensitivity varied by the size of the AAA (29 %, 50 %, and 76 % for AAAs 3.0–3.9, 4.0–4.9, and ≥ 5.0 cm, respectively).³ Another study demonstrated the sensitivity of PE to range from 61 % for AAAs 3.0–3.9 cm to 82 % for AAAs ≥ 5.0 cm.⁴ The overall specificity was 75 %. Sensitivity also increased with decreasing abdominal girth (91 v. 53 % for abdominal girth <100 cm and >100 cm, respectively). Another study evaluating the accuracy of self exam found a range of sensitivities from 50 % for AAAs <4 cm to 93 % for AAAs >5 cm with an overall specificity of 69 %.⁵ The data suggests the examiner is unlikely to miss AAAs large enough to require surgery. PE should be interpreted with caution in obese patients and should not replace US. Patient reports of pulsatile abdominal masses should raise clinical suspicion for AAA. Additionally, self-examination or PE may be a potential screening method in populations not routinely offered US screening. Elective repair is recommended for all patients who are fit for surgery with an asymptomatic AAA ≥ 5.5 cm. The risk of rupture increases dramatically and the risk of rupture outweighs the risk of surgery in patients with an AAA ≥ 5.5 cm. Other factors including female gender, younger age, rapid expansion (>5 mm/6 months or >10 mm/year), and coexistent aneurysms or peripheral artery disease in patients with an asymptomatic AAA <5.5 cm may influence the decision of elective repair and should prompt referral to vascular surgery. Otherwise, tobacco cessation counseling and periodic US surveillance are appropriate for patients with an asymptomatic AAA <5.5 cm. Optimal US screening intervals are still being investigated. The 2009 Society for Vascular Surgery guidelines recommend abdominal US every 5 years, 3 years, 12 months, and 6 months for AAAs 2.6–2.9, 3–3.4, 3.5–4.4, and 4.5–5.4 cm as the rate of expansion increases with increasing aneurysm size.⁶ Current tobacco use is the only known modifiable risk factor for AAA expansion rate. Treatment with beta blockers, angiotensin receptor blockers/angiotensin converting enzyme inhibitors, diuretics, calcium channel blockers, statins, antibiotics, anti-platelet agents, and anti-inflammatory agents have not been consistently shown to decrease AAA expansion rate. DON'T FALL FOR IT: A CAREFUL HISTORY AND PHYSICAL REVEALING SUPERIOR VENA CAVA SYNDROME (SVC) MAY BE CRUCIAL IN EARLY DETECTION OF SMALL CELL LUNG CANCER (SCLC) Daniel S. Zhang. Baylor College of Medicine, Houston, TX. (Tracking ID #2199519)

LEARNING OBJECTIVE #1: Recognize that isolated SVC syndrome may be the initial presentation of SCLC in particular

LEARNING OBJECTIVE #2: Early diagnoses and detection of SCLC through a detailed history and physical results in improved cure rates

CASE: A 68 year old black male with a history of colorectal cancer cured with resection and chemotherapy, along with extensive tobacco use was admitted with worsening right shoulder pain and neck swelling after an accidental fall from a ladder 3 days prior to presentation. Upon further questioning, patient revealed that these symptoms were actually present prior to the fall, but denied any history of cough, dyspnea or hematemesis. A right shoulder x ray was unremarkable, however his physical exam was noticeable for impressive distention of his neck veins bilaterally as well as facial plethora concerning for SVC syndrome. Initial CXR showed a 3 cm right lung mass, which upon further imaging with PET-CT revealed extensive invasion into mediastinal lymph nodes and compression of the SVC, without further evidence of metastasis. A biopsy was performed that same day which was consistent with SCLC. The patient underwent emergent chemotherapy with radiation therapy with curative intent.

DISCUSSION: Superior vena cava syndrome usually occurs as a result of compression of the vessel from an external mass. Initial physical presentation may be subtle including mild facial fullness, hoarseness, dysphagia before advancing to more classic signs including dyspnea and venous distention of neck and chest wall. This is an important physical finding since an estimated 80 % of the time the cause is a malignant tumor involving mediastinal lymph nodes. SCLC comprises the majority of these tumors given its central lung location and tendency for rapid growth into adjacent lymph nodes. In the event SVC syndrome is diagnosed, further workup must be pursued, typically with additional imaging and biopsy of the mass causing compression. In this instance, elucidating a concise and accurate history and physical was vital for this patient. Our case emphasizes the importance of recognizing a pathological physical exam finding that could have easily been incorrectly attributed to an unrelated event. Because of the early detection of malignancy in this patient, it was classified as limited stage SCLC, which has a median survival twice as long with treatment compared to extensive stage SCLC, with four to five times greater survival rates at 5 years.

DON'T UNDERESTIMATE IRON OVERLOAD Merrill H. Stewart. Tulane University School of Medicine, New Orleans, LA. (Tracking ID #2199872)

LEARNING OBJECTIVE #1: Appreciate the pathophysiology of iron overload and recognize how this relates to its key clinical characteristics

LEARNING OBJECTIVE #2: Realize the diverse etiologies of iron overload in addition to hereditary hemochromatosis

CASE: A 57 year-old man presented with 3 weeks of shortness of breath and palpitations. He also reported several months of polyuria and polydipsia. His history was remarkable for a microcytic anemia and hepatitis C with cirrhosis. He was afebrile, tachycardic, and in slight respiratory distress. He had an irregularly irregular pulse and bilateral lung rales. Skin exam revealed diffuse bronze pigmentation. His blood glucose was 282 mg/dL, hemoglobin 7.1 gm/dL, mean corpuscular volume 69 fL, and a peripheral smear displayed target cells. Atrial fibrillation with rapid ventricular response was delineated on the electrocardiogram, and a depressed ejection fraction of 35 % was seen on the echocardiogram. No ischemia was found on a nuclear stress test. Serum iron was 171 mcg/dL, transferrin saturation 95 %, and ferritin 1268 ng/mL. A gene analysis showed a heterozygous H63D hemochromatosis mutation and a hemoglobin electrophoresis was run with 95 % hemoglobin A1 and 5 % hemoglobin A2.

DISCUSSION: Iron is found in the body in red blood cells, attached to transferrin circulating in the serum, and stored as ferritin in the bone marrow and liver. In iron

overload conditions as the total body iron content increases, the production of ferritin increases and the transferrin protein becomes saturated. It is this saturation that causes iron to spill over and form complexes with other plasma components such as albumin, complexes collectively called Non-Transferrin Bound Iron (NTBI). Only those cells that have mechanisms to do so take up the NTBI: mainly the heart, liver, and endocrine cells. Once inside the cell, the iron catalyzes reactions to form reactive oxygen species that result in tissue damage. The clinical effects are related directly to the NTBI accepting organs and can include any of the following: hepatitis, cardiomyopathy, diabetes mellitus, hypogonadism, hypothyroidism, arthropathy, and bronzed skin. Individually these are common diseases, however in constellation in the right clinical picture they can suggest a diagnosis of iron overload. Our patient has a history of hepatitis C with cirrhosis, but in the last several months has developed new conditions such as bronzed skin, congestive heart failure, and diabetes mellitus. An elevated ferritin >500–1000 ng/mL is suggestive of an iron overload condition however non-specific, and an elevated transferrin saturation >60 % is more specific but still does not specify an etiology. Most internists are familiar with hereditary hemochromatosis as the prototypical iron overload syndrome, however other conditions can present similarly. Excretion of iron is minimal and fixed through skin, sweat, and menses at 1–2 mg/day, so most overload is the result of inappropriate addition of iron. The addition can be from parenteral infusions, red blood cell transfusions, massive iron consumption, or increased absorption of normal dietary iron. Parenteral iron (such as for those undergoing hemodialysis) or iron containing products (such as hematin for patients with porphyria) present an obvious risk of iron overload. Regular transfusions for chronic anemias also pose a risk. Both of these groups should have regular monitoring, and over time may require chelation therapy. Massive ingestion of enteral iron is rare, and only known to exist in some African countries where large quantities of beer are consumed that have been brewed in iron containing canisters. Finally increased absorption of normal dietary iron is more common but less understood. This group shares a common pathway through the down regulation of the iron controlling protein hepcidin. Various causes of ineffective erythropoiesis such as sideroblastic anemia, thalassemias, and myelodysplastic syndromes all lead to a down-regulation of hepcidin which in turn increases intestinal absorption of iron. In our patient we see he is only heterozygous for the hemochromatosis mutation, an autosomal recessive condition. He has no risk factors of chronic transfusion or ingestion, however we also see microcytosis, target cells, and elevated hemoglobin A2 percentage. These together suggest a possible diagnosis of beta thalassemia trait driving an inappropriate absorption of iron leading to an iron overload state. Iron overload is not a difficult diagnosis to make once the clinical signs and symptoms are understood. However once the diagnosis is made, careful consideration must be taken to determine the exact etiology of the disease.

DRESSLER-LIKE SYNDROME Venkatesh Alapati; Radeyah Hack; Irida Balili. Montefiore Medical Center, Bronx, NY. (Tracking ID #2199677)

LEARNING OBJECTIVE #1: Identify acute pericarditis as a rare complication of pulmonary embolism and infarction

LEARNING OBJECTIVE #2: Identify clinical signs and treatment for acute pericarditis

CASE: A 26 year old woman with history of systemic lupus erythematosus (SLE) and pulmonary emboli (PE) initially presented with chest pain and hemoptysis. She was tachycardic and tachypneic. She was found to have acute left lower lobe pulmonary embolism and infarction on CT Angiogram, and was started on heparin infusion. Four days into her hospital stay, she became febrile and developed intense chest pain. She was tachycardic and a new friction rub was present. Her C4 and C3 complements and troponins were within normal limits. Electrocardiogram showed new diffuse ST elevations in all leads which were not present at admission. Her echocardiogram showed moderate plural effusion. There was no evidence of cardiac tamponade. Patient had no symptoms suggestive of a lupus flare. She was treated with ibuprofen, colchicine and prednisone. Her symptoms resolved, and she was discharged home. Her pericarditis was unlikely to be secondary to lupus as patient had normal complements and no other clinical signs of a lupus flare. She was thought to have Dressler's-like syndrome, in which acute pericarditis occurs after 5–15 days after pulmonary embolism and infarction, usually in left lower lobe.

DISCUSSION: Acute pericarditis presents with chest pain, pericardial friction rub, typical electrocardiographic changes and pericardial effusion. Two of the previous four symptoms are required to make a diagnosis. About 80–90 % of cases are thought to be secondary to viral infections. The remaining cases are thought to be associated with post-cardiac injury syndromes, connective-tissue diseases or cancer. Nonsteroidal anti-inflammatory drugs (NSAIDs) have long been the mainstay of initial treatment of acute pericarditis. Most common agents are ibuprofen, indomethacin and aspirin. Recent evidence has shown addition of colchicine reduces persistent or recurrent pericarditis. Patients with cardiac tamponade should undergo urgent therapeutic pericardiocentesis. Pericarditis after myocardial infarction (Dressler's syndrome) has been well described. A similar syndrome of pericarditis after pulmonary embolism has been described in the

literature. Symptoms occur usually five to fifteen days after PE and infarction. Left lower lobe of the lung seems to be most common site of PE and infarction. Most patients clinically improve when treated with NSAIDs and steroids. The patho-physiology is not clear, but it is thought that anatomic vicinity of PE and pericardium and possible hypersensitivity induced by the infarction might play a role.

DRUG REACTION DRESSED UP AS SEVERE SEPSIS Rekha Kambhampati; Ahmed Khan; Manish Patel. Rutgers-Robert Wood Johnson Medical School, North Brunswick, NJ. (Tracking ID #2200034)

LEARNING OBJECTIVE #1: Recognize that the presenting signs and symptoms of DRESS syndrome can mimic severe sepsis.

LEARNING OBJECTIVE #2: Recognize that DRESS syndrome can occur despite appropriate dose escalation of antiepileptics.

CASE: The patient was a 21-year-old female with borderline personality disorder who had initiated lamotrigine 25 mg daily six weeks prior to admission and was appropriately titrated up to 50 mg daily three weeks later. She began to have high-grade fevers up to 105 °F with myalgias and fatigue ten days prior to admission and subsequently developed an extensive rash across her face and body. On admission, the patient was found to have a temperature of 103.3 °F and a blood pressure of 67/44. Physical exam revealed a confluent, morbilliform, and erythematous rash with desquamation affecting her face, torso, back, and all extremities, as well as cervical and inguinal lymphadenopathy. Initial laboratory findings included a white blood cell count of 23,200 with 13 % eosinophils, AST 818, ALT 670, and alkaline phosphatase 208. She had voluntarily discontinued her lamotrigine on onset of symptoms and it was not restarted on admission. Given the concern for severe sepsis, the patient was volume resuscitated and started on broad-spectrum antibiotics. However, blood and urine cultures were negative and blood pressure improved after fluid administration. Antibiotics were promptly discontinued after a diagnosis of drug reaction with eosinophilia and systemic symptoms (DRESS) syndrome was made based on the RegiSCAR diagnostic criteria. Further extensive infectious work-up revealed negative viral hepatitis serologies, HIV, Epstein Barr Virus IgM, RPR, influenza A and B, HHV-6, parvovirus B19, and HSV 1 and 2. Thyroid function tests and ANA were also within normal limits. The patient was evaluated by dermatology and prescribed hydrocortisone topical cream. However, given worsening liver function tests and persistent symptoms, the patient was started on prednisone 1 mg/kg/day, resulting in dramatic improvement in liver function abnormalities to AST 65, ALT 308, and alkaline phosphatase 168. At the same time, her rash improved with near complete resolution.

DISCUSSION: DRESS is a rare and possibly deadly syndrome that has been estimated to occur in 1 in 1000 to 1 in 10,000 exposures to many commonly prescribed medications, including antiepileptics, sulfonamides, and allopurinol. Mortality has been reported to be up to 10 %, most commonly in severe hepatic involvement, which was of concern with our patient given her significant transaminitis. We present an unusual case of DRESS syndrome which highlights several important issues in clinical practice. The diagnosis of DRESS can be made using the RegiSCAR scoring system, which requires hospitalization for acute rash in the setting of a medication associated with the syndrome, with at least three of the following additional features: (1) fever greater than 38 °C, (2) lymphadenopathy in two or more locations, (3) involvement of one or more visceral organs, and (4) hematologic abnormalities, including leukocytosis or leukopenia, elevated eosinophils, and/or thrombocytopenia. Hypotension is not commonly seen in DRESS syndrome and, consequently, this patient's case appeared to represent severe sepsis on admission despite her meeting the RegiSCAR diagnostic criteria. It is thus important for clinicians to know that DRESS syndrome can masquerade as severe sepsis and to be able to recognize when it does so, as treatment regimens vary greatly between the two. Furthermore, lamotrigine has been established as a cause of DRESS syndrome when it is initiated at high doses or when it is titrated up in sooner than two week intervals. However, our patient developed DRESS syndrome despite correct prescribing practices, as her dose was started at the lowest available amount and increased at the appropriate time. This case emphasizes that the prompt diagnosis and treatment of DRESS syndrome relies on the appropriate index of suspicion in the correct clinical setting, even with uncommon presentations of DRESS syndrome.

DRUG-INDUCED PSORIATIC ARTHRITIS—RARE PRESENTATION AFTER HEPATITIS C TREATMENT Dilpreet K. Singh; Jasdeep S. Badwal; Dominic Demello. Baystate Medical Center/Tufts School of Medicine, Springfield, MA. (Tracking ID #2192195)

LEARNING OBJECTIVE #1: Recognize possible rare side effect of hepatitis C treatment.

LEARNING OBJECTIVE #2: Management of psoriatic arthritis in the setting of chronic hepatitis C.

CASE: A 52 year old Hispanic male with medical history significant for Hepatitis C, genotype 1a, in the setting of IV drug abuse presented for a rheumatology consultation with a complaint of swelling and warmth of several digits, plaques of psoriasis on both knees, darkened nails with pitting, and morning stiffness lasting one hour. Three months prior, he had completed treatment for hepatitis C with triple therapy consisting of sofosbuvir, ribavirin and peginterferon alfa 2b with undetected viral load. He denied a history of similar symptoms prior to initiating hepatitis C therapy, and denied a personal or family history of skin or rheumatological diseases. On presentation, his vitals were stable. Physical exam was significant for scaly red patches over both knees, finger nail pitting, mild pain on flexion of his wrists, fusiform swelling and warmth of both thumbs and the first two fingers, mild dactylitis in his feet and crepitus in both knees. With the onset of dactylitis, psoriasiform rash and arthralgia after Hepatitis C treatment, a diagnosis of psoriatic arthritis was suspected. A short course of prednisone and naproxen was commenced. Laboratory testing revealed an elevated CRP, elevated ESR, normal liver function tests and renal function tests, elevated rheumatoid factor and normal anti-CCP. On follow-up visit, the patients' swelling, arthralgia, dark nail color and scaly knee rash markedly improved. However, he had persistent swelling of the distal phalangeal joints bilaterally, pitting of the nails, and scaly salmon color rash on his knees. He was then started on methotrexate and folic acid for treatment of psoriatic arthritis.

DISCUSSION: Interferon alpha induced psoriatic arthritis is rare, cited as case reports in the literature, being more common from interferon alpha as monotherapy or in combination with ribavirin (1, 2). We report the first case of psoriatic arthritis induced in a patient with hepatitis C treated with triple therapy with sofosbuvir, ribavirin, and peginterferon alfa 2b. As psoriatic arthritis is a T-cell mediated disease with a strong cytokine component, the likely mechanism is mediated by the release of interferon alpha induced cytokines through a T-cell response. Interferon alpha induces the production of interleukins (IL-12 and IL-23), with resultant proliferation of T helper (TH-1 and TH-17) cells. TH-17 produces IL-17 that induces the production of pro-inflammatory cytokines. This mechanism is supported given the presence of high levels of IL-17, IL-12, and TH1 in the synovium of people with psoriatic arthritis (3). Cases of interferon-induced psoriasis have shown to improve with cessation of interferon alpha (1). In cases where symptoms and clinical exam for synovitis and psoriasis do not resolve, such as in our case, it is important to consider the possibility of hepatotoxicity associated with the use of conventional agents (disease modifying anti-rheumatic drugs) used to treat psoriatic arthritis in the setting of hepatitis C, prior to initiating therapy. In our case, the initial exacerbation had some improvement with a course of prednisone. His hepatic function was determined to be normal for which treatment with methotrexate and folic acid was then initiated. Psoriatic arthritis has also been successfully treated with biologics such as etanercept in hepatitis C patients (4). This case highlights the need for physicians to recognize the rare adverse effect of interferon alpha induced psoriatic arthritis in a patient being treated for chronic hepatitis C with interferon alpha. Management involves using conventional agents for psoriatic arthritis with special risk consideration for hepatotoxicity in the setting of hepatitis C. **References:** 1. Taylor C et al. ELDERLY MAN WITH GENERALIZED WEAKNESS Dima Dandachi; Chandramohan Meenakshisundaram. Saint Francis Hospital, Evanston, IL. (Tracking ID #2199375)

LEARNING OBJECTIVE #1: Recognize the clinical manifestations of Endocarditis due to L. monocytogenes that can present insidiously with non-specific symptoms as weakness, dyspnea, and cardiac murmur and causes significant morbidity and mortality.

LEARNING OBJECTIVE #2: Treat Listeria endocarditis with appropriate antibiotic therapy taking into consideration reported resistance and reserve surgical options to resistant cases,

CASE: Eighty-five year old man presented to our Emergency Department after he sustained a mechanical fall and injury to his left forehead. Patient denied any lightheadedness, palpitations or headache before the fall. He denied loss of consciousness and he was able to ambulate after, with the help of his wife. His review of system was positive for progressive generalized weakness of 2 weeks duration and loss of appetite. His past medical history was significant for Hypertension, coronary artery disease, coronary artery bypass grafting, aortic stenosis, bioprosthetic aortic valve replacement, atrial fibrillation, chronic kidney disease (CKD) stage III. His medications included Amiodarone, Metoprolol and Apixaban. At that time, the patient was afebrile, and he was hemodynamically stable. On physical examination he had ecchymosis over the left orbit but no

obvious scalp injuries and grade 2/6 ejection systolic murmur at the apex, there were no abnormal neurological findings and the rest of his physical exam was unremarkable. Initial workup revealed anemia with hemoglobin of 8.4 (Baseline 11 g/dl), normal WBC count. Urinalysis was positive for leucocytes and nitrite. CT Brain revealed hemorrhagic contusion over the Left frontal region with no mass effect. CT Cervical spine was negative for fracture. Patient was admitted for observation and Apixaban was held and ciprofloxacin was started for possible urinary tract infection after blood cultures has been collected. On second day of his admission, 1 blood culture grew gram positive rods later identified as *Listeria* (L.) monocytogenes. Repeated blood cultures grew L. monocytogenes sensitive to ampicillin (minimum inhibitory concentration MIC 0.06 ($\mu\text{g/mL}$)) and trimethoprim (MIC 0.25 ($\mu\text{g/mL}$)). Subsequently, trans-thoracic echocardiogram and trans-esophageal echocardiograms revealed the bioprosthetic aortic valve riddled with vegetations, Ejection fraction was decreased to 55 % and aortic incompetence was increased compared to echocardiogram done 2 years earlier. No abscess or fistula of the perivalvular annular region were detected. According to modified Duke's criteria, we diagnosed the patient with infective endocarditis caused by L. monocytogenes and antibiotic treatment was initiated with Ampicillin IV 2 g Q 8 h adjusted for his CKD. Gentamycin was not added because of his underlying kidney disease. Surgery was not considered given his co-morbid conditions. After 3 days of antibiotics, blood cultures were negative, patient remained afebrile. His hospital course was complicated by acute kidney injury, acute respiratory failure secondary to fluid overload. Later during his admission, patient was enrolled in hospice based on his wishes and he went home after that under hospice care.

DISCUSSION: L. monocytogenes is a gram positive coccobacillus that has aerobic and facultatively anaerobic characteristics. *Listeria* infection is an important public health problem in the United States and has been associated with several outbreaks. It is a food borne illness transmitted by consumption of contaminated food such as uncooked meats or vegetables, unpasteurized milk and cheeses. The clinical manifestations can be self-limited gastrointestinal tract illness in immunocompetent patients or can cause serious morbidity and mortality mainly in pregnant women, elderly individuals, and immunocompromised patients. The most serious presentation being bacteremia and meningitis. Endocarditis secondary to *Listeria* is rare and has been reported mostly in patients with underlying cardiac valve disease. There has been no available clear guidelines regarding management of *Listeria* endocarditis. The evidence behind choice of antibiotics is not clear. -Ampicillin is generally considered the preferred agent however -its superiority to Penicillin is questionable. Course of antibiotics should be for at least 4 weeks for native valve endocarditis and for 6–8 weeks for prosthetic valve infections. On the basis of synergy observed in vitro and in animal models the combination of ampicillin with aminoglycosides, usually gentamycin, has been used for serious infections. Moreover, surgical treatment has been controversial, available data did not show any significant difference in mortality between surgical and non-surgical treatment. Surgery has been reserved for cases that are resistant to eradication with antibiotics. We report a case of *Listeria* endocarditis in an elderly men presenting with non-specific symptoms which makes early diagnosis challenging. We were able to reach microbiological cure with Ampicillin treatment without surgical treatment.

ENCAPSULATING PERITONEAL SCLEROSIS Abdel Rahman A. Omer; Omar Nadhem; Nibras Talibmamury; Mohammed A. Bahaa Aldeen; Roger D. Smalligan; Mashrafi Ahmed. Texas Tech University Health Sciences Center, Amarillo, TX. (Tracking ID #2198214)

LEARNING OBJECTIVE #1: Recognize the diagnostic approach and pathophysiology of encapsulating peritoneal sclerosis.

LEARNING OBJECTIVE #2: Focus on the importance of early diagnosis and management of encapsulating peritoneal sclerosis.

CASE: A 49 years old male presented with abdominal pain for 7 days. The abdominal pain was mainly in the epigastric region, and occasionally diffuse around the umbilicus. It was intermittent, but became more constant with increased severity over period of time. He graded it as 8/10 in intensity. The pain was aggravated to a certain extent by food, and relieved only by pain medications. It did not radiate to the back. The patient denied complains of fever, nausea, vomiting, constipation and diarrhea. His past medical history was significant for hypertension, type 2 DM, end stage renal disease, on hemodialysis 3 times a week. He was recently switched to hemodialysis from peritoneal dialysis due to recurring episodes of peritonitis, hyperlipidemia and peripheral vascular disease. In the past, he was admitted on three occasions with peritonitis. The patient also had bilateral lower limb amputation secondary to his PVD and diabetes. On physical exam his vitals were within normal limits, and oxygen saturation was 99 % in room air. He was alert and oriented. Abdominal exam revealed a distended and tense abdomen with slight rigidity. There was guarding on percussion and presence of ascetic fluid was noted. Bowel sounds were diminished. No organomegaly was appreciated due to the fluid. A CT angiogram with a CT scan of the abdomen revealed extensive calcification without any evidence of mesenteric ischemia. Esophagogastroduodenoscopy showed gastric antral thickening.

Finally an exploratory laparoscopy with peritoneal biopsies was done and visualization showed extensive areas of fibrosis and sclerosis in the peritoneum. Biopsy results were consistent with encapsulating peritoneal sclerosis. After the diagnosis of encapsulating peritoneal sclerosis (EPS), the patient was started on 40 mg Prednisone orally. He continued with his hemodialysis 3 times per week. Eight days after admission the patient was discharged in a stable condition. The abdominal pain was under control when the patient was discharged.

DISCUSSION: The case illustrated above explains the potential of developing encapsulating peritoneal sclerosis after long duration of ambulatory peritoneal dialysis. It is believed that the continuous exposure of the peritoneum to the bio-incompatible peritoneal dialysis compounds is the cause behind the progressive peritoneal membrane damage. Recent data also stated that the disease was observed more frequently after discontinuation of the peritoneal dialysis and conversion to hemodialysis, which is also observed in the above case. It is also suggested that persistent and recurrent episodes of peritonitis strongly contribute to the development of this disease; this is perhaps due to the inflammatory response that the peritonitis imposes on an already damaged peritoneum. Early recognition of Encapsulating Peritoneal Sclerosis and its association with peritoneal dialysis is important in preventing common surgical emergencies that can develop. The use of the newer generation of the more biocompatible peritoneal dialysis fluids that are low in glucose degradation products might be promising, but long term study results are still lacking.

EPIPERICARDIAL FAT NECROSIS: AN UNUSUAL AND UNDER-DIAGNOSED CAUSE OF CHEST PAIN Jacob E. Berchuck¹; Shalini Patel². ¹UCSF Medical Center, San Francisco, CA; ²UCSF/San Francisco VA, San Francisco, CA. (Tracking ID #2199499)

LEARNING OBJECTIVE #1: Recognize epipericardial fat necrosis (EPFN) as an uncommon, but benign clinical entity that mimics more serious causes of chest pain

LEARNING OBJECTIVE #2: Learn the diagnostic work-up and management of EPFN

CASE: An 80 year-old man with history of coronary artery disease requiring PCI, heart failure with preserved EF, hypertension, chronic tobacco use, COPD, provoked DVT 2 years earlier treated with 6 months of oral anticoagulation, untreated latent TB, and Barrett's esophagus, was admitted from the emergency room for left-sided chest pain and hypoxia. The pain had been present intermittently for 6 months, was located both anteriorly and posteriorly, described as stabbing, and worse with inspiration. In the preceding 6 months, he presented to multiple hospitals with the same complaint and was treated for pneumonia once, COPD exacerbation multiple times, and underwent thoracentesis for a left-sided pleural effusion. These interventions resulted in transient improvement, but the chest pain continued to recur. Physical exam was notable for an oxygen saturation of 85 %, bibasilar rales, asymmetric lower extremity swelling, normal cardiac exam, no chest wall tenderness or rash, and no expiratory wheeze. Initial labs revealed a normal leukocyte count, stable mild anemia, normal renal function, and negative troponin. ECG was normal sinus rhythm and otherwise unremarkable. Chest CT with contrast showed no evidence of pulmonary embolism, pneumonia, empyema, pneumothorax, tuberculosis, or chest injury, but demonstrated a small left-sided pleural effusion and new diffuse inflammatory changes within the epipericardial fat of the left mediastinum with prominent stranding and swirling soft tissue density extending to the pericardial surface with mild inflammatory changes of the pericardium. During the admission tuberculosis was ruled out with negative AFB smears and cultures. The patient was treated with diuretics for decompensated heart failure with resolution of hypoxia, but the chest pain persisted. Both the radiologists and pulmonary consultants felt that in the absence of a compelling alternative diagnosis, the chest pain and radiographic findings were consistent with pleurisy due to EPFN. Ibuprofen was started prior to discharge. At 3-month follow-up the patient reported resolution of chest pain after 2 months without recurrence of symptoms. Repeat CT showed no pleural effusion and near complete resolution of epipericardial fat stranding.

DISCUSSION: Recent studies indicate that although uncommon, EPFN is not as rare as previously thought, and is under-diagnosed in patients with acute chest pain and an otherwise negative cardiopulmonary work-up. In most instances the onset is acute, but as in this patient, pain can persist for up to a year. Chest pain is usually ipsilateral to the lesion, which is more commonly on the left than right side. The pain is often intermittent and worsens with movement and deep inspiration. A history of trauma or infection is usually absent. ECG, cardiac enzymes, leukocyte count, and other lab tests are usually normal. Chest radiography often shows a paracardiac opacity, occurring predominantly on the left side, occasionally with an associated pleural effusion. On CT scan EPFN appears as an ovoid mediastinal fatty lesion with epipericardial fat stranding with or without adjacent pericardial thickening. Until recently, definitive diagnosis required surgical resection and pathologic examination given radiographic resemblance to other fat containing mediastinal lesions, including liposarcoma. With advances in imaging, however, these classic radiographic findings, in the setting of acute pleuritic chest pain and a

negative cardiopulmonary work-up, are highly suggestive of EPFN. Because of its benign, self-limited nature, conservative management with anti-inflammatories is recommended. Repeat CT scan should also be obtained to confirm resolution of the radiographic inflammatory changes associated with EPFN and to rule out neoplastic disease. Both radiologists and clinicians should be aware of the clinical presentation of this benign condition and should include it in their differential diagnosis of chest pain once other more serious etiologies have been ruled out.

EPITHELIOID ANGIOSARCOMA PRESENTING AS SHOULDER PAIN Akash

Gupta²; Michael Cecchini¹; Frederick L. Altice³; Dana W. Dunne³; David B. Banach³.
¹Yale Internal Medicine Residency, New Haven, CT; ²Yale School of Medicine, Easton, CT; ³Yale School of Medicine, New Haven, CT. (Tracking ID #2198461)

LEARNING OBJECTIVE #1: Recognize that common primary care complaints may be caused by serious and uncommon underlying pathology.

LEARNING OBJECTIVE #2: Work through the differential diagnosis for a bloody pleural effusion.

CASE: A 37-year old male presented with severe right chest pain, which began in the right shoulder 7 months earlier while he was incarcerated. A shoulder x-ray was normal, and he was told he had a rotator cuff injury. Over several months, the pain began progressively radiating into the right chest. Two months earlier, the patient was released from prison. Three weeks earlier, he presented to the emergency department with shoulder pain radiating across the chest. Shoulder and chest x-rays were normal. He was again assessed to have a rotator cuff injury. Three days before admission, the pain greatly increased. On presentation, he reported 10/10 pleuritic right lower chest and upper abdomen pain associated with new dyspnea. He denied any trauma and had no significant medical history aside from a 24 pack-year smoking history. On exam, the patient was afebrile, had right-sided splinting, and had diminished breath sounds and dullness to percussion in bilateral lower lung fields and right middle lung field. A chest x-ray showed a large right-sided pleural effusion with near total opacification of the hemithorax. A chest CT scan showed numerous nodular lesions in the left lung. Due to concerns for active tuberculosis (TB), the patient was placed on airborne precautions. A thoracentesis removed 1860 mL of bloody pleural fluid, with reaccumulation within 1 day. Pleural fluid studies showed protein of 4.5 g/dL (serum protein 6.3 g/dL), lactate dehydrogenase (LDH) of 251 U/L (serum LDH 186 U/L), hematocrit of 10.0 % (blood hematocrit 35.3 %), glucose of 54 mg/dL, and adenosine deaminase of 12.3 U/L. No acid-fast bacilli (AFB) were seen. During Video-Assisted Thoracoscopic Surgery (VATS), a mediastinal mass and several pleural lesions were seen and biopsied. A chest tube was placed, followed later by doxycycline pleurodesis. The biopsies and pleural fluid cytology showed a poorly differentiated epithelioid angiosarcoma. The biopsies showed no AFB or granulomas. Airborne precautions were discontinued, and the patient was discharged to start outpatient chemotherapy. The patient was re-admitted 2 days later for Acute Respiratory Distress Syndrome. He was treated for Health-Care Associated Pneumonia, and intubated for 4 days. He then began paclitaxel treatment in the hospital before discharge. After 6 cycles of paclitaxel, the patient had a repeat chest CT scan, which showed regression of his mediastinal mass and decreased intrathoracic lymphadenopathy. He is currently stable at home, continuing chemotherapy.

DISCUSSION: Shoulder pain is a common primary care complaint usually ascribed to a musculoskeletal cause. In this case, however, there was a life-threatening etiology. According to one study of ambulatory visits for shoulder pain in the 1990s, an x-ray was performed in 29.0 % of visits, and further imaging was performed in only 6.5 % of visits (Wofford et al., BMC Musculoskeletal Disord 2005). For our patient, a consistent primary care physician might have found the progress unusual enough to order further imaging, potentially detecting the tumor before it metastasized. After discharge from prison, he was seen repeatedly in the emergency department, resulting in fragmented care (Kulkarni et al., J Community Health 2010). Another major teaching point is the workup of a bloody pleural effusion, which can be either a hemothorax or hemorrhagic effusion. Traditionally, hemothorax is defined by a pleural fluid/blood hematocrit ratio >50 %, while hemorrhagic effusions have a ratio <50 %. Yet because blood can congeal over time, a ratio of 25–50 % can be consistent with a hemothorax. Hemothorax can be caused by trauma, coagulopathies, vascular malformations, certain neoplasms, and other miscellaneous causes. Hemorrhagic effusion is most commonly caused by infections such as tuberculosis, malignancy, or pulmonary infarction. (Ali et al., Chest 2008) Our patient had a borderline pleural fluid/blood hematocrit ratio of 28 %, but the clinical picture seemed consistent with a hemorrhagic effusion. Given his incarceration history, he was initially treated under airborne precautions. However, the lack of constitutional symptoms, negative PPD, negative AFB smears, lack of granulomas on pleural biopsy, and low ADA made active TB less likely. Our workup ultimately led to the diagnosis of a rare malignancy: epithelioid angiosarcoma. This is a rare soft tissue sarcoma with a male

predilection, occurring most commonly in the seventh decade. The tumors are aggressive with early spread and high mortality, but some evidence suggests paclitaxel can improve survival in angiosarcomas. (Hart et al., Arch Pathol Lab Med 2011). In conclusion, this case demonstrates the potential serious etiologies for common primary care complaints, which may be detected earlier with less fragmented care.

ERODING THROUGH: AN UNCOMMON CAUSE OF DYSPHAGIA Aaron K.
 Goodwin; Kristi M. Moore; Rebecca Rawl; Dan Collins. Carolinas Medical Center, Charlotte, NC. (Tracking ID #2197723)

LEARNING OBJECTIVE #1: Surgically implanted cervical hardware may erode into the esophagus months or even years after initial implantation.

LEARNING OBJECTIVE #2: Early diagnosis of esophageal perforation may require multiple diagnostic modalities with prompt surgical management crucial for minimizing morbidity and mortality.

CASE: A 44 year-old man presented to the emergency department with an 8–12 month history of progressive dysphagia to solids and liquids, 80 lb weight loss, odynophagia, and significant dyspepsia. Review of systems was significant for episodic productive cough and orthopnea. Medical history included type 2 diabetes mellitus and a cerebral vascular accident 3 years prior with residual left-sided extremity motor weakness but no resultant speech or swallowing dysfunction. Surgical history was significant for remote traumatic right arm amputation and multiple cervical spine surgeries, with most recent anterior fixation of C3–C7 2 years prior for critical cervical stenosis. Physical examination showed a thin-appearing male in no acute distress with stable vital signs. Neurologic exam showed no cranial nerve dysfunction and stable weakness in left sided extremities. Head and neck exam were unremarkable without palpable abnormality or pain on movement of the neck. Auscultation of the chest was remarkable for mild inspiratory stridor. Initial plain films and computed tomography imaging of head and neck showed surgical fixation of C3–C7 with anterior displacement of C6/C7 hardware and screws into the prevertebral soft tissue without frank intrusion in the esophagus. Barium esophagram with fluoroscopic evaluation showed no esophageal abnormalities. Flexible laryngoscopy was unremarkable for significant findings of the nasopharynx, hypopharynx, and larynx. Gastroenterology was consulted for upper endoscopy which found surgical hardware visualized at the level of the cricopharyngeus. Six days after presentation, the patient underwent removal of cervical hardware and repair of esophageal perforation with placement of percutaneous endoscopic gastrostomy, tracheostomy, and salivary bypass tube. Purulent fluid was found surrounding implanted hardware, and cultures isolated viridans streptococci, *Candida albicans* and Methicillin-resistant *Staphylococcus aureus*. He was treated with a total antibiotic course of four weeks with IV vancomycin and oral fluconazole. Post-operative course was relatively unremarkable, and after an 18 day hospitalization he was transferred to a rehabilitation facility. He has now returned home and denies dysphagia with oral intake.

DISCUSSION: Anterior cervical spinal fixation has become a common management modality for multiple spinal pathologies including fracture, degenerative disc disease and neoplasm. Esophageal erosion and perforation by surgical hardware is uncommon with rates reported as low as 0.15 %. While most often occurring in the early post-operative phase, late-onset cases have been reported with erosion and perforation occurring more than 10 years after surgery. The most common symptoms include neck and throat pain, odynophagia, dysphagia, hoarseness, and aspiration. Less-common presenting symptoms include recurrent pneumonia, fever, cough, subcutaneous emphysema, and neurologic deficits. Our patient presented with progressive dysphagia, odynophagia, and weight loss with recurrent episodes of productive cough. Physician awareness is vital for identifying pertinent presenting symptoms which, in the setting of previous anterior cervical instrumentation, should raise concern for esophageal compression, erosion, and/or perforation. Prompt detection and intervention is crucial as mortality and complication rates rise significantly with delayed detection and intervention. Multiple modalities including CT imaging, endoscopy, and even surgical exploration may be required for diagnosis. In one study of patients with esophageal injury only 72.7 % were accurately diagnosed by imaging. Consequently, negative imaging should not be used as the sole means to rule out esophageal erosion or perforation. Esophageal perforation, as with our patient, is most common at the C5/C6 or C6/C7 level. Underlying causes which commonly lead to erosion include hardware migration, new trauma and chronic compression. Irrespective of cause, essential components of therapy include surgical removal of hardware, abscess drainage with culture-directed parental antibiotics, and salivary fluid diversion. Reports have noted normal swallowing function within 10–14 days after the surgical repair. Often temporary placement of gastrostomy tube is warranted for nutritional support. Esophageal erosion of surgical hardware, though typically occurring in the early post-operative course, may present years later with progressive dysphagia, cough, voice changes, neck pain or recurrent pneumonias among some of the many presenting symptoms. Clinician awareness with prompt diagnosis and surgical intervention are crucial for minimizing morbidity and mortality.

ERUPTIVE XANTHOMATOSIS: A SIGN OF POOR DIABETIC CONTROL
Sue-Wei Luu; Umma Ashfaq. University of Florida, Gainesville, FL. (Tracking ID #2193597)

LEARNING OBJECTIVE #1: This case highlights the importance of recognizing eruptive xanthoma as initial manifestation of hypertriglyceridemia induced acute pancreatitis in the setting of poorly controlled diabetes mellitus. Recognizing clinical manifestations that indicate underlying systemic disease, assessing patient compliance during routine clinic visits, and modifying medication regimen as appropriate is paramount to preventing medical complications and frequent hospitalizations.

LEARNING OBJECTIVE #2: Lastly, we would like to remind clinicians about the importance of glycemic control in preventing eruptive xanthomatosis and associated hypertriglyceridemia induced pancreatitis.

CASE: A 39-year-old Caucasian female with Type 2 diabetes mellitus, hypertension, depression, and body mass index of 40.2 kg/m² presented to clinic with sudden onset of diffuse, pruritic, erythematous papules on the arms, thighs, and behind both knees over the past 5 days. Physical exam showed 3 mm erythematous pustules/papules along the medial aspect of the corresponding areas. Her medications at the time were metformin 1 g twice a day, atorvastatin 40 mg at bedtime, tricar 145 mg every day, and lisinopril 5 mg daily. She reported taking her morning medications consistently but tended to forget the ones to be taken at night. Three weeks later, she was subsequently admitted to the hospital with acute pancreatitis, hyperglycemia (random glucose of 345 mg/dL) and marked hypertriglyceridemia (6000 mg/dL). She was negative for autoantibodies related to Type 1 diabetes and had no family history of diabetes or hyperlipoproteinemia. She improved with intravenous fluids and supportive care. Upon hospital discharge, she was advised to take her evening medications with meals or get a pill box to enhance medication compliance. The eruptive xanthomas had resolved upon routine clinic follow-up two weeks after hospital discharge. Six months later, she was again hospitalized for acute pancreatitis. Of note, she had erythematous, vesicular appearing pustules/papules along back of the neck, medial aspect of both arms, and both thighs starting 2–3 weeks prior to hospitalization. On admission, she had labs consistent with diabetic ketoacidosis (metabolic acidosis with anion gap 18 and elevated beta-hydroxybutyrate), triglyceride 9693 mg/dL, lipase 3883 U/L, random blood glucose 520 mg/dL, and hemoglobin A1C 11.7 %. Her current medications included metformin 1 g twice a day, lantus 50U BID, atorvastatin 40 mg at bedtime, fenofibrate 200 mg daily, Lovaza 4 mg twice a day, and lisinopril 5 mg daily. However, six weeks prior to hospitalization, she had decided to stop atorvastatin, fenofibrate, and Lovaza as she was starting a PlexusSlim diet for weight loss. She was counseled extensively on the importance of medication compliance and received diabetes education during her hospitalization. She was seen by endocrinology and her diabetes medication regimen was adjusted to include Lantus 65 units twice a day and pre-meal Humalog 7 units three times per day with correction scale 2 units: 50 points for blood glucose >150. Skin lesions resolved 3 weeks after initiation of insulin therapy. Repeat lipid panel after 3 months showed triglyceride 811 mg/dL and total cholesterol 228 mg/dL. Subsequent clinic follow-up at monthly interval to assess compliance, barriers to compliance, and glycemic control resulted in gradual improvement in glycemic control with most recent hemoglobin A1C 8.7 % and no further hospitalizations to date.

DISCUSSION: Xanthomas are skin lesions, which develop in the setting of altered systemic lipid metabolism and are characterized by accumulation of lipid-laden macrophages in the dermis. Eruptive xanthomas commonly arise over the buttocks, shoulders, and extensor surfaces of extremities and typically spontaneously resolve over several weeks. Elevated plasma cholesterol or triglyceride levels is present in primary hyperlipoproteinemia in which genetic mutations yield defective Apo lipoproteins or secondary hyperlipoproteinemia, which is seen in diabetes mellitus, nephrotic syndrome, cholestasis, pregnancy, and hypothyroidism. While, eruptive xanthomas have commonly been associated with hypertriglyceridemia, these skin lesions are not a common manifestation of diabetes mellitus. Meanwhile, diabetes mellitus is the most common secondary cause of chylomicronemia, known as diabetic lipemia. Due to the temporal relationship of events and the association of diabetes with secondary hyperlipidemia, this patient's eruptive skin lesions were attributed to hypertriglyceridemia and hyperglycemia. Early recognition of dermatological manifestations of hypertriglyceridemia and hyperglycemia is vital as early medical intervention in the form of medication adjustment could have prevented repeated episodes of pancreatitis and hospitalizations in this patient.

ERYTHEMA MULTIFORME CAUSED BY MYCOPLASMA INFECTION IN AN ELDERLY MAN Noeru Miyake²; Christine Kwan¹. ¹Teine Keijinkai Hospital, Arlington, TX; ²Teine Keijinkai Hospital, Sapporo, Japan. (Tracking ID #2199808)

LEARNING OBJECTIVE #1: Recognize that *Mycoplasma pneumoniae* pneumonia can present with erythema multiforme

LEARNING OBJECTIVE #2: Recognize that mycoplasma pneumonia can also cause uveitis, rhabdomyolysis, and glomerulonephritis

CASE: A 79 year-old Asian man presents with 3 days of rash on his entire body, including face, palms, soles, and genitals but without pain, itchiness, or discharge. He also reports fever, sore throat, dry cough, decreased appetite, and sick contact last week. Other review of systems is within normal limits (WNL). Past medical history includes hypertension, dyslipidemia, atrial fibrillation, unstable angina, and asthma. The patient takes candesartan, nifedipine, rosuvastatin, rivaroxaban, and nicorandil; he has no allergies. He has a 20 pack-year smoking history but quit. He is a social drinker but does not use recreational drugs. His family history is unknown. On exam, vital signs show temperature 39.1, heart rate 120, blood pressure 187/106, respiratory rate 31, and O₂ sat 98 % room air. He appears in no acute distress and is alert/oriented x 3. Head exam shows right eye clear discharge and dry oral mucosa. Skin exam reveals 1–15 mm red macules, papules, plaques, and vesicles, including some target lesions, with ill-defined borders on his head, neck, trunk, extremities, palms, soles, and genitals. The rest of his exam, including his lungs, is WNL. Labs, including complete blood counts and chemistries, are WNL except platelets 101 × 10³ /μL, Na 123 mmol/L, Cl 90 mmol/L, AST 51 U/L, lactate dehydrogenase 288 U/L, creatine kinase 1668 U/L, and C-reactive protein 19 mg/dL. Coagulation panel shows slightly increased PT, APTT, fibrinogen, and D-dimer. Autoimmune panel, including MPO-ANCA, RP3-ANCA, and anti-nuclear antibody, is WNL. Urinalysis detects protein, red blood cells (RBC), and RBC casts. Chest x-ray is WNL. Polymerase chain reaction (PCR) of mycoplasma IgG illustrates a titer of 1:80; cold agglutinin titer is WNL. The patient is thus given ciprofloxacin x 14 days for his mycoplasma pneumonia. He also develops uveitis, transaminitis, and congestive heart failure exacerbation for which furosemide is given. Repeat PCR of mycoplasma IgG after 2 weeks shows a titer of 1:640. His rash, most likely erythema multiforme from multi-organ involvement, in addition to the other organ dysfunction, improves within 2 weeks.

DISCUSSION: *Mycoplasma pneumoniae* commonly causes community-acquired pneumonia typically in school-aged children. It produces an exotoxin, community-acquired respiratory disease toxin, which may affect the severity of the disease. Typical signs and symptoms include headache, malaise, fever, sore throat, productive cough, and rales; the disease is usually self-limited. Extrapulmonary signs and symptoms, including hemolysis, skin rash, and heart/gastrointestinal/central nervous system/joint involvement, occur in <5–10 % of patients. This patient also has other less-common organ dysfunction, like uveitis, rhabdomyolysis, and glomerulonephritis. Erythema multiforme, a rare manifestation of <1 % of outpatient visit, is caused by infections (90 %), medications, malignancies, autoimmune diseases, immunizations, radiation, sarcoidosis, and menstruation. Of the infections, herpes simplex virus is the most common cause although *Mycoplasma pneumoniae* is also considered an important cause. Because the rash occurs on this patient's mucous membranes, his erythema multiforme is classified as major. The rash usually resolves spontaneously although oral steroids may be given for severe oral involvement.

ESSENTIAL MIXED CRYOGLOBULINEMIA PRESENTING AS A FEVER OF UNKNOWN ORIGIN IN A MIDDLE AGED WOMAN Mark Schwartz; Sabiha Hussain; Amanda Kaveney. Rutgers Medical School, Morganville, NJ. (Tracking ID #2153573)

LEARNING OBJECTIVE #1: What is the differential diagnosis and initial workup in a patient with fever of unknown origin?

LEARNING OBJECTIVE #2: How should an internal medicine physician manage a patient with essential cryoglobulinemia?

CASE: A 47 year-old female with history of hypertension, type 2 diabetes, asthma, and non-alcoholic liver disease presented with a 3-week history of fever and erythematous rash of the head and trunk. Workup at another hospital 8 days prior to admission was significant for negative blood cultures and mediastinal adenopathy on CT chest. She was treated with a 7 day course of antibiotics with no improvement in symptoms. On presentation to our hospital, significant findings included blood pressure of 79/48, pulse of 120, fever of 39 °C, and altered mental status. Labs were pertinent for leukocytosis, anemia, hyponatremia, transaminitis, lactic acidosis, and elevated inflammatory markers (ESR and CRP). Blood and urine cultures were negative. She was admitted to the ICU and remained febrile despite treatment with broad spectrum antibiotics. She was placed on a cooling blanket and developed a diffuse purple macular papular rash. Addition infectious workup including HIV, hepatitis, cytomegalovirus (CMV), Epstein Barr virus (EBV), adenovirus, human herpesvirus 8 (HHV-8), and tick-borne illnesses was negative. Bone marrow biopsy showed pancytopenia without evidence of malignancy. The patient was found to have positive serum cryocrit and immunofixation suggestive of cryoglobulinemia. The diagnosis of essential CG was made and the patient was treated with Methylprednisolone, plasmapheresis, and Rituximab without improvement. The patient developed ARDS, acute renal failure, and DIC. The patient passed away from a large intracerebral hemorrhage.

DISCUSSION: Fever of unknown origin (FUO) is defined as a temperature greater than 38.3 °C for at least 3 weeks duration and with no established diagnosis after a 1-week

workup. The workup of FUO includes a thorough history, physical examination, laboratory studies, and imaging. The most common causes of FUO include infections, malignancies, and connective tissue disorders. Essential Mixed Cryoglobulinemia (Essential CG) is a vasculitis of the small and medium vessels secondary to the deposition of cryoglobulins, which are polyclonal IgG and IgM immune complexes that precipitate at low temperatures. Essential CG can be associated with viral illnesses, hematologic malignancies, and rheumatologic diseases. The gold standard for diagnosis is a positive serum cryocrit. In patient's experiencing arthralgia's or fatigue, the treatment involves non-steroidal anti-inflammatory drugs. When evidence of end organ damage is present, steroids and immunomodulators are indicated. In severe cases where hyper viscosity syndrome is present, treatment should include plasma exchange. This case illustrates the extensive workup a primary care physician should perform on patients presenting with FUO and a review of Essential CG. When a patient remains febrile on broad spectrum antibiotic therapy, less common causes of FUO such as Essential CG should be considered.

EVALUATION OF PERICARDITIS Jennifer Huang; Ginger W. Wey. Montefiore Medical Center, Bronx, NY. (Tracking ID #2197638)

LEARNING OBJECTIVE #1: Recognize indications for further work-up in a patient with pericarditis.

LEARNING OBJECTIVE #2: Identify common and rare causes of pericarditis.

CASE: A 41 year old African American man with no significant past medical history presented with one day of pleuritic chest pain. His maximal temperature was 103 F, his blood pressure was 120/80, and his heart rate was 100. His lungs were clear to auscultation, and cardiac exam was significant for a pericardial friction rub, but no murmurs. His electrocardiogram revealed diffuse ST elevations with reciprocal ST depression in aVR. He was diagnosed with acute pericarditis, which was managed with colchicine and ibuprofen. Upon further questioning, he also reported concomitant night sweats, a 10-lb unintentional weight loss, progressive dyspnea on exertion in the preceding months, and dysphagia to liquids. He did not report Raynaud's phenomenon, and he had not travelled recently. On closer examination, erythematous nodules were noted on the extensor surfaces of his legs, but no joint swelling or erythema was found, nor was he noted to have any lymphadenopathy or elevated jugular venous pressure. Labs were remarkable for negative serial cardiac enzymes, blood urea nitrogen of 8 mg/dL, creatinine of 0.8 mg/dL, C-reactive protein of 22 mg/dL, angiotensin-converting enzyme level of 60 U/L, and erythrocyte sedimentation rate of 71 mm/h. His autoimmune work-up, including anti-dsDNA, anti-Ro/La, anti-centromere, and anti-RNA polymerase antibodies, was negative. He screened negative for HIV and hepatitis B and C. Tuberculin skin testing revealed 0 mm of induration 2 days after placement. Chest x-ray was negative. No pericardial effusion was noted on echocardiogram. CT chest was notable for mediastinal and bilateral hilar adenopathy, as well as extensive peripheral cystic and fibrotic changes. An endobronchial ultrasound-guided fine needle aspiration of mediastinal lymph nodes was performed. Cultures were negative, but pathology showed non-necrotizing granulomas. He was diagnosed with sarcoidosis and started treatment with oral prednisone with improvement in his rash and respiratory symptoms.

DISCUSSION: Acute pericarditis is the most common manifestation of pericardial disease, occurring in up to 5 % of patients presenting to emergency rooms with non-ischemic chest pain. Patients who present with pericarditis are often not extensively evaluated due to the usually benign course of the illness and the low diagnostic yield of such work-ups. Idiopathic pericarditis accounts for nearly 90 % of all cases in some studies, and a specific etiology is found in less than a quarter of patients, with neoplasia, tuberculosis, and autoimmune disease being the most common causes. Among these patients with known etiologies, most patients in developed nations are thought to have viral etiologies, whereas patients in developing countries are later diagnosed with HIV or tuberculosis. All patients should be questioned about other systemic symptoms to evaluate for possible underlying diseases. Patients who do not respond appropriately to anti-inflammatory medications should also be further evaluated. Further testing for those with a positive review of systems or poor clinical response can include chest x-ray, electrocardiogram, echocardiogram, tuberculin skin testing, blood tests (e.g. complete blood count, basic metabolic panel, blood cultures, thyroid-stimulating hormone level, HIV screening), and an autoimmune work-up (e.g. antinuclear antibodies, rheumatoid factor, anti-dsDNA antibodies). In addition, those at high risk for coronary artery disease should be ruled out for myocardial ischemia. Patients should also be evaluated for possible pericardial effusion or cardiac tamponade due to the possible need for pericardiocentesis. Pericardial biopsy is reserved for those with recurrent cardiac tamponade or for patients in whom bacterial or neoplastic pericarditis is suspected. In the case of the described patient, the presence of multiple systemic symptoms prompted further evaluation, which led to his eventual diagnosis. Systemic inflammatory diseases in which pericarditis is more commonly seen include systemic lupus erythematosus, adult Still's disease, systemic sclerosis, and mixed connective tissue disease. Pericarditis is much rarer (less than 10 % of patients) in sarcoidosis, rheumatoid arthritis, dermatomyositis, polymyositis, Sjogren's syndrome,

and Behcet's disease. Although most patients with idiopathic or viral pericarditis have a good prognosis, it is important for the general clinician to recognize high risk patients to diagnose and treat underlying systemic disease.

EXPANDING THE DIFFERENTIAL DIAGNOSIS FOR PAINLESS JAUNDICE

Andrew Whipple¹; Christopher M. Begley¹; Devin B. Malik². ¹Western Michigan University Homer Stryker M.D. School of Medicine, Kalamazoo, MI; ²Western Michigan University School of Medicine, Kalamazoo, MI. (Tracking ID #2194782)

LEARNING OBJECTIVE #1: Recognize that Bouveret's syndrome can manifest in a wide variety of clinical presentations, which includes painless jaundice.

CASE: A 62 year-old female presented with a 3 week history of increasing jaundice, fatigue, and nausea with an associated 15 lb weight loss. The patient denied abdominal pain and abdominal examination was unremarkable. Initial laboratory studies were significant for total bilirubin 9.3 mg/dL, alkaline phosphatase 477 U/L, aspartate aminotransferase 95 U/L, and alanine aminotransferase 111 U/L. Initial ultrasound revealed intrahepatic and extrahepatic biliary dilatation. Magnetic resonance cholangiopancreatography (MRCP) showed a suspected calculus located in the proximal portion of the duodenum with surrounding soft tissue thickening. Endoscopic gastroduodenoscopy (EGD) confirmed a large gallstone in the duodenal bulb which occupied the entire lumen and partially protruded through the pylorus. As this was unable to be removed endoscopically, the patient underwent gastrostomy and removal of a 3.3 cm gallstone. No fistulous tract was appreciated intraoperatively and is considered to have closed spontaneously. Subsequently, the patient was treated supportively and discharged home on post-operative day 7 with resolution of her symptoms and normalization of her laboratory values.

DISCUSSION: Bouveret's syndrome refers to gastroduodenal obstruction from gallstone impaction which occurs in the setting of a cholecystoduodenal fistula. Depending upon the exact location and size of the gallstone, a variety of clinical manifestations are possible. Bouveret's syndrome was first reported in 1896 and remains an uncommon variant of gallstone ileus, for which it comprises only 1–3 % of cases. While a wide variety of presenting symptoms have been reported, to our knowledge no reported case of Bouveret's syndrome has presented as painless jaundice, which in this case was a result of external common bile duct compression. The largest review was published in 2006 by Cappell and Davis where they describe 128 cases. The most common presenting symptoms were nausea, vomiting, abdominal pain, hematemesis, and weight loss. Less commonly, patients reported an absence of abdominal pain in 29 % and Jaundice in less than 2 % of cases. The mean age of patients at diagnosis was 74, and had a female predominance of nearly a 2:1 ratio. As in our case, EGD reveals gastric outlet obstruction in almost all cases; however, the etiology of obstruction can only be determined 69 % of the time. While EGD is useful diagnostically, endoscopic gallstone retrieval is usually unsuccessful due to the size of the gallstone. Thus, treatment of the obstructive process most often requires gastrostomy or enterolithotomy and is 90 % successful.

EXPECTING THE EXPECTED EVEN AT UNEXPECTED TIMES Hirotaka Kato; Nehal Galal; Patricia Dharapak. Mount Sinai Beth Israel, New York, NY. (Tracking ID #2197680)

LEARNING OBJECTIVE #1: Recognize the diverse manifestations of cryoglobulinemia.

LEARNING OBJECTIVE #2: Early consideration of cryoglobulinemia in a patient with HCV and unexplained symptoms.

CASE: A 51 year-old man with a history of untreated HCV diagnosed in 2002, prior heroin abuse on methadone maintenance presented with a 2-day history of hematuria and right upper quadrant pain. The physical exam was significant for mild diffuse discomfort to palpation of the abdomen and no evidence of ascites or peripheral edema. Initial labwork revealed stable normocytic anemia and hepatic function compared to prior values: HB 11.7G/DL, Platelet 251 K/UL, AST 36U/UL, ALT 50 U/L, Total bilirubin 1.8MG/DL, albumin 3.1 G/DL, INR 1.3, HCV-RNA 460978 IU/ML, Genotype 3a. Amylase and lipase were normal. Rapid HIV 1/2AB was nonreactive. BUN 26MG/DL and Cr 1.54MG/DL were elevated from normal values 4 months earlier. Urinalysis was notable for 30 protein, 19 RBC and 11–25 granular casts. Results of an abdominal CT suggested cirrhosis and splenomegaly. A HIDA scan was negative. Despite medical therapy, the patient's abdominal pain persisted and he soon developed non-oliguric acute kidney injury with peak Cr 2.71MG/DL. Repeat urinalysis showed worsening hematuria (>182 RBC) and proteinuria (300) with a spot urine protein/creatinine ratio of 0.97G, fulfilling criteria for nephritic syndrome. There was new microcytic anemia: HB 7G/DL, MCV 78FL and a palpable purpuric rash developed on the patient's extremities with spread to his face and trunk. Additional workup suggested mixed cryoglobulinemia: isolated low C4 (3MG/DL), elevated serum IgM (288MG/DL), elevated RF (249 IU/ML), positive serum cryoglobulin, negative ANA, normal UPEP and serum viscosity.

Renal biopsy showed proliferative glomerulonephritis with cryoglobulin deposits. The patient was treated with plasmapheresis and intravenous pulsed dosed steroids with renal function recovery to BUN 25MG/DL, Cr 0.9MG/DL. He was discharged on an oral steroid taper with plans to initiate outpatient treatment for HCV. Shortly after discharge, the patient was readmitted twice for recurrent episodes of diffuse pulmonary alveolar hemorrhage requiring intubation and plasmapheresis. Fortunately, his clinical course stabilized such that he was finally initiated on Ribavirin and Sofosbuvir with good virologic response to date (HCV-RNA: undetectable IU/ML). His most recent renal function is stable at Cr 1.31MG/DL and his hemoglobin has improved to 11.1G/DL.

DISCUSSION: Cryoglobulins are single or mixed immunoglobulins that undergo reversible precipitation at low temperatures. The clinical manifestations of cryoglobulinemia relate to the type of cryoglobulin involved but all typically cause a syndrome of systemic inflammation in part from immune complex deposition. The mean reported age is 42–52 with a female: male ratio of 3:1. Mixed cryoglobulinemia is commonly associated with chronic inflammatory states and viral infections including HCV and rarely associated with lymphoproliferative disorders. The diagnosis is mainly clinical with supportive laboratory and histology. Cutaneous manifestations are almost always present—typically palpable purpura over dependent areas. Other manifestations can include arthralgias, myalgias, fatigue, peripheral neuropathy, abdominal pain, pulmonary infiltrates and renal disease. As one of the most serious complications, renal involvement manifests early and with an incidence of up to 60 %. Failure to treat may result in renal failure—those with HCV associated disease appear to be at greater risk. Membranoproliferative glomerulonephritis is almost always the histologic lesion in mixed cryoglobulinemia. Isolated proteinuria and hematuria are typical clinical findings. While mixed cryoglobulins are present in >30 % of patients with chronic HCV, the clinical syndrome of cryoglobulinemia remains uncommon. Our case highlights the importance of keeping a high index of suspicion of acute cryoglobulinemia in patients with HCV presenting with nonspecific abdominal pain and acute kidney injury, even when these symptoms precede cutaneous manifestations. Prompt diagnosis and control of the immune phenomena with immunosuppressive medications and/or plasmapheresis and early antiviral treatment of HCV is indicated to prevent catastrophic outcomes. The prognosis in patients with HCV will depend on their response to anti HCV therapy.

EXTENDING THE DIFFERENTIAL FOR CHRONIC COUGH: AN ATYPICAL PRESENTATION OF BACTERIAL ENDOCARDITIS Rachel Solomon²; Aparna Sarin²; Jenny J. Lin¹. ¹Mount Sinai, New York, NY; ²Mount Sinai Medical Center, New York, NY. (Tracking ID #2196114)

LEARNING OBJECTIVE #1: Recognize endocarditis as a potential cause of chronic cough

CASE: A 61 year old man with history of hypertension on lisinopril presented to clinic with 2 months of dry cough that began immediately following the first of five surgeries requiring intubation for vitreous hemorrhage. He worked as an administrator, had a distant smoking history, and drank one alcoholic beverage each night. He denied dyspnea, fevers, chills, and night sweats, but continued to have significant lacrimation from the right eye. He had a history of seasonal allergies and stated that he had found Afrin nasal spray helpful in relieving his symptoms. On exam, his lungs were clear; he had boggy turbinates and cobblestoning of the posterior oropharynx. He was treated for likely postnasal drip with nasal corticosteroids and loratadine. Two months later, he returned with recurrent dry cough off treatment. In the interim, he had seen specialists who had stopped his lisinopril, treated him for cough variant asthma with albuterol, and started him on omeprazole for possible GERD. Exam remained unchanged. The initial regimen was re-started. A week later, the cough persisted and he reported new night sweats. He had no daytime symptoms or increased fatigue. Chest x-ray was negative for pulmonary process, but showed possible tracheal thickening. Subsequent CT scan was completely unremarkable. However, labs showed WBC 12.5 (85 % neutrophils) and hemoglobin drop to 13.3 from 14.9. The following week he returned with daily drenching night sweats. Urine dip was normal. Given absence of localizing symptoms, blood cultures were sent. Within two hours, both bottles grew out gram-positive cocci in chains. The patient was admitted to the hospital where he was found to have a small vegetation on his mitral valve. Cultures later grew out *Streptococcus mitis*. Cough resolved following appropriate antibiotic therapy for infective endocarditis; and the patient has remained symptom free for 11 months.

DISCUSSION: Chronic cough, a dry cough lasting more than 3 weeks, is a common complaint in primary care. When evaluating patients, most internists employ a diagnostic algorithm that guides consideration of the most common diagnoses: upper airway cough syndrome (often due to allergic rhinitis or sinusitis), asthma, GERD and medication side effect (ACE-inhibitors and Angiotensin Receptor Blockers). Where common causes of chronic cough are absent, infective endocarditis—a potentially life-threatening ailment requiring prompt treatment with prolonged antibiotics—becomes an important consideration. Cough is rarely remembered as a presenting symptom of infective endocarditis (IE). However, in both the pre- and post-antibiotic eras, cough has been described as an early

symptom of IE. A review published by Pelletier et al. reports accompanying cough in 8 to 24 % of cases of bacterial endocarditis. Cough secondary to endocarditis is often described as a “tickle,” worse with standing, and improved on lying down. It can be spasmodic; worse in late afternoon and at night. Not much is known about how or why infective endocarditis causes cough. In some cases, progression of valvular disease causes congestive heart failure or embolization to lung results in pulmonary infection. Our patient did not have either of these associated complications. A case report from Mayo Clinic in 1995 describes a similar situation in which a patient presenting with chronic cough and elevated inflammatory markers was found to have IE uncomplicated by either CHF or pulmonary infection. In this patient, as in ours, cough improved within 24 h of initiating antibiotic therapy. This association suggests that bacteremia may, itself, be the etiology for cough in IE. Our patient was worked up and treated appropriately for common causes of chronic cough. However, his cough persisted and he began to display symptoms of systemic disease (night sweats) and changes in his laboratory profile (leukocytosis). In patients presenting with persistent chronic cough, especially when accompanied by “B symptoms” and abnormal laboratory findings, bacterial endocarditis should be a part of the extended differential and ESR, CRP and blood cultures should be obtained.

EXTRAHEPATIC BILIARY ADENOMAS: RARE BUT WITH AGGRESSIVE CLINICAL COURSE Kah Poh Loh; Deborah Nautsch; David Desilets; James Mueller; Vaibhav Mehendiratta. Baystate Medical Center/Tufts University, Springfield, MA. (Tracking ID #2197713)

LEARNING OBJECTIVE #1: Identify the clinical course of extrahepatic biliary adenomas

LEARNING OBJECTIVE #2: Recognize the challenges in the distinction between extrahepatic biliary adenomas vs adenocarcinomas

CASE: Biliary adenomas are rare entities that are usually detected incidentally in gallbladders removed for cholelithiasis or chronic cholecystitis. They can also occur anywhere in the extrahepatic biliary tree. Currently, there is limited understanding of the malignant potential of biliary adenomas involving the extrahepatic tree, and there are no guidelines for management. The aim of our study was to identify all extrahepatic biliary adenomas diagnosed at our tertiary care institution and review the natural course and management. Additionally we performed a literature search on published cases of extrahepatic bile duct adenoma. The pathology database (CoPath) at our institution was used to identify patients with a diagnosis of biliary adenoma or adenomatous change on biopsy or surgical resection specimens from year 2000 to 2013. Pathology results from 8774 cholecystectomies (with or without bile excision) and 1785 bile duct punch biopsies were reviewed. Twenty-three patients with biliary adenomas were identified, arising either in the gallbladder (20/23) or the extrahepatic biliary tree (3/23). All gallbladder biliary adenomas were detected incidentally during cholecystectomy for unrelated indications. Patient's medical records from the three patients with extrahepatic biliary adenomas were reviewed for demographics, clinical presentations, imaging, operative findings and surgical pathology results. The study was approved by the institutional review board at our institution. All three patients with extrahepatic biliary adenomas (2 in common bile ducts, 1 in hepatic duct) were female with a mean age of 74 years. On initial presentation, none of the patients had obstructive jaundice but two of three patients had symptoms of biliary origin. Case 1 had biliary dilation seen on chest imaging and endoscopic ultrasound revealed a sessile adenomatous polyp in the distal bile duct. Patient refused surgery and presented with occlusive biliary stricture and jaundice 5 months after initial presentation. Brush cytology confirmed malignant progression. Case 2 had history of primary sclerosing cholangitis and presented with cholangitis, gram-negative sepsis. A polypoid lesion was seen on imaging in the common hepatic duct and direct cholangioscopy with biopsies confirmed the presence of adenoma with high-grade dysplasia. Patient underwent successful total bile duct resection and hepaticojejunostomy but represented 1 year later with diffuse metastatic disease to the bone, liver and peritoneum. Case 3 presented with symptoms suggestive of gallbladder pathology and was found to have polypoid bile duct lesion on intraoperative cholangiogram. Endoscopic retrograde cholangioscopy showed adenomatous polyp with high-grade dysplasia involving distal common bile duct. Patient underwent distal bile duct resection with choledochojejunostomy but presented with jaundice 4 years after surgery. She was found to have adenocarcinoma involving small bowel in the Roux limb of jejunum and transverse colon.

DISCUSSION: Extrahepatic bile duct adenoma appears to be disease of older patients. In our review of literature, the age of presentation ranged from 15 to 85 years with a mean age of 62.5±16.0 years (male, 60.8±15.6 years; female, 64.6±16.8 years). Affected gender was male in 23 cases and female in 18 cases with gender not reported in 3 cases. Thirteen

cases were reported in the US, 15 in the UK, 13 in Asia with the rest in the Middle East. The most common presenting complaints were abdominal pain, jaundice, fever, pruritus, and abnormal liver tests. Management for extrahepatic bile duct adenoma is not clearly defined. Most patients with CBD adenomas in the reported cases underwent Whipple's procedure. Radiofrequency ablation or photodynamic therapy have been shown to be safe and effective in the management of malignant biliary obstruction and treatment of benign biliary strictures, and may be reasonable alternatives to surgery for removal of adenomas. However, this needs to be further evaluated in prospective clinical trials. Majority of the patients had good short-term outcomes. Five cases (including our 3 patients) had interval malignancy including cholangiocarcinoma, small and large bowel carcinoma. Associations were found with certain malignancies and syndromes either at presentation or follow-up which includes Gardner's syndrome, familial polyposis coli or periampullary carcinoma. In summary, we highlight the rarity of extrahepatic bile duct adenoma with three additional cases from our institution adding to the paucity of literature on the subject. All three patients in our series presented with interval gastrointestinal malignancy. We recommend aggressive surgical intervention and close postoperative surveillance when diagnosis of extrahepatic bile duct adenoma is made.

EXTRANODAL LYMPHOMA IN THE ELDERLY PATIENT Keerthi R. Karamched; Lauren Ludwig, Washington University, Saint Louis, MO. (*Tracking ID #2195143*)

LEARNING OBJECTIVE #1: Recognize the subtle and various presentations of undiagnosed lymphoma in the elderly population.

CASE: This patient is a 73-year-old Caucasian female with a history of hypothyroidism, osteopenia, and hypertension who presented to clinic with lower left thigh pain. Patient reported waking up in the middle of the night with a spasm in her thigh. She immediately jumped out of bed and started walking. After approximately 10 min, her spasm subsided. The first time this episode happened was 8 months prior. The second episode of similar but more severe pain happened 2 months ago lasting about 1 week. She had two more episodes of this spasm and pain. Her pain was described as a sharp left knee pain with radiation to the left groin. Her pain initially used to improve with physical activity, but as time progressed, activity seemed to no longer have an effect. At the time of presentation, the patient reported that her pain episodes were occurring about once every 2 weeks. She denied any fevers, chills, erythema, or swelling. Physical examination showed the patient was afebrile with stable vital signs. Examination showed no significant restriction of range of motion on the left thigh. Physical examination was otherwise unremarkable. X-ray of her left hip showed a marrow replacing process within the femoral shaft with periostitis and cortical thickening. PET scan showed abnormal uptake in vertebrae, ribs, pelvis, femur, and inguinal lymph node. Biopsy of the left femur showed Diffuse Large B-cell Lymphoma.

DISCUSSION: Malignant tumors of the hematopoietic cells and lymphoreticular system are called lymphomas. In general, lymphomas are divided into Hodgkin's and Non-Hodgkin's Lymphoma. Non-Hodgkin's Lymphoma is three times more common than Hodgkin's Lymphoma and has a greater tendency to metastasize to extra-nodal tissues. Up to 20–40 % of Non-Hodgkin's Lymphomas are extra-nodal at the time of diagnosis. Lymphoma has a bimodal distribution of presentation with the first peak of diagnosis in the teens followed by the next peak in people greater than 65 years of age. While nodal disease is more prevalent in younger patients, elderly patients have more extra nodal disease, as was the case in our patient. Commonly involved sites in extra-nodal disease include Intestinal, Vascular, Bone, Bone Marrow, Uterine, Oral, etc. We present a case of extra-nodal Non-Hodgkin's lymphoma in an elderly female which, in this case, had bone involvement. Typically, symptoms of nodal disease include malaise, fevers, weight loss, and drenching night sweats; these symptoms are classified as "B" symptoms which occur in about 50 % of lymphoma presentations. With bone involvement, patients present with bone pain, swelling, palpable mass, neurologic symptoms, or even a pathologic fracture. The differential diagnosis for intermittent muscle spasm and bone pain is fairly broad and can include muscular strain, ligamentous injury, fracture, or malignancy given the intermittent nature and duration of symptoms. The differential for malignancy leading to bone pain includes multiple myeloma, osteosarcoma, lymphoma, chronic osteomyelitis, primary bone sarcoma, leukemic infiltrate, and metastatic cancer. It is most remarkable in our patient that the nature of her complaint was mild and intermittent. She did not have the typical "B" symptoms of lymphoma. Because older patients are more likely to present with extra nodal disease, it is important to recognize that even mild symptoms can be indicative of lymphoma.

FALLING THROUGH THE GAP: FATIGUE AND A LOW ANION GAP AS PRESENTING FEATURES OF MULTIPLE MYELOMA IN A 48 YEAR OLD PATIENT. Andrew Trifan, University of Pittsburgh, Pittsburgh, PA. (*Tracking ID #2196693*)

LEARNING OBJECTIVE #1: Differentiate cancer related fatigue from generalized fatigue.

LEARNING OBJECTIVE #2: Recognize the causes of a low anion gap and that myeloma can present in younger individuals with only anemia as a main feature.

CASE: A 48 year old truck driver presented with a several month history of fatigue and shortness of breath. Aside from a heavy smoking history (60 pack-years), he had no other pertinent past and could not recall the last time he saw a physician. His symptoms started 5 months prior to presentation, around the end of November. They gradually worsened to the point that he could not perform even the most routine tasks at work without becoming severely short of breath. Two separate urgent care centers both diagnosed him with viral bronchitis, and given his smoking history, sent him home with antibiotics each time. The antibiotics did not help and no amount of rest improved his fatigue. He was forced to call off work a few weeks prior to arrival, something he had never done in his career. With an associated 30 lb weight loss over the same time period, he came in to the hospital for evaluation. On arrival his vitals were stable and exam noteworthy for trace diffuse expiratory wheezing and a 2/6 flow murmur at LLSB with the remainder of the exam within normal limits. Pertinent labs included a sodium 121 mEq/L, creatinine 1.0 mg/dL, glucose 120 mg/dL, calcium 8.0 mg/dL, anion gap 2 mEq/L, WBC 6.1, Hgb 5.6 gm/dL, and MCV 110. Malignancy was highest on the differential, however CT chest and stool hemocult were both negative. The low anion gap however was striking, prompting further lab tests. His albumin was 2.6gm/dL and total protein was 15.8 gm/dL. Bone survey did not show any lesions nor did the patient ever mention pain as a symptom. SPEP/UPEP and serum free light chain assay demonstrated an IgG kappa monoclonal protein with an M-spike 7.44, B2 microglobulin of 11 and serum viscosity 4.2. Bone marrow aspirate revealed 95 % plasma cells and circulating plasma cells <10 % of total cells in peripheral blood. He was diagnosed with stage III multiple myeloma as per the International Staging System. He was referred to hematology to begin treatment.

DISCUSSION: Fatigue is a common complaint encountered in the primary care setting. While everyone in their lives at some point feels tired, usually temporally associated with an event and relieved after rest, fatigue from an underlying malignancy is different. It is perceived as more intense, not relieved by rest or sleep and completely interferes with all aspects of living. Up to 40 % of patients with underlying malignant disease report fatigue as an early symptom. In this case, the patient described fatigue that interfered with his ability to do work and that sleeping over 12 h per day did not help. While anemia from malignancy proved to be the reason for his symptoms, it is important in the primary care clinic to consider other common etiologies, like depression. Common teaching in medical school and residency emphasizes the mnemonic CRAB (hyper-Calcemia, Renal insufficiency, Anemia, Bone lesions) as a useful aid in the presentation of multiple myeloma. It is important to recognize that this disorder, associated with aging (median age 66), does not always present with this constellation of findings and care must be taken to not disregard a differential because it does not present in a typical age group or in a classic way. While anemia itself is seen in 80 % of cases, bone pain is present only 50 % of the time, and hypercalcemia or renal insufficiency are even less common. There are also several laboratory features associated with multiple myeloma that are exemplified in this case. The marked anemia stands out as the most striking, however the pseudohyponatremia and elevated MCV, due to elevated proteins, are also remarkable. The low anion gap is of interest as well. Causes of a low anion gap include lab error (most common), a decrease in anions (low albumin) or elevation in cations (elevated proteins, calcium or potassium, or lithium intoxication). An isolated low anion gap is not a sensitive marker for myeloma, however if present in correct clinical context, such as in this patient, further workup clarifying the etiology for the low gap is warranted. To summarize this case, internists need to have a fine tuned ear when patients come in with complaints of fatigue, whether in the hospital or clinic, to help decide how aggressively to pursue a further workup. It is also important to recognize that disorders do not always present in the "classic" ways or in association with mnemonics that have been taught in training, such as this case of myeloma with only anemia, and to remember that even something as trivial as an anion gap can sometimes help make the right diagnosis.

FANCONI SYNDROME AND AKI SECONDARY TO TENOFOVIR THERAPY IN AN HIV PATIENT: A CASE REPORT Mark P. Dresselhouse²; Bassam Bader¹; Ijeoma Nnodim Opara¹. ¹Detroit Medical Center, Detroit, MI; ²Wayne State University School of Medicine, Detroit, MI. (*Tracking ID #2193672*)

LEARNING OBJECTIVE #1: Diagnose Fanconi Syndrome in a patient taking Tenofovir (especially in combination with other medications) for the treatment of HIV

LEARNING OBJECTIVE #2: Recognize that routine monitoring of kidney function is essential in HIV patient

CASE: We describe the case of a 62-year-old woman with a past medical history of hypertension, hyperlipidemia, and HIV (diagnosed in 1997) that presented to our hospital in November 2014 at the request of her primary care physician due to abnormal routine labs. She described a 4-month history of polyuria, polydipsia, nocturia, fatigue, a 10 lb weight loss, dizziness, and changes in vision along with a 9-day history of bilateral proximal thigh pain and weakness. Her follow-up for her routine management was discontinued because the patient lost her health insurance in June 2014. For the last 4 years she has taken Atazanavir, Ritonavir, and Emtricitabine-Tenofovir Diproxil Fumarate (Truvada) with no complications. Her CD4 count the day before admission was 644 with an undetectable HIV RNA level. On admission, she presented with severe hypokalemia (1.9 mEq/L), normal anion gap metabolic acidosis (Bicarbonate 16 mEq/L, Anion Gap 14), and acute kidney injury (Creatinine 1.84 mg/dL, BUN/Cr Ratio 6). Urinalysis showed a pH of 6.5, 1.010 specific gravity, 1+ blood, 2+ protein, and 2+ glucose with fine granular casts in urine sediment. Physical exam was benign except for 4/5 strength on right hip flexion and extension. Bilateral renal ultrasound was negative. The patient was additionally taking lisinopril, atorvastatin, and gemfibrozil. Further labs revealed uricosuria, aminoaciduria, hypophosphatemia, hyperchloremia, and hypomagnesemia. Fanconi Syndrome was diagnosed secondary to Tenofovir treatment for HIV. Patient's HIV medication and lisinopril was discontinued. She was given IV fluids, bicarbonate, potassium, and magnesium replacements. Her creatinine improved and electrolytes stabilized over her 6-day course. She was discharged in stable condition on oral electrolyte replacements and eventually recovered back to her baseline.

DISCUSSION: Tenofovir was approved in 2001 by the FDA for the treatment of HIV. During major clinical trials, renal toxicity was not a significant finding but it was observed in a dose-dependent manner in animal trials. Several case reports in the last 13 years have showed that Fanconi Syndrome, Diabetes Insipidus, and renal toxicity are uncommon but possible reactions to Tenofovir treatment. This case describes yet another patient taking Tenofovir that developed Fanconi Syndrome and AKI with severe symptomatic hypokalemia, hyperchloremic normal anion gap metabolic acidosis and proteinuria. Interestingly, the symptoms that she experienced developed soon after she lost her health insurance. During this time, she was not followed routinely by a primary care physician and obtained her HIV medication through state aid. If she had a way to easily see her doctor, she likely would have, and the progression of her clinical symptoms could have been prevented. Previously published case reports have highlighted the need for routine monitoring of Tenofovir treatment, especially when combined with Ritonavir (which was also taken by the patient). Ritonavir has been shown to increase intracellular concentrations of Tenofovir in the proximal tubule by inhibiting Multidrug Resistance Protein 2 (MRP2) on the apical side of the proximal tubule. This increase in concentration inside the proximal tubule increases the risk of dose-dependent toxicity and tubular damage—necessitating strict monitoring of kidney function. In conclusion, this case further adds to the evidence supporting the need for strict monitoring of renal function while patients are on combination antiretrovirals including Tenofovir. Furthermore, it provides an educational opportunity to physicians, identifying a rare but serious side effect of a commonly used HIV medication.

FAVISM CAUSING METHEMOGLOBINEMIA IN G6PD DEFICIENCY Anupam Kotwal; Rand Nashi; Oliver Marasigan. University of Massachusetts, Worcester, MA. (Tracking ID #219352)

LEARNING OBJECTIVE #1: Recognize the clinical features of hemolytic anemia and methemoglobinemia

LEARNING OBJECTIVE #2: Understand the management of methemoglobinemia in the setting of G6PD deficiency

CASE: A 43 year old Albanian man without any significant past medical history, presented to the hospital with sudden onset intermittent dyspnea, chills and dark urine of 4 days duration. He had started consuming fava beans for the first time in his life, 2 weeks prior to presentation. Examination revealed scleral icterus, conjunctival pallor and sublingual cyanosis. His arterial oxygen saturation (SaO₂) was 86 % on pulse-oximetry but 100 % on arterial blood gas (ABG). This prompted checking a methemoglobin (MetHb) level which was elevated at 8 %. He did not have hepatomegaly or splenomegaly. Laboratory workup revealed hemoglobin of 8 g/dL (14 g/dL at baseline), leukocytosis, hyperbilirubinemia, hemoglobinuria, elevated LDH, high reticulocyte index and low haptoglobin. Peripheral smear demonstrated polychromasia, nucleated RBCs, anisocytosis and spherocytes. EKG, chest x-ray and troponin were unremarkable. Management was initiated with oxygen, RBC transfusion, intravenous fluids and low dose ascorbic acid. During his hospital course of 3 days, leukocytosis resolved and anemia

responded adequately to transfusion. His symptoms, cyanosis and jaundice also resolved and oxygen saturation normalized to 100 % on pulse-oximetry. He was prescribed folic acid on discharge, and provided with a list of medications and foods including Fava beans to avoid. On follow up, he remained asymptomatic, anemia resolved and G6PD level was 1.5 unit/g of Hemoglobin (normal 8–13).

DISCUSSION: Glucose-6-phosphate dehydrogenase (G6PD) deficiency is an X-linked disorder which makes red blood cells (RBCs) more susceptible to oxidant stress. It is the most common enzyme deficiency of the RBCs, affecting approximately 400 million people around the world. The ingestion of Fava beans in these individuals usually triggers acute hemolysis, but is rarely severe enough to cause Methemoglobinemia. Studies report certain medications and infections triggering isolated hemolysis in G6PD deficient adults. A thorough PubMed search yielded only 4 reports of G6PD deficient adults developing both hemolysis and Methemoglobinemia and none of these cases implicated Fava beans as the inciting factor. Our patient demonstrated clinical and laboratory features of hemolytic anemia. The cyanosis, discrepancy between SaO₂ on pulse-oximetry and ABG with a normal paO₂ pointed towards Methemoglobinemia, which was confirmed by elevated MetHb. His Mediterranean descent raised concern for G6PD deficiency. Methylene blue is considered if the patient is symptomatic or if MetHb is greater than 20 %, however it is ineffective and may worsen the hemolysis in G6PD deficiency. Low enzyme level obtained after resolution of acute hemolysis established the diagnosis of G6PD deficiency. The ingestion of Fava beans shortly prior to symptom onset, and resolution of illness on avoidance, implicates it as the oxidant stress. Hemolysis in an adult of Mediterranean descent should raise concern for G6PD deficiency. Heinz bodies and Bite cells are characteristic of these cases but their absence does not exclude the diagnosis. Methylene blue should not be used to manage Methemoglobinemia in diagnosed or suspected G6PD deficiency. Ascorbic acid should be used as antioxidant as it does not require G6PD to reduce MetHb. This case demonstrates the “textbook” presentation of Favism causing hemolytic anemia along with Methemoglobinemia in a G6PD deficient adult, which is unique to the current body of literature.

FLUOROQUIN-OW!-LONES Olivia Van Gerwen. Tulane University Health Sciences Center, New Orleans, LA. (Tracking ID #2198437)

LEARNING OBJECTIVE #1: Recognize the importance of considering drug side effects in creating a differential diagnosis

LEARNING OBJECTIVE #2: Understand the impact of fluoroquinolone-induced tendon rupture on patients, especially the elderly

CASE: A 69-year-old man presented with two days of left lower extremity pain, erythema, as well as bilateral lower extremity weakness. Review of systems was also positive for subjective fevers, chills, night sweats, and rigors during this time. At the time of admission, he was being treated as an outpatient for a recurrent epididymitis/orchitis infection, for which he had received 7 days of levofloxacin therapy. On admission, his vitals were temperature of 99.6, heart rate of 74, respiratory rate of 18, blood pressure of 133/57 and he was saturating 99 % on room air. On exam, he was noted to have a diffusely erythematous, non-edematous scrotum that was extremely tender to palpation. There was no discharge and no ulceration noted on the penis. His left lower extremity had decreased range of motion, was warm to touch, and was edematous on the lateral aspect of the ankle. Notable labs included a WBC count of 19.6 with a neutrophilic predominance of 81 %. Initially these symptoms were thought to be due to a lower extremity cellulitis or septic arthritis of the ankle, so he was started on vancomycin and piperacillin-tazobactam. Throughout the hospitalization, however, his leukocytosis persisted and he began to spike daily fevers to 102. Multiple sets of blood cultures, including those initiated prior to the initiation of broad-spectrum antibiotics, were negative. Orthopedics performed an arthrocentesis that revealed no infective organism. MRI of the left calf and ankle revealed multiple torn ligaments. After many days without any improvement of the patient's fevers, leukocytosis, and ankle pain, the decision was made to stop antibiotics, as the team no longer felt that these symptoms were infectious in origin. Likely, the fevers were secondary to the new antibiotics started during the admission and the ankle symptoms were secondary to fluoroquinolone-induced tendon rupture. After these changes were made, the patient's fevers and leukocytosis improved within days and he was discharged with plans for physical therapy to address his tendon injury.

DISCUSSION: Oral antibiotics are prolific in general internal medicine practice, even in the presence of increased stewardship among practitioners. Since they are so often prescribed in outpatient settings, it can be easy to view them as essentially harmless medications. However, fluoroquinolones can have serious side effects. Patients taking fluoroquinolone antibiotics are four times more likely than the general population to experience Achilles tendon rupture. Such complications can occur days to weeks after the initiation of the antibiotic and can be debilitating enough to merit hospitalization and cause prolonged periods of disability, especially in the elderly. The mechanism of this adverse reaction is not fully understood. When prescribing fluoroquinolones, especially to elderly patients, practitioners should consider potential adverse effects like tendon injury

and the potential disability they could cause. Additionally, drug side effects are an important part of any differential diagnosis, especially in patients recently placed on a new medication.

FROM BAD TO WORSE: RECURRENT FLASH PULMONARY EDEMA FROM NATIVE AORTIC VALVE ENDOCARDITIS Ranjan Pathak¹; Smith Giri³; Paras Karmacharya¹; Ana Abaroa-Salvatierra²; DILLI R. POUEL¹; Sushil Ghimire²; Raju Khanal²; Christian Espana Schmidt². ¹Reading Health System, West Reading, PA; ²Reading Hospital, West Reading, PA; ³University of Tennessee Health Science Center, Memphis, TN. (Tracking ID #2199034)

LEARNING OBJECTIVE #1: Recognize aortic regurgitation as a complication of acute aortic valve endocarditis

CASE: A 71-year-old-man, recently discharged from the hospital with streptococcal agalactiae bacteremia and native aortic valve endocarditis on ceftriaxone, was readmitted with acute onset dyspnea from acute decompensated heart failure. After initial improvement with diuretics, patient developed worsening shortness of breath on day 2 with repeated episodes of flash pulmonary edema. Transesophageal echocardiogram revealed worsening left ventricular ejection fraction (46 to 30 %), severe aortic regurgitation with prolapse of the left and non-coronary cusps and multiple valvular vegetations. He underwent emergent bioprosthetic aortic valve replacement. Ceftriaxone was continued for a total of six weeks.

DISCUSSION: Acute aortic regurgitation (AR) is a life threatening medical emergency that has high morbidity and mortality if not recognized early. Infective endocarditis of the aortic valve can cause valvular destruction and acute regurgitation, which may present as acute flash pulmonary edema. Rapid valve destruction or rupture of peri-valvular abscess into left ventricle can result in acute AR. Acute AR presents with sudden cardiovascular collapse with features of cardiogenic shock like profound hypotension and acute dyspnea. In the setting of new onset or worsening heart failure, the suspicion for acute AR should be high. Diagnosis can be confirmed by echocardiography. Intra-aortic balloon pump is contraindicated for the management of cardiogenic shock in AR. Emergent cardiothoracic surgery evaluation with replacement or repair of the valve is the treatment of choice.

FROM STING TO STEMI: MECHANISMS AND MANIFESTATIONS OF KOUNIS SYNDROME Ryan J. Gosselin; Ian S. Gross. North Shore Medical Center, Salem, MA. (Tracking ID #2199106)

LEARNING OBJECTIVE #1: Recognize Kounis Syndrome as an uncommon entity which initially manifests as common acute coronary syndrome.

LEARNING OBJECTIVE #2: Describe the three variants of Kounis syndrome and the postulated mechanisms that lead to them.

CASE: A 69 year old man with past medical history of hyperlipidemia became unresponsive while driving his car and was discovered by EMS to be hypotensive and with weak pulses. EKG in the field showed ST elevations in leads II, III, and aVF. He was intubated enroute to the emergency department, and placed on a dopamine drip on arrival for a blood pressure of 55/31. Repeat EKG in the emergency department showed ST depressions in II, aVF, V2, V3, V4, and V5. He was given an aspirin suppository, placed on a heparin drip, and transitioned from dopamine to norepinephrine for vasopressor support before being sent for urgent cardiac catheterization. A single 40 % fixed defect was discovered in the patient's RCA with TIMI-3 flow across the lesion; pressure catheter showed an FFR of 0.87 after administration of adenosine. His distal RCA appeared normal, and no other lesions were found. Ventriculogram showed no wall motion abnormalities. No stent was placed. Norepinephrine was rapidly weaned during the catheterization and through his transfer to the ICU. Troponin I elevated to 0.07 after an initial normal finding. He regained consciousness and was extubated shortly after arriving to the ICU. He subsequently recalled having been stung by a "large wasp" minutes prior to getting in his car, with ensuing onset of lightheadedness as he backed out of his parking spot. Yellow Jacket IgE was elevated to 7.36 kU/L.

DISCUSSION: Kounis Syndrome is defined as the concurrence of acute coronary syndromes with platelet activation and mast cell mediated anaphylactic or anaphylactoid reactions. Three variants of this entity have been described: the Type I variant includes patients with normal coronary arteries and no CAD risk factors in whom coronary artery spasm manifests along a spectrum from angina without elevated cardiac enzymes all the way to STEMI with significant myocardial damage. Type II includes those with preexisting but previously stable atheromatous disease, as was the case with our patient, in which the inflammatory cascade induces coronary spasm and/or plaque rupture. The Type III variant includes stented patients in whom in-stent thrombosis develops, with subsequent staining of the thrombotic aspirate showing presence of eosinophils and mast

cells. It appears that inflammatory cells are activated even prior to the coronary event, and that mast cell degranulation precedes the acute coronary event in addition to subsequent infiltration of the culprit lesion. Guinea pig models have shown that pump failure precedes hypotension, showing that vascular permeability and decreased venous return are unlikely the primary causes of depressed cardiac output, and suggesting that the ischemic myocardial damage seen in Kounis Syndrome is a primary event, not just a downstream effect from systemic vasodilation. Certainly the initial presentation of our patient was consistent with cardiogenic shock from right ventricular failure in the setting of inferior STEMI. And though elevated levels of mast cell contents such as histamine, tryptase, and arachadonic acid products are seen in ACS without correlation to an allergic event, it may be a critical threshold level of these mediators that lead to coronary artery spasm and/or plaque rupture in Kounis Syndrome.

FULMINANT TYPE 1 DIABETES MIMICKING ACUTE PANCREATITIS Naoki Matsuura; Hiroko Morisaki; Satoshi Matsunaga; Syunpei Yoshino; Masatomo Kiyota; Hiroshi Imura; Mitsuo Kozuru. Aso Iizuka Hospital, Iizuka, Japan. (Tracking ID #2192667)

LEARNING OBJECTIVE #1: Recognize the clinical features of fulminant type 1 diabetes

LEARNING OBJECTIVE #2: Recognize errors led by the heuristics in the daily practice

CASE: A 36 year-old male with no significant past medical history but who had been drinking excessive amounts of alcohol for several years presented at another hospital with left upper quadrant abdominal pain, vomiting and thirst. The symptoms had started the previous day. He was 173 cm tall and weighed 67 kg, his BMI was 22.4 kg/m². Though the abdominal ultrasound examination was unremarkable, abdominal tenderness and elevated pancreatic enzymes (serum amylase 309 U/L and lipase 793 U/L) resulted in a diagnosis of acute alcoholic pancreatitis. His physician had tried to have him hospitalized but the patient had refused and started taking clear liquid at home. After 4 days, his symptoms worsened and he presented again at his former hospital. Further laboratory tests revealed severe metabolic acidosis (pH 7.119), positive urine ketones by dipstick test, and hyperglycemia (24 mmol/l). His HbA1c was 6.3 % (NGSP). He was hospitalized with a diagnosis of pancreatitis and subsequent hyperglycemia. IV fluids, antibiotics, gabexate mesilate and SC insulin were started. Although his symptoms improved, at his request he was transferred to our hospital 4 days later. Following the fine course on symptoms and normalized laboratory tests we initiated oral feeding and continued insulin therapy but the hyperglycemia persisted. Six days after admission to our hospital, his fasting serum C-peptide level was low (0.04 ng/mL) and a glucagon injection yielded no response. We finally decided on a diagnosis of fulminant type 1 diabetes and after instruction about diabetes and insulin usage he was discharged.

DISCUSSION: Type 1 diabetes is characterized by the inability to secrete insulin resulting from the selective destruction of the pancreatic beta cells. Since 2000, fulminant type 1 diabetes, a novel subtype which occurs abruptly, has appeared in Asia, mostly in Japan. This subtype is characterized by 1) ketosis or ketoacidosis within a week of the onset of hyperglycemic symptoms, 2) a relatively low level of HbA1c on the first visit and 3) elevated pancreatic enzymes. The prevalence of fulminant type 1 diabetes is very rare among Caucasians and tends to be disregarded in Western countries. A nationwide survey in Japan reported some unique findings in this subtype; 71.7 % of the patients had flu-like symptoms; 72.5 % had abdominal symptoms, and 98 % showed an increased level of serum exocrine pancreatic enzymes. Interestingly, only 4.8 % of patients in this subtype were positive for islet-related autoantibody (all of them were positive for anti-GAD antibody), which suggests that this subtype would belong to "type 1B" of the American Diabetes Association classification, an idiopathic form of type 1 diabetes. In this case, prolonged hyperglycemia gave us an important clue and the existence of ketoacidosis at the onset of symptoms supported our suspicions. Ironically, the presentation of a heavy drinker at the hospital complaining of abdominal pain with elevated pancreatic enzymes artfully mimicked that of acute alcoholic pancreatitis and misled the physician. To make matters worse, the facts that the patient had already been diagnosed and his symptoms had improved, clouded our judgment. In other words, "confirmation bias" was precipitated by the presentation of the patient and our "anchoring and adjustment" was largely a waste of time. Reference: Imagawa A, Hanafusa T, Uchigata Y, et al. Fulminant Type 1 Diabetes: A nationwide survey in Japan. Diabetes Care 2003; 26(8): 2345-2352

FUNGUS FUNGUS EVERYWHERE! Michelle O. Forson¹; Sathish kumar Krishnan²; Navdeep Kaur¹. ¹Presence St Francis Hospital, Evanston, IL; ²St. Francis Hospital, Evanston, IL. (Tracking ID #2180818)

LEARNING OBJECTIVE #1: Emphasizing the rising incidence of invasive aspergillosis in non neutropenic patients.

LEARNING OBJECTIVE #2: Recognizing the role of a short course of steroid therapy in the development of invasive aspergillosis.

CASE: A 79 year old female presented with a 3 day history of rash over her back which developed following a course of ciprofloxacin for her urinary tract infection. Her past medical history includes diabetes mellitus, COPD and congestive heart failure. Physical examination revealed desquamating maculopapular rash involving the anterior and posterior torso with ulcers in her oral mucosa. We made a diagnosis of Steven Johnson Syndrome and started intravenous methylprednisolone 80 mg every 12 h with intravenous immunoglobulin. On day 3 of admission, she developed cough and dyspnea. Physical examination showed bibasilar crackles and chest X-ray revealed bibasilar infiltrates. She was treated with intravenous aztreonam and vancomycin for suspected hospital acquired pneumonia. As the patient's skin and mucosal lesions improved, we tapered her dose of methylprednisolone to 40 mg daily. Her dyspnea however continued to worsen and she developed encephalopathy and acute kidney injury. A CT scan revealed consolidation of the lower lobe of left lung. A bronchoscopy with broncho-alveolar lavage was performed. Smear from broncho-alveolar lavage (BAL) showed many polymorphonuclear leukocytes, gram positive cocci in clusters and rare *Aspergillus* mold. Legionella antigen was negative. Therapy with Tigercycline and Voriconazole was instituted. Nevertheless, her overall condition worsened: she developed multiorgan failure with features of disseminated intravascular coagulation and expired. Autopsy revealed invasive pulmonary aspergillosis with extensive hematogenous dissemination to the stomach, spleen, brain and heart (including septic embolic in coronary vessels and concomitant myocardial infarction). Culture from the BAL identified the *Aspergillus* specie as *Aspergillus flavus*.

DISCUSSION: Invasive Aspergillosis (IA) is a severe fungal infection with progression across tissue planes. *Aspergillus fumigatus* accounts for 67 % of IA cases. Our patient had *Aspergillus flavus* which accounts for about 10–13 % of IA cases. Experimental data on *A. flavus* also suggests it is more virulent than *A. fumigatus*. IA is relatively common in neutropenic patients; however our patient's absolute neutrophil count was between 1900 and 10,000 during her admission. Invasive Aspergillosis has a high mortality rate (50–80 %); and a few studies show an even higher mortality in non neutropenic patients. Current recommendations though, do not include prophylaxis for non-neutropenic patients. The higher mortality rate seen in non neutropenic patients is partly due to the difficulty in diagnosing IA in this population, especially considering the ubiquitous nature of *Aspergillus*. The diagnosis of IA is usually based on clinical probability as well as isolation of the organism. However clinical probability is founded on the presence of risk factors and clinical features. The traditional invasive aspergillosis risk factors clinicians are conversant with include; neutropenia, hematologic malignancies, organ transplant, liver cirrhosis, and immunosuppression. Long-term steroid use (greater than or equal to 30 days) is a widely accepted risk factor for IA. However, IA is considered a rare complication in patients who have received intense immunosuppressive regimen used to treat autoimmune disorders, but have not undergone transplantation. Nevertheless, it is likely in our patient that short course steroid therapy was a predisposing factor. Our patient received only 10 days of steroids before developing fulminant pulmonary features. Invasive aspergillosis is an emerging cause of mortality in non neutropenic patients with nontraditional risk factors including short course steroid therapy. Therefore, a high index of suspicion will aid in the diagnosis and initiation of appropriate antifungal therapy.

GASTRIC BYPASS...THE START OF A CHAIN REACTION Amy H. Farkas¹; Kevin Kraemer². ¹UPMC, Pittsburgh, PA; ²University of Pittsburgh Medical Center, Pittsburgh, PA. (Tracking ID #2198090)

LEARNING OBJECTIVE #1: Recognize the risk of alcohol use disorders (AUD) after gastric bypass surgery

LEARNING OBJECTIVE #2: Assess other etiologies for cirrhosis in patients with AUD

CASE: A 36 year-old woman with Roux-en-Y gastric bypass 7 years ago presented with worsening ascites and leg edema. She did well after gastric bypass until 1 year ago when she started drinking heavily, progressing to "one-fifth" hard liquor daily. She stopped alcohol use completely 8 months ago after she was diagnosed with Wernicke-Korsakoff syndrome. One month ago, she presented to an outside hospital with new ascites. Outside work-up revealed a CT scan with hepatic steatosis and cirrhosis, AST 41 IU/L, ALT 15 IU/L, negative hepatitis A, B, and C titers, and negative mitochondrial and anti-smooth muscle antibodies. She was diagnosed with alcoholic cirrhosis. Upon presentation to our service, she reported increasing abdominal and leg swelling. Family history included a niece with Wilson's disease. Our exam revealed ascites, pitting leg edema, and poor short-term memory. She did not have Kayser-Fleischer rings but no slit-lamp exam was done. A diagnosis of Wilson's disease was confirmed by laboratory evaluation: ceruloplasmin 13.2 mg/dL (normal 22–58 mg/dL) and 24-h urinary copper 139 ug (normal 20–65 ug).

DISCUSSION: With over 1/3 of the US population qualifying as obese¹, more patients are being considered for gastric bypass surgery. Evidence suggests that AUD increase after

gastric bypass surgery, specifically Roux-en-Y procedures. A prospective cohort study of 1945 adults undergoing gastric bypass surgery found the prevalence of AUD was significantly higher in the second postoperative year (9.6 %) compared to the year prior to surgery (7.6 %, $p=0.01$)². Patients who were male, younger, smokers, had regular use of alcohol prior to surgery or prior recreational drug use, had lower sense of belonging, or had Roux-en-Y compared to gastric band procedures were more likely to develop AUD. A recent study found that 7 % of patients at year 1 and 6 % of patients at year 2 develop new high risk drinking behaviors following gastric bypass; however the overall rate of AUD was unchanged from baseline³. Gastric bypass, particularly Roux-en-Y, alters alcohol metabolism resulting in higher blood alcohol concentrations and longer time to return to sobriety^{4–5}. This may place patients at risk for developing AUD. While patients are screened for AUD prior to undergoing gastric bypass, it is important to provide education to patients regarding changes in alcohol metabolism after bypass and to continue screening these patients for AUD as they may represent a high risk group. This case also illustrates the importance of assessing for other etiologies of cirrhosis, even in patients with known AUD. In our patient, the relatively brief (<6 months) period of reported heavy alcohol use should have raised suspicion for an additional etiology. Ultimately, she was diagnosed with Wilson's disease. While her elevated AST/ALT ratio was considered evidence of alcoholic cirrhosis, this ratio is also elevated in Wilson's disease, particularly in patients with acute liver failure⁶. In individuals under 40 years-old, Wilson's disease should be considered as it tends to present at younger ages⁷. In this patient, the interaction of AUD and Wilson's disease possibly led to a more accelerated course to cirrhosis. Further, Wilson's disease may have contributed substantially to her cognitive impairment, which was initially thought to be secondary to gastric bypass-related nutritional deficiencies and AUD. GASTROINTESTINAL TRACT INVOLVEMENT IN A PATIENT WITH SYSTEMIC AL AMYLOIDOSIS. Dhruvan Patel¹; Aparna Basu¹; Smarika Sapokota¹; Indumathy Varadarajan². ¹Mercy Catholic Medical Center, Philadelphia, PA; ²Hanemann University Hospital, Philadelphia, PA. (Tracking ID #2200278)

LEARNING OBJECTIVE #1: Gastrointestinal amyloidosis should be considered as a differential diagnosis in a patients with unexplained chronic gastrointestinal symptoms.

LEARNING OBJECTIVE #2: Congo Red Staining of biopsy specimen should be considered a routine for patients undergoing endoscopy directed biopsy for chronic gastrointestinal symptoms associated with unintentional weightloss

CASE: Thirty-nine year old man with B/L carpal tunnel syndrome presented with 4 month history of nausea, vomiting, abdominal bloating, non bloody diarrhea. His symptoms were intermittent with a loss of ten pounds in 3 months. He denied any loss of appetite. He denied any bone pain. He had previously been treated with omeprazole with no relief. CT abdomen and pelvis was negative for any acute pathology. His physical examination was unremarkable. Given chronicity of symptoms, he underwent upper endoscopy, which showed mild gastric inflammation. Biopsy of the gastric antrum showed amorphous eosinophilia proteinaceous material which appeared apple green refringent under polarized light with congo red stain, consistent with gastric amyloidosis. Further evaluation showed a high kappa light chain level of 4090 mg/l with low lambda light chain level of 3 mg/l and a high free kappa to lambda ratio of more than 1000. Bone marrow biopsy was done which demonstrated increased plasma cell. Flow cytometry of bone marrow biopsy showed 11.9 % of monoclonal plasma cells with cytoplasmic kappa light chain. A skeletal survey was negative for lytic lesions. Thus final diagnosis of gastrointestinal involvement with immunoglobulin Kappa chain amyloidosis was made. He was started cyclophosphamide, bortezomib and dexamethasone. Following initiation of treatment his kappa light chain level decreased from 4090 to 700 and his symptoms gradually resolved.

DISCUSSION: AL amyloidosis is caused due to deposition of protein derived from immunoglobulin light chain fragments in different tissues, resulting in disruption of tissue

structure or function. It is usually caused by an underlying monoclonal plasma cell dyscrasia. It can be systemic involving different organ system or localized to a single organ. However, GI involvement is very rare. GI involvement in amyloidosis is defined as the presence of GI symptoms with direct biopsy verification. In a large series of patients with AL amyloidosis 8 % of 769 patients had biopsy proven disease and 1 % were symptomatic. The symptoms vary from GI bleeding, malabsorption, protein losing enteropathy to chronic gastrointestinal dysmotility presenting as nausea, vomiting, constipation or diarrhea. These symptoms are believed to be due to mucosal infiltration and neuromuscular infiltration of the bowel by amyloid. Treatment of the underlying plasma dyscrasia leads to resolution of symptoms of the organs affected by amyloidosis. As seen in our case the patient's symptoms resolved as his free kappa chain levels decreased. The underlying plasma cell dyscrasia in our patient was immunoglobulin light chain disease. The definitive treatment of immunoglobulin light chain disease is hematopoietic stem cell transplant. Patients who are ineligible for hematopoietic stem cell transplant can be treated with mephan plus dexamethasone or bortezomib based regime such as CyBORd (cyclophosphamide, bortezomib, dexamethasone). Most patients have good response to therapy and an excellent median-survival. But untreated and undiagnosed AL amyloidosis is invariably fatal. Our case highlights that gastrointestinal amyloidosis should be considered as a differential diagnosis in a patients with unexplained chronic gastrointestinal symptoms.

GENDER INEQUALITY? A CASE OF AORTIC DISSECTION PRESENTING AS ALTERED MENTAL STATUS IN AN OTHERWISE HEALTHY 46 YEAR OLD WOMAN Devin B. Malik; Akshay Amaraneni; Sukhpreet Singh; Sourabh Aggarwal. Western Michigan University School of Medicine, Kalamazoo, MI. (Tracking ID #2197569)

LEARNING OBJECTIVE #1: To recognize that the classic signs and symptoms of aortic dissection are typically absent in females

CASE: A 46 year old lady with a 60-pack-year smoking history presented to the emergency room with a one day history of numbness and tingling in her right face with progressed to confusion, agitation within hours. Non-contrast computed tomography (CT) of the head was negative for hemorrhage and Magnetic Resonance Imaging (MRI) of the brain was ordered to evaluate for stroke. The patient became unresponsiveness on the table with vitals and exam consistent with impending cardio-pulmonary collapse. She was subsequently intubated and started on an epinephrine drip. Physical exam showed facial plethora, non-collapsing internal jugular veins, and skin mottling from chest cephalad. No murmurs or extra heart sounds were auscultated. A chest radiograph, electrocardiogram, complete blood count, electrolyte panel and cardiac enzymes were all normal. Patient had a stat CT chest done to evaluate for possible pulmonary embolism. Surprisingly, a 4.6 cm type A dissecting thoracic aneurysm with pericardial tamponade was discovered. She was taken for emergency surgery where a Dacron sleeve was placed. Patient remained on vasoactive-pressor support for 24 h and eventually died of disseminated intravascular coagulation.

DISCUSSION: Aortic Dissection is a life threatening condition that classically presents as tearing chest pain in a middle aged hypertensive man with a pulse deficit. Women, however, often present without the above classic symptoms which unfortunately leads to a delayed diagnosis and increased mortality. Clinicians often rely on classic symptoms of sudden tearing chest pain that occur in a 40-70 year-old man with hypertension and atherosclerotic disease. The objective findings of a pulse deficit, widening of the mediastinum on radiograph are common findings in men. Gender-related differences in aortic dissection are often overlooked and an international registry was created and published in *Circulation* in 2004. Most notably women with aortic dissection were older, waited a longer period before first medical contact, were diagnosed later in the hospital and had a higher in hospital mortality than their male counterparts. Furthermore, women presented with altered mental status and had higher complications of pericardial effusion and tamponade. In our case, the patient was fairly young and without hypertension and dyslipidemia. The etiology of her thoracic aortic aneurysm remains unknown. She was not tested for syphilis and there was no reported family history of collagen disorders. This case highlights the importance of educating clinicians about gender related differences in the presentation of acute aortic dissection.

GETTING INTO THE GROOVE: A RARE TYPE OF PANCREATITIS Sarah Fishman; Dmitry Kozhevnikov. Lenox Hill Hospital, New York, NY. (Tracking ID #2200764)

LEARNING OBJECTIVE #1: Describe a rare type of segmental pancreatitis

LEARNING OBJECTIVE #2: Understand the presentation and diagnosis of groove pancreatitis

CASE: A 61 year old male with a history of heavy alcohol use and multiple admissions for chronic pancreatitis presented with a 4 day history of nausea and vomiting. Nine months

earlier he had been evaluated by his primary care doctor for a one month history of progressive jaundice. Initial workup revealed a cholestatic elevation in liver enzymes and a direct bilirubinemia. MRCP suggested distal common bile duct stricture. ERCP confirmed this finding and suggested possible cholangiocarcinoma or pancreatic adenocarcinoma. Tumor markers including CA 19-9 and CEA were normal. A biliary stent was placed and jaundice resolved. Subsequent ERCP to exchange the stent revealed chronic calcified pancreatitis and adenopathy in the peripancreatic and porta-hepatis areas with persistent distal common bile duct stricture. Biopsies were taken from the pancreatic head which were suggestive of chronic pancreatitis but were negative for malignant cells. On this admission, blood-work revealed profound hypokalemia and a severe metabolic alkalosis along with elevations in alkaline phosphatase, GGT, and bilirubin while amylase and lipase were normal. Abdominal CT with oral contrast revealed partial gastric outlet obstruction. A nasogastric tube was placed to decompress the stomach. Repeat MRCP was notable for gastric outlet obstruction and a pancreatic head mass involving the second portion of the duodenum. Repeat ERCP showed partial obstruction in the duodenal cap with edematous folds. Biopsies were again taken from the head of the pancreas, which were negative for malignancy. Tumor markers CA 19-9 and CEA were again normal. The decision was made to place a PEJ tube for patient nutrition and a venting PEG tube was placed for oral liquid intake. The patient was started on prednisone to reduce pancreatic inflammation and was discharged to a subacute rehabilitation facility. Patient was readmitted 5 days later with biliary sepsis and once stabilized, was evaluated for gastrojejunostomy and transferred to the surgical service.

DISCUSSION: Paraduodenal pancreatitis, also known as "Groove pancreatitis" is a rare type of segmental pancreatitis affecting the potential space between the head of the pancreas, the duodenum, and the common bile duct. The clinical manifestations and the radiographic appearance of this entity make it a diagnostic challenge. A rare condition in the US, groove pancreatitis is associated with male gender and alcohol abuse. This variety of pancreatitis can mimic the effects of a pancreatic mass and can cause biliary and gastric outlet obstruction. The diagnosis is frequently delayed by concern for malignancy due to its imaging characteristics and functional biliary obstruction.

GETTING TO THE HEART OF IT: AN UNEXPECTED METASTASIS OF A COMMON MALIGNANCY Nicole R. Zeisig; Ahmed Ansari; Jill Grounds; Shima Mousavi; Neda Zarrin-Khameh; Chirayu Shah. Baylor College of Medicine, Houston, TX. (Tracking ID #2194836)

LEARNING OBJECTIVE #1: Diagnose newly discovered cardiac masses

LEARNING OBJECTIVE #2: Recognize cervical cancer as a rare cause of metastatic cardiac tumors

CASE: A 51 year old woman presented with 1 month of progressive dyspnea on exertion, increasing abdominal girth and 20 lbs weight gain. She denied fevers, night sweats, nausea, vomiting, chest pain, orthopnea, paroxysmal nocturnal dyspnea, cough, abdominal pain, change in bowel habits, or bleeding. She was found to have significant JVD, clear lungs, hepatomegaly, abdominal distension, and lower extremity edema. Labs were remarkable for a platelet count of 10 K/uL, BNP of 937 pg/mL, and LDH of 904 U/L. EKG was notable for low voltage without ischemic changes or right-sided strain. The echocardiogram showed an 8x5 cm mass occupying most of the right ventricle with extension into the tricuspid and pulmonic valves. Further imaging with CT Chest showed similar right ventricular findings, a moderate pericardial effusion, and multiple bilateral pulmonary emboli. CT of the abdomen and pelvis showed small ascites, but no other masses. The patient underwent a right heart catheterization for biopsy of the mass. Immediately after the biopsy the patient went into PEA arrest and died. Autopsy showed the mass to be metastatic non-keratinizing squamous cell carcinoma of the uterine cervix. The cervix appeared nodular and erythematous with lower uterine segment narrowing but no distinct masses.

DISCUSSION: The discovery of cardiac masses can lead to diagnostic challenges as direct biopsy of the mass can be associated with significant complications. Metastatic disease to the heart is 40 times more common than primary cardiac tumors. Therefore, extensive imaging and age-appropriate cancer screening should be performed to identify another source amenable to biopsy. The incidence of cardiac metastases in cancer patients at autopsy ranges from 1.5 to 20.6 % (average of 6 %). Intracavitary growth of secondary heart tumors is unusual. In a retrospective study of over 12,000 autopsies, the three most common secondary cardiac tumors originated from lung, esophagus, and lymphoma. For women, metastatic breast cancer should also be considered. Most cardiac metastases are found at autopsy, but reported antemortem cases have presented with cardiac arrhythmias, heart block, heart failure, valvular or intracavitary obstruction, pericardial effusions, and pulmonary embolisms. Metastases from uterine cervical cancer have decreased drastically due to routine Pap tests, but when present most often involve lung, bone, and cervical or supraclavicular lymph nodes. Cardiac metastasis from uterine cervical cancer is extremely rare with an incidence of 3-4 % on autopsy. Only a handful of cases of cervical cancer have presented with cardiac metastasis as their first presentation. This case represents the first reported patient in which cervical cancer manifested with an isolated cardiac mass without

a discrete cervical mass. Because this condition is usually associated with widely metastatic disease and carries such a grave prognosis, a limited number of case reports describe antemortem diagnoses of cardiac metastasis from cervical cancer, and even less data exist to guide life-prolonging therapies.

GETTING TO THE HEART OF LOWER BACK PAIN Julie Burgess. UCSF, San Francisco, CA. (Tracking ID #2199038)

LEARNING OBJECTIVE #1: Recognize vertebral osteomyelitis as a commonly subtle clinical syndrome often without findings classically associated with infection

LEARNING OBJECTIVE #2: Appreciate the role of erythrocyte sedimentation rate (ESR) in the initial evaluation of complicated lower back pain

CASE: A 76 year-old man with hypertension and depression presented with 2 weeks of lower back pain. He reported the gradual onset of progressively worsening, constant, non-radiating left lower back pain that was aching at rest and sharp with movement. Pain was most severe with movement and at night, interfering with sleep. He tried Ibuprofen, Hydrocodone-Acetaminophen, and warm compresses without improvement. He denied preceding trauma. For the 4 days prior to presentation he had been nearly bedbound because of pain, whereas at baseline he would bike for one hour per day. He noted a 10 to 15 lb weight loss over the month prior to presentation, significant fatigue, decreased appetite, and depression. He denied lower extremity weakness, sensory change, incontinence, fever, or history of intravenous drug use. He was afebrile and appeared uncomfortable due to significant pain with movement. He had a II/VI systolic murmur. He had mild tenderness over the left lumbosacral paraspinal muscles, with no spinal tenderness. Straight leg raise was negative bilaterally, with normal strength, sensation, and rectal tone. Initial evaluation showed a white blood cell (WBC) count of $9 \times 10^9/L$ and X-Ray of the lumbar spine showed severe osteoarthritis, but was otherwise unremarkable. After 3 days, his pain had not improved, and he was noted to have a diastolic murmur. ESR obtained at that time was >100 mm/h and C Reactive Protein (CRP) was 95 mg/L. Two of two blood cultures grew *Viridans Streptococcus*. MRI of the lumbar spine showed osteomyelitis and discitis of L4/5 with a large epidural phlegmon extending into the left psoas. Transthoracic and transesophageal echo demonstrated new moderate to severe aortic insufficiency without vegetation. He was diagnosed with vertebral osteomyelitis secondary to aortic valve subacute bacterial endocarditis.

DISCUSSION: Back pain is one of the most common complaints in outpatient medicine, with approximately 95 % of cases attributable to a mechanical etiology. Vertebral osteomyelitis is a rare but serious cause of back pain commonly initially misdiagnosed as mechanical in nature, which often leads to a delay in diagnosis. As seen in this case, approximately 30 % of patients with pyogenic vertebral osteomyelitis have associated endocarditis. The red flags of acute lower back pain include not only the neurologic signs and symptoms heralding cauda equina or acute cord compression, but also constitutional symptoms, fever, weight loss, nocturnal pain, and spinal tenderness which may be associated with malignancy or infection. Forty to sixty-five percent of patients with vertebral osteomyelitis have a normal WBC count, and fewer than 33-50 % have fever. Plain films of the spine are normal in up to 50 % of patients, particularly early in the course. The vast majority of patients with back pain due to osteomyelitis have an elevated ESR, and more than half have positive blood cultures. Joint clinical practice guidelines published by the American College of Physicians and the American Pain Society recommend consideration of ESR as part of the initial evaluation of patients with lower back pain and indicators of a potentially serious condition, which include history of malignancy, unexplained weight loss, age over 50, fever, intravenous drug use, or recent infection. ESR is a relatively inexpensive and sensitive test for pyogenic vertebral osteomyelitis (sensitivity of 85 %) and should be strongly considered in the initial evaluation of complicated lower back pain and of pain not improved after 4–6 weeks of conservative management. Infection and malignancy are highly unlikely with a normal ESR. If ESR is found to be elevated, the next step in evaluation should be spine MRI.

GI BLEEDING IN SYSTEMIC SCLEROSIS Jianhua A. Tau; Andrew Caruso; Jeffrey T. Bates. Baylor College of Medicine, Houston, TX. (Tracking ID #2200300)

LEARNING OBJECTIVE #1: Recognize the association of Systemic Sclerosis (SSc) and Gastric Antral Vascular Ectasia (GAVE)

CASE: A 38 year old female with a history of diffuse Systemic Sclerosis on prednisone (5 mg daily) presents with a two month history of worsening dyspnea on exertion, fatigue and exercise intolerance. She was diagnosed with Systemic Sclerosis within the past year after developing characteristic skin changes on her face and extremities. She was started on prednisone alone and tapered gradually over the past 6 months. Clinically, she had improvement in her skin tightness, but developed very subtle but progressive dyspnea on exertion and fatigue. She denies dysphagia and significant weight loss. On exam, she is pale but without icterus. Her skin exam reveals no new changes. Her heart, lung and

abdominal exam are benign. She has no organomegaly. A rectal exam does not reveal gross fresh blood or melena. A complete blood count and ferritin revealed a new microcytic anemia consistent with iron deficiency anemia. Hemoglobin was 6.9 g/dL, MCV was $71 \mu m^3$, ferritin was 16 ng/mL. She denies NSAID use, hematochezia, hematemesis, hematuria, menorrhagia, jaundice, personal or family history of bleeding disorders. Her family history is significant for fatal gastric cancer in her mother at the age of 50. An endoscopy was done which revealed severe Gastric Antral Vascular Ectasia (GAVE), which was promptly treated with argon plasma coagulation with success. The patient required no further therapy besides iron supplementation. Her anemia improved and notably resolved after 3 months.

DISCUSSION: Gastric Antral Vascular Ectasia (GAVE) is an uncommon and poorly-understood gastrointestinal manifestation of Systemic Sclerosis (SSc) which can lead to chronic anemia. On endoscopy, characteristic dilated small blood vessels are found in the antrum radiating out from the pylorus. These dilated or ectatic vessels result in intestinal bleeding and also give the characteristic “watermelon stomach” appearance as the the long red vascular ectasias resemble closely the markings on watermelon. The gastrointestinal manifestations of SSc are numerous and can affect the GI tract from mouth to anus. They include dental caries, Sicca syndrome, hypomotility (diffuse), gastroparesis, esophageal stricture, GERD, PUD (prednisone, NSAID), colonic pseudo-diverticula and pseudo-obstruction. Specifically, the differential diagnosis of GI bleeding in a patient with SSc should focus on peptic ulcer disease (chronic corticosteroids), GAVE, and pseudo-diverticulosis. Unfortunately, the mechanisms for the development of GAVE is not clear. GAVE has well-known associations with cirrhosis, but transjugular intrahepatic portosystemic shunting (TIPS) to resolve portal hypertension has notably not resolved GAVE, which indicates that the mechanism is not portal hypertension. A less appreciated association is that of SSc and GAVE. While GAVE is an uncommon itself, it has a significant association with SSc. In a recent large retrospective study of 264 patients with SSc found a prevalence of 5.7 % [1] In the SCOT trial (Scleroderma Cyclophosphamide Or Transplant study), where asymptomatic deSSc patients had to be screened with an endoscopy before entering the study, 10.8 % of them had silent GAVE [2]. While the vast majority (80–90 %) of patients already carry the diagnosis of SSc before GAVE manifests itself [3], it can be the initial manifestation of the disease [4,5]. GAVE is often diagnosed early in the course of the disease when presenting with symptomatic anemia. As in our patient, this typically within the first 3 years from diagnosis [6].

GOUT MIMICKING OSTEOMYELITIS Ming Zhao; Mohammad Jawish; Gerald Ryan; Michael DiSalle. Unity Hospital, Rochester Regional Health System, Rochester, NY. (Tracking ID #2193781)

LEARNING OBJECTIVE #1: Recognize the common clinical as well as radiological findings of acute gout

LEARNING OBJECTIVE #2: Distinguishing acute gout from osteomyelitis

CASE: Patient is an 86 year old female, with diagnosis of hypertension, hyperlipidemia and type II diabetes, was admitted with a 4 to 5 days history of painful and erythematous second toe of the right foot. Patient was treated for cellulitis as outpatient with oral antibiotic without any improvement. Patient denies any fever or other joint pain. No history of gout or prior similar episodes. On physical examination, her vital signs were within the normal range. Cardiovascular, respiratory and abdominal exam were normal. The second toe of right foot was severely tender and erythematous. Laboratory data revealed WBC of 10600, ESR of 66 mm/h and CRP of 1.65 mg/L. Two sets of blood cultures were negative. Plain radiography of right foot was normal. Right foot MRI was done, with radiology report showing moderate soft tissue swelling of the second digit and enhancing bone marrow edema involving the middle and distal phalanges, concerning for osteomyelitis. No tophi were identified on MRI. Patient refused joint aspiration due to severe pain. Given the MRI finding of bone marrow edema consistent with osteomyelitis, a diagnosis of second toe osteomyelitis was made and patient was started on intravenous Vancomycin and Cefepime. However, despite adequate antibiotic coverage, the patient did not respond to treatment and continued to have a severely tender and erythematous toe. Serum uric acid was checked and it turned out to be elevated at 11.3 mg/dl. Acute gouty arthritis was suspected and patient was treated with ibuprofen and colchicine. Within 24 h, the patient showed striking improvement of her symptoms. This was unusual for osteomyelitis and further supported our suspicion of gout. Antibiotics were stopped and patient was discharged. One month follow up showed no recurrence of symptoms.

DISCUSSION: Gout is the most common inflammatory arthritis in the United States and its prevalence has increased dramatically in the past several decades. Factors contributing to increased gout prevalence include the aging population, kidney disease, and changes in dietary habits. Acute gouty arthritis may be clinically difficult to distinguish from infection. The two conditions may present with similar signs and symptoms, including joint pain, swelling, erythema and sometimes systemic illness with fever, elevated WBC and ESR. Plain radiographs may be useful to distinguish gout from infection when typical

findings of gout are present, such as punched out lesions in the subchondral bone representing areas of urate deposition, or, in some patients, massive and joint-destroying tophi indicating a chronic history of gout in the past. Rarely, the expansive and destructive radiologic findings associated with gout may be mistaken for osteomyelitis and have sometimes led to erroneous amputation of involved digits. Isabelle Rousseau reported five patients with acute gout who presented with clinical as well as radiological findings mimicking septic arthritis or osteomyelitis. Two patients underwent digit amputation for not responding to antibiotic treatment and had histological findings confirming the diagnosis of gout. In our case, the initial diagnosis of osteomyelitis was made due to the MRI finding of bone marrow edema, which was concerning for osteomyelitis. However, it is also not unusual for acute gouty arthritis to present as bone marrow edema on MRI. Poh YJ have studied a total of 47 patients with gout. Fifty-three percent of the patients showed MRI finding of bone marrow edema. Other MRI features included tophi, erosions, synovitis, tenosynovitis and tendinosis. Patients suspected of acute gout should undergo arthrocentesis. The diagnosis of acute gout is most secure when supported by visualization of urate crystals under polarized microscopy in a sample of fluid aspirated from affected joint. In patients whom crystal confirmation of the diagnosis cannot be made, such as our patient who refused joint aspiration, a provisional diagnostic impression may be made on the basis of clinical criteria, as illustrated by American College of Rheumatology criteria for the classification of gout, including history, physical examination, laboratory tests and imaging studies. A quick and striking improvement to empirical treatment of gout may also argue against infection and help with differential diagnosis. Appropriate diagnosis of gout, as demonstrated in our case, results in different and definitive treatment choices, and spares the patient from further unnecessary antibiotic therapy or surgery. Thus, it is important for the internist and the radiologist to be aware of the radiological manifestations of acute gout that can resemble infection in order to avoid inappropriate diagnosis and delay in adequate treatment.

GREEN SPUTUM IN PRIMARY SCLEROSING CHOLANGITIS Gwen Thompson; Douglas A. Simonetto; William Sanchez. Mayo Clinic, Rochester, MN. (Tracking ID #2197978)

LEARNING OBJECTIVE #1: Recognize bronchobiliary fistula as a cause of chronic cough in patients with biliary obstruction.

LEARNING OBJECTIVE #2: Diagnose and manage bronchobiliary fistulas. **CASE:** A 44-year-old Caucasian female with a history of primary sclerosing cholangitis-autoimmune hepatitis overlap presented with a chronic productive cough of 4 months duration. The patient was initially diagnosed with *Escherichia coli* bacteremia and pneumonia secondary to ascending cholangitis 4 months prior to presentation. At that time an endoscopic retrograde cholangiopancreatogram (ERCP) was completed that demonstrated a large amount of debris and purulent material in the intra- and extrahepatic biliary trees with multiple strictures. Bilateral biliary stents were placed at this time. Despite appropriate antibiotic therapy, the patient continued to have a chronic cough. Her sputum production continued to increase and changed in coloration from yellow to green six weeks prior to presentation. During this time course, the patient was treated with multiple courses of antibiotics as an outpatient with no improvement. The patient was admitted for inpatient evaluation and treatment. Review of systems was significant for chronic cough, occasional night sweats, generalized fatigue and musculoskeletal chest pain. Remainder of review of systems including hemoptysis, weight loss, fevers, and chills was unremarkable. Physical exam revealed tachycardia with a pulse of 109 and bilateral coarse breath sounds throughout. Suction was used to measure the patient's sputum production which ranged from 200 to 1100 mL per day. Remainder of physical exam was unremarkable. Laboratory results revealed an elevation of total bilirubin at 3.2 mg/dL (reference range <1.2 mg/dL). All other laboratory results including transaminases were within normal limits. Chest x-ray was completed and revealed bronchial thickening and right lower lobe consolidation with a small pleural effusion. Bronchoscopy was performed and revealed copious bile-stained secretions. Cultures from bronchoscopy grew *Pseudomonas* and *Citrobacter*. An esophagram was negative for a tracheoesophageal fistula. The patient was started on piperacillin-tazobactam for presumed *Pseudomonas aeruginosa* pneumonia with no improvement. CT abdomen was performed that showed evidence of a bronchobiliary fistula. ERCP was completed that demonstrated a bile leak from the right anterior hepatic duct into a collection above the diaphragm. Biliary stents were placed. Post-procedure, the patient progressively improved.

DISCUSSION: Bronchobiliary fistula is a rare condition, usually resultant of hepatic malignancies or bile duct obstruction from cholangiolithiasis, chronic pancreatitis, or postoperative stricture. Other rare causes include trauma or hepatic infections such as abscess or hydatidosis. Biliaryitis is pathognomonic for bronchobiliary fistula and is usually present in copious volumes from 200 to 1200 mL daily. The growth of *Pseudomonas* in our patient's bronchoalveolar lavage delayed our diagnosis as this was initially thought to be the cause for the noted green sputum. Diagnosis can be confirmed by ERCP, magnetic resonance cholangiopancreatography (MRCP) or hepatobiliary imino-diacetic

acid (HIDA) scan. Although the latter two are noninvasive alternatives, ERCP also provides therapeutic opportunities and may be a preferred option if suspicion is high. Management includes endoscopic or percutaneous drainage versus surgery. With the advance of less invasive procedures, surgery has been typically reserved for refractory cases or when the fistula is a result of a potentially resectable tumor. The majority of patients with bronchobiliary fistulas recover after appropriate management. Without management, significant morbidity can occur from severe chronic cough and electrolyte disturbances secondary to large volume bile loss. Hence, increased awareness and early recognition is important.

GROUP A STREPTOCOCCAL SEPTIC ARTHRITIS Julia Manasson¹; Hannah Kirsch¹; Vanessa Charubhumi¹; Ann Garment¹; Taiye Odedosu². ¹New York University School of Medicine, New York, NY; ²NYU Medical Center, New York, NY. (Tracking ID #2175644)

LEARNING OBJECTIVE #1: Recognize the specific features of Group A streptococcal septic arthritis, a rare causative organism for joint infection.

CASE: A 44 year-old woman with a history of untreated rheumatoid arthritis initially presented to an outpatient gynecologist with several days of vaginal discharge and itching, which was diagnosed as bacterial vaginosis. Examination revealed a small excoriation on her labia. The following day, she experienced fevers, chills, headache, and malaise. She presented to the emergency room, where she had a temperature of 104.3 F. Labs were remarkable for leukocytosis of 12.1 10⁹/L (95.4 % neutrophils, 8 bands). Blood cultures were drawn. Urinalysis, chest X-ray, and lumbar puncture were inconsistent with infection. The patient was diagnosed with likely influenza despite a negative nasal swab and discharged to home. That night she developed new excruciating left elbow pain. Concurrently, her blood cultures grew out gram-positive cocci in pairs and chains, and she was immediately recalled for admission to the hospital. The patient was febrile, tachycardic, and now hypotensive to 85/55. Her exam was notable for a clear oropharynx, no lymphadenopathy, no murmurs, mild bibasilar crackles, and a swollen, extremely tender left elbow with poor range of motion. A new set of labs revealed a lactate of 2.9 mmol/L and c-reactive protein (CRP) of 200 mg/L. A left elbow X-ray showed extensive joint erosion and joint space narrowing. Joint fluid analysis was significant for 288,000 WBC/mm³ (90 % neutrophils) without crystals. The patient was diagnosed with severe sepsis from gram-positive bacteremia and septic arthritis presumably from hematogenous seeding. She was initially treated with fluid resuscitation, vancomycin and piperacillin-tazobactam, and a prompt joint washout by orthopedics on hospital day two. Subsequent echocardiography ruled out endocarditis. Blood and joint fluid cultures eventually speciated to Group A streptococcus (GAS), the most likely source thought to be skin flora that entered the blood through the patient's labial excoriation. She was placed on penicillin G and clindamycin for antibiotic synergy. Within days she made a rapid recovery and was continued on intravenous antibiotics for a total of two weeks, followed by a prolonged oral course.

DISCUSSION: Septic arthritis is a rheumatologic emergency that can lead to rapid joint destruction. This case demonstrates a rare type of septic arthritis caused by GAS. Few such cases are described in the literature, but this one demonstrates several typical features, including portal of entry through a skin lesion, infection associated with severe systemic symptoms, and predilection for young women. Early recognition even of rare causative bacteria is crucial for rapid initiation of appropriate therapy to prevent joint destruction and further spread of infection.

GUM SHOCK: PREVENTABLE ORAL DISEASE CAUSING SEPTIC SHOCK IN A YOUNG ADULT WITH TYPE 1 DIABETES Matthew R. Augustine; Rachel Appelblatt; Mack Lipkin; Kathleen Hanley. New York University Medical Center, New York, NY. (Tracking ID #2198957)

LEARNING OBJECTIVE #1: Recognize dental infection as plausible source for systemic infection

LEARNING OBJECTIVE #2: Identify the gaps in oral health care and importance for physician-led preventative services

CASE: A 22-year old man was brought into the emergency department (ED) after collapsing. The patient had a history of type 1 diabetes mellitus with hemoglobin A1c of 9.7 %. For 1 week prior to presentation, he reported progressive right upper maxillary oral pain focal to teeth and gingiva. He denied prior fevers, chills, night sweats and other symptoms of localizing infection. Oral pain prompted the patient to present to urgent care of dental clinic. While awaiting therapy, he experienced syncope. In the ED, the patient's temperature was 104.0 F; pulse, 160 beats per minute; respiratory rate, 26 breaths per minute; and blood pressure (BP), 100/64 mmHg. The patient was agitated with an altered mental status (AMS) and multiple additional signs of

end-organ hypoperfusion, including lactic acidosis (venous lactate 4.4 mmol/L) and acute kidney injury. Oral examination revealed diffuse periodontal disease with induration of right upper maxillary soft tissue without overt purulence or fluctuance. Facial computer tomography showed asymmetric, right paranasal and premolar soft tissue swelling without fracture or invasion of cranial structures. The patient became somnolent and hypotensive (BP 89/44). Despite seven total liters of crystalloid and empiric antibiotics (vancomycin and cefepime), hypotension, tachycardia, AMS, and lactic acidosis persisted. Norepinephrine was initiated, and the patient was admitted to Medical Intensive Care Unit for septic shock. Given his suspected oral source, piperacillin/tazobactam was given for expanded coverage of oral anaerobic organisms. Within 12 h, the patient's hemodynamics improved, mental status returned and lactic acidosis resolved. Norepinephrine was discontinued. On hospital day 2, oral exam revealed increased swelling with new overt right frontal maxillary fluctuance and purulent drainage. Oral-maxillofacial surgery incised and drained a periapical abscess. On hospital day 3, patient was discharged on oral amoxicillin-clavulanic acid with dental follow-up for definitive endodontic treatment.

DISCUSSION: This rare etiology of septic shock highlights a potential risk of inadequate access to oral care. Dental caries, severe periodontal disease, and progression to oral abscess are preventable infections with serious systemic consequences. Without oral hygiene and routine care, dental caries progress to involve the dental root, or apex, and surrounding soft tissue, leading to cellulitis and abscess formation. Acute management includes incision and drainage with systemic antibiotics, targeted to oral streptococcal and anaerobic organisms, followed by definitive therapy with root canal or extraction. Optimal oral health services for at-risk populations are limited by access, physician training, and care coordination. Oral disease disproportionately affects minority and vulnerable populations and is more severe amongst patients with diabetes and other co-morbidities. The restriction of Medicaid coverage for adult dental care has led to decreased routine care and increased rates of unmet dental needs. As a result, more patients, mostly 18–49 years old, present with oral complaints to emergency departments and ambulatory medical care sites. Physicians lack formal training. National guidelines lack direct recommendations on oral health care. Physicians resort to providing bridge therapy with antibiotics and narcotic medication, and patients are left without definitive therapy from an oral health professional. Severe cases of oral cellulitis or abscess formation results in nearly 8000 admissions and \$100 million in costs each year. This case highlights the rare yet avoidable and costly consequences of preventable oral disease. Early counseling, oral examination, and recognition by this patient's physician may have led to an earlier referral to routine dental care and avoidance of this severe complication. Enhanced integration of oral health care into physician training and advocacy for policies to improve access and collaboration might potentially provide comprehensive care, improve quality of life, and reduce costs.

HARBINGER OF BAD NEWS: RASHES AS PRESENTING FEATURE FOR NEWLY DIAGNOSED HIV IN A PATIENT WITH NO SELF-REPORTED RISK FACTORS. Andrew Trifan. University of Pittsburgh, Pittsburgh, PA. (*Tracking ID #2196782*)

LEARNING OBJECTIVE #1: Recognize the association of key rashes with underlying HIV infection.

LEARNING OBJECTIVE #2: Illustrate the importance of clinical intuition regarding screening for HIV in patients who report no risk factors, especially in a new patient visit.

CASE: A 50 year old man with no past medical history presented to the office with complaints of several rashes over the last few weeks. He was in his usual state of health till 2 months prior when he developed a pruritic erythematous scaling rash on his scalp. A few days later he noticed a non-scaling erythematous rash in his axilla/intertriginous region that was even more pruritic than his scalp. A week prior to arrival in the office he developed an intense sharp pain in his left arm that within 2 days had multiple vesicular lesions, diagnosed at the ED as shingles and discharged to follow up with a PCP, whom he had not seen in 20 years. On arrival for our first visit, he was afebrile and hemodynamically stable. Physical exam showed seborrheic dermatitis on the scalp, candida infection in skin folds, and vesicular lesions in a dermatomal distribution that were crusting over. Review of systems was unremarkable except for a 10 lb weight loss over last few months. He had no known allergies, no recent illness or stressors at home and no history of rashes as a child. He was sexually active with one female partner of 6 years and used condoms consistently. There was no prior history of STI or drug use but he did admit to having a minimum of 15 drinks/week. He stated he was checked for HIV a few years ago at an urgent care for his work and was negative. With his multitude of rashes, concern for immunosuppression was high and a repeat HIV was ordered. It returned positive with a CD4 count of 50 and viral load of 20,000. After discussing the results with him at our next visit, he acknowledged that he had omitted several key aspects of his social history because he was ashamed. He noted that his current partner was an IV drug user, that he did not practice safe sex consistently, had been with another woman in last few years, and

that the mother of his 8 year old daughter was HIV positive (though child herself was not). Counseling was given and he was referred to our HIV specialist clinic to begin treatment.

DISCUSSION: It is estimated that roughly 20 % of individuals with HIV in America are unaware of their diagnosis. HIV can present in a variety of ways based on the duration and control of the disease. One presentation is the development of common rashes in unusual situations. Seborrheic dermatitis and candidal infections, while common in children and adolescents, are quite rare to be newly diagnosed in adults, especially if there is no prior history of dermatitis. Both rashes, however, have high prevalence rates in HIV positive individuals. Coupled with shingles in a young patient with no other pertinent history, one should remember that a myriad of new onset rashes signals the need for further work up, including checking or rechecking for HIV. It is also important to keep in mind that patients may not fully disclose their risk factors, especially in the first meeting with a new doctor. A hazardous drinking level increased the concern for other risky behaviors and was another reason his HIV status was checked. Once the diagnosis is made the provider should proceed with further investigation to identify any contributing risk factors. HIV education was provided to the patient, including the importance of disclosure to partners, consistent use of barrier methods to decrease transmission, and awareness that risk of transmission persists even with undetectable viral levels. This case demonstrates that HIV does not always present with rare physical exam findings, and that a common disorder in an unusual setting may be enough to warrant a further work up. This case also shows that patients may not always reveal, consciously or not, risk factors when asked for variety of reasons, such as embarrassment. Finally, whether the diagnosis is confirmed or not, patients in clinic who are deemed to be at high risk or engaging in high risk behavior should be counseled on preventative measures. This will help serve as a way to not only decrease risk of acquisition but also disease transmission.

HAVING A ROAD BLOCK: WHEN TO SUSPECT POLYCYTHEMIA VERA
Maria M. Zlobinsky Rubinstein; Sheira Schlair. Montefiore Medical Center, New York, NY. (*Tracking ID #2195030*)

LEARNING OBJECTIVE #1: Understand erythrocytosis evaluation

LEARNING OBJECTIVE #2: Recognize clinical and hematological features of Polycythemia Vera (PV)

CASE: A 36 year old man presented with new onset blurry vision and jaw claudication associated with headaches. Initially, the headaches were mild, but then intensified with the development of blurred peripheral vision, photophobia, and then complete opacification of vision. Additionally, he also reported a one year history of progressive paresthesias which he described as “bugs crawling” on the right side of his lower face, and intermittent vertigo. He reported facial asymmetry, decreased sensation, intermittent jaw pain and weakness on the right side of his face. On review of systems he reported fatigue, joint pains, stiffness and pruritis (no rash). Extraocular movements were intact, and pupils were symmetrical, round and reactive. He had decreased sensation on the right side of his face in the V1-V3 distribution, and decreased motor strength in the V2-V3 distribution with visible atrophy. The rest of his neurological, cardiac and pulmonary exams were within normal limits. Basic metabolic panel and liver function tests were within normal limits. Complete blood count showed hemoglobin of 20.0 g/dL (normal range: 15–17.4 g/dL). Platelets were 405 g/dL and white blood cell count was within normal limits. Iron studies were unremarkable. Further evaluation of erythrocytosis revealed a markedly decreased erythropoietin level at 0.4 U/L, and a positive Janus family tyrosine kinase (JAK2) mutation. MRI of the brain was unremarkable and ultrasound revealed splenomegaly. He was diagnosed with PV and underwent immediate therapeutic phlebotomy. After five sessions of therapeutic phlebotomy his hemoglobin stabilized to 15.2 g/dL. Low dose aspirin was prescribed and the patient reported almost immediate resolution of his headaches and pruritis and restoration of vision.

DISCUSSION: Regardless of the presence or absence of symptoms, the incidental finding of polycythemia warrants evaluation. Men with hemoglobin of greater than 18.5 g/dL and women with hemoglobin of greater than 16.5 g/dL should undergo further testing. Initial testing with erythropoietin aims to distinguish between primary and secondary polycythemia. Elevated erythropoietin levels are consistent with secondary polycythemia, most commonly caused by hypoxic disease states. If erythropoietin levels are decreased, a JAK2 mutation is ordered. A positive JAK2V617F mutation confirms the diagnosis of PV. Frequently, PV is diagnosed by routine blood work in asymptomatic individuals and symptoms tend to develop gradually due to blood hyperviscosity. PV has a relatively low prevalence of approximately 22 patients per 100,000. It is a clonal stem cell disorder that results in overproduction of erythrocytes and frequently overproduction of leukocytes and platelets. PV was first described as part of spectrum of myeloproliferative disorders, and more recently has been identified with a single acquired mutation of the JAK2. JAK2 is a mandatory tyrosine kinase for erythropoietin and thrombopoietin receptors. More than 95 % of patients with PV express JAK2V617F, essentially confirming the diagnosis. PV should be suspected in patients found to have polycythemia and present with transient neurologic symptoms, headache and visual changes, as in the

case of this patient. Also akin to our patient, patients with PV frequently report paresthesias and/or pruritis. Splenomegaly and portal vein thrombosis should raise the suspicion of PV regardless of other symptoms since the increased blood viscosity can also increase risk of thrombosis. Similarly, PV should be suspected in patients with polycythemia and have evidence of thromboses, including cerebrovascular events, transient ischemic attacks and splenic infarction. According to the World Health Organization (WHO), a diagnosis consists of hemoglobin greater than 18.5 g/dL in men (16.5 g/dL in women) or elevated red cell mass greater than 25 % above normal predicted value with a Jak2 mutation. Minor criteria include: bone marrow biopsy with hypercellularity, serum erythropoietin levels below normal range or endogenous erythroid colony formation in vitro. The natural history of PV is generally insidious and can vary among individuals. It rarely progresses to acute myeloid leukemia and myelofibrosis. The treatment aims to maintain hematocrit under 45 % in men and 42 % in women. Therapeutic phlebotomy is considered the first line treatment and is extremely effective at rapidly reducing symptom burden, as in the case of our patient. Aspirin is prescribed to reduce the risk of thrombosis. In addition, hydroxyurea or interferon can be used to suppress bone marrow production of erythrocyte precursors. Our patient continues to tolerate phlebotomy. He has experienced improvement in his red blood cell counts and had clinical resolution of his symptoms associated with hyperviscosity.

HEARTBROKEN: CARDIAC REJECTION MASQUERADING AS AN ST-ELEVATION MYOCARDIAL INFARCTION. Peter P. Vlismas; Pedro Villablanca; Andrew Krumerman; Snehal Patel; J. Julia Shin; Ulrich P. Jorde; Daniel B. Sims. Montefiore Medical Center, Bronx, NY. (Tracking ID #2198887)

LEARNING OBJECTIVE #1: Recognize alternate causes of ST-elevation other than myocardial infarction

CASE: A 74 year-old male with chronic heart failure due to an ischemic cardiomyopathy who underwent heart transplantation five years previously presented with left sided chest pain of four days duration. Associated symptoms included dyspnea on exertion, fatigue, orthopnea, paroxysmal nocturnal dyspnea, and nausea. The past medical history was notable for an episode of acute cellular rejection four years prior to admission. The patient's medications included aspirin, rosuvastatin, clonidine and a two-drug immunosuppression regimen consisting of tacrolimus and mycophenolate mofetil. On presentation, the patient's blood pressure was 150/86 mm Hg, heart rate 106 beats/minute, and respiratory rate 30 breaths/minute. He was afebrile. Physical exam was remarkable for jugular venous distension, bibasilar crackles, and 1+ bilateral LE edema. Electrocardiogram (ECG) revealed sinus tachycardia with ST-segment elevations in leads I and aVL with reciprocal changes in the inferior leads consistent with a lateral myocardial infarction. The patient was taken for emergent coronary angiography which revealed no obstructive coronary lesions. Echocardiogram obtained in the cardiac catheterization lab revealed a left ventricular ejection fraction of 25 % and severe right ventricular dysfunction. A right heart catheterization performed while the patient was receiving dobutamine infusion showed severely elevated biventricular filling pressures and low cardiac index. An endomyocardial biopsy was performed. Laboratory analysis sent off in the emergency department returned a CPK of 983 U/L, troponin T 1.28 ng/mL, pro-BNP 146,128 pg/mL, potassium 5.0 mEq/L, creatinine 5.0 mg/dL, AST 2676 U/L, and ALT 1911 U/L. The patient was diagnosed with cardiogenic shock resulting in renal and hepatic failure. He was empirically started on intravenous methylprednisolone because of suspicion for acute allograft rejection. Blood pressure declined and he required vasopressor support in addition to inotropic support. He was started on continuous renal replacement therapy. Tacrolimus level returned undetectable. The endomyocardial biopsy revealed both severe acute cellular and antibody-mediated rejection. The patient was started on cytolytic therapy with thymoglobulin for cellular rejection. He received intravenous immunoglobulin and plasmapheresis to treat the antibody-mediated rejection. ST-elevation resolved on hospital day #5. Repeat endomyocardial biopsy on hospital day #12 showed resolved cellular rejection with minimal evidence of antibody-mediated rejection. Echocardiogram that day showed minimal improvement in function. Repeat echocardiogram on hospital day #23 showed normalized biventricular function.

DISCUSSION: Acute allograft rejection is a major cause of early mortality after heart transplantation. Cellular rejection, mediated by a T lymphocyte response to the allograft tissue, is the most common form of rejection in heart transplant recipients. Antibody-mediated rejection occurs due to antibody fixation and activation of the complement cascade resulting in tissue injury. Although acute rejection is a common complication post-heart transplantation, ST-elevation has not been associated with rejection. Review of the literature reveals only one case report of a patient 2 weeks post-heart transplantation that developed ST-elevation on the ECG. Autopsy revealed acute cellular rejection. ECG findings commonly seen with rejection are low QRS voltage and atrial flutter or atrial fibrillation. While low QRS voltage during severe rejection has been explained by edema between the myocytes, the mechanism of ST-elevation has not been elucidated. We surmise that intense inflammation caused by the combined cellular and antibody-

mediated rejection led to an injury current and ST-elevation manifest on the ECG. Heart transplant patients can develop ST-elevation, however this often occurs in the setting of a myocardial infarction due to coronary allograft vasculopathy (CAV), also called transplant coronary artery disease. CAV is an immune-mediated process involving smooth muscle hyperplasia characterized by diffuse, concentric proliferation rather than the focal, eccentric lesions of coronary atherosclerosis. Other conditions such as left ventricular hypertrophy, early repolarization, hyperkalemia, myocarditis, pericarditis, coronary vasospasm, and pulmonary embolism can all present with ST-elevations mimicking myocardial infarction. In conclusion this is the first case to our knowledge of mixed cellular and antibody-mediated rejection presenting with ST-elevation. It exemplifies the difficulty of rapid and accurate diagnosis of the etiology of acute ST-elevation. Our case highlights the need for awareness of this rare ECG manifestation in transplant recipients and the importance of recognizing imitators of acute myocardial infarction presenting with ST-elevation.

HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS SECONDARY TO MILIARY TUBERCULOSIS Puja D. Chokshi¹; Anjani Pilarisetty¹; Allan- Louie E. Cruz²; Kelly W. Fitzpatrick². ¹Washington Hospital Center, District of Columbia, WA; ²Washington Hospital Center, Washington, DC. (Tracking ID #2199238)

LEARNING OBJECTIVE #1: Recognize Tuberculosis as an underlying cause to developing hemophagocytic lymphohistiocytosis.

LEARNING OBJECTIVE #2: Diagnose Miliary Tuberculosis from radiographic imaging.

CASE: A 37 year old African female with no past medical history presented to the emergency department (ED) with fever and left flank pain. Initial workup done in the ED was unremarkable and patient was sent home with pain medications and ciprofloxacin for a presumptive UTI. When she did not improve, PCP recommended she return to the ED where she was admitted for fever, new unexplained thrombocytopenia, and an enlarged spleen on CT of the abdomen. She has no past medical history, no surgeries, and was not a smoker or alcohol user. At the time of presentation, vitals were temperature 38.9 C, heart rate 92, respiratory rate 20, blood pressure 127 mmHg /DysBP 58 mmHg, O2 Sat 99 % on room air and physical exam was only remarkable for left hand ecchymosis. Her initial blood work was significant for platelets of 57, Na of 132, AST of 165, ALT of 196, and albumin of 2.8. UA was unremarkable and CXR was read as unremarkable. Patient was thought to have a viral infection and was admitted to the regular medicine floors to be managed with supportive care. However, on the second day of hospitalization, she developed increased work of breathing and was intubated for airway protection and transferred to the MICU. Hematology was consulted for new thrombocytopenia with transaminitis. Infectious disease was consulted for persistent fever. Numerous tests were ordered for further evaluation including a hepatitis panel, HIV, CMV, Malaria smear, AFB smears, EBV, parvovirus B19, urine Streptococcus antigen, urine Legionella antigen, C-ANCA, P-ANCA, serum and urine protein electrophoresis, and ANA titer which all returned negative. Bronchoscopy was performed and bronchoalveolar lavage (BAL) was sent out for cultures. After hematological evaluation, patient was also found to have an elevated ferritin (1899), low fibrinogen (180), and elevated triglycerides (500) worrisome for hemophagocytic lymphohistiocytosis (HLH). Bone marrow confirmed HLH showing multiple histiocytes with hemophagocytes. Thought to be the primary etiology, she was started on HLH 2004 chemotherapy protocol with Etoposide 150 mg/m² twice a week for 2 weeks, Dexamethasone 10 mg/m² every day for 2 weeks, cyclosporine 275 mg PO 2x/day. Her bone marrow was successfully suppressed only to have the BAL cultures return 3 weeks later, positive for tuberculosis (TB). Once TB diagnosis was made, chemotherapy was stopped and steroids were tapered. She was then started on Rifampin, Isoniazid, Pyrazinamide, and Ethambutol and slowly showed clinical improvement.

DISCUSSION: Primary HLH, also called familial hemophagocytic lymphohistiocytosis (FHL), refers to HLH caused by a gene mutation, often inherited. The mutation is either at one of the FLH loci or in a gene responsible for one of several immunodeficiency syndromes. Cells of the immune system do not work properly to destroy infected or damaged cells as they should causing the immune system to become over activated which then leads to the body damaging its own tissues and organs. However, HLH can also be acquired or be secondary to an underlying process such as an infection, an autoimmune disorder, or a malignancy. TB can lead to HLH but is often not seen in the developed world. Miliary TB is especially uncommon in the developed world and due to its vague and varied presentation, and negative initial testing such as AFB smears, is often forgotten in the differential. However, it needs to be promptly recognized since it is almost always fatal when left untreated. The first clue is often radiographic imaging but without clinical correlation it can easily be missed in the early stages. Therefore it is important to review these images as internal medicine physicians to help raise concern when the clinical symptoms are not fitting with the more common illnesses. There have been case reports demonstrating the link between TB and HLH but this is unique to show this manifestation in an immunocompetent patient in the developed world. It is important for

internal medicine physicians to recognize both TB and HLH and understand the link between the two.

HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS: A SYNDROME OF PATHOLOGIC INFLAMMATION David Kudlowitz¹; Ping Gu¹; Alana Sigmund². ¹NYU, New York, NY; ²NYULMC, New York, NY. (Tracking ID #2162177)

LEARNING OBJECTIVE #1: To be able to diagnose hemophagocytic lymphohistiocytosis.

LEARNING OBJECTIVE #2: To be able to describe the pathophysiology of hemophagocytic lymphohistiocytosis.

CASE: This is a 41-year-old man with no past medical history who was referred by his provider to the inpatient setting with an enlarged left external iliac lymph node in the setting of 40-lb weight loss over 3 months and generalized fatigue. On admission, the patient's vital signs were: T103°F, HR 150, BP 90/60, Saturation 99 % on room air. His exam was significant for a dry, scaly rash on the scalp, bilateral legs, flanks, buttock, and arms with reticular erythema on bilateral flanks. Lab data was notable for hemoglobin of 8.4 grams/deciliter and platelets of 94,000 per microliter. Due to hemodynamic instability, the patient was evaluated for sepsis and pulmonary embolism, with a pulmonary embolism noted on computed tomography with contrast. Bone marrow biopsy showed macrophages with hemophagocytosis. Other notable labs included fasting triglycerides 334 and ferritin 6850. Skin biopsy confirmed acquired ichthyosis, likely a paraneoplastic reaction. Lymph node biopsy pathology confirmed ALK-1 Negative Anaplastic Large Cell Lymphoma. Of note, his entire infectious work up (including EBV) was negative and antibiotics were discontinued. He was treated with four cycles of Hyper-CVAD with complete remission (and improvement in his rash). Additionally, he underwent autologous stem cell transplant and is currently doing well more than 100 days post-transplant.

DISCUSSION: Hemophagocytic lymphohistiocytosis (HLH) was first recognized as a genetic disorder in 1952, at that time named “familial hemophagocytic reticulosis”. Now, there are two classifications of HLH, genetic and acquired. Acquired HLH is triggered by an entity that leads to decreased cytotoxic immune activity and uncontrolled immune hyperactivation. Examples of these triggers include infectious (viral, bacterial, fungal, or parasitic), rheumatologic (commonly referred to as Macrophage Activation Syndrome) and malignancy (mostly hematologic). In addition to dysregulated immune function, partial or completely defective Natural Killer Cells (NKC) or Cytotoxic T Cells (CTL) lead to an immunodeficiency. Also, immunopathology at the tissue level is usually evident (hemophagocytosis, cytopenia) as it was in this case. The diagnostic guidelines for this clinical syndrome were edited in 2004. These criteria are markers of pathologic inflammation (Table 1). Our patient met 5/8 criteria: fever, cytopenia, phagocytosis, elevated ferritin, and hypertriglyceridemia. sCD25 and NK-cell activity were not tested. Interestingly, HLH shares many laboratory and histologic similarities with sepsis. Both likely appear on a spectrum of pathologic immune response, presenting a challenge for the diagnosing clinician. However, it is important to make the diagnosis of HLH as it would drastically alter treatment options. HLH, when associated with malignancy, is most commonly seen with lymphoma. Our patient was diagnosed with anaplastic large cell B-cell lymphoma. In a single institution study from France, of 50 consecutive children with ALCL, 12 % had HLH and there was no difference in mortality between the two groups. Generally, lymphomas that trigger HLH have a poor prognosis, but B-cell lymphomas fare better than T cell lymphomas in this clinical situation. The treatment for this disease mostly is primarily focused on treating the underlying process, however, there may be some role for controlling the initial cytokine storm with plasmapheresis, as seen in several case reports.

HEMORRHAGIC PANCREATIC PSEUDOCYST—BLOOD WEEPING PSEUDOCYST WITH FISTULIZATION, AN UNCOMMON COMPLICATION OF PANCREATIC PSEUDOCYST Dilpreet K. Singh; Dr. Mini Hariharan; Dr. Jasdeep S. Badwal; Dr. Mary Jo Farmer. Baystate Medical Center/Tufts School of Medicine, Springfield, MA. (Tracking ID #2190507)

LEARNING OBJECTIVE #1: Recognize complications of a pancreatic pseudocyst.

LEARNING OBJECTIVE #2: Manage a patient with complicated pancreatic pseudocyst in septic shock with transarterial embolization and cystogastrostomy.

CASE: A 59 year old male with a medical history significant for oliguric end stage renal disease (ESRD) secondary to atypical hemolytic uremic syndrome on hemodialysis and eculizumab therapy, infrarenal abdominal aortic aneurysm, hypertension, dilated cardiomyopathy, congestive heart failure, liver cirrhosis, alcohol abuse history and a known pancreatic pseudocyst (7.8 cm 2 months prior to admission) presented from a skilled nursing facility with a 3 day history of abdominal pain, chest pain, nausea, and vomiting after missing his hemodialysis session. On admission, he was hypotensive, mildly tachycardic and hypothermic. The patient was ill appearing, cachectic, with a soft

abdomen and diffuse tenderness but no peritoneal signs. An electrocardiogram revealed normal sinus rhythm, hyperacute T-waves in V2-V3, and ST depressions in V4-V6. Laboratory findings were significant for leukocytosis with a left shift, anemia, an elevated lipase, and lactic acidosis. An abdominal computed tomography (CT) revealed a heterogeneous complex hemorrhagic cystic mass (15.5 cm×13.9 cm) in the pancreas. The patient was fluid resuscitated and received DDAVP, blood transfusions, IV antibiotics, and was transferred to the ICU. An abdominal CT angiogram (CTA) did not reveal active extravasation; therefore, arterial embolization was not pursued. Surgery deemed the patient a poor surgical candidate and did not offer emergent intervention. He was managed supportively with serial hemoglobin and hematocrit levels, transfusions as needed, pain control, nutritional support, and ESRD management. Repeat CTA demonstrated continued hemorrhage into the pancreatic cyst for which prophylactic splenic artery embolization was performed. Repeat abdominal CT scan revealed an interval increase in size of the pseudocyst now compressing the stomach, liver, and duodenum for which endoscopic cystogastrostomy with placement of two pigtail stents was performed. Antibiotics were begun for a suspected infected pseudocyst. A follow-up abdominal CT revealed spontaneous fistulization of the pseudocyst into the stomach for which the patient underwent ERCP revealing a gastric ulcer with spontaneous perforation into the pseudocyst cavity. The patient was discharged to rehab in stable condition with surgical outpatient follow-up for a semi-elective distal pancreatectomy and splenectomy, and repeat ERCP for removal of the cystogastrostomy stents.

DISCUSSION: Pancreatic hemorrhage arising from a pancreatic pseudocyst is a rare complication with incidence ranging from 1.4 to 8.4 %. Mortality rates can reach as high as 40 %. Indications for surgical intervention of large pancreatic pseudocysts include no regression after six weeks of observation, increase in size greater than 6 cm, cyst wall maturity, and development of symptoms. Chronic pancreatic pseudocysts rarely regress after six weeks if larger than 6 cm and have an increased risk of complications such as hemorrhagic conversion as in our patient's case. With his known pancreatic pseudocyst, our patient could have benefitted from surgical intervention 2 months prior. However, with his current presentation surgery was not an immediate option given the high mortality risk and risk of uncontrolled bleeding. Transarterial embolization is a minimally invasive, non-surgical and effective treatment for controlling hemorrhage in patients with pseudocysts. Embolization involving occlusion of the hemorrhaging vessel with platinum coils or gelatin sponges is a potential treatment option for the management of arterial bleeding. The inability to demonstrate the culprit vessel on CTA imaging in our patient necessitated a prophylactic embolization of the splenic artery as a targeted approach could not be achieved to treat the persistently hemorrhaging pseudocyst. As a result, our patient was managed with placement of an endoscopic cystogastrostomy with the creation of a fistula and stent insertion between the pseudocyst and the stomach. This procedure is associated with a treatment success rate of 89–100 % and a mortality rate of less than 1 %. Rupture of a pseudocyst into the peritoneal cavity, biliary tract, and as in our case into the GI tract is a very uncommon complication of hemorrhagic pseudocyst. This case demonstrates the complications that arise from pancreatic pseudocyst as well as various management strategies.

HENOCH-SCHONLEIN PURPURA IN AN ADULT Stephen C. Chow; Sarah Kuhn. Carolinas Medical Center, Charlotte, NC. (Tracking ID #2197757)

LEARNING OBJECTIVE #1: Describe a severe presentation of HSP in an adult, a syndrome more commonly seen in children.

LEARNING OBJECTIVE #2: Increase clinical suspicion of HSP in adults in hopes that earlier identification and treatment will improve clinical outcomes.

CASE: A 66-year-old Caucasian female with a history of Sjogren's disease, chronic obstructive pulmonary disease, mild chronic kidney disease, and diabetes mellitus type 2 presented with a rash that began 2 days prior to arrival. The rash initially began as an intensely pruritic, dark red to purple lesions that appeared on her feet bilaterally which then coalesced. The patient decided to come to the hospital after she noticed the rash appearing on her hands and spreading up to her upper arms. She was on azithromycin 2 weeks prior for acute bronchitis but otherwise denied any new medications or environmental exposures. She complained of diffuse joint pain but no abdominal pain. Her daughter felt she was more confused than her baseline. Physical exam revealed a chronically ill appearing female in no acute distress. Mucous membranes were moist with no xerostomia or keratoconjunctivitis sicca. There was a diffuse palpable purpuric rash on the anterior lower extremities involving the dorsum and plantar surfaces of both feet. There were also coalesced areas on the dorsum and palmar surfaces of her hands and upper arms. She was alert and oriented. Initial laboratory evaluation revealed creatinine of 2.21 mg/dL elevated from baseline of 1.1 mg/dL and blood urea nitrogen (BUN) of 45 mg/dL. Sedimentation rate and C-reactive protein levels were both within normal limits. Urinalysis was significant for over 100 red blood cells and white blood cells per high-powered field, large leukocyte esterase, and many bacteria. Rheumatology workup ruled out autoimmune processes including antinuclear antibody, anti-double stranded DNA, Sjogren's SS A and SS B, rheumatoid factor, and anti-neutrophil cytoplasmic antibody. Hepatitis panel

was negative, and ammonia level was normal. Antibody levels were obtained which showed IgA level of 711 mg/dL. A punch biopsy of one of her skin lesions showed leukocytoclastic vasculitis. She was started on prednisone 60 mg with some improvement in her rashes, but then she began to have increasing episodes of confusion with rising BUN up to 72 mg/dL and creatinine to 4.39 mg/dL. Nephrology initiated the patient on hemodialysis on hospital day #8. She also developed pancytopenia with white blood cell count dropping to 1.8 K/uL, hemoglobin 7.3 gm/dL, and platelets 57 K/uL. Renal biopsy was performed which was consistent with IgA nephropathy but no crescents were seen. Repeat skin biopsy showed IgA deposition in the cutaneous vasculature likely consistent with Henoch-Schönlein purpura (HSP). The patient was continued on prednisone for a total of 4 weeks. Immunosuppressants were not initiated given her pancytopenia. The patient's rash did show improvement with steroids, and her mental status improved with hemodialysis. Unfortunately, she did not show any evidence of renal recovery at the time of transfer to long-term acute care center and was continued on dialysis.

DISCUSSION: Henoch-Schönlein Purpura (HSP) is typically thought of as a pediatric syndrome and is the most common pediatric vasculitis affecting the skin. The joints, gastrointestinal tract and kidneys can also be involved in HSP. The annual incidence of IgA vasculitis has been reported as ranging from 3 to 26.7/100,000 for children, while the annual incidence for adults is 0.8–1.8/100,000. The cause of HSP is unclear, but genetics and environmental triggers have been investigated. It is more common in the fall and winter in children which suggests an infectious cause; however, no single organism has been isolated. The same seasonal pattern does not hold true for adults. Medications, including vaccinations, have also been suggested as the precipitating cause but have not been substantiated. The risk of renal insufficiency appears to be higher in adults than children (30 % versus 5–15 %). Renal insufficiency is usually more severe in adults, and older adults who present with renal insufficiency and proteinuria >1 g/24 h have a poorer prognosis. Other elements associated with renal disease include fever, recent infection, elevated inflammatory markers, anemia, hematuria, and purpura above the waist. Treatment of HSP is supportive in mild cases. Corticosteroids have been used in varying doses and durations, with and without immunosuppressants. While early intervention has not been studied, given the poorer prognosis in older adults and those with renal disease, it is important to diagnose and initiate treatment for HSP as early as possible. The clinician must maintain a clinical suspicion for HSP in adults that present with any combination of skin rash, renal insufficiency, joint involvement, and abdominal pain or hemorrhage; as it can be an overlooked diagnosis.

HEPARIN AND HYPERKALEMIA—AN UNCOMMON CAUSE OF A COMMON EFFECT

Malini Ganesh; Ankit Mangla; Isaac Paintsil; Fady Iskander. John H Stroger Hospital of Cook County, Chicago, IL. (Tracking ID #2191562)

LEARNING OBJECTIVE #1: Recognize early the side-effect of hyperkalemia with a commonly used drug, heparin

CASE: A 60 year old man with no previous medical history, presented with intermittent fever, productive cough, hemoptysis and 30-pound weight loss for the 3 months prior to admission. Review of systems was negative. Vitals at admission were significant for blood pressure (BP) of 88/63. Systemic examination showed a thin man, breathing comfortably, in no acute distress. Lung exam revealed broncho-vesicular breathing over the left lung field. Labs were obtained which showed hyponatremia to 128 mmol/L which resolved with intravenous hydration, and microcytic anemia with hemoglobin (Hgb) of 9.8. Other labs were unremarkable. A chest X-ray revealed left UL consolidation with multiple cavitary lesions, which was confirmed on subsequent Computed tomography of the chest. The patient was placed on respiratory isolation, and sputum samples sent before initiation of empiric tuberculosis treatment. Sputum smears returned positive for acid-fast bacilli 4+ growth, following which the patient was initiated on anti-tuberculosis therapy. His only other medications during the hospitalization were a single dose of broad spectrum antibiotics in the ER, and subcutaneous heparin for VTE prophylaxis. The patient remained in hospital on anti-tuberculosis therapy (ATT) awaiting setup of directly observed treatment (DOTS). On the third day of hospitalization, routine labs were obtained, which showed a serum potassium of 5.5. Renal function had remained normal on the same panel, and there were no electrocardiographic changes on a subsequently obtained EKG. Potassium remained high on repeat testing the next day, with a value of 5.6. Due to mild hypotension and hyponatremia on admission, 8 AM cortisol was obtained, and ACTH stimulation test done which showed adequate adrenal response. Medications were reviewed, and pneumatic compression device substituted for heparin prophylaxis. The next morning, serum potassium obtained was 4.6. The patient remained stable and was discharged on ATT.

DISCUSSION: In this patient, other causes of hyperkalemia, including renal failure, adrenal insufficiency, medications such as NSAIDs, ACE inhibitors, and volume depletion were ruled out. The hyperkalemia resolved immediately after withdrawal of heparin, with objective evidence of normalization of serum potassium after. Naranjo adverse

reaction probability score was calculated at six, making the possibility of heparin-induced hyperkalemia very likely. First described in the 1960s, the suppression of aldosterone by heparin is a well-documented but lesser known side-effect. It leads to hyperkalemia, and in rare cases hyponatremia and hypotension. This seems a phenomenon exclusive to the zona glomerulosa, sparing the other two cortical axes. Though this effect occurs in normal patients, it appears to be more frequent in patients with pre-existing defects in potassium homeostasis. Predisposed patients with persistent hyperkalemia may even require Fludrocortisone for correction. Frequent monitoring of serum potassium in patients on heparin, and early institution of potassium lowering therapy when needed may reduce life-threatening consequences of hyperkalemia.

HEPATOCELLULAR CARCINOMA PRESENTING AS AN ISOLATED NECK MASS Melinda M. Katz¹; Alice Tang¹; Eleonora Teplinsky²; Barbara Porter¹. ¹New York University School of Medicine, New York, NY; ²NYU Langone Medical Center, New York, NY. (Tracking ID #2192552)

LEARNING OBJECTIVE #1: Recognize a rare and unique presentation of HCC

CASE: A 55-year-old male with a history of hepatitis C virus (HCV), treatment-naïve non-progressive HIV, and chronic osteomyelitis of the left foot presented with 1.5 weeks of isolated neck pain and left arm radiculopathy. He was near completion of his HCV treatment with sofosbuvir, peg-interferon, and ribavirin. His exam revealed decreased strength and sensation in his left upper extremity and tenderness at the posterior base of the neck. Laboratory data was significant for hemoglobin of 10.9 g/dL, erythrocyte sedimentation rate (ESR) of 87 and C-reactive protein (CRP) of 29. Cervical spine angiogram showed a 2.5×3.5 cm destructive lytic mass at the left C7 vertebral body extending into the prevertebral and paraspinal soft tissues, consistent with a metastatic lesion. Computer tomography (CT) scans of the chest, abdomen, and pelvis revealed a 10x17mm lingular nodule and noncirrhotic liver with two ill-defined hepatic lesions (12×11×20 mm and 14×12 mm), which were indeterminate on abdominal magnetic resonance imaging (MRI). Tumor markers, including alpha-fetoprotein (AFP), were all within normal limits. CT-guided biopsy of the C7 mass was performed. Pathology revealed metastatic carcinoma, consistent with hepatocellular origin. There was proliferation of tumor cells with prominent nucleoli and bile pigment in the cytoplasm, morphologically resembling atypical hepatocytes. The tumor cells were positive for Hepar-1 and negative for TTF-1, PSA and PSAP.

DISCUSSION: To our knowledge, this is the first case of hepatocellular carcinoma (HCC) presenting as an isolated cervical mass. Extrahepatic metastases have been described in 14 to 42 % of HCC patients. The lung is the most frequent site involved, followed by lymph nodes, bone, and adrenal glands. However, while extrahepatic metastases are common, they are rare at the time of initial presentation and diagnosis of HCC. In a retrospective study of 4953 patients with HCC, only 0.75 % had bone metastases at diagnosis, with a solitary cervical spine metastasis reported in 2 patients. Further, in a report of 151 patients with primary HCC, the vast majority (93 %) had intrahepatic tumors at the time of diagnosis of extrahepatic metastasis. Of the 28 patients in this study with stage T0-T2 HCC, 96 % had a previously treated intrahepatic malignancy, suggesting that the extrahepatic metastases signified recurrence rather than primary HCC. Although HCC metastases limited to the neck were exceedingly rare, there have been few accounts of skip metastases where the disease bypassed regional lymph nodes. One case reported a 6x6cm periduodenal lymph node determined to be a HCC metastasis without involvement of the hepatoduodenal ligament. Another case reported HCC metastasis to cervical lymph node without regional lymph node involvement. Unlike our patient, these patients each had elevated alpha-fetoprotein levels and fibrotic changes secondary to HCV and notably, our patient did not have a primary lesion. It is unclear whether our patient's HCV infection contributed to this unique presentation of HCC. At the time of presentation, the patient was near completion of his HCV therapy. Treatment of HCV and achievement of sustained virologic response (SVR) is independently associated with a 3.1 times decreased risk of developing hepatocellular carcinoma. However, clearance of hepatitis C does not eliminate the risk of HCC. Patients during and immediately after peginterferon and ribavirin treatment had a 3.4 % rate of HCC. To date, there is no established association between sofosbuvir and increased risk for hepatocellular carcinoma. In conclusion, this patient presented with an isolated cervical metastasis of HCC, which is an extremely rare presentation of this disease. With the rising incidence of HCC, we will likely see more atypical presentations and it is critical for clinicians to consider HCC in patients with a history of HCV, even in the absence of classical symptoms. Ultimately, a better understanding of the pathogenesis of HCV-related HCC is needed to understand the pathogenesis of these unusual presentations and improve outcomes for this patient population.

HERPES ZOSTER IN AN IMMUNE COMPETENT HOST Kent S. Tadokoro; Joanne Bernstein; Soumya Rangarajan; Pinky Jha. Medical college of Wisconsin, Milwaukee, WI. (Tracking ID #2155623)

LEARNING OBJECTIVE #1: To report an unusual case of Varicella Zoster Virus (VZV) infection in an immune competent host

CASE: A 22 year old male presents to urgent care with headache, fever, painful scalp rash, and photophobia. He is given four tablets of ibuprofen and ice packs but does not relieve his symptoms. The patient subsequently presents to a university hospital. Upon presentation, he denies eye pain, change in hearing, taste sensation, weight loss, sick contacts, and new sores on his lips or genitals. Past history is only significant for chicken pox as an infant and mononucleosis in eighth grade. He otherwise does not have any medical problems or prior surgeries. The patient is sexually active with his girlfriend of two years. He works as a teller at a financial institution and attends a university at night. He does not live in the dormitories. Vital signs are within normal limits except for a mild fever of 100.7 ° F. The patient is alert and oriented without changes in mental status. Physical exam is significant for a 1.5 cm by 3 cm left sided postauricular lymph node, as well as a generalized anterior cervical lymphadenopathy. There is a vesicular lesion on his occipital scalp. Nuchal rigidity and decreased active neck flexion due to pain are present. Brudzinski's and Kernig's signs are negative. All other physical exam findings are negative. Lumbar puncture is performed and CSF fluid analysis shows leukocytes of 6 cells/ μ L, 94 % lymphocytes, protein of 50 mg/dL, and normal glucose of 60 mg/dL. PCR analysis of the CSF fluid for HSV-1, HSV-2, and enterovirus is all negative. Blood serology for HIV-1, HIV-2, and infectious mononucleosis is also negative. CT of the head without contrast and chest radiograph is normal. Finally, skin biopsy of the lesion returns positive for VZV. Acyclovir is started for concern of viral meningitis in response to the CSF findings. The patient's headache is treated with hydromorphone, meperidine, ketorolac, and diphenhydramine. Ondansetron and prochlorperazine are given for the nausea. He is admitted to the general medicine service and the infectious disease service is consulted. Their recommendation is to continue IV acyclovir. The pain, nausea, vomiting, photophobia, neck stiffness, and fever all markedly improve on day three and the patient is discharged on IV acyclovir 10 mg/kg q8hr for 14 days. Weekly CBC, CMP, and ESR are checked. At a follow up appointment 3 weeks after discharge, the patient has persistent headaches of lesser severity.

DISCUSSION: Herpes zoster manifesting as acute meningitis in a young, healthy, immune-competent male is extremely rare. It is a reactivation of varicella zoster virus lying dormant in the dorsal root ganglia of sensory neurons after a chicken pox infection. The cell-mediated immune system eradicates the initial viral infection, producing memory cells that prevent re-infection in healthy individuals. Clinically, herpes zoster presents as painful, dermatomal, vesicular papules with a variety of complications. Risk factors for reactivation include advanced age, immune suppressed state, trauma, malignancy, disorders of cell-mediated immunity, and chronic lung or kidney disease. History and laboratory testing for this patient did not show evidence of these risk factors. A possible mechanism of his pathology could be due to his contraction of chicken pox as an infant. Infants have not established a strong cell-mediated immune system; therefore, they do not develop enough memory cells to prevent herpes zoster later in life. Furthermore, meningitis is a rare complication of herpes zoster (0.5 % of cases). Pathogenesis of VZV meningitis is likely due to virus spreading through the choroid plexus by infecting the capillary endothelial cells. In only 10 % of patients, VZV is the causal organism for aseptic meningitis. As opposed to bacterial meningitis, treatment for less severe viral meningitis is usually supportive. This patient was started on empiric acyclovir because of cutaneous clues of herpes zoster; however, standard therapy for VZV meningitis has not been established. In pediatrics, acyclovir is used empirically on a case by case basis depending on severity of disease. Patients who are elderly, immune suppressed, or have received antibiotics prior to hospitalizations should receive empiric antibiotics even if bacteria is negative in the CSF.

HERPES ZOSTER MANIFESTING WITH DYSPHAGIA AND FACIAL DROOP: A UNIQUE PRESENTATION Deepika Sriram¹; Appesh Mohandas³; Sarah Nickoloff^{2, 4}. ¹MCW, Milwaukee, WI; ²Medical College of Wisconsin, Milwaukee, WI; ³Medical College of Wisconsin Affiliated Hospitals, Milwaukee, WI; ⁴Zablocki VA Medical Center, Milwaukee, WI. (Tracking ID #2198669)

LEARNING OBJECTIVE #1: Recognize that dysphagia and facial droop may be associated with herpes zoster.

LEARNING OBJECTIVE #2: Treat Ramsay Hunt syndrome with antiviral therapy and steroids in a timely manner for better prognostic outcome.

CASE: A 67 year old male with a past medical history significant for hypertension, hyperlipidemia, and type 2 diabetes, presented with a bump behind his right ear, swollen and tender ear, and dysphagia. The patient initially noticed dysphagia and pain behind his right ear and subsequently a lesion developed where the pain was located. His primary care provider prescribed clindamycin for presumed skin infection. The pain persisted, and when the lesion developed vesicles, the patient sought further care in the emergency department. He was admitted with a diagnosis of presumed herpes zoster. He was started

on acyclovir, continued his home dose of gabapentin, and was given oxycodone for pain control. Dysphagia persisted, and included both solids and liquids, without odynophagia. He also noticed hoarseness of his voice. The day after admission, he developed right-sided facial droop and lagophthalmos of the right eye. Ophthalmology and otolaryngology were consulted. Otolaryngology visualized his vocal cords and found right cranial nerve VII paralysis, right vocal cord paralysis, and right pharyngeal weakness. Ophthalmology reported exposure keratitis due to lagophthalmos, and hemifacial dyskinesia. MRI brain was unremarkable, and the patient's symptoms were attributed to right cranial nerve VII palsy due to Ramsay Hunt syndrome. He was started on prednisone in addition to the acyclovir. Varicella zoster virus (VZV) IgG and IgM antibodies were positive as were VZV rapid culture and VZV DNA PCR from vesicular fluid. At follow up with his primary care provider a month after discharge, he reported some continued mild tenderness at the site, but his facial droop had improved and dysphagia had nearly completely resolved.

DISCUSSION: Herpes zoster involves the reactivation of the varicella zoster virus and is a very common infection. It may rarely present with multiple cranial neuropathies, with or without skin or ear vesicles, in a syndrome known as Ramsay Hunt. Specifically, the virus reactivates in the geniculate ganglion of the facial nerve with resultant facial palsy, otalgia, and ear vesicles. Per one study, only five percent of patients with herpes zoster develop cranial and peripheral nerve palsies. Recovery rate remains low (26 %), with many patients having long-term deficits, though prognosis is better when treatment is initiated within three days of symptoms. Treatment with steroids and antiviral agents is associated with better prognosis than steroids alone. Clinicians should be aware of the rare and variable presentations of herpes zoster, including dysphagia and facial droop, to ensure timely initiation of appropriate therapy.

HICKAM'S DICTUM OR OCCAM'S RAZOR Jason Dinsmoor; Michael P. Smith. University of Nebraska Medical Center, Omaha, NE. (Tracking ID #2200074)

LEARNING OBJECTIVE #1: Recognize the classic triad of Normal Pressure Hydrocephalus (NPH) and how it affects prognosis and management of NPH

LEARNING OBJECTIVE #2: Recognize geriatric patient's risks for multiple disease processes

CASE: A 79 year-old man presented with encephalopathy after ground level fall. The patient had a history of cognitive decline and multiple falls over the past year. In this particular instance, the patient was found naked on the floor of his skilled nursing facility with no witnesses. He was noted to be incontinent of urine when he was found. His family believed his recent mental decline was due to Alzheimer's disease. The patient's exam was only notable for a minimal exam was 10, a volar dislocation of the fifth distal interphalangeal joint, and a magnetic gate on neurologic testing. He did have a leukocytosis of 34.8 and a urine culture with greater than 100,000 colonies of Escherichia Coli. In addition, imaging of the head with computed tomography showed enlargement of the lateral ventricles including the temporal horns and subsequent MRI confirmed ventriculomegaly consistent with NPH

DISCUSSION: Geriatric patients frequently present to the general Internist with multiple problems. It is up to the Internist to determine which are isolated problems, which problems are interconnected, and which problems are normal parts of aging. Although the patient's recent one year cognitive decline was attributed to Alzheimer's disease and his most recent fall attributed to a complicated urinary tract infection; the patient's triad of cognitive impairment, gait disturbance, and urinary incontinence is classically associated with normal pressure hydrocephalus. A brain magnetic resonance imaging on a patient with normal pressure hydrocephalus demonstrates ventriculomegaly out of proportion to sulcal enlargement without cerebral spinal fluid obstruction. A lumbar puncture can help identify patients likely to respond to shunt placement. In some studies, up to two-thirds of patients can expect some benefit post shunting; however, this improvement will remain for only one half of these patients. With shunting, normal gait is more likely to return than cognitive deficits. In this case, the patient's family was aware his cognition may not return to baseline; however, the family was in favor of shunting the patient. Considering the patient's multiple falls over the prior year, shunting could improve his gait and his quality of life quite significantly. Our patient's case illustrates the importance of recognizing geriatric patients' risks for multiple disease processes by reviewing the classic presentation of NPH. It is important for the general Internist to know this presentation because early recognition and treatment can lead to a significant increase in length and quality of life for the affected patient

HIDING IN PLAIN SIGHT—ACUTE CHOLANGITIS WITHOUT RADIOGRAPHIC FINDINGS Shetal Patel¹; Tyler Stewart¹; Oanh K. Nguyen². ¹UT Southwestern, Dallas, TX; ²UT Southwestern Medical Center, Dallas, TX. (Tracking ID #2197585)

LEARNING OBJECTIVE #1: Diagnose acute cholangitis despite the absence of radiographic findings.

CASE: A 62 year-old man with a history of central diabetes insipidus presented with worsening fever, chills, night sweats and rigors for 6 months associated with a 40-lb weight loss. Rigors had progressed from once a week to daily over the 6 months. Review of systems was otherwise negative for cough, hemoptysis, chest pain, shortness of breath, abdominal pain, nausea, vomiting, constipation, diarrhea, change in urine, rash, swelling, myalgias or arthritis. He attributed his weight loss to a healthy diet over the previous 4 months. Past medical history was notable for malaria and dengue fever acquired in Venezuela in the 1970s and Rocky Mountain spotted fever acquired in New Mexico in 1978 with no residual sequelae. Past surgical history included remote appendectomy, tonsillectomy and right hip replacement. Family history included a maternal aunt and maternal grandmother with rheumatoid arthritis. Social history was notable for occupation as a pilot, though travel history only included a trip to England in the previous year. He had no animal or environmental exposures and no illicit drug use. Vital signs on presentation were: temperature of 38.4 °C, heart rate 90 bpm and blood pressure of 140/60 mmHg. Physical exam demonstrated a well-appearing male in no apparent distress. His lungs were clear, heart was regular without murmurs or rubs. His abdomen was soft, non-tender, non-distended. He had no jaundice, scleral icterus, rashes, joint swelling or lymphadenopathy. Laboratory evaluation revealed a white blood cell count (WBC) of $19.9 \times 10^9/L$, hemoglobin of 15.4 g/dL, aspartate aminotransferase 287 IU/L, alanine aminotransferase 436 IU/L, alkaline phosphatase 390 IU/L, total bilirubin 4.7 mg/dL and direct bilirubin 3.7 mg/dL. Antinuclear antibody was negative. Creatinine kinase and lactate dehydrogenase were within normal limits. Transabdominal ultrasound (TUS) showed mild fatty liver and common bile duct (CBD) at 4 mm with no evidence of cholelithiasis or cholecystitis. On hospital day #1, he developed severe, diffuse abdominal pain. Subsequent computed tomography (CT) of the abdomen and pelvis was unremarkable other than for questionable dense material in the gallbladder, thought to be due to artifact or an adjacent vessel. Repeat labs demonstrated further elevation of WBC to $37.5 \times 10^9/L$ and total bilirubin to 6.2 mg/dL. Urgent endoscopic retrograde cholangiopancreatography (ERCP) was performed, showing an enlarged, bulging ampulla. A complete sphincterotomy revealed abundant purulent material and a 4 mm pigmented bile stone. A diagnosis of acute cholangitis was made. The patient tolerated the procedure without complications, with resolution of all symptoms and leukocytosis over 24 h, and a steady decrease in liver enzyme elevations. He was discharged the following day with a 10-day course of ciprofloxacin and metronidazole with plans for follow up cholecystectomy.

DISCUSSION: Acute cholangitis is a life-threatening medical emergency; untreated, mortality is as high as 90 %. With advances in diagnosis and treatment, including imaging, biliary drainage techniques, antibiotics and intensive care medicine, mortality rates have dropped over the last four decades to less than 11 %. However, mortality for patients with severe cholangitis remains as high as 30 % and may partially reflect those with delay in diagnosis due to atypical presentations. In the above vignette, we describe an atypical presentation of acute cholangitis presenting as prolonged fever of unknown origin without associated abdominal pain. Acute cholangitis classically presents with Charcot's triad (fever, right upper quadrant pain and jaundice) and is supported by laboratory tests (elevated WBC, AST, ALT, alkaline phosphatase, bilirubin) and imaging studies demonstrating CBD stones or biliary duct dilation. Because of easy access and relatively non-invasive nature, TUS and CT are the most commonly used imaging modalities. Both TUS and conventional CT have low sensitivities for detecting CBD stones. TUS has a high sensitivity for detecting biliary duct dilation when present (96 %); however, when CBD stones are small or the obstruction is acute, biliary dilation may not be present, as in our case above. Based on the patient's worsening clinical picture and laboratory tests suggestive of an obstructive pattern, our clinical suspicion for acute cholangitis remained high. Despite his atypical presentation and negative imaging, ERCP was performed. When imaging is inconclusive and clinical suspicion remains high particularly in critically ill patients, ERCP provides timely diagnostic and therapeutic results. In conclusion, internists should be aware of atypical presentations and warned of the limitations of imaging in the diagnosis of acute cholangitis.

HIV/AIDS AND OCCAM'S RAZOR: A HEART-STOPPING REALIZATION

Robert P. McClung¹; Sophia Hussien². ¹Emory University School of Medicine, Atlanta, GA; ²Emory University, Atlanta, GA. (Tracking ID #2200042)

LEARNING OBJECTIVE #1: Recognize the relationship between HIV/AIDS and cardiovascular disease.

LEARNING OBJECTIVE #2: Identify anchoring bias in evaluating patients with complications of HIV/AIDS.

CASE: A 29 year-old African-American female with a history of HIV/AIDS (CD4 count of 12/4 %) off anti-retroviral therapy, diet-controlled type-2 diabetes mellitus, obesity, and

depression was admitted to the hospital with three weeks of pain in her throat, chest, and epigastrium. The pain was rated 8-10/10 in severity and was described as dull and constant. It was not associated with exertion, but worsened with swallowing and was associated with a sensation of food becoming stuck in the throat. She had been evaluated in the emergency department twice in the previous three weeks for these symptoms and treated for GERD and candida esophagitis without relief. Her admission exam revealed normal vital signs, mild oropharyngeal thrush, shoddy cervical lymphadenopathy, and benign cardiac, pulmonary, and abdominal exams. Laboratory testing was notable only for a total white blood cell count of 1800 and hemoglobin of 9.3 mg/dl consistent with her known anemia of chronic disease. She was admitted for esophagogastroduodenoscopy to further assess her continued pain and odynophagia with concern for esophagitis due to candida, HSV or CMV infection. On the third day of admission while awaiting endoscopy, safety labs obtained while on empiric fluconazole revealed an isolated AST elevation (271 U/L, from 12 U/L on admission). Reassessment of the patient demonstrated new sinus tachycardia with a rate of 130 and unchanged chest and epigastric pain. Subsequent testing to identify the source of AST release revealed creatine phosphokinase level of 2581 U/L, troponin-I of 57 ng/ml, and an EKG with anteroapical Q waves and ST elevations in V3 and V4. Emergent echocardiography revealed severe hypokinesis of the anterior wall and apex consistent with a large myocardial infarction. Given her ongoing chest pain, she was taken for emergent cardiac catheterization and underwent thrombectomy and percutaneous coronary intervention for a 100 % occlusion of the proximal left anterior descending artery. Her troponin level peaked at 170 ng/ml and her recovery was marked by residual compromise of left ventricular function with an ejection fraction of 25 %. Of note, subsequent endoscopy also revealed esophageal ulcerations consistent with severe esophagitis.

DISCUSSION: This case highlights two significant diagnostic challenges beyond this patient's notably atypical chest pain presentation. First, it underscores the importance of HIV/AIDS as an independent risk factor for cardiovascular disease (CVD), a risk attributed to numerous factors including increased inflammation, altered coagulation, and endothelial dysfunction observed in chronic HIV infection. Multiple large cohort studies have identified a specific increase in acute myocardial infarction (AMI) in patients with HIV/AIDS regardless of treatment status, even when controlled for traditional CVD risk factors¹⁻³. Furthermore, our patient's race (African-American) and sex (female) indicate additional risk, with one study reporting AMI to be nearly three times more likely in HIV-infected women than in uninfected matched controls². Importantly, elevated risk of AMI in HIV/AIDS also extends to patients under age 30 where the long-term effects of a serious cardiac event may be especially costly. Second, this case demonstrates the peril of anchoring bias in patients with advanced HIV/AIDS. Though this patient's presentation appeared most consistent with gastroesophageal disease, her atypical symptoms, poor response to treatment, and severely immunocompromised state called for a low threshold for re-evaluation and consideration of alternative or additional diagnoses. This HIV-specific caveat to Occam's razor is frequently invoked in considering concomitant opportunistic infections but should extend to key non-communicable conditions with increased prevalence in HIV/AIDS including cardiovascular disease. Attention to this challenge in clinical reasoning may have dramatic implications for the timely recognition of conditions with high morbidity and mortality. 1. Freiberg, MS et al. HIV infection and the risk of acute myocardial infarction. *JAMA Internal Medicine* 2013. 173(8):614-622. 2. Triant, VA et al. HOT MESS: DIAGNOSING DENGUE IN A RETURNING TRAVELER

Heidi J. Schmidt. University of California, San Francisco, San Francisco, CA. (Tracking ID #2195044)

LEARNING OBJECTIVE #1: Recognize key features that distinguish Dengue from other febrile illnesses common in travelers returning from tropical areas

LEARNING OBJECTIVE #2: Risk-stratify Dengue patients' need for inpatient admission based on an understanding of Dengue Hemorrhagic Fever and Dengue Shock Syndrome

CASE: A 26-year old female presents to the emergency department 10 days after returning from the Philippines. The patient complains of worsening fever, myalgias, pharyngitis, and headache for three days. While in the ER, she develops new nausea and vomiting accompanied by bloody diarrhea. She did not use any malaria chemoprophylaxis during her travels and recalls many daytime mosquito bites. She drank bottled water and only ate food prepared at her relatives' house; she denies any sexual contact. The patient's past medical history is significant for mild asthma, and her only medication is albuterol. She has no allergies. She does not drink alcohol, smoke, or use recreational drugs. She is in a monogamous relationship with a male partner and tested negative for HIV two years ago. Her family history is non-contributory. Physical exam is notable for

temperature of 39.2°C, pulse of 95, and an abdomen tender to deep palpation only with no organomegaly. She has rubbery mobile cervical lymphadenopathy and a faint morbilliform rash covering her back and chest. Her CBC shows an increased hematocrit, she has a mildly elevated Cr (1.31), and her PT/PTT are within normal levels. The following tests are negative: rapid influenza, HIV antibody, malaria thick and thin smears, heterophile agglutination, E.coli 0157, shiga toxin, and stool O&P. Dengue serologies are sent and IgG is 1.65 (negative <0.90) and IgM is 0.16 (negative <0.90). A diagnosis of Dengue is made, and the patient is admitted because her bloody diarrhea and lab evidence of hemoconcentration are concerning for the development of Dengue Hemorrhagic Fever (DHF). She is managed with conservative treatment including IV hydration, avoidance of NSAIDs, and daily CBC to monitor for signs of DHF.

DISCUSSION: Dengue, an arbovirus with four distinct serotypes, is a common cause of fever in tropical regions. Dengue's incubation period is 4–8 days. Importantly, nighttime mosquito nets are not protective because the Aedes mosquito that transmits Dengue bites during the day [1]. Common symptoms of Dengue are fever, retro-orbital headache, myalgias, arthralgias, and rash [2]. Spontaneous bleeding, including GI bleeding like that experienced by our patient, can also be seen. Diarrhea occurs in almost one third of patients and URI symptoms are common. In resource-poor areas, the tourniquet test can be used to diagnose capillary fragility or thrombocytopenia associated with Dengue [1]. Although serological tests are available, Dengue remains a clinical diagnosis given the poor sensitivity of the antibody tests. For example, IgM positivity can lead to a presumptive diagnosis but is only present in 50 % of patients on day 4 of illness. IgG antibodies are diagnostic only if a convalescent sample is available to compare to titers from the acute illness [3]. For most patients, Dengue is a self-limited and mild febrile illness. However, about 1 % of patients will develop Dengue Hemorrhagic Fever (DHF). DHF is defined by [3]: 1. Plasma leak 2. Thrombocytopenia 3. Fever lasting 2 to 7 days and 4. Hemorrhagic tendency. The most severe form of DHF is Dengue Shock Syndrome (DSS), which is diagnosed when a patient meets all four criteria for DHF plus has evidence of circulatory failure (shock). Fatality rates for DSS are as high as 10 %, but decrease to 1 % with adequate support care [4]. DHF/DSS tends to develop on days 3–7, often as fever subsides; this time is called the critical period. If a Dengue patient is cared for in an ambulatory setting, providers should consider trending CBCs during the critical period to triage the need to manage DHF/DSS by inpatient admission. Providers should also consider inpatient admission if patients meet one of the following criteria [4]: 1. Persistent vomiting 2. Third-spacing or hemoconcentration 3. Spontaneous mucosal bleeding 4. Lethargy or restlessness 5. Liver enlargement. The treatment for Dengue is supportive and includes hydration, avoiding NSAIDs given the propensity for hemorrhage, and monitoring for signs of DHF/DSS as above [1]. HYDRALAZINE INDUCED ANCA VASCULITIS Siddhartha Kattamanchi¹; Pooja Kumar²; Rahul Sehgal¹; Satya Varre¹. ¹Marshfield clinic, Marshfield, WI; ²marshfield clinic-st joshp's hospital, Marshfield, WI. (Tracking ID #2195532)

LEARNING OBJECTIVE #1: Diagnose hydralazine induced vasculitis.

CASE: Sixty-one year old female with past medical history of type 1 Diabetes mellitus, hypertension allergic to multiple antihypertensive medications on hydralazine 50 mg four times daily presented to our hospital with fatigue, fever, pleuritic chest pain and SOB. Going back, her symptoms started about 3 years ago with migratory arthralgia and history of tick bite and were treated as Lyme disease 3 times in 3 years with doxycycline, with improvement on 2 occasions but no improvement on recent episode after 4 month of treatment with doxycycline. She was experiencing migratory joint pains, fatigue, difficulty thinking straight, pleuritic chest pain and progressive SOB and fever ranging between 100 and 103 F. When Evaluated at other hospital, where CXR showed questionable left sided pneumonia and elevated inflammatory markers and negative Lyme serology, was treated with levofloxacin for 20 days without significant improvement in her symptoms. Subsequently developed hemoptysis, CT chest was done that showed picture suspicious for atypical pneumonia and was treated with IV antibiotics for 10 days with no response, therefore patient presented to our facility. Repeat chest CT showed presence of new sub centimeter pulmonary nodules besides ground glass opacities throughout bilateral lung fields and bilateral pleural effusions. Due to extensive nature of the infiltrates vasculitis was also considered in the differential. Work up came back positive for a p-ANCA MPO antibody and a very low titer Pr3 antibody, low positive ANA titer at 1:160 homogenous pattern, positive anti ds DNA antibody, negative c-ANCA antigen and normal complement level, negative rheumatoid factor, high markers of inflammation, ESR between 90 and 100, CRP around 15, normocytic anemia, normal white count and

normal platelet count, normal BNP and CK level. Rheumatology was consulted who did further workup for the autoimmune vasculitis. Anti-histone antibody and lupus anticoagulant was positive. Hydralazine was stopped with initial thought for Hydralazine-induced systemic lupus erythematosus (SLE) in regard to positive anti-histone antibodies. Subsequently Bronchoscopy with Broncho alveolar lavage showed numerous hemosiderin-laden macrophages and total neutrophil count of 567 and negative cultures so a diagnosis of diffuse alveolar hemorrhage due to Hydralazine-induced vasculitis was considered. Patient was started on Prednisone. Her symptoms dramatically improved and were discharged. She continued follow up with rheumatology and repeat CT chest in 2 months showed resolution of ground glass opacities and pleural effusion with improvement in symptoms.

DISCUSSION: Hydralazine was first introduced in 1951 and since then has been mainly used for management of hypertension and heart failure. Hydralazine induced lupus was first described in 1953 and can be found in 5.4 to 10.4 % of hydralazine users. Hydralazine induced vasculitis is a more serious and rare complication. Drug induced lupus presents usually as myalgia, arthralgia, malaise, fever, weight loss. Renal involvement attributable to this condition is rare and when present resembles lupus nephritis with immune complex, immunoglobulin and complement deposits. Hydralazine induced ANCA vasculitis on the other hand usually involves skin and the kidneys. Unlike lupus there is a relative lack of immunoglobulin and complement deposition on histopathology and immunostaining. Pulmonary renal syndrome is the most severe presentation of hydralazine induced vasculitis. There have only been 14 case reports of this condition and only one case of vasculitis with isolated involvement of lungs. Lung involvement presents as pulmonary hemorrhage, which in our patient explains by the hemosiderin laden macrophages on lavage. Most commonly accepted theory for pathogenesis is that, hydralazine accumulates in the neutrophils and binds to myeloperoxidase and induces neutrophil apoptosis. The apoptotic blebs of the neutrophils act as the source of immunogens as evident by the presence of various antibodies which can be seen in hydralazine induced ANCA vasculitis. In hydralazine induced lupus we usually see ANA, Anti histone antibody (AHA), and ANCA (MPO), but anti ds DNA antibodies are usually absent. Whereas in hydralazine induced ANCA vasculitis apart from ANA, AHA, ANCA (MPO) we also see positive anti ds DNA, anti-elastase antibody, low C3 and C4 and occasionally antibodies to proteinase3, anti SSA and anti SSB. Our case is only the second case where patient along with having antibodies to myeloperoxidase has antibodies to proteinase3 (PR3). Anemia is not a feature of drug induced lupus. Management of these cases includes early recognition and discontinuation of the drug. This alone might be enough in mild cases but in cases where discontinuation is delayed or the symptoms are severe, corticosteroids with or without immunosuppressive agents is needed.

HYPEREMESIS GRAVIDARUM FROM SUSPECTED GRAVES' DISEASE

Amaninder Jeet S. Dhaliwal; Garen Derhartunian; Katerina Oikonomou; Rachana Koya; Marina Iskandir; Getaw Hassen. Lutheran Medical Center, Brooklyn, NY. (Tracking ID #2194891)

LEARNING OBJECTIVE #1: Graves' disease is the most common cause of hyperthyroidism in women within reproductive age. Several studies have shown that pregnancy-associated changes in the immune system may influence the onset of Graves' disease or unmask it. We present a case of a 26-year-old female with symptoms of hyperemesis gravidarum likely exacerbated by Graves' disease.

CASE: A 26-year-old female (gravid3, parity2, abortion0) with no significant past medical history presented with a 10 days history of intractable vomiting. The patient stated that for last 10 days she was having more than 12 episodes of non-bilious and non-bloody vomiting on a daily basis. Her symptoms were more frequent and severe in the morning. She reported decreased appetite, heat intolerance, weight loss and palpitations. The rest of her review of systems was unremarkable. At presentation, she was tachycardic with a heart rate of 110 beats per minute and appeared severely dehydrated. She was given intravenous fluids and antiemetics. The rest of her physical examination was normal. A pelvic sonogram confirmed a single intrauterine gestation with estimated gestational age of 10 weeks and 3 days ruling out molar pregnancy. Initial laboratory results were significant for a thyroid stimulating hormone (TSH) level of less than: 0.008mIU/ml, free thyroxine (FT4), 6.10 ng/dl and free triiodothyronine (FT3), 14.1 pg/ml. A working diagnosis of Graves' disease was entertained based on the profound changes of her thyroid function tests. She was started on propylthiouracil (PTU) 100 mg daily and propranolol 10 mg every 8 h with improvement of symptoms. On follow-up the patient's symptoms resolved and her thyroid function tests improved significantly (TSH, 0.008mIU/ml; FT4, 1.81 ng/dl; and FT3, 4.5 pg/ml). TSH receptor antibody titer was normal (0.90 IU/ml) after 6 weeks of treatment.

DISCUSSION: Hyperemesis gravidarum is a common entity among pregnant women. It is usually self-limited and improves during the course of pregnancy. Prolonged hyperemesis may result from a number of conditions such as molar pregnancy, twin gestation and Graves' disease. Graves' disease and human chorionic gonadotrophin

(HCG)-mediated hyperthyroidism are most common causes of hyperthyroidism in pregnancy. HCG-mediated hyperthyroidism is transient and does not require any treatment, as it is self-limiting with fall in HCG levels, typically around 14–18 weeks of gestation. Graves' disease in pregnancy is diagnosed in symptomatic woman with low TSH and FT₃ and FT₄ > 1.5 times the upper limit of non-pregnant normal value and should be treated immediately. In Graves' disease, TSH receptor antibodies (TSHR-AB) are detectable in almost all patients and tend to decline when treated with antithyroid drugs. If TSHR-AB are persistently elevated despite treatment, there is a high probability of recurrence upon discontinuation of antithyroid medications. The drugs of choice for treatment of Graves' disease are PTU, methimazole (MMI) depending upon gestational age, along with beta-blockers. Other therapeutic options are thyroidectomy or plasmapheresis for patients who are intolerant or refractory to thionamides (PTU, MMI). A screening for Graves' disease should be considered in pregnant women with severe and prolonged hyperemesis gravidarum, as this condition requires prompt treatment to prevent maternal and fetal complications.

HYPERMAGNESEMIA CAN STOP THE HEART Chandana Shekar, Sonam Puri. University of Connecticut School of Medicine, Farmington, CT. (Tracking ID #2199441)

LEARNING OBJECTIVE #1: To recognize hypermagnesemia as an important cause of asystolic cardiac arrest.

CASE: A 94 year old female with past medical history of hypertension, congestive heart failure with an ejection fraction of 15 %, chronic kidney disease stage 4, type 2 diabetes mellitus not on insulin, hyperlipidemia, cerebrovascular accident and dementia was brought to the hospital via Emergency Medical Services(EMS) as she was found to be unresponsive by her caregiver. She was in her usual state of health until a few hours before admission, when she started complaining of weakness, dizziness and diaphoresis. She subsequently became unresponsive and EMS was called. She was found to be hypoglycemic with a finger stick glucose reading of 45 mg/dL. Further history was obtained from the caregiver who reported that the patient did not complain of fever, chest pain, difficulty breathing, change in bowel habits, nausea or vomiting. She denied any recent changes in her medications or medication non-compliance. There was no history of use of magnesium containing laxatives or herbal supplements. On her way to the emergency department, she received a 50 mg ampule of dextrose 50 %. On arrival to our hospital, patient was found to be hypothermic with a measured temperature of 83.8 °F and was not able to follow commands. She was noted to be bradycardic with a heart rate of 30 beats per minute and a blood pressure of 115/45 mm Hg. She was maintaining her airway and did not appear to be in respiratory distress. Her bradycardia persisted despite normalization of her blood glucose and core body temperature. She was subsequently started on a dopamine drip. Initial blood work revealed a normal complete blood count and chemistries significant for patient's baseline level of renal dysfunction (blood urea nitrogen 89 mg/dL, creatinine 3.7 mg/dL) with an elevated magnesium level of 4.0 mg/dL. Electrocardiogram showed atrial fibrillation with slow ventricular rhythm, bradycardia in the 50s, no ST or T segment changes, an old right bundle branch block and left ventricular hypertrophy. Cardiac enzymes, prothrombin time, activated partial thromboplastin time and international normalized ratio were within normal limits. Chest X ray showed mild congestive heart failure and vascular congestion. Computed Tomography scan head was negative for any intracranial pathology. Blood cultures drawn in the emergency department did not show any evidence of infection. During her hospital stay, patient remained bradycardic despite being on a dopamine drip. She was subsequently evaluated for pacemaker placement by cardiology. However, on her way to the catheterization lab, she sustained an asystolic cardiac arrest. She was resuscitated as per advanced cardiac life support protocol and spontaneous circulation was restored after 30 min. Pacemaker placement was cancelled and she was admitted to the intensive care unit for monitoring. Nephrology was consulted for persistent hypermagnesemia in the setting of bradycardia. She subsequently underwent hemodialysis for hypermagnesemia. After dialysis, her magnesium levels decreased to 2.1, she was taken off the dopamine drip and her bradycardia resolved.

DISCUSSION: In the hypermagnesemic state, excessive peripheral vasodilation and atrioventricular nodal conduction delays cause hypotension and atrioventricular nodal blocks. Hypermagnesemia is a relatively under recognized but easily treatable cause of bradycardia and cardiac arrest. High index of suspicion is thus required when a patient has elevated magnesium. Treatment of magnesium overload has focused upon hemodialysis, forced diuresis and the use of intravenous calcium salts.

HYPERTENSION: A DELICIOUS DISEASE? Wade Brown. University Of Utah, Salt Lake City, UT. (Tracking ID #2200360)

LEARNING OBJECTIVE #1: Recognize indicators of secondary hypertension.

LEARNING OBJECTIVE #2: Recognize, diagnose, and treat a rare, but notable cause of secondary hypertension

CASE: A 34-year old female was seen for follow up of hypertension. The patient had been diagnosed and started on lisinopril about three weeks prior by an alternate provider. On history, the patient recalled being informed that she had high blood pressure (BP) at about age thirty. She also recounted occasionally being told that she had elevated BPs since that time. The patient reported BPs in the "170 s/100 s" when self-checking at a local pharmacy. She endorsed a reading as high as 201/119 mmHg about 2 months prior. At the time of diagnosis, her BP was 159/104 mmHg via BpTRU®. The patient denied a history of snoring or apnea. She denied use of oral contraceptives, NSAIDs, tobacco, significant alcohol, complimentary medications, or supplements. She denied a family history of early hypertension. The patient denied episodes of chest pain, headaches, palpitations, or diaphoresis. On exam, the patient's BP was 124/88 mmHg with no notable disparity between arms. Pulse was 65 bpm. No Cushingoid features. Cardiac auscultation revealed a regular cardiac rhythm and normal rate. No murmurs or gallops were noted. No renal bruits were appreciated. No edema was present. A basic metabolic panel revealed no abnormalities. A urinalysis showed trace protein, and no blood. A renin to aldosterone ratio was 0.2. An ECG showed no abnormalities. Further discussion revealed that the patient had a history of consuming large quantities of "Australian" black licorice stating, "It's my comfort food." The patient was changed to spirinolactone and strongly encouraged to discontinue consumption of black licorice. The patient's BP improved.

DISCUSSION: Less than 10 % of all hypertensive patients have secondary hypertension (1,2). Indications for screening for secondary hypertension include: age less than 30, hypertension resistant to three medications, severe hypertension, sudden increase in a previously stable BP, or end organ damage (1). This patient's age raised concerns for a secondary cause. In general, a careful history has been shown to reveal a correct diagnosis in about 80 % of medical outpatients (3). In this case, discussion revealed a history of significant chronic ingestion of imported licorice. Hypertension secondary to excessive licorice ingestion is rare, but documented (4, 5). Glycyrrhizic acid (GZA), the molecule responsible for natural licorice flavor, is an extract from the root of the *Glycyrrhiza glabra* shrub (5). A metabolite of GZA inhibits 11-beta hydroxysteroid dehydrogenase, an enzyme that catalyzes the oxidation of cortisol to cortisone. Because cortisol is active at mineralocorticoid receptors, while cortisone is not, accumulation of cortisol results in sodium retention, hypokalemia, alkalosis, and hypertension (5). Because of these, and other known, deleterious effects of GZA, black licorice is generally artificially flavored in North America. However, GZA can be found in imported licorice, soft drinks, teas, and tobacco products (5). Thought the dose-response relationship for GZA has not been fully elucidated, consumption of as little as 50 g of licorice per day has been associated with elevated BP (5). Diagnosis is made by history. Confirmatory findings include hypokalemia, increased urine cortisol, increased cortisol to cortisone metabolite ratio, and low urine aldosterone. In this case, the patient's lab findings were complicated by the recent introduction of lisinopril. The cornerstone of treatment is discontinuation of licorice. Resolution of BP and electrolyte abnormalities can take from 2 to 4 weeks (5). Spirinolactone or triamterene can be used to treat hypertension during that time period. In conclusion, GZA-mediated hypertension is an easily treatable condition diagnosed by knowledge of indicators of secondary hypertension and careful history taking. 1. HYPERTROPHIC CARDIOMYOPATHY PRESENTING AS POST-PRANDIAL DYSPNEA Alice Tang^{2, 1}, Andrew A. Chang¹. ¹NYU/Gouverneur, New York, NY; ²New York University, New York, NY. (Tracking ID #2191271)

LEARNING OBJECTIVE #1: Recognize post-prandial shortness of breath as a presenting symptom of hypertrophic obstructive cardiomyopathy.

CASE: A 55-year-old Chinese man with a history of untreated hypertension presented with a 10-year history of post-prandial shortness of breath. The patient noted a gradual decline in exercise tolerance from unlimited to 2–3 blocks and a 10-pound weight gain over the preceding year. Three weeks prior to presentation, the patient experienced an

episode of post-prandial dyspnea with palpitations resolving after 15 min of rest. He denied chest pain, dizziness, diaphoresis, nausea, vomiting, wheezing, cough, or anxiety. The patient had a 30 pack-year smoking history. He denied family history of cardiac disease or sudden death. His exam was notable for blood pressure of 149/81, heart rate 90, and a 2/6 holosystolic murmur heard throughout precordium, accentuated by standing and diminished by handgrip. Electrocardiogram revealed left ventricular hypertrophy with repolarization abnormalities. Transthoracic echo showed preserved ejection fraction, severe left ventricular hypertrophy with asymmetric septal hypertrophy, systolic anterior motion of the mitral valve, and severe left ventricular outflow tract gradient of 40 mmHg at rest, consistent with hypertrophic cardiomyopathy. The patient was started on Metoprolol 12.5 mg every 12 h with significant improvement in symptoms.

DISCUSSION: Hypertrophic cardiomyopathy (HCM) is a clinical diagnosis consisting of unexplained left ventricular hypertrophy associated with nondilated ventricular chambers in the absence of another cardiac or systemic disease capable of producing the magnitude of hypertrophy¹. It is a heterogeneous disorder most often caused by an autosomal dominant mutation in genes encoding sarcomere-associated proteins². It manifests with variable clinical severity, from asymptomatic to sudden cardiac death^{2, 3}. Most common symptoms include exertional dyspnea, fatigue, chest discomfort, palpitations, and syncope. However, postprandial dyspnea has been reported in up to one-third of HCM patients in retrospective studies of echo-proven HCM^{4,5}. Post-prandial symptoms are related to splanchnic vasodilation from the food bolus, resulting in preload and afterload reduction and worsened left ventricular outflow obstruction⁶. Post-prandial symptoms confer a 52 % decrease in quality of life and increase in New York Heart Association class III/IV dyspnea and presyncope³. Given these associations, patients complaining of post-prandial dyspnea should undergo complete evaluation for structural heart disease and consideration of HCM. Pharmacologic treatment with beta blockers reduces the incidence of non-sustained ventricular arrhythmias, as well as minimizing outflow obstruction through decreasing heart rate, contractility, and ventricular stiffness⁷.

HYPOMAGNESEMIA MANAGEMENT WITH MULTIPLE MEDICAL CONDITIONS: A DELICATE BALANCE Adrienne N. Poon¹; Jillian S. Catalanotti². ¹George Washington School of Medicine and Health Sciences, Washington, DC; ²The George Washington University, Washington, DC. (Tracking ID #2198932)

LEARNING OBJECTIVE #1: Recognize that etiology of hypomagnesemia may be multifactorial and generate a broad differential

LEARNING OBJECTIVE #2: Describe the physiology and management of renal magnesium wasting

CASE: A 58 year old woman has a history of diabetes mellitus, hyperlipidemia, gastroesophageal reflux disease, chronic leg cramps, chronic diarrhea, depression, and fibromyalgia as well as a prolonged history of hypomagnesemia managed by oral magnesium oxide repletion. After briefly switching magnesium oxide to magnesium chloride (Slow-Mag) due to chronic diarrhea, the patient's Mg acutely dropped to 1.1 mg/dL with worsening of bilateral leg cramps. She was sent to the ED for repletion with IV magnesium sulfate. Two weeks later, she reported cramping in all extremities with spasms and twitching affecting her quality of life by night-time awakenings despite good hydration. The patient's medications included magnesium oxide, metformin, esomeprazole, insulin glargine, liraglutide, furosemide verapamil, and levothyroxine. Vital signs were unremarkable. Physical exam revealed bilateral calf tenderness, no edema, good distal pulses, and pain with motion of the left lower extremity at hip and knee. Repeat magnesium was 1.2 mg/dL. Other labs included: K 4.7 mmol/L, CO2 19, Creatinine 0.81 mg/dL, Glucose 197 mg/dL, PTH 16 pg/ml, Calcium 9.2 mg/dL, Phosphorus 3.9 mg/dL, and Hgb A1C 7.5 %. A 24-h urinary magnesium revealed daily excretion of 62.1 mg and fractional excretion of magnesium of 4 %, suggesting renal loss as a major contribution to her hypomagnesemia. She visited the ED on multiple occasions for IV magnesium repletion given the severity of cramps. On one occasion she was discharged after repletion to 2.0 mg/dL but was found to have Mg of 1.3 mg/dL several days later. The patient was treated with rifaximin for possible small intestinal bacterial overgrowth (SIBO), and afterwards noted significant improvement in diarrhea. Her proton pump inhibitor was switched to an H2 blocker, amiloride started, and furosemide discontinued. Oral magnesium was stopped in favor of repletion through diet, and she received calcium carbonate to alkalinize serum. Magnesium improved significantly and stabilized at ~1.6 mg/dL with significant improvement in cramps and resolution of diarrhea and calf tenderness on exam.

DISCUSSION: Hypomagnesemia in the setting of multiple chronic medical conditions must be managed carefully. Steady improvement addressing the root causes in an outpatient setting is preferred rather than using rapid parenteral repletion unless hypomagnesemia is severe. This patient's hypomagnesemia was most likely multifactorial in nature; thus it is important to develop a broad differential diagnosis. Renal wasting was the primary cause, with significant improvement upon starting amiloride, stopping furosemide, and inducing metabolic alkalosis. The majority of magnesium is reabsorbed through

the cortical thick ascending limb (~72 %) through a paracellular pathway driven by a voltage gradient. Reabsorption also occurs through the distal convoluted tubule (DCT) (~10 %) both passively through a transmembrane voltage gradient and then actively against electrochemical gradients. Amiloride blocks DCT sodium channels to hyperpolarize cells and induce passive Mg reabsorption through a voltage gradient. Although the patient rarely took furosemide, it was important to discontinue because its NA-K-2Cl cotransporter inhibition reduces the voltage gradient driving paracellular reabsorption. Inducing metabolic alkalosis through administration of calcium carbonate also increases paracellular Mg reabsorption through a more favorable gradient as well as through the DCT, possibly by reducing protonation of the Mg pathway. PPIs may inhibit GI absorption of magnesium. In this patient, it was important to monitor calcium levels since she was taking a higher dose of calcium carbonate than advised due to persistent heartburn after switching from a PPI to H2 blocker. Hypercalcemia inhibits magnesium reabsorption in the cortical thick ascending limb through a calcium/magnesium-channel sensor that inhibits paracellular reabsorption. This patient likely also had GI losses through diarrhea associated with SIBO that was worsened with oral magnesium supplementation. This was evidenced by the patient's improvement in magnesium as well as resolution of diarrhea after receiving rifaximin and discontinuing oral magnesium supplements. The patient was ultimately able to maintain magnesium levels through diet and avoid oral supplements. One key element of this patient's course was repeated ED visits for IV repletion with magnesium. Unfortunately, high serum magnesium levels stimulate the calcium/magnesium-sensing receptor and likely reduce paracellular absorption of magnesium, worsening renal loss. A delicate balance was needed to replete by IV only if severely low and symptomatic, while otherwise addressing the root multifactorial causes of hypomagnesemia.

I BRUISE EASILY Meredith M. Barr; Benjamin Bailey. Tulane University Health Sciences Center, New Orleans, LA. (Tracking ID #2198570)

LEARNING OBJECTIVE #1: Review the work-up of isolated prolonged PTT

LEARNING OBJECTIVE #2: Discuss the causes of acquired factor VIII deficiency

CASE: A 55-year-old African American woman presented with complaints of 4 days of oral swelling and difficulty swallowing with associated dyspnea. Her past medical history only included chronic obstructive pulmonary disease. She reported a 1-month history of spontaneous bruising of the extremities and vaginal spotting. Review of systems was also positive for 1 month of subjective fever, and morning stiffness, bilateral knee and wrist pain. She had no previous history of clotting disorder or family history of clotting disorders. On triage in the emergency room, she was found to have scattered oral ecchymosis. Given her dysphagia, a laryngoscopy was performed showing laryngeal bruising. Laboratory abnormalities showed an isolated PTT prolongation of 46.6 s. Mixing study showed failure of PTT to correct. Subsequent evaluation of Factor VIII was ordered showing a low level of 1.03 (normal 50–150) testing suggestive of acquired factor VIII inhibitor (Factor VIII inhibitor elevated). An underlying reason for acquired factor VIII inhibitor was considered including concern for rheumatologic condition or malignancy given risk factors and review of systems suggestive of arthralgias. Rheumatologic history was not consistent with any clear disease process; antinuclear antibody and rheumatoid factor negative. Further malignancy screening was negative for both signs of hematologic and solid tumor malignancy. She was subsequently placed on high dose prednisone and cyclophosphamide in order to suppress factor VIII inhibitor. She was placed on recombinant factor VIIa twice daily with close inpatient monitoring of symptoms and factor VIII levels as an inpatient. At the time of discharge she had increased factor VIII level to 3.04 % (off recombinant factor) and was discharged with hematology follow up on continued prednisone, cyclophosphamide, and tranexamic acid.

DISCUSSION: Isolated prolonged PTT has a narrow differential of diseases affecting the intrinsic pathway of the clotting cascade. Often PTT is prolonged by iatrogenic causes including low molecular weight heparin or heparin use. Outside of medication causes patients presenting with prolonged PTT fall in two major groups: factor deficiency (primarily factor VIII) or lupus anticoagulant, which is more likely to cause hypercoagulable state. When factor deficiency is considered, a mixing study must be obtained to distinguish factor deficiency from the existence of factor inhibitors. A mixing study that does not correct to normal is suggestive of a factor inhibitor or acquired hemophilia A. Acquired hemophilia A is a rare bleeding disorder caused by autoantibodies directed against clotting factor VIII. As opposed to a factor deficiency, it is more likely to occur in adults and often presents with hemorrhages in the soft tissues. Acquired hemophilia A has an association with multiple disease processes including rheumatologic disease, solid tumor malignancy, chronic pulmonary disease, pregnancy, diabetes and hepatitis. In spite of these associations, the etiology of the disease remains idiopathic in greater than 50 % of cases. Treatment of acquired hemophilia A concentrates on controlling acute bleeding and suppressing the autoantibody. Treatment of bleeding is achieved with replacement of the lost factor, factor VIII concentrates in low titer inhibitors, or factor VIII bypassing agents such as recombinant factor VII in patients with high inhibitor titers. Long-term

suppression of the factor VIII antibody is achieved with cyclophosphamide and high dose steroids.

IDIOPATHIC NON-UREMIC CALCIPHYLAXIS: A CASE STUDY Shakil Shaikh; Kah Poh Loh; Behdad Besharatan. Baystate Medical Center/Tufts University, Springfield, MA. (Tracking ID #2199344)

LEARNING OBJECTIVE #1: Recognize and diagnose calciphylaxis in a non-uremic patient.

LEARNING OBJECTIVE #2: Identify causes of non-uremic calciphylaxis, and possible treatment modalities.

CASE: A 77-year old female with a history of vascular insufficiency, atrial fibrillation on warfarin (started a year prior to current admission), and hypertension, presented to our facility on multiple occasions for worsening lower extremity necrotic ulcers of unknown etiology, refractory to previous treatment modalities. She presented to us on current admission for intractable pain secondary to the ulcers, and was further admitted for pain management, along with further work-up regarding etiology of ulcers. No associated systemic symptoms were noted and she denied any weight loss. She did not drink, smoke or use recreational drugs. Her ulcers began approximately 3 years prior, and started on her left lower extremity that gradually progressed to the right lower extremity. Biopsies showed epidermal ulceration with underlying inflammation and fibrosis, along with calcification of the vasculature. She was initially managed conservatively with topical treatment, followed by prednisone, to which there was no significant improvement of the ulceration. Given no definite diagnosis and her increasing narcotic requirement, a repeat biopsy was performed during hospitalization, which showed progressive intravascular calcifications in smaller blood vessels; large caliber vessels were identified without calcium deposition, highly suggestive of calciphylaxis. Of note, her renal function was normal throughout. Concerning for non-uremic calciphylaxis, work-up for secondary causes were sought but were essentially unremarkable, including normal metabolic, autoimmune, infectious, vasculitic and hormonal (TSH, PTH, vitamin D) panel, as well as protein C and S. She was up-to-date with age appropriate cancer screening, with negative CT chest, abdomen and pelvis. She was eventually diagnosed with idiopathic non-uremic calciphylaxis, started on 20 mg IV infusion of sodium thiosulfate (STS), three times a week, for a 3-week duration with plans to taper off prednisone and warfarin. While on STS, her primary care physician is actively following up with her for resolution of ulcers.

DISCUSSION: Calciphylaxis is a progressive syndrome of small vessel arteriolar calcification, resulting in ischemia and necrosis, commonly seen in patients with end stage renal disease (ESRD) secondary to abnormalities in the calcium-phosphate axis. It has been reported as low as 4 % in patients undergoing hemodialysis. Although bone and mineral metabolism, hyperparathyroidism, and vitamin D therapy have all thought to contribute to uremic calciphylaxis, the exact cause of the disease process remains unknown. Calciphylaxis in non-uremic patients is furthermore a rarity, as research has only been able to cite less than 100 cases since 1990, most commonly seen in Caucasian females. Diagnosis of calciphylaxis is based on clinical, biochemical, histopathological and radiological findings. In our patient of non-uremic calciphylaxis, the diagnosis was deduced clinically from her necrotic ulcers confirmed by calcium deposition by histopathology and normal laboratory and radiological work-up. Causes of non-uremic calciphylaxis are hypothesized to include malignancies, parathyroid hormone effects on RANK ligand expression, or secondary to warfarin use, which can inhibit vitamin K-dependent carboxylation of matrix-Gla protein, decreasing the activity of the aforementioned protein to inhibit calcification deposition. Other causes, as seen in a systematic review of cases reported before 2007, also include diabetes, alcoholic liver disease, weight loss, CKD (not ESRD), Crohns disease, vitamin D deficiency and protein C/S deficiency. Warfarin and prednisone were identified as possible triggers although in our patient, her ulcers preceded the initiation of both medications by at least 1.5 years. Treatment for calciphylaxis secondary to ESRD involves intravenous STS; due to limited cases of non-uremic calciphylaxis, treatment is often empiric. The reported duration of IV STS treatment ranges from 3 to 12 weeks. As per previous cases, treatment for non-uremic calciphylaxis involved treatment with IV STS 25 mg every morning, with improvement noted in 2 months, and complete resolution in 6 months. Other cases discussed IV STS 20 mg infusions three times weekly with resolution in 3 weeks. In our patient, we initiated IV STS 20 mg infusions three times per week, and she was closely followed up for adverse side effects and resolution of ulcerative lesions. It has been seen that IV STS can be effective in refractory calciphylaxis in non-uremic patients. Larger studies, however, are needed to determine the exact mechanism of IV STS in non-uremic calciphylaxis patients.

IDIOPATHIC OCCIPITAL NEURALGIA A RARE CAUSE OF DEBILITATING HEADACHE Larry J. McMann; Tiba Alwardi; Vesna Tegeltija; Salwan Al-Mutar; Reem Al-Mahdawi; Hussam Sabbagh; Sarwan Kumar; Khalid Zakaria; Zain Kulairi; Alex Adams. Wayne State University, Rochester, MI. (Tracking ID #2182557)

LEARNING OBJECTIVE #1: Identify the presentation of occipital neuralgia

LEARNING OBJECTIVE #2: Judicious use of diagnostic tools and treatment

CASE: A 27-year-old female presented to the ER with episodes of severe intermittent headache over the past 3 weeks. Prior to her presentation at admission she reported 2 episodes of intermittent pain on the right occipital region. She promptly followed with her primary care physician who prescribed her oral steroids. The 2 weeks following the initial episodes were symptom free. On the day of admission she was watching television when she experienced a recurrence of the 10/10 right sided occipital headache with radiation over her vertex. Initial vital signs were unremarkable, however, physical exam was significant for tenderness over the right occipital region of the scalp. Labs were within normal limits. MRI did not reveal any abnormality. A consultation to neurology was obtained and the patient was started on carbamazepine, gabapentin and narcotics, which provided little relief. The patient's distribution of pain in the greater occipital area in addition to ruling out secondary causes of headache made ON the likely diagnosis. Pain management was consulted and greater occipital nerve block was performed which provided complete resolution of her symptoms. She was discharged home with carbamazepine the following morning and continued to be symptom free at follow up.

DISCUSSION: Occipital neuralgia is usually defined as paroxysmal stabbing pain in the greater or lesser occipital nerve distribution. Although there is no published data to suggest the incidence of occipital neuralgia (ON), it is generally considered a very rare cause of headache. ON is a rare cause of headache that has no published data on incidence. Since this is a rare disorder there is limited evidence in the literature to support the full understanding of its physiology and treatment. Currently, the diagnosis is made by history, characteristics described in the International Headache Society, exclusion of referred pain by CT/MRI and anesthetic block of the occipital nerve. Patients with severe symptoms can continue to have a debilitating headache despite conservative management. The best treatment in the acute setting is the same intervention for diagnosis, which is an occipital nerve block. Patients with recurrent ON symptoms despite steroid injections benefit from botulinum injections and pulsed radiofrequency. This case illustrates the detailed diagnostic evaluation and the need for high suspicion by the primary physicians to consider ON. It is often challenging to diagnose, yet it is critical to do so as early diagnosis and treatment can maximize recovery.

IDIOPATHIC PANCREATITIS: AN UNCOMMON INITIAL PRESENTATION OF ULCERATIVE COLITIS Ana I. Velazquez; Naoka Murakami; Priyanka Mittar. Mount Sinai Beth Israel, New York, NY. (Tracking ID #2198057)

LEARNING OBJECTIVE #1: Recognize extraintestinal manifestations of Ulcerative Colitis (UC) and their presentation as early disease manifestation.

CASE: A previously healthy 26 year old Caucasian (Ashkenazi Jew) male presented with 7 days of crampy left upper quadrant abdominal pain radiating to his back and blood-tinged diarrhea (5–10 episodes/day). Patient had visited his primary care provider and had been prescribed amoxicillin for “community-acquired diarrhea” without improvement. Denies sick contacts, unintentional weight loss, and personal or family history of gastrointestinal disease. Physical exam was significant for abdominal tenderness to palpation over left upper quadrant without rebound and guarding. Labs were significant for elevated lipase 1380 U/L (normal 23–300), C-reactive protein (CRP) 3.1 mg/dL (normal <1.0), and CBC, serum albumin, bilirubins and Alkphos were within normal range. These results support acute inflammatory process including acute pancreatitis and/or colitis, but inconsistent with chronic long-standing inflammation. Given clinical picture of pancreatitis on presentation, CT abdomen pelvis was ordered, which revealed mild peripancreatic stranding and thickening of the entire colon and rectum consistent with acute pancreatitis and diffuse colitis. Complete investigation aiming to discover a possible cause for the acute pancreatitis such as biochemical disturbances, including calcium, autoimmune causes, including ANA and IgG4, tryglycerides, cholelithiasis, and drug or alcohol consumption was negative. Given patient's age, ethnicity, elevated inflammatory markers and presenting symptoms, inflammatory bowel disease (IBD) was suspected; infectious causes were ruled out with negative stool cultures, ova and parasite as well as C. difficile toxin. Colonoscopy showed inflammatory changes in a continuous and circumferential pattern from the anus to the cecum suggestive of ulcerative colitis (UC). Pathology showed chronic colitis without granulomas or dysplasia, consistent with UC. A diagnosis of idiopathic acute pancreatitis in the setting of newly diagnosed IBD was made. Our patient was discharged on mesalamine with resolution of diarrhea and improvement in left abdominal cramping on 2-week post discharge follow up.

DISCUSSION: UC and Crohn Disease are associated with a number of extraintestinal chronic inflammatory diseases that can present following a diagnosis of IBD or as initial presentation. These diseases include primary sclerosing cholangitis, PBC, ankylosing spondylitis, iritis/uveitis, pyoderma gangrenosum, and erythema nodosum. Our case described a case of acute idiopathic pancreatitis as an initial manifestation of UC. Patients with IBD have a 1.5- to 2.1-fold increased incidence of both acute and chronic

pancreatitis, however, clinical symptoms of IBD-associated acute pancreatitis are found only in approximately 1.4–2.7 % of patients. The most frequent causes of acute pancreatitis in UC are cholelithiasis, drug-induced (mainly by mesalazine, immunosuppressors, glucocorticoids and metronidazole), duct obstruction, autoimmune, and alcohol induced; in our case, common causes of acute pancreatitis were ruled out. Idiopathic pancreatitis has been described as an extraintestinal manifestation of UC that rarely can present as an initial manifestation of newly diagnosed UC. It's important to recognize the association of acute pancreatitis and IBD, given that the predominant findings may be caused by acute pancreatitis rather than colitis, delaying the time of diagnosis. Clinicians should pay extra attention to obtaining a detailed history and thorough physical exam in order to recognize the multiple extraintestinal manifestations of UC that may present prior to gastrointestinal symptoms.

ILIACUS MUSCLE ABSCESS COMPLICATING CROHN'S DISEASE IN PREGNANCY Lara Dakhoui; Charles Berkelhammer. UIC/Advocate Christ Medical Center, Oak Lawn, IL. (Tracking ID #2202900)

LEARNING OBJECTIVE #1: Recognize the complications of Crohn's disease (CD) in pregnancy.

LEARNING OBJECTIVE #2: Diagnose pyogenic skeletal iliacus muscle complicating Crohn's disease in pregnancy without the use of ionizing radiation. Manage skeletal muscle abscesses in pregnancy without the use of ionizing radiation.

CASE: A 24 year old female presented during her pregnancy, at 31 weeks gestation, with a complaint of right flank pain of 3 weeks duration. The pain radiates to her right groin and thigh, and is exacerbated by minor movements of her right lower extremity (RLE). It progressed till she found ambulation difficult. She was diagnosed with CD at age 18 and has been on remission with azathioprine, but the patient elected to discontinue azathioprine when she found out she is pregnant. Her pregnancy was uneventful until 31 weeks gestation when she complained of right groin and thigh pain. She denied fever and chills. On physical exam, there was a significant tenderness with any movement of the RLE, pain on raising the right leg off the bed with a positive psoas sign. Magnetic resonance imaging (MRI) revealed an abscess in the right iliacus muscle with thickening of the adjacent ileum. Ultrasound (US) guided drainage of the abscess was performed with 90 ml of purulent fluid retrieved. The fluid cultured multiple enteric organisms. She received 4 weeks of intravenous cefepime. A repeat MRI confirmed the resolution of the abscess. She had uneventful induced delivery at 37 weeks with a healthy infant. Post partum, the patient underwent elective ileocecal resection.

DISCUSSION: Purulent musculoskeletal complications can occur as a result of abscessing/fistulizing CD.¹ These complications can also occur during pregnancy as well. Our patient chose to stop her Azathioprine during pregnancy which may have increased her likelihood of a flare-up of CD and subsequent complications. An iliacus muscle abscess was able to be diagnosed by MRI without gadolinium, and the abscess was treated by US guided drainage without the use of ionizing radiation. MRI and US guided drainage are the preferred methods for the diagnosis and management during pregnancy. Purulent musculoskeletal complications of CD have been described in 4 % of patients.¹ MRI has been utilized to diagnose muscle abscesses in CD, 2 which is the optimal imaging technique during pregnancy. Abscesses that had been described include gluteal muscle abscesses, iliopsoas muscle abscesses, rectus muscle abscesses and sacral osteomyelitis. In conclusion, physicians should be aware of pyogenic complications of CD including during pregnancy. MRI is a useful imaging modality to diagnose a muscle abscess in pregnant women. US guided drainage of these abscesses is helpful in avoiding ionizing radiation in this setting. Management of patients with Crohn's related abscesses in pregnancy requires the expertise of multiple specialties. **References:** 1- Berkelhammer C, Debre M, Gutti P. Piriformis muscle abscess complicating Crohn's ileitis. *Inflamm Bowel Dis*. 2005 Nov;11(11):1028–9. 2-Tonolini M, Ravelli A, Campari A, Bianco R. Comprehensive MRI diagnosis of sacral osteomyelitis and multiple muscle abscesses as a rare complication of fistulizing Crohn's disease. *J Crohns Colitis*. 2011 Oct;5(5):473–6.

IMMUNE THROMBOCYTOPENIC PURPURA IN A PATIENT WITH SARCOIDOSIS: CASE REPORT AND REVIEW OF THE LITERATURE. Mohammed A. Bahaa Aldeen¹; Nibras Talibmamy²; Omar Nadjem¹; Essam Nakhla¹; Abdel Rahman A. Omer¹; Steven Urban¹. ¹Texas Tech Univ Health Sciences Center, Amarillo, TX; ²Kufa, Alnajaf, Iraq. (Tracking ID #2195203)

LEARNING OBJECTIVE #1: Investigate the association between sarcoidosis and immune thrombocytopenic purpura.

LEARNING OBJECTIVE #2: The prognosis of ITP in patients with sarcoidosis has become more favorable in response to modern therapies. The cause for the association of these two diseases remains unknown.

CASE: A 42 year old man presents with 1 day history of spontaneous bleeding from gums and oral cavity as well as generalized purpura. The patient has noted black stools for several days. He denies recent fever or infectious symptoms. Past medical history is remarkable for pulmonary sarcoidosis confirmed by excisional biopsy of a periportal lymph node 3 years before admission. The patient also has moderate intellectual impairment. The patient does not use ethanol, tobacco, or any non-prescribed drugs. P/E BP 130/70, HR 120 and regular, RR 20, temperature 99.1, oxygen saturation 95 % on room air. Diffuse petechiae on the face, neck, chest, and legs were noted (see images). There was stable clot in the gum area and two 1 cm diameter hemorrhagic bullae on the oral mucosa. No lymphadenopathy was detected. Lungs: clear to auscultation bilaterally, without rales or wheezing. Normal cardiac exam. Abdominal exam: normal bowel sounds, but splenomegaly was present. Lab: WBC 4.7, Hb 12.5 gm/dL, Hct 39 %, MCV 75 fl, platelets 5000 mm³, neutrophil 73 % and lymphocytes 14.8 %. PT 12.8 s with INR 1.08. BUN 16 mg/dL, creatinine 0.6 mg/dL. Serology negative for Hepatitis/HIV/H Pylori. Peripheral blood smear showed no schistocytes or abnormal platelets. **Hospital Course:** The patient was resuscitated with IV fluids and started on prednisone 60 mg orally daily as well as proton pump inhibitor. After three days of prednisone therapy, there was no improvement in platelet count or clinical status. The patient's hemoglobin declined, requiring the administration of 2 units of packed rbc's, and melena continued. At this point, intravenous immunoglobulin (IVIG) was instituted, again with no effect on platelet number. On day 8, the patient developed headache and confusion as well as limited alveolar hemorrhage. He was moved to MICU, where a head CT showed intracranial hemorrhage without midline shift. Rituximab and five units of platelets were given, still without improvement in the platelet count. The patient and his guardian refused the option of splenectomy, and the patient was discharged to a hospice facility. Upon return to the clinic (24 days after institution of steroids, 18 days after the third and last dose of rituximab), however, his platelets had risen from 9000 to 206,000, and the petechiae and mucosal bleeding had resolved.

DISCUSSION: In 1938, Jersild et al. were first to report the occurrence of thrombocytopenia in sarcoidosis (9). Since then, only 65 cases have been reported (1,6,7,8). In their 2011 review of the topic (1), Mahevas et al. indicate that thrombocytopenia in sarcoidosis can stem from three main mechanisms: hypersplenism, bone marrow infiltration, and immune thrombocytopenia (ITP), with this last mechanism accounting for 80 % (16 of 20) of cases. Unlike thrombocytopenia in lupus erythematosus or other autoimmune diseases, sarcoidosis-associated ITP has been reported as particularly severe at presentation and outcome, with a trend to unresponsiveness to available treatments and to death (5). In a review by Dickerman et al. in 1972, 5 deaths related to bleeding were reported among 33 patients (15 % mortality rate) (11). After the development of immunoglobulin therapy, less death were reported among ITP patients. Most reported observations, however, have involved single cases or small series, leading to possible biases by selecting the most severe patients, as well as patients treated before the era of modern management of ITP. Mahevas et al. (1), in their retrospective study of 20 cases of ITP and sarcoidosis, came to these conclusions: 1) ITP at presentation was usually severe, but response to treatment was favorable in almost all cases, with no deaths and no severe bleeding, in contrast with older reports. 2) the sarcoidosis in cases with ITP was often characterized by acute onset, chronic course, and the need for prolonged prednisone therapy, and 3) the onset and evolution of sarcoidosis and ITP were not always synchronous. Our patient presented with severe, symptomatic thrombocytopenia and was initially refractory to steroids and IVIG. In this regard, he was similar to cases reported by Dickerman, emphasizing severity of the disease process at presentation. Like the patients reported by Mahevas after the development of more advanced therapy for ITP, however, our patient eventually responded favorably to rituximab-based treatment. Despite his high risk of surgical mortality, our patient was considered for splenectomy, but he and his decision-makers refused consent. In retrospect, it might be advisable to manage patients with high surgical risk conservatively to give a chance for platelets to recover with medical intervention.

IN SEARCH OF A CULPRIT: A CASE OF MASSIVE HEMOLYSIS FROM A COMMONLY USED DRUG Jane M. Zhu; Timothy Schmidt; Marcia Glass. University of California, San Francisco, San Francisco, CA. (Tracking ID #2195025)

LEARNING OBJECTIVE #1: Recognize a rarely reported and catastrophic adverse reaction of piperacillin, a frequently used antibiotic

LEARNING OBJECTIVE #2: Review the management of drug-mediated hemolysis.

CASE: A 47-year-old paraplegic man presented with severe pain from his sacral decubitus ulcers. On exam, he was tachycardic, diaphoretic, and had multiple foul-smelling, full thickness ulcers. He had no allergies and took no medications. Labs were notable for a white blood count of 22,000/mm³, hemoglobin of 8.5 g/dL, and creatinine of 4.2 mg/dL. He was empirically started on vancomycin and piperacillin-tazobactam for sepsis. Within 24 h of admission, a nurse performing routine vital signs found the patient unresponsive and without a pulse. A code blue was activated. Pericardial, the patient's hematocrit was 4.4 %, with hemoglobin "unmeasurable due to interfering substances." Platelets were

196,000/mm³, down from 317,000/mm³ at admission. Stat CT imaging of the chest, abdomen, and pelvis did not demonstrate a source of bleeding. His bedside nurse denied any melena or hematochezia during the day. A number of hemolysis labs were sent and were notable for lactate dehydrogenase 2411 u/L, haptoglobin 25 mg/dL, reticulocyte percentage 2.62 %, and total bilirubin 2.4 mg/dL. A peripheral smear revealed severe anemia, red cell agglutination, microspherocytes, and hemophagocytosis by neutrophils. The team initiated massive transfusion protocols and attempted to locate more complete records from outside hospitals. Records from one area hospital revealed that the patient had been transfused for a 6-point hemoglobin drop after receiving piperacillin-tazobactam during a hospitalization only three weeks earlier. There, he had received empiric steroids in the ICU before leaving against medical advice. Against this information, piperacillin-tazobactam was discontinued immediately. Further work-up at our hospital revealed that the patient had a strongly positive direct antiglobulin test as well as a positive indirect antiglobulin test. An antibody screen later returned positive piperacillin antibodies in both the serum and eluate. Because he developed worsening renal insufficiency from sepsis and hemoglobinuria, the patient was started on plasmapheresis in an attempt to remove the antibodies mediating this reaction and to decrease the level of piperacillin in the blood more quickly. His blood counts eventually stabilized with supportive care, but he was found to have evidence of severe anoxic brain injury.

DISCUSSION: This patient had massive piperacillin-induced hemolysis and subsequent pulseless arrest. Historically, methyldopa and high-dose penicillin have been responsible for the majority of drug-induced hemolysis cases. Complex penicillins, including piperacillin, and second- and third-generation cephalosporins, such as cefotetan and ceftriaxone, are increasingly associated with this adverse reaction, which involves the development of an antibody to a drug, a red blood cell (RBC), or a combination of the two. Drug-induced processes therefore can be serologically indistinguishable from primary autoimmune or warm hemolytic anemia, and a presumptive diagnosis can be made only if the patient responds to withdrawal of the drug. This patient's strongly positive direct antiglobulin test was consistent with an immune-mediated mechanism, and was verified to be due to piperacillin antibodies against RBCs in subsequent testing. Piperacillin-induced hemolytic anemia has been reported to have a 6 % fatality rate in one case series, although these numbers are as high as 50–100 % in pediatric and cystic fibrosis patients and are likely underreported. Hemolysis usually resolves within several days of discontinuing the medication but occasionally requires months to fully resolve. In cases of severe hemolysis, and when drug-dependent antibodies are involved, limited data suggest that corticosteroids may aid in recovery. RBC transfusions also can be given, but the transfused cells may hemolyze at a similar rate as the endogenous RBCs if drug and antibody are still present. Because significant concentrations of residual drug or drug-antibody complexes may be present in the patient's serum, drug-dependent antibodies will react frequently against non-drug-treated RBCs. This finding is highly contingent on plasma drug concentration, and more commonly described with anti-cefotetan, anti-ceftriaxone, and anti-piperacillin antibodies. The role of plasmapheresis in such cases is not yet established but can theoretically facilitate removal of the offending agents. Piperacillin-tazobactam is a first-line broad spectrum antibiotic with millions of doses administered annually. Although it is a reported cause of drug-mediated hemolysis, many clinicians are not aware of its potentially catastrophic adverse effects.

INFLUENZA VACCINE TRIGGERING THROMBOTIC THROMBOCYTOPENIC PURPURA (TTP) Neil Gupta^{1, 2}; Yihan Yang¹. ¹Yale, New Haven, CT; ²Yale University, New Haven, CT. (Tracking ID #2199392)

LEARNING OBJECTIVE #1: Know the mysterious signs and symptoms associated with TTP

LEARNING OBJECTIVE #2: Recognize the rare risks of vaccines, including TTP

CASE: A 40-year-old African-American female with hypertension, hyperlipidemia, and type 2 diabetes was initially admitted to an outside facility with diarrhea and severe lightheadedness. Two weeks prior to presentation, she received the influenza vaccine at a local pharmacy and immediately developed cough and flu-like symptoms for one week. During the second week, she began experiencing fatigue, headaches, dizziness, abdominal pain, confusion, and dark urine, rendering her unable to complete her tasks at work. Review of systems was also notable for shortness of breath and increased bruising. Home medications included Zocor, Metformin, Lisinopril/HCTZ, Prevacid, and Toprol XL. Her vitals on admission were within normal limits with an unremarkable physical exam. Her labs were significant for platelet count 10,000, LDH 800, fibrinogen 419, and schistocytes on peripheral smear. ADAMTS13 level was <3 %. Other work-up, including direct Coombs test, HIV, and hepatitis panel, was negative. Her presentation was felt to be consistent with TTP, though she had normal creatinine. She underwent four rounds of plasmapheresis but continued to have recurrent thrombocytopenia. During her fourth treatment, she had an anaphylactic reaction. She was started on high dose prednisone

and was able to tolerate two additional rounds of plasmapheresis with good response. At the time of discharge, her platelet count was above 200, and her symptoms had resolved.

DISCUSSION: Our patient was diagnosed with acute TTP caused by autoantibody-mediated ADAMTS-13 deficiency. TTP is typically diagnosed based on a pentad, including microangiopathic hemolytic anemia with schistocytes on smear, fever, renal dysfunction, neurological signs, and thrombocytopenia. TTP can be familial or can occur due to various secondary causes, including viral or bacterial infection, pregnancy, autoimmune disease, organ transplant, cancer, or immunosuppression. The acquired deficiency of von Willebrand factor (vWF) cleaving protease, ADAMTS-13, has been associated with the diagnosis of TTP. Acquired TTP can occur due to inhibitory antibodies against the vWF cleaving protease. Our patient's clinical signs and symptoms as well as laboratory data all supported the diagnosis of TTP. After an extensive work-up, the development of our patient's TTP was attributed to the influenza vaccine. While vaccination is an important part of preventive medicine, vaccines have been associated with autoimmune events in rare instances. In our particular patient, we believe that our patient acquired TTP since the vaccine produced anti-ADAMTS IgG inhibitor. There are minimal case reports in the literature of TTP following administration of the flu vaccine, and this is known as a rare side effect. However, our patient responded to plasmapheresis and corticosteroids, the known treatments for acquired TTP, and her platelet count recovered. In conclusion, we present a patient with TTP following the flu vaccine. The patient initially presented with various mysterious symptoms after the flu vaccine and was ultimately found to have TTP. Signs and symptoms of TTP can be varied and subtle, but it is important to remain alert to them. The association with the influenza vaccine is seen in few case reports in literature but demonstrates the rare side effects of vaccines.

INTEGRATIVE MEDICINE THERAPIES FOR CHRONIC HEADACHE: A CASE REPORT Justin G. Laube^{1, 2}; Lawrence Taw^{1, 2}. ¹UCLA, Los Angeles, CA; ²David Geffen School of Medicine, Los Angeles, CA. (Tracking ID #2194040)

LEARNING OBJECTIVE #1: Recognize the potential role of integrative medicine therapies in the management of chronic headaches.

LEARNING OBJECTIVE #2: Recognize the overlapping features of chronic migraine and chronic tension-type headache.

CASE: A 59 year old male attorney with a past medical history of anxiety, sleep apnea and migraines was seen at a university-based integrative medicine clinic with a complaint of daily headaches. His headache was described as a "tension" that radiated from the occiput to his orbits, moderate severity, bilateral and was worse in the afternoon and upon awakening. His headaches improved with massage of the neck, and avoidance of work-related stress. He recalls having headaches since childhood and both his mother and sister have chronic migraines. Three times per week his headache worsens and is accompanied by unilateral blurring of vision, nausea, vomiting, and photophobia. This worsening can be precipitated by alcohol and weather changes. To manage both types of headaches he regularly uses sumatriptan, aspirin and hydrocodone, prescribed by his PCP. He had previously seen a neurologist and was prescribed amitriptyline and propranolol for prophylaxis which were ineffective despite 6 month trials. He denied any persistent visual changes, hearing loss, numbness or weakness. His sleep was poor and he sparingly uses his CPAP because of mask fitting issues. He reports eating large amounts of red meat with limited fruit and vegetables. On exam, he is overweight. His neck was supple with a full range of motion. Palpation of his upper trapezius muscles and base of occiput reproduced the radiating pain to his orbits. Neurologic exam was normal. No prior imaging of his head or spine was reported, and recent blood tests were within normal limits. Treatment focused on his chronic daily headaches for which he was seen every 2 weeks for a total of 5 visits. Each visit included acupuncture for 15 min and trigger point injections with 1 % lidocaine to the trapezius and splenius capitis musculature. A self-care plan incorporating self-massage and stretching of the neck/shoulder region was implemented. Stress management included walking and meditation. He was advised to reduce alcohol use and increase his intake of vegetables. After the first treatment he reported no migraine symptomatology and had reduced his PRN pain medication use to only ½ tablet of hydrocodone per week. He reported ongoing reduction of headache frequency and severity at each visit. By his last visit, the frequency had fallen to twice per week, severity was rated as mild, had not required any PRN pain medications, and his overall quality of life had greatly improved. During his treatment, he was adherent to the dietary recommendations, self-massage plan, and relaxation techniques.

DISCUSSION: Chronic daily headache (CDH) is characterized by having symptoms > 15 days/month for 3 months or 180 days/year. Prevalence is estimated to be 4 % of the adult population¹. CDH encompasses multiple different headache diagnoses, most commonly chronic migraine (CM) and tension type headache (TTH). There is significant overlap between migraine and TTH, with one study finding 58 % of migraine patients reporting tension-type symptoms and 68 % of TTH reporting migraine-type symptoms². This patient case exhibits features of both chronic TTH and CM complicated by medication overuse, undertreated sleep apnea, and unmanaged stress. Many patients with chronic

headache are dissatisfied with a purely pharmacotherapy-based approach because of side effects and refractory symptoms. Rates of complementary and alternative medicine (CAM) use by headache sufferers is reported as high as 50 %³. A Cochrane review in 2009 investigating the use of acupuncture for migraine prophylaxis concluded acupuncture is at least as effective as, or possibly more effective, than prophylactic drug treatment, and has fewer adverse effects⁴. Similarly, in the same Cochrane release, it was concluded acupuncture could be a valuable option to treat frequent episodic or chronic TTH⁵. A meta-analysis in 2007 strongly supported the use of other CAM interventions including mind-body therapies in the management of recurrent migraine and TTH⁶. This case exhibits the potential of utilizing an evidence-based, integrative medicine approach that incorporates conventional and CAM therapies while encouraging patient participation in the treatment of chronic headache conditions. 1-Garza I, Schwedt T. Diagnosis and management of CDH. *Semin Neurol* 2010;30(2):154–66. 2-Turkdogan D, Cagirci S, et al. Characteristics and overlapping features of migraine and TTH. *Headache* 2006;46:461–68. 3-Adams J, Barbary G. IS HIV ALWAYS ON OUR RADAR? Kristen Hysell; Onyema Ogbuagu; Lydia A. Barakat. Yale New Haven Hospital, New Haven, CT. (Tracking ID #2194841)

LEARNING OBJECTIVE #1: Recognize specific clinical signs and symptoms of chronic HIV infection.

LEARNING OBJECTIVE #2: Review current guidelines for universal HIV screening.

CASE: Patient #1 is a 60 year old Caucasian male with a history of coronary artery disease with ischemic cardiomyopathy, chronic obstructive pulmonary disease, and lupus in remission, who had been evaluated over a two year period for pancytopenia and fatigue, during which time he was also noted to have recurrent esophageal candidiasis. In the most recent 8 months he had a 40 lb weight loss and complained of worsening, disabling fatigue. He denied any history of risky sexual contact or illicit drug use. Patient #2 is a 55 year-old African American male with a 4 year history of severe psoriasis, 2 year history of pancytopenia, recurrent oral candidiasis, and recurrent herpes zoster who presented with 25 lb weight loss over a four month period, fatigue, and non-productive cough of one month duration. Both patients had been followed closely by multiple subspecialists for several years and had undergone, extensive work-ups targeting their individual problems. However, human immunodeficiency virus (HIV) testing was not offered until their disease was advanced. Abnormal CD4 counts in bone marrow examination of the first case and flow cytometry testing in the second case finally prompted HIV testing. Unfortunately, both patients tested positive and were found to have very low CD4 counts of 18 and 1 cell(s)/microliter, respectively, indicating advanced acquired immunodeficiency syndrome (AIDS). Upon more extensive history-taking, it was discovered that the first patient had received a blood transfusion in the pre-HIV screening era and the second patient had a remote history of risky sexual behavior. Both individuals were ruled out for active opportunistic infection (OI) and subsequently started on antiretroviral therapy and appropriate OI prophylaxis.

DISCUSSION: These two cases highlight the need for providers to be properly trained on the signs and symptoms suggestive of chronic HIV infection, including unexplained weight loss, diffuse lymphadenopathy, recurrent oral or esophageal candidiasis, herpes zoster, severe dermatological conditions including psoriasis, or unexplained anemia, leukopenia, or thrombocytopenia. Furthermore, health care providers need to be aware of and consistently practice the current guidelines for routine HIV screening. Currently, in the United States it is estimated that more than 1.2 million people are living with HIV/AIDS and approximately 20 % are undiagnosed. The most recent CDC guidelines advise universal opt-out HIV screening for all adolescents and adults (ages 13–64) at least once and more frequently in the setting of certain risk factors. However, as illustrated in the described cases, some patients, particularly those over the age of 50 and without obvious high risk behaviors, may fail to be tested. It is crucial that residents in training and internists are appropriately trained in caring for the HIV population with emphasis on early diagnosis and linkage to care in order to prevent adverse outcomes related to AIDS and the risk of HIV transmission to others.

ISCHEMIC STROKE WITH HEMORRHAGIC CONVERSION: AN UNCOMMON COMPLICATION OF HYPEROSMOLAR HYPERGLYCEMIC STATE
Andrew Kelly; Vinay Rao. University of Connecticut, Hartford, CT. (Tracking ID #2199117)

LEARNING OBJECTIVE #1: Recognize the utility of serial neurologic examinations in patients with hyperosmolar hyperglycemic state to investigate for alternative etiologies of persistent unresponsiveness

CASE: A 50-year-old female with a past medical history of type 2 diabetes mellitus was found unresponsive naked on the floor of her house by her significant other. When paramedics arrived, she was responsive only to painful stimuli. She was transported to the emergency department with stable vital signs but she was intubated for airway protection. Initial laboratory evaluation revealed serum glucose 2205 mg/dL, Na⁺ 124 mmol/L, K⁺ 3.1 mmol/L, Cl⁻ 86 mmol/L, bicarbonate 15 mmol/L, BUN 17 mg/dL, creatinine 2.5 mg/dL, lactic acid 8.1 mmol/L, and trace serum ketones. Urinalysis was positive for glucose (>1000 mg/dL), but negative for ketones. Measured serum osmolality was 397. HbA1c was 13.2 %. Amylase 506 U/L (range 29–103) and lipase was 1299 U/L (range 11–82). Of note, 2 years previously, the patient presented with the same sequelae of uncontrolled diabetes mellitus, altered mental status, hyperosmolar hyperglycemic state with a serum glucose >2000 mg/dL as well as pancreatitis with lipase >1200 U/L. On this admission, original head CT to evaluate for additional causes of altered mental status did not reveal any acute intracranial process. Serial neurologic exams were performed. With the administration insulin and aggressive fluid resuscitation, the patient's serum glucose levels and serum osmolality improved. However, there was minimal improvement in her mental status, prompting persistent, thorough neurologic examinations. On day 2, focal neurologic deficits were found. A repeat head CT demonstrated a 3.5×1.8 cm left cerebellar hemorrhagic infarct. Neurology was consulted. They suggested possible ischemic component on original imaging, now with hemorrhagic conversion. Serial neurologic examinations continued and revealed gradual deterioration to decerebrate posturing. A third head CT at this time was read as stable hemorrhagic infarct. Miraculously, over the next few days, the patient's neurologic status improved. She became increasingly responsive and was successfully extubated. Her recovery was remarkable with slight left-sided weakness (4/5 muscle strength in upper and lower extremities). The patient progressed to ambulating with a rolling walker. She was discharged to a skilled nursing facility for further rehabilitation.

DISCUSSION: This case reinforces the importance of clinical bedside evaluations. Despite the patient's improvement in serum glucose levels and serum osmolality, her mental status did not correspondingly improve. Only through persistent serial neurologic examinations, the new diagnosis of hemorrhagic infarct was established. Had her sustained altered mental status solely been attributed to the original diagnosis of hyperosmolar hyperglycemic state, the opportunity to diagnose this uncommon and serious complication would have been missed. Extensive review of the literature corroborates the rarity of intracranial hemorrhagic infarction as a complication of hyperosmolar hyperglycemic state. Most literature describes hyperglycemia as a consequence of strokes rather than their potential precipitant. The causal relationship between these two disease states deserves further consideration.

IT IS NOT A MIGRAINE Arthur O. Omondi. Montefiore Medical Center, Bronx, NY. (Tracking ID #2197161)

LEARNING OBJECTIVE #1: Understand the pathophysiology of polyarteritis nodosa

LEARNING OBJECTIVE #2: Establishing the diagnosis of PAN

CASE: Twenty-nine year- old man with Ulcerative Colitis on mesalamine presented with fever and occipital headache of 2 days duration. He also noted myalgias and photophobia. He had no recent travel or sick contacts. He had a history of treated hepatitis b infection. On physical exam his neck was noted to have full range of motion with subjective stiffness. He was febrile and hypertensive. Lab work revealed leukocytosis, elevated creatinine above his baseline, low hemoglobin and hematocrit. Cerebrospinal fluid from spinal tap revealed lymphocytic pleocytosis. Reactive markers; Erythrocyte Sedimentation Rate and C reactive protein were elevated. Urinalysis revealed proteinuria, hematuria but no red blood cell casts. A few days after presentation he developed scrotal pain and bilateral conjunctival injection. Fundoscopic exam revealed retinal Roth spots and micro-vascular infarcts. Computed tomography angiography done to evaluate for pulmonary embolism had incidental finding of coronary arteriomegaly. Repeat Computed Tomography of thorax, abdomen and pelvis showed arterial ectasia, beading and multiple aneurysms involving multiple arteries. A diagnosis of polyarteritis nodosa was made based on these findings. He was started on high dose methylprednisone and cyclophosphamide. Patient was discharged after a prolonged hospitalization with outpatient follow up with rheumatology with daily prednisone 20 mg and monthly cyclophosphamide infusions. His initial presenting symptoms had resolved.

DISCUSSION: Fever and headaches are commonly encountered by internists. A good history and physical and a methodical approach is essential in determining the less common causes of this presentation. Vasculitis is generally considered within the broader category of immune-complex diseases. Pathogenic mechanisms of vasculitis involves immune-complex formation and deposition, antineutrophil cytoplasmic antibodies(ANCA) or pathogenic T—lymphocyte responses and granuloma formation. Polyarteritis nodosa (PAN) is an ANCA- negative multisystem, necrotizing vasculitis of small and medium- sized muscular arteries in which involvement of renal and visceral arteries is characteristic. PAN may be idiopathic or triggered by specific agents. The most

typical is hepatitis B virus (HBV). The reduction in the incidence of PAN may be related to the decrease in HBV infection achieved by widespread vaccination. Moreover, other systemic necrotizing vasculitides (i.e. ANCA associated vasculitis, cryoglobulinemic vasculitis) are recognized as distinct entities due to increased awareness and improved diagnostic techniques. Non specific signs and symptoms are the hallmark of PAN. Fever, weight loss and malaise are present in over one-half of cases. The non specific presentations sometime lead to CT imaging with incidental discovery of arterial aneurysms that are characteristic of PAN. Histopathologically, in the acute stages, polymorphonuclear leukocytes infiltrate all layers of the vessel wall and perivascular areas. Mononuclear cell infiltration follows as the lesions become subacute and chronic. Intimal proliferation, vessel wall degeneration with fibrinoid necrosis, thrombosis, ischemia, and infarction are seen in varying degrees. Aneurysmal dilations up to 1 cm in size along the involved arteries are characteristic of PAN. Multiple organ systems are involved and the clinicopathologic findings reflect the degree and location of vessel involvement and the resulting ischemic changes. The pathology in the kidney is that of arteritis without glomerulonephritis. There are no diagnostic serologic tests for PAN. The diagnosis of PAN is based on the demonstration of characteristic findings of vasculitis on biopsy material of involved organs. In the absence of easily accessible tissue for biopsy, the arteriographic demonstration of involved vessels, particularly in the form of aneurysms of small and medium-sized arteries in the renal, hepatic, and visceral vasculature, is sufficient to make the diagnosis. Treatment of PAN is determined by the extent of disease. Mild forms of PAN are treated with steroids only. In life threatening or rapidly advancing PAN, methylprednisone pulses and immunosuppressants like cyclophosphamide are used. Although the incidence of vasculitis is low, physicians should have it in their differential in patients presenting with meningitis like symptoms.

IT'S ALL IN THE CRESCENTS- RAPIDLY PROGRESSIVE GLOMERULONEPHRITIS Manisha Bhide, University of Colorado Denver, Aurora, CO. (Tracking ID #2200841)

LEARNING OBJECTIVE #1: Recognize the urgent workup necessary for new onset hypertension, lower extremity edema, microscopic hematuria, and elevated creatinine.

LEARNING OBJECTIVE #2: Understand the differential diagnosis and appropriate studies when rapidly progressive glomerulonephritis is suspected

CASE: R. is a healthy 60 year-old woman with no significant past medical history who presented after incidental discovery of abnormal labs during a local health fair. The patient also had concern for new onset hypertension- although her home systolic blood pressures (BP) have historically been 120–130 s, the patient's BP at the health fair was 161/90; subsequent home BP checks were also as high as 160 s/90s. The patient also noticed new onset lower extremity edema in the 2–3 weeks leading to the clinic visit. Her past medical history is remarkable for borderline hyperlipidemia, which she manages with exercise and dietary modification. Patient's family history is pertinent for a brother with hypertension and no history of other renal disease. The patient takes supplemental vitamins only- no prescription medications. Physical exam at the clinic visit was remarkable for blood pressure of 145/86, 2+ bilateral lower extremity edema extending to mid-shin with 1+ edema up to the knees; she had no periorbital edema. The patient's health fair labs from the preceding month were remarkable for a creatinine of 1.68, with CBC and electrolyte panel within normal limits. Previous labwork 6 months previously were all within normal limits; creatinine was 0.95. Clinic visit labs are remarkable for a creatinine of 1.9 with positive ANA titer (1:320), C3 & C4 within normal limits, negative HIV/Hepatitis serologies, negative SPEP/UPEP, and negative ANCA testing. She had a Hemoglobin A1c at 6.0 % 6 months prior to this presentation, but had improved to 5.6 % with lifestyle modification at the time of the abnormal creatinine. Point-of-care Urinalysis was remarkable for 4+ protein, large blood, negative leukocyte esterase and nitrite. Twenty-four hours urine studies were remarkable for 2.6 g of protein. The patient was started on 20 mg PO furosemide with some improvement in lower extremity edema. Repeat BMP 1 week later was remarkable for creatinine of 2.25 with intermittent worsening of lower extremity edema. The patient was admitted for further evaluation- renal ultrasound with Doppler study was remarkable for mildly elevated resistive index of the right kidney but otherwise negative for evidence of obstruction, stenosis, or abnormal kidney size. The patient underwent renal biopsy of the left kidney. Pathology revealed focal segmental necrotizing and crescentic glomerulonephritis with 15 % fibrocellular crescents, pauci-immune, without significant nephrosclerosis or basement membrane disease. The patient was started on 60 mg prednisone; ultimately Ms. R. will be treated with cyclophosphamide therapy for pauciimmune focal segmental crescentic glomerulonephritis.

DISCUSSION: Rapidly progressive glomerulonephritis (RPGN) is a condition that can be insidious in onset. It can present with symptoms of macroscopic hematuria, decreased urine output, and edema over days-weeks-months. If left untreated, this condition can lead to end-stage renal disease in weeks to months; it is crucial for internists to act quickly and arrange urgent nephrology evaluation if RPGN is suspected. The differential for this patient prior to biopsy included ANCA associated vasculitis, lupus nephritis, anti-

Glomerular basement membrane (GBM) antibody disease, and IgA nephropathy. There are multiple subsets of RPGN, including Anti-GBM antibody disease, immune complex, pauci-immune, and idiopathic RPGN. It is important to obtain any history of concurrent upper respiratory symptoms (hemoptysis, etc.), which may suggest ANCA mediated autoimmune disease. The pathognomonic finding for inflammatory glomerulonephritis consists of multilayered accumulations of proliferating cells in Bowman's capsule (crescents). The severity of the renal disease is dependent on the extent of circumferential crescents present on renal biopsy. Patients with crescentic involvement of less than 50 % of glomeruli have less severe disease, which may lead to remission with appropriate treatment. Urgent workup entails complete metabolic panel, CBC, 24-h urine protein/creatinine, urine protein electrophoresis studies, and autoimmune studies including ANCA serologies, ANA, Anti GBM antibodies, and complement levels. Renal biopsy is crucial for characterization of the RPGN. The internist should closely monitor blood pressures; adequate blood pressure control is necessary prior to renal biopsy. Further treatment is dependent on the type of glomerulonephritis- it often entails immunosuppression in the form of high-dose steroids, cyclophosphamide or rituximab, and even plasmapheresis in severe cases. The role of the internist in quickly recognizing this condition and arranging appropriate workup and diagnosis impacts the overall prognosis in each patient with RPGN.

IT'S NOT A TUMOR: A CASE OF NONMALIGNANT BRAIN AND LUNG MASSES Annelys Roque³, Ryan Nall², Umna Ashfaq¹, Yaseen Perbtani¹, Margaret C. Lo³. ¹University of Florida, Gainesville, FL; ²University of Florida, Gainesville, FL; ³University of Florida College of Medicine, Gainesville, FL. (Tracking ID #2128899)

LEARNING OBJECTIVE #1: Recognize the clinical manifestations of Nocardia infection

LEARNING OBJECTIVE #2: Diagnose disseminated Nocardiosis in an immunocompetent individual and recognize common diagnostic pitfalls.

CASE: A 56-year-old male presented from an outside hospital with 1 week history of fever, chills, headaches, blurry vision, and fatigue. Outside head CT revealed a right 1.2 cm parietal mass; chest x-ray showed a left lower lobe (LLL) density with small pleural effusion, suspicious for a lung mass. He was referred for neurosurgical intervention of his presumed brain metastases from a primary lung malignancy. Upon transfer, the patient had no focal weakness, confusion, cough, hemoptysis, dyspnea, or rash. His medical history was significant for Type 2 diabetes (A1c 10.2 %), active smokeless tobacco use, and extensive traveling as a cattle buyer across the Southern U.S. Lab values were notable for elevated ESR 44 mm/h and glucose 261 mg/dL with normal CRP, CMP, CBC, HIV, blood, fungal, and AFB cultures. Full-body CT showed 4 cm×2.2 cm LLL lung mass and mediastinal lymphadenopathies. Brain MRI exhibited two ring-enhancing right parietal lesions. The patient underwent a CT-guided biopsy of the LLL lung mass. Meanwhile, Neurosurgery continued to counsel the patient on his grave prognosis and prepped him for palliative resection of the brain metastases. However, lung cytology revealed active and chronic non-caseating granulomas; tissue histopathology ultimately grew *Nocardia beijingensis*. The patient was started on a 6-week course of IV Amikacin, Bactrim, and Meropenem, later to be transitioned to oral Bactrim for 12 months. His course was complicated by cerebral edema requiring right craniotomy. Intraoperative drainage of the parietal mass exhibited abscesses. The patient was eventually stabilized and discharged to a rehabilitation facility.

DISCUSSION: This case illustrates the susceptibility of clinicians to label a diagnosis as malignancy based on others' preset diagnosis and on pattern recognition of lung masses. Literature have cited cases of Nocardiosis mistaken for malignancy given its nonspecific presentation. Diagnosing Nocardia is further problematic due to limited case reports in the U.S. and its isolation difficulties in microbiology cultures.¹ Nocardia species are ubiquitous actinomycetes found primarily in soil. Most recent geographical prevalence has cited the Southern U.S. region due to its hot, dry climate.¹ Nocardia is known to infect certain animals i.e. cats, dogs, cattle.² As an opportunistic pathogen, Nocardia targets patients with impaired immunity i.e. malignancy, HIV, transplant recipients. Clinically, nocardiosis manifests in 3 patterns—pulmonary, cutaneous, and disseminated. As the most common, pulmonary nocardiosis follows inhalation of aerosolized bacteria and presents as bronchopneumonia. Hematogenous dissemination from the lung spreads most often to the brain. Alcoholism and immunocompromised states are predisposing factors to brain dissemination. With its vague symptoms, clinical risk factors and detailed social history remain important diagnostic clues for disseminated nocardiosis. Our patient's profession as a cattle buyer, repeated exposure to soil, and extensive travels in the Southern U.S. were key social risk factors. His immunocompetent state should not mislead clinicians. Both pulmonary and systemic nocardiosis have been reported in relatively immunocompetent patients with COPD or diabetes,^{1,3} as true in our case. Poor prognostic indicators include older age, concurrent pulmonary aspergillosis, and trimethoprim-sulfamethoxazole resistance³—which our patient had none. *Nocardia*

asteroides is the most frequent nocardiosis in the U.S.⁴ The isolation of *Nocardia beijingensis* in our patient with only diabetes makes this case exceedingly rare. Most cases are reported in Asia and Europe. There has only been one other case report of *Nocardia beijingensis* infection in the U.S., specifically a pulmonary case at Mayo Clinic in Jacksonville, Florida.⁵ Given the dangerous nature of *Nocardia* and the prolonged treatment course required for eradication, prompt recognition of *Nocardia* is needed for optimal patient outcome. The diagnosis of *Nocardia* infection requires its identification from tissue specimens. Acid-fast and gram stains are insufficient. Species identification is important to determine antibiotic resistance profiles of the different *Nocardia* species.⁵ Lastly, this case teaches clinicians the need to recognize and confront three common diagnostic errors, specifically anchoring, premature closure, and pattern recognition. Such faulty cognitive approaches can have negative downstream effects, including patient anxiety, treatment delays, and unnecessary tests. Given its similar clinical presentation to malignancy, recognizing the pathogenesis of disseminated Nocardiosis, reassessing our patient's risk factors, and obtaining tissue histopathology were crucial in the proper diagnosis of his lung and brain masses.

IT'S NOT YOUR TYPICAL COUGH. PULMONARY KAPOSI SARCOMA IN A NON-HIV PATIENT Arber Kodra; Maciej Walczyszyn; Bushra Mina. Lenox Hill Hospital, New York, NY. (Tracking ID #2198471)

LEARNING OBJECTIVE #1: Kaposi Sarcoma (KS) is an angioproliferative tumor associated with human herpes virus 8 (HHV-8). Often known as one of the AIDS defining skin diseases, pulmonary involvement in KS has only been discussed in a handful of case reports, rarely in a non-HIV patient. The infrequency with which it is encountered makes Pulmonary KS a formidable diagnostic challenge. The purpose of this vignette is to provide an example of the clinical and radiographic findings seen in this disease.

CASE: Seventy-seven year-old male, presented with a 6-week history of progressive dyspnea on exertion accompanied by cough productive of yellow sputum and intermittent hemoptysis. On admission, the patient denied fever, chest pain, recent travel, or sick contacts. Past medical history was significant for Non-Hodgkin Follicular B-Cell Lymphoma treated with three rounds of R-CHOP chemotherapy for recurrent disease. Patient also had biopsy-confirmed cutaneous KS status post treatment with Doxorubicin. His vital signs on admission were temperature 99.8 °F, blood pressure 94/60 mmHg, heart rate 110 beats/min, respiratory rate 16 breaths/min, and oxygen saturation 92 % on room air. Physical exam was notable for a 2 cm firm, non-tender, mobile right submandibular lymph node. Lungs were clear to auscultation. Multiple violet non-tender skin lesions were localized to edematous lower extremities. The patient's labs were grossly unremarkable. No leukocytosis was noted. An outpatient CT scan of the chest had shown bilateral hilar lymphadenopathy, numerous peribronchovascular nodular opacities, and small pleural effusions. Chest X-ray on admission showed a worsening right basilar opacity. Subsequently, a bronchoscopy revealed diffusely hyperemic, swollen mucosa of the lower airways with mucopurulent secretions. Treatment was started for suspected pneumonia. Due to clinical deterioration, a repeat CT scan of the chest was performed, demonstrating increased bilateral pleural effusions. A thoracentesis showed sero-sanguineous exudative effusions. Histopathology failed to demonstrate malignant cells or lymphoma. Stains and cultures of urine, blood, BAL, and pleural fluid were negative. Pneumocystis jiroveci PCR and fluid cytology were also negative. The PCR for HHV-8 showed 5800 DNA copies/mL. The final impression was that his pulmonary symptoms were likely due to KS. Upon addressing goals for care, the patient decided not to undertake any further treatment. He was discharged home.

DISCUSSION: This case illustrates the potential for lung injury from KS. Distinctive manifestations that separate KS from other pathologic processes in the lungs have not been identified. However, recognition of this syndrome is critical to the institution of appropriate therapy. This case is unique in that the patient did not match the typical KS subgroup. Moreover, in non-HIV patients, it clinically resembles classic KS but occurs at a younger age, is limited to the skin, and has a good prognosis. However, our elderly patient demonstrated both dermatologic and pulmonary manifestation suggesting a disseminated and aggressive form of the disease.

ITCHING THE WAY TO A CURE FOR CHRONIC ABDOMINAL PAIN Carolyn Koulouris; Rachel Stark. Cambridge Health Alliance, Somerville, MA. (Tracking ID #2198659)

LEARNING OBJECTIVE #1: To identify the signs and symptoms of chronic infection with *Schistosomiasis mansoni* in an immigrant from an endemic country

LEARNING OBJECTIVE #2: To appreciate that pruritic dermatitis can be a manifestation of chronic infection with schistosomiasis, though more commonly presents with abdominal pain or symptoms of portal hypertension

CASE: A 49-year old woman with a history of hypothyroidism, seronegative arthritis, depression, fibromyalgia, and chronic abdominal pain presented to a Boston area community based primary care clinic in the summer of 2014 with a complaint of 8 months of unremitting pruritus and dermatitis. The patient had been evaluated for the same complaint at three previous appointments, and was treated on separate occasions with topical steroids for presumed contact dermatitis, avoidance of sun exposure for possible photosensitivity, and discontinuation of all medications for presumptive drug reaction. The patient's past medical history is significant for more than 10 years of left upper quadrant abdominal pain, depression, and chronic joint pain. Previous work up for abdominal pain over the past 10 years included two positive fecal occult blood screens with negative endoscopy and colonoscopy, unremarkable abdominal ultrasound, abdominal CT scan, and negative stool ova and parasites. Hematocrit ranged from 38 to 41 during this time period. The patient's social history was significant for immigration from a rural area in the Minas Gerais region of Brazil 20 years prior to presentation, without having ever returned to Brazil since relocating to the United States. She is employed as a housecleaner. Her family history is significant for CVA in her mother and splenectomy in two brothers from complications of schistosomiasis. On physical exam, she was noted to be a tearful, overweight woman. Faint pink papules and excoriation were noted on bilateral forearms. The remainder of the skin exam was otherwise unremarkable. Cardiac and pulmonary exams were within normal limits. Abdominal exam was notable for left upper quadrant tenderness to palpation, without notable splenomegaly. Testing for schistosomiasis with a schistosomal IgG antibody was positive at 51.81 (upper limit of normal 11.01). This assay has a sensitivity of 87 % and specificity of >95 %. She denies ever having previously been treated for schistosomiasis. The patient was treated for presumed chronic schistosomiasis with two doses of praziquantel. She reported resolution of her pruritus as well as her chronic abdominal pain within days of treatment.

DISCUSSION: Schistosomiasis is a neglected tropical disease caused by a freshwater parasitic blood fluke, which can persist long past relocation to a non-endemic area. It is a widely underreported disease, but USAID estimates more than 200 million individuals are infected with schistosomiasis worldwide. There are several species of schistosomiasis, though *S. mansoni* is endemic to Brazil. This chronic infection can present as abdominal pain, gastrointestinal blood loss, portal hypertension, and, rarely, pulmonary hypertension or neurologic disease. This patient had several typical symptoms of chronic schistosomiasis, and had several risk factors for the illness, and yet her infection went unrecognized for many years. In particular, the patient lived with household members previously diagnosed with schistosomiasis and previously lived in an endemic region. Immigrants from Sub-Saharan Africa, western South American, and southern Caribbean islands are at risk for *S. mansoni*. Kato-Katz thick stool smears have been considered the gold standard in identification of schistosome infection, though this test is insensitive in low worm burden or non-endemic areas. Screening can be performed with antibody testing, though a positive titer does not differentiate between previously treated infection and active infection. Chronic abdominal pain is a common symptom of chronic infection with schistosomiasis, but this patient's presenting complaint of pruritic dermatitis is not previously well described in the literature. It is clear that acute schistosomiasis can cause pruritus; however, this patient had no acute exposures to schistosomes. The marked temporal association between her treatment and resolution of this disabling subacute complaint makes a strong case for schistosomiasis as the cause of her dermatitis. The general internist caring for the US population should consider schistosomiasis as a cause of chronic abdominal pain in patients from endemic regions including Brazil and sub-Saharan Africa; further, physicians should consider testing in patients with atypical symptoms, including dermatologic manifestations. Failing to diagnose schistosomiasis in immigrant patients can lead to morbidity and mortality when simple and inexpensive treatment is widely available.

JARISCH-HERXHEIMER REACTION (JHR) IN THE SETTING OF SYPHILIS AND HUMAN IMMUNODEFICIENCY VIRUS (HIV) Charlie Lee²; Jessica Logan¹. ¹DC VA Medical Center, Washington, DC; ²George Washington University, Washington, DC. (Tracking ID #2192078)

LEARNING OBJECTIVE #1: Recognize the clinical features of Jarisch-Herxheimer Reaction

LEARNING OBJECTIVE #2: Prevention and management of Jarisch-Herxheimer Reaction

CASE: A 47-year-old male with HIV presented with one week of blurry vision in the left eye. He denied fevers, chills, ocular pain, confusion, and neck stiffness. He was not on anti-retroviral therapy. The patient was unable to read fine print within 1-foot length of the left eye. Ophthalmologic exam was significant for chorioretinitis of the left eye. Laboratory studies revealed a positive Serum FTA-Abs and RPR (titer 1:512). CD4+ count was 470 and HIV viral load was 39,172. Lumbar puncture was performed with cerebrospinal fluid positive for VDRL. The patient was immediately started on IV penicillin G. Within three hours, the patient endorsed rigors and chills. Vital signs showed fever, tachycardia,

and mild hypotension. Given concern for Jarisch-Herxheimer Reaction (JHR), he was moved to a medical intensive care step-down unit for aggressive supportive care. Vital signs normalized within 24 h and penicillin was continued for treatment of syphilis.

DISCUSSION: The Center for Disease Control (CDC) estimates there are approximately 55,000 new cases of syphilis in the U.S. annually. In the current HIV pandemic, management of syphilis is crucial as syphilis may increase the rate of acquisition and transmission of HIV. JHR, a complication of syphilis treatment, has been reported at rates of 10–25 % and may be as high as 50–75 % in cases of primary and secondary syphilis. It is rare in latent and late syphilis. Rates are even higher in HIV patients. JHR is mostly self-limited, but consequences include discontinuation of treatment and rarely death. Although the cause of JHR is unknown, it is proposed that release of cytokines after administration of anti-microbial agents is responsible. Commonly associated with underlying syphilis or louse-borne relapsing fever, it can also occur with non-spirochete disease including brucellosis and meningococcal septicemia. JHR occurs with numerous agents including penicillins, tetracyclines, macrolides, and sulfonamides. JHR occurs within hours to one day of administering penicillin. Clinical features include fever, tachycardia, tachypnea, and hypotension. Patients may endorse chills, myalgias, and flushing. If a syphilitic rash is present, it may worsen. Current treatment options are supportive only (anti-pyretics, fluids). Discontinuation of the treatment agent or transfer to ICU level care may be considered, although no studies exist that support these measures. Corticosteroids have been studied as pre-treatment measures for JHR and showed decreased incidence or duration of fever. However, none demonstrated a mortality benefit. United Kingdom guidelines recommend use of steroids in certain cases of neuro- and cardiac-syphilis while CDC guidelines do not endorse use of steroids. Given lack of evidence and consensus, steroids are not considered routine treatment of JHR. In patients with louse-borne relapsing fever, murine Anti-TNF- α antibodies have shown to reduce vital sign disturbances and levels of cytokines. These agents could be promising in prevention of JHR. Syphilis is a common disease that has become more important in the setting of the HIV pandemic. JHR is a complication associated with the treatment of syphilis. Although usually self-limiting, it can lead to treatment failure and death. Therefore, it is essential to recognize JHR and understand current and future management options.

KEEP A “LOOKOUT” FOR SYPHILIS Mekhala Chandra²; Sara L. Swenson¹.
¹California Pacific Medical Center, San Francisco, CA; ²California Pacific medical center, San Francisco, CA. (Tracking ID #2198454)

LEARNING OBJECTIVE #1: Recognize the importance of the sexual history and risk factors for HIV infection in diagnosing syphilitic uveitis

LEARNING OBJECTIVE #2: Screen for HIV infection in patients who present with uveitis

CASE: A 36-year-old white male with a history of high-risk sexual behavior, injection drug use, and homelessness presented to the emergency department complaining of seeing intermittent “floaters” for 10 days and acute, progressive painful vision loss over the past 4 days. His ocular exam showed mildly swollen, red lid margins and conjunctival injection with ciliary flush. His pupils were non-reactive bilaterally. Iris exam revealed bilateral posterior synechiae. Visual acuity of the right eye was 20/400, but the left eye distinguished only hand-waving. Laboratories revealed a positive RPR titre of 1:128. The FTA antibody was reactive. HIV RNA of 69,464 per ml. He was started on a 14-day course of intravenous penicillin along with oral prednisone. His vision gradually improved. He subsequently started antiretroviral therapy as an outpatient.

DISCUSSION: The recently increased incidence of ocular syphilis has stimulated interest in this old disease. In the USA, the rates of primary and secondary syphilis have doubled from 2000 to 2013: 2.1 vs 5.3 cases per 100,000. The epidemic has disproportionately affected the MSM population. Ocular syphilis is a form of neurosyphilis that can occur at any stage of *T. pallidum* infection. It may be the only clinical manifestation of disease. Although syphilis presents with a wide range of ocular manifestations, including optic neuropathy, interstitial keratitis, chorioretinitis, and retinal vasculitis, uveitis is the most common. There are no pathognomonic findings since syphilitic uveitis appears similar to uveitis from other etiologies. Syphilis accounts for fewer than 5 % of uveitis cases overall; consequently, an accurate sexual history is of paramount importance for making the diagnosis. Ocular syphilis does not require immunosuppression and should be considered in the differential diagnosis of HIV-infected patients with visual complaints regardless of their CD4 counts. In fact, one case series reported a prevalence of ocular syphilis of 9 % in HIV+ individuals. Conversely, syphilitic uveitis is a predictor of HIV infection; a recent case series found that 35 % of patients with syphilitic uveitis had undiagnosed HIV infection. In HIV-infected patients, syphilitic involvement of the eye has been shown to occur earlier than in HIV-uninfected patients. Ocular syphilis in the setting of untreated HIV is more frequently bilateral and more likely to involve the posterior chamber. Because *T. pallidum* cannot be cultured, diagnostic testing for syphilis typically consists of nontreponemal and treponemal serologic tests from the serum. Serologic tests for syphilis are occasionally falsely positive or negative in

HIV-infected patients so clinicians should pursue direct methods of diagnosis in HIV patients where a high index of clinical suspicion exists. Case series of HIV-infected individuals with ocular syphilis demonstrate excellent response to treatment with over 90 % of patients recovering at least partial vision, as did our patient. Given its potential reversibility and high prevalence in patients with known or undiagnosed HIV infection, clinicians should maintain a high index of suspicion for ocular syphilis in at-risk patients who present with unexplained visual complaints and tailor their history-taking accordingly.

KOUNIS SYNDROME—THE ALLERGIC HEART Sumant Arora¹; Ronak Patel¹; Sonali Advani²; Mario Fadila¹. ¹UAB Montgomery Health Center, Montgomery, AL; ²University of Alabama at Birmingham, Montgomery, AL. (Tracking ID #2200347)

LEARNING OBJECTIVE #1: Recognize potential of myocardial involvement in form of Kounis syndrome in suspected anaphylaxis, and include it in differential diagnosis of ischemic heart disease.

LEARNING OBJECTIVE #2: Recognize lack of standard treatment guidelines for Kounis syndrome and need for an international consensus on therapy.

CASE: A 70-year-old African American female presented with new onset breathing difficulty. She was found by her family members gasping for air and was rushed to the Emergency Department (ED) where she was emergently intubated by ED physician, who noted significant tongue and upper laryngeal swelling. Her only other complaint was worsening generalized pruritis treated with topical steroids and antihistamines. Her medical history was significant for asthma and hypertension. Her medications were notable for Naproxen, Ibuprofen, Folic acid and Hydroxyzine. An initial diagnosis of angioedema was presumed and she was treated with intravenous corticosteroids, Histamine (H1 and H2 receptor blockers. Her initial labs (complete blood count and chemistries) were within normal limits and chest x-ray showed clear lungs. Electrocardiogram (EKG) revealed sinus tachycardia with 2 mm ST-segment elevation in the inferior and lateral leads. Cardiac panel showed troponin of 5 ng/ml, CK257 units/l and CK-MB 18.2 ng/ml. An echocardiogram showed apical and septal wall hypokinesis. Patient underwent left heart catheterization, which revealed normal coronary arteries, apical, and inferior wall hypokinesis, and significantly reduced ejection fraction of 20 %. Her second and subsequent troponins elevated to a maximum of 5.6 ng/ml while the EKG changes returned to baseline. Because of hemodynamic instability, patient was started on norepinephrine drip. A diagnosis of Type I Kounis syndrome was suggested based on the concurrent occurrence of angioedema and ST-elevation myocardial infarction in the setting of normal coronary anatomy. Her subsequent labs showed elevated IgE levels of 221 IU/ml, normal C1 Esterase inhibitor, C3, C4 and Trypsin levels. By day 4 of hospitalization, she was weaned off pressors and mechanical ventilation, and her troponins trended down to normal levels. A repeat echocardiogram showed ejection fraction of 20 %. On the hospital day 8, she was discharged to rehab with a Life-vest in stable condition.

DISCUSSION: Kounis Syndrome is the concurrence of acute coronary syndromes (ACS) (angina and/or myocardial infarction) with allergic reactions (hypersensitivity, anaphylaxis or anaphylactoid reaction) due to coronary artery vasospasm caused by inflammatory mediators (histamine, neutral proteases, arachidonic acid derivatives, cytokines and chemokines) released during the allergic insult. Three variants have been recognized: type I variant in patients with normal or near normal coronary arteries, type II in those with preexisting atheromatous disease, and type III in those with coronary stent thrombosis. Various drugs, environmental exposures and conditions are implicated in causation with the most recent offenders being scombroid syndrome (histamine fish poisoning), exposure to gelofusine and the drug losartan. Clinical spectrum includes chest pain with or without elevation of cardiac enzymes and troponins along with dermatologic and/or systemic manifestations of allergic reaction. However, reported cases suggest that both signs of cardiac disease or hypersensitivity may be absent. Spectrum of ECG changes range from ST-elevation or depression to cardiac arrhythmias, but degree of ST-elevation may not necessarily correlate with troponin levels unlike that in ACS. The latter makes Kounis syndrome an easily overlooked diagnosis in the differential for ACS, without a high index of clinical suspicion. Further, there is no established way to predict the risk of Kounis syndrome, though recent reports suggest increased baseline serum trypsin levels to be associated with both increased susceptibility to allergic reactions as well as asymptomatic coronary disease. Treatment is challenging due to need to target cardiac and allergic symptoms simultaneously, as well as lack of uniform consensus on treatment guidelines with most recommendations derived from anecdotal case reports or case series. In a 2009 review of reported cases with Kounis syndrome, intravenous steroids (76 %), nitroglycerine (47 %), H1-blockers such as diphenhydramine (70 %), and H2-blockers such as ranitidine (35 %) were found as most commonly used medications in the treatment. Beta-blockers and epinephrine should be avoided in suspected case of Kounis syndrome as may exacerbate coronary spasm due to unopposed alpha- adrenergic activity. Further, opioids commonly used in ischemic heart disease can exacerbate allergic reaction by inducing

mast cell degranulation. Also, data supporting the use of prophylactic medications such as H1-blockers to avoid recurrence of such a life threatening condition is lacking.

LESSONS FROM THE PASTURE: PASTEURELLA MULTOCIDA INFECTION RESULTING FROM A HORSE HOOF INJURY Nicholas Duca; Asher Tulskey. University of Pittsburgh, Pittsburgh, PA. (*Tracking ID #21919117*)

LEARNING OBJECTIVE #1: Recognize that *Pasteurella multocida* is a common pathogen in animal-associated infection and must be considered when choosing an empiric antibiotic regimen.

LEARNING OBJECTIVE #2: Recognize that antibiotics commonly prescribed for soft tissue infections are ineffective against *Pasteurella multocida*.

CASE: A 51 year old woman with no significant medical history and an allergy to penicillin was admitted with fever, chills, and a left calf wound. Two weeks prior to presentation, the patient was stepped on by a horse while working on her farm. Three days following the injury, she presented to her local emergency department with calf pain and swelling; she was discharged with cephalexin 500 mg PO twice daily. Despite compliance with this regimen, the patient returned one week later with worsening symptoms. This time, she was prescribed clindamycin 300 mg PO three times daily. Three days into treatment, the patient developed fevers and chills, at which time she sought care at our facility. Upon admission, the patient was afebrile with normal vital signs. There was a 2 cm ovoid wound on the medial aspect of her left calf, with surrounding erythema and induration. Significant pus and coagulated blood were expressed from the wound. Using a probe, the wound tracked 7 cm both superiorly and inferiorly and 4 cm both anteriorly and posteriorly. Labs, including WBC, were unremarkable. Deep wound cultures were obtained at the bedside, and broad spectrum antibiotics including vancomycin, aztreonam, and metronidazole were initiated. MRI revealed a 5 cm×7 mm non-enhancing fluid collection consistent with fat necrosis, without soft tissue gas or osteomyelitis. On hospital day two, the patient underwent debridement of the wound with placement of a wound vac. Subsequently, wound cultures obtained upon admission and in the operating room grew *P. multocida*. The antibiotic regimen was narrowed to moxifloxacin, and the patient was discharged home. She underwent successful closure of the wound one week later.

DISCUSSION: *Pasteurella multocida* is a common gram negative bacillus present in the oral mucosa of many animals, including dogs, cats, rabbits, and as in this case, horses. The organism is typically transmitted to humans via bites. However, infection can also occur from scratches, presumably from saliva contaminated claws or hooves. Specific infections caused by *P. multocida* include cellulitis, necrotizing soft tissue infection, septic arthritis, and osteomyelitis. *P. multocida* is susceptible to a number of antibiotics including penicillins, extended spectrum cephalosporins, carbapenems, tetracyclines, trimethoprim-sulfamethoxazole, fluoroquinolones, and aztreonam. There is lack of in vitro activity of vancomycin, clindamycin, cephalexin and erythromycin against *P. multocida*. The Infectious Disease Society of America recommends amoxicillin-clavulanate for management of animal or human bite wounds. In penicillin-allergic patients, fluoroquinolones such as moxifloxacin are effective alternatives. When promptly recognized and treated, most soft tissue infections caused by *P. multocida* resolve without serious complications. In this case, it was only after failing standard outpatient treatment of cellulitis and subsequently undergoing wound debridement with positive wound cultures, that appropriate treatment was initiated. While no specific guidelines address animal scratches or licks, based on this and other case reports, it may be best to initiate empiric treatment for *P. multocida* while awaiting confirmatory cultures.

LEVAMISOLE-LACED COCAINE INDUCED VASCULITIS Rachel Kapelow. Ameral University of Antigua, Brooklyn, NY. (*Tracking ID #2160165*)

LEARNING OBJECTIVE #1: Recognize the clinical features of levamisole adulterated cocaine induced vasculitis.

CASE: A 54-year-old woman with a past medical history of chronic cocaine, marijuana, opioid abuse and a 10 pack-year smoking history presented to the ED with an increasingly painful and burning purpuric rash and skin necrosis of two days duration on her extremities, ear lobes, and cheeks. Additional history revealed that she had previous episodes of a purpuric rash, which was linked on this admission to smoking crack cocaine continuously for several days. A diagnosis of levamisole-induced vasculitis was suspected. A urine toxicology screen was positive for cocaine and marijuana. Laboratory testing showed leukopenia with a white blood cell count (WBC) of 3200 cells/mL, neutropenia with an absolute neutrophil count (ANC) of 800 cells/mm³, positive perinuclear-antineutrophil cytoplasmic antibody (p-ANCA) and increased erythrocyte sedimentation rate (ESR) of 49 mm/h. Skin biopsy of the left ear revealed leukocytoclastic vasculitis with acute and chronic inflammation and thrombosis of small vessels. Treatment of wound care was initiated with bacitracin ointment and IV methylprednisolone with which the patient

improved tremendously. Three days later, new lesions stopped appearing and expanding and the patient was discharged.

DISCUSSION: Levamisole-induced vasculitis in association with people who use cocaine is characterized by purpuric skin lesions and necrosis. Recently, there has been an increase in prevalence and it is important for physicians to be informed of this emergent entity in order to make it less challenging to diagnose. Levamisole was used as an antihelminthic medication and later withdrawn from use in the U.S. in 1999 due to its adverse effects. This case illustrates the potential adverse effects including skin vasculitis, agranulocytosis and even severe necrosis of soft tissue and cartilage. The value of a thorough history is essential to explore in patients presenting with these symptoms. Recognition of this syndrome is critical for symptomatic patients as discontinuation of exposure and a correct diagnosis prevents unnecessary, costly and potentially dangerous use of other treatment modalities.

LOIN PAIN HEMATURIA SYNDROME Jill B. Feffer; Pauline Leong. North Shore-LIJ/Hofstra School of Medicine, Lake Success, NY. (*Tracking ID #2160392*)

LEARNING OBJECTIVE #1: Diagnose loin pain hematuria syndrome as a rare cause of flank pain.

CASE: Twenty-four year-old female with no known medical history except two hospitalizations during the prior 6 months for flank pain treated for presumed pyelonephritis during which she was told she had "small kidneys," now presented with one day of severe bilateral flank pain. Her pain was chronic with intermittent flares since her first hospitalization, radiated to both groins and was associated with nausea and gross hematuria. She denied fever, chills, vomiting, dysuria, or history of nephrolithiasis. Family history was significant for paternal grandfather requiring hemodialysis for unknown reason. Of note, the patient is allergic to acetaminophen so she had been taking ibuprofen at home. On admission, the patient was afebrile, hypertensive (150 s/90s) and tachycardic (90s). Physical exam showed a young, healthy-appearing woman with severe bilateral costovertebral angle angle tenderness and no peripheral edema. Labs revealed: normal white blood count with normal differential, mild normocytic anemia (Hgb 11.2, MCV 87.7), elevated BUN/creatinine (37/2.62), normal total bilirubin, negative ANA (<1:80), normal ESR and CRP, low C3 with normal C4, urinalysis with nephritic-range proteinuria and microscopic hematuria but negative leukocyte esterase and nitrite without bacteria, urine culture growing 60,000 mixed Gram positive flora, lipid profile within normal limits, and vitamin D deficiency (17.7) with high PTH (147). CT abdomen/pelvis showed bilateral atrophic (~8 cm) kidneys without nephrolithiasis or pyelonephritis; renal ultrasound with Dopplers ruled out renal artery stenosis. Creatinine remained stable (2.3–2.6), blood pressure decreased to 120 s/70s without intervention, nausea resolved, pain was better controlled with short-acting oxycodone as needed, and hemoglobin remained stable so the patient was discharged with nephrology follow-up.

DISCUSSION: This patient's constellation of signs and symptoms did not fit common infectious or metabolic etiologies of flank pain, ultimately leading to a diagnosis of exclusion: loin pain hematuria syndrome (LPHS). Knowledge of LPHS has been gleaned from surgical and nephrology case reports because it has a prevalence of only 0.012 %, sufficiently low to preclude systematic studies. It occurs either as a self-limited primary condition without compromised renal function or secondary to underlying medical renal disease, typically IgA nephropathy. Our patient's atrophic kidneys and CKD, as evidenced by imaging and findings of secondary hyperparathyroidism, support the diagnosis of secondary LPHS. Biopsy was not performed due to renal atrophy. Pathogenesis is unknown but has been postulated to be of either immunologic or vascular etiology and has been associated with somatoform disorders. Clinical manifestation involves intermittent flares of chronic flank pain which radiates to the groin, unilateral more commonly than bilateral, associated with nausea and hematuria. This rare condition is therefore difficult to distinguish from pyelonephritis. Treatment currently consists of pain management, while extreme cases have been treated with experimental modalities including stripping of the affected renal capsule or autonephrectomy with reimplantation.

LOOK BEYOND THE HEART: ACUTE PANCREATITIS MIMICKING STEMI Sonali Advani²; Sumant Arora¹; Jewell Halanach². ¹UAB Montgomery Health Center, Montgomery, AL; ²University of Alabama at Birmingham, Montgomery, Montgomery, AL. (*Tracking ID #2200129*)

LEARNING OBJECTIVE #1: To understand that acute pancreatitis may be associated with electrocardiographic and biochemical abnormalities similar to acute myocardial infarction.

LEARNING OBJECTIVE #2: It is initially important to rule out cardiac ischemia in these patients if they have electrocardiographic and biochemical evidence of myocardial damage.

CASE: A 34-year-old African American man with no past medical history presented to the Emergency Room (ER) at an outside hospital with severe abdominal pain and flu like symptoms- fevers, chills and body aches for 2 days. He was prescribed antihistamines with antibiotics and discharged home the same day. He failed to take these medications at home and continued to run a fever with chills (Tmax 103 F). Over the next 3 days, his abdominal pain increased in severity and he became nauseated and diaphoretic. He also developed crushing chest pain, 8/10 in intensity, radiating to his left axilla, associated with shortness of breath at rest, 3-pillow orthopnea and palpitations. He returned to the outside hospital the following night. His initial blood work in the ER revealed elevated troponins (4 mg/dl) and lipase levels over 4000. His electrocardiogram (EKG) at that time showed ST segment elevation in the inferior leads 2, 3 and aVF. He was transferred to our hospital for further management. On arrival to our ER, he was febrile with Tmax 101.8 F, with a blood pressure of 108/60 mm Hg, heart rate of 95 beats/min, respiratory rate of 24 breaths/min and normal oxygen saturation. He was a tall well-developed male who appeared anxious, diaphoretic and in severe distress from pain. Lung fields were clear to auscultation, while cardiac exam revealed normal heart sounds, tachycardia with regular rhythm and absence of murmurs rubs or gallops. There was no evidence of pericardial friction rub. Abdominal exam revealed increased tenderness in epigastric and left quadrant with guarding, and absent bowel sounds. The rest of the physical examination was unremarkable. Chest X-ray and abdominal ultrasound were unremarkable. The 12-lead ECG recorded in our ER sinus tachycardia with ST-segment elevations in leads 2, 3 and aVF. His serial troponins drawn were 2.9 mg/dl and 1.8 mg/dl. Serum electrolytes were normal with C Reactive Protein of 15.69 mg/dl, and creatine phosphokinase of 278 U/L. Lipid profile revealed total cholesterol of 153 mg/dl, LDL of 86 mg/dl, HDL of 43 mg/dl and triglycerides 106 mg/dl. An echocardiographic examination at the bedside disclosed left ventricular ejection fraction of 65 % without any wall motion abnormalities, diastolic dysfunction or hypertrophy. Cardiology was consulted and he underwent an emergent diagnostic coronary angiography, which revealed no evidence of obstructive coronary disease. His initial lipase was 2157 U/L and repeat lipase was 3817 U/L. Abdominal computed tomography scan revealed some peripancreatic stranding consistent with acute pancreatitis. We treated him as acute pancreatitis, kept him N.P.O., hydrated him with IV fluids, and managed his pain and nausea symptomatically. We also ordered Immunoglobulin G4 levels to rule out autoimmune pancreatitis, which was also normal. Over the next 2-3 days, his pain started to subside and appetite improved. We started him on clear liquid diet and advanced him slowly to a regular diet. He was discharged home in stable condition and his post discharge course was unremarkable.

DISCUSSION: Electrocardiographic changes of acute myocardial infarction in patients with acute pancreatitis have been documented before. Similar changes have also been documented in some patients with myocarditis, cholecystitis, chest trauma, pneumonia and CNS injury. Various hypotheses have been formulated to explain underlying mechanisms of electrocardiographic abnormalities and/or biochemical changes in these conditions. These include proteolytic effects of pancreatic enzymes in addition to (vasoactive substances such as prostaglandins and bradykinins) on myocardium, cardio-biliary reflex, vagal coronary artery spasm, metabolic and electrolyte abnormalities, hemodynamic instability and systemic inflammatory response-induced cardiac damage. In patients who present with electrocardiographic and biochemical evidence of myocardial damage, it is initially important to rule out cardiac ischemia. But we must maintain a high clinical suspicion of other conditions mimicking acute MI to avert complications of antithrombin and antiplatelet therapy. These agents are contraindicated in at least some conditions mimicking STEMI and those requiring surgery. There are reports of antithrombin and antiplatelet therapy causing hemorrhagic pancreatitis, aortic dissection, subarachnoid hemorrhage and death in these cases. In conclusion, acute pancreatitis may be associated with electrocardiographic and biochemical abnormalities similar to acute myocardial infarction. The timely and correct diagnosis of such these conditions is critical since they can adversely affect the clinical outcome.

LYME CARDITIS Shilpa Mukunda. Boston Medical Center, Boston, MA. (Tracking ID #2198766)

LEARNING OBJECTIVE #1: Recognize early Lyme disease

LEARNING OBJECTIVE #2: Diagnose and manage first degree AV block from Lyme carditis

CASE: Thirty-three year old male with no significant past medical history presents with new onset of palpitations. Six weeks ago, the patient had gone on a hiking trip in New Hampshire, during which he had not noticed any ticks. Three weeks later, he had presented to urgent care with fevers to 102 and a pruritic, circular lesion in his left popliteal area. He was diagnosed with cellulitis (Lyme IgG and IgM were negative at this time) and given a one week course of cephalexin. After two more weeks, he had re-presented to his primary care doctor due to persistent myalgias, arthralgias, and low-grade fevers. At this time, the diagnosis of Lyme disease was made with positive Lyme EIA to 2.1 with confirmatory positive Western blot for both Lyme IgG and IgM antibodies, and the patient was started

on doxycycline 100 mg BID. The patient's current complaint was a new onset of transient palpitations, which started the day after he had been diagnosed with Lyme disease. The patient reported feeling uncomfortable with the palpitations, but denied chest pain, shortness of breath, syncope, or dizziness. Physical exam revealed tachycardia and hyperpigmentation in the left popliteal fossa at the site of his former rash. EKG showed sinus tachycardia with 1st degree AV block with PR of 336 msec. The patient was admitted to the hospital and started on IV ceftriaxone 2 g daily. His PR interval decreased through admission to 320 ms on day 2 and 288 ms on day 3. He remained asymptomatic through admission without palpitations. He was discharged on PO amoxicillin 500 mg TID for a total 28-day course.

DISCUSSION: Lyme disease, caused by the spirochete *Borrelia burgdorferi*, is the most common vector-borne disease in the United States and Europe.¹ This patient initially presented with fevers and a pruritic rash, which was misdiagnosed as cellulitis. His rash was likely erythema migrans, which is the most common sign of early localized infection in Lyme disease.² Erythema migrans is a rapidly expanding, erythematous skin lesion that appears at the site of the tick bite 1-2 weeks later.² The diagnosis of erythema migrans should be based on the clinical history, including potential exposure to ticks, and physical exam.³ Importantly, serologic tests for antibodies *B. burgdorferi* are not useful in patients with erythema migrans during the acute phase, as false negative results, as seen in this patient, occur in up to 50 % of cases.² While cellulitis is in the differential diagnosis for patients with erythema migrans and both can be warm and erythematous, cellulitis is often at the site of trauma to skin, usually tender, and is rarely circular.³ Days to weeks after the onset of erythema migrans, *B. burgdorferi* spreads hematogenously to other sites.¹ This stage, known as early disseminated infection, is often accompanied by headache and myalgias¹, and includes extracutaneous manifestations such as neurologic and cardiac complications.³ Most cases of Lyme carditis are clinically asymptomatic, though some patients present with palpitations, syncope, and chest pain.⁴ While Lyme disease affects men and women equally, Lyme carditis is more common in men with a ratio of 3:1.⁴ The most common cardiac abnormality is heart block. Patients with minor cardiac involvement, defined as 1st degree AV block and PR interval <0.3 s, can be treated orally with doxycycline or amoxicillin.⁵ Patients with PR interval greater than 0.3 s have a higher risk of developing complete heart block, a progression that can occur in minutes.⁵ For this reason, patients with first degree AV block with a PR>0.3 s, as well as those with second or third degree block, should be hospitalized and treated with IV ceftriaxone 2 g daily or high dose penicillin G.⁵ Complete recovery of Lyme carditis is seen in 90 % of patients.⁵ After advanced heart block resolves, treatment can be completed with an oral agent, such as doxycycline or amoxicillin, for a total 21-28 day course.² This patient had complete recovery from his carditis and has had no further sequelae from his Lyme disease. 1. Steere AC. Chapter 173. Lyme Borreliosis. In: Longo DL, Fauci AS, Kasper DL, Hauser SL, Jameson J, Loscalzo J, eds. Harrison's Principles of Internal Medicine, 18e. LYME CARDITIS: PAUSE IT! Kamran Hassan, california pacific medical center, San francisco, CA. (Tracking ID #2183864)

LEARNING OBJECTIVE #1: Lyme carditis can cause heart blocks from the more common AV node blocks to the rare SA node blocks.

LEARNING OBJECTIVE #2: Sinus node arrest if recognized and managed appropriately with antibiotics, may negate the need for permanent pacer placement.

CASE: The patient is an 81-year-old Caucasian male with history of hyperlipidemia, BPH and SCC who presented with recurrent episodes of dizziness occurring once or twice a week for about a month with one episode of loss of consciousness. Of note, he reported a rash around his waist about 2 months ago. He did not recall any insect bites. The physical examination at the time of admission and his initial labs were unremarkable except for an elevated D-Dimer. A CTA was done and ruled out pulmonary embolism. During his admission, he endorsed episodes of lightheadedness which correlated with multiple sinus pauses on telemetry lasting about 5-6 s each. A temporary pacer was placed and intravenous ceftriaxone was started for the treatment of possible Lyme carditis. His sinus pauses decreased in number and eventually stopped over the next few days. Later, his western blot returned positive for Lyme disease. On Day 6 the patient was discharged on oral Doxycycline without a permanent pacer.

DISCUSSION: Lyme disease or Lyme borreliosis is the most commonly reported vector-borne disease in the United States. It is caused by the spirochete *Borrelia burgdorferi* and transmitted to humans by the bite of Ixodes tick. Lyme carditis is a relatively uncommon

sequelae in 4–10 % of the patients with untreated Lyme disease and occurs about 1–2 months after the primary infection. Although all layers of the heart can be affected; most common cardiac manifestations are tachyarrhythmia, myopericarditis and various conducting defects. A hypothesis supporting these heart blocks is the possible dissemination of spirochetes and inflammatory cell infiltration in the conductive tissue of the heart. Majority of the conduction defects are secondary to involvement of the AV node with only two documented cases of sinus node involvement to our knowledge. The usual symptoms include chest pain, shortness of breath, palpitation, lightheadedness and syncope. Alternating bradycardia with tachycardia is a common EKG finding with a rapid progression from first degree to complete heart block in some cases. The diagnosis of Lyme carditis is by detection of Lyme antibodies by ELISA and western blot. The management of Lyme carditis is based on the degree of heart block and the prolongation of the PR interval with higher degree of blocks requiring intravenous antibiotics with or without temporary/permanent pacer placement. Our patient had a rare presentation of Lyme disease with sinus node involvement that was adequately treated with antibiotics negating the need for permanent pacer placement.

MAD AS A HATTER: A PUZZLING CASE OF ACUTE DELIRIUM
Nivedita Gunturi; Eric Anish. University of Pittsburgh, Pittsburgh, PA. (*Tracking ID #2195128*)

LEARNING OBJECTIVE #1: 1. To recognize the signs and symptoms of anticholinergic toxicity, even in the absence of an obvious history of anticholinergic drug use.

LEARNING OBJECTIVE #2: 2. To appreciate the potential systemic effects of certain topical medications.

CASE: We present the case of an 89-year-old female with a past medical history of atrial fibrillation on warfarin, hereditary deafness, sick sinus syndrome with dual chamber pacemaker placement, hypothyroidism, traumatic brain injury following a fall and subsequent subdural hematoma, mild cognitive impairment, migraines and depression who presented to our emergency department from an assisted living facility with delirium. Until the day prior to admission, the patient had been at her baseline and able to complete ADLs, converse with facility staff and her family, and follow commands. After returning from lunch with her family and a routine optometrist appointment, she seemed irritable to the staff at the assisted living facility. She continued to become more agitated and combative and was brought to the emergency department for evaluation. Her regular medications included diltiazem, donepezil, escitalopram, furosemide, levothyroxine and warfarin. There had been no recent changes. The patient had no significant travel or ingestion history, and no history of sick contacts. Upon arrival to the emergency department, her vital signs were unremarkable. Physical exam revealed an agitated, combative elderly woman who appeared her age, with equal and reactive pupils, flushed face, irregular heart rhythm with no murmurs, clear lungs to auscultation, mildly distended but soft abdomen and spontaneous movement of all extremities. Reflexes were 3+ throughout. The patient could not follow commands due to agitation. No meningeal signs were elicited. Lab work was significant for WBC 11.4 with 88.4 % PMNs, INR 1.9, and negative troponin. Ammonia, TSH and vitamin B12 levels were all within normal limits. Urine toxicology screen for drugs of abuse was negative. Blood salicylate and ethanol levels were negative. Electrocardiogram revealed rate-controlled atrial fibrillation with intermittent ventricular pacing. Chest x-ray and head CT scan with and without contrast were unremarkable. The patient was catheterized for 700 cc of foul smelling urine with unremarkable urinalysis. Blood and urine cultures collected at that time were subsequently negative for infection. The patient received 10 mg of intramuscular olanzapine in the emergency department and was subsequently somnolent throughout the rest of the night. The patient was admitted to the geriatric medicine service and monitored overnight. Neurology service was consulted and an electroencephalogram was obtained. This showed left temporal sharp waves and seizure tendency in the region corresponding to her previous head trauma, but no acute seizure activity. Upon awakening the next morning, the patient was back to her baseline mental status, conversational and able to follow commands. Further conversation with the patient and her family revealed that during the optometry appointment the previous day, she had received ophthalmic tropicamide drops for pupillary dilation. In the absence of laboratory, radiographic or clinical evidence of other reasons for the patient's acute change in mental status, it was presumed that this patient's delirium was due to the anticholinergic effect of the cycloplegic eye drops.

DISCUSSION: This case illustrates the adverse systemic effects that can result from the use of anticholinergic ophthalmic agents, particularly in an elderly patient with underlying dementia. The patient's acute urinary retention and delirium point to a diagnosis of anticholinergic toxicity. In this case, it is also possible that the patient's post-dilation blurred vision, combined with her hearing impairment, resulted in further sensory deprivation, contributing to her delirious state. Although systemic anticholinergic effects are more likely with homatropine than with tropicamide, they can be seen with the latter as well. For the conscientious primary care practitioner, it is important to be aware of the potential for such side effects to occur, in order to counsel patients appropriately. This case

also demonstrates the importance of obtaining additional history from other sources when the patient is unable to provide reliable information.

MAKE THE DIAGNOSIS: ANTISYNTHEASE SYNDROME Emma Johns. Emory University, Atlanta, GA. (*Tracking ID #2196243*)

LEARNING OBJECTIVE #1: Recognize the clinical manifestations of antisynthetase syndrome.

LEARNING OBJECTIVE #2: Appreciate the importance of the physical exam in establishing a unifying diagnosis.

CASE: A 36 year-old female with untreated hypertension presents with a complaint of worsening shortness of breath for 6 months. She reports being unable to walk twenty feet, rise from a seated position, and unload trucks for her job. She had difficulty getting out of the ambulance without assistance. She felt some improvement with her daughter's albuterol inhaler. She has a 10 year smoking history but quit smoking two years ago. On admission, she was afebrile and her oxygen saturation was 94 % on room air. Crackles were noted at the right lung base. There were no murmurs, jugular venous distension, or edema. She had normal sensation. Strength was 4/5 bilaterally in biceps, triceps, deltoids, quadriceps, and hip flexors but 5/5 in distal muscle groups. Her initial labs showed mild transaminitis (AST of 112, ALT of 116) and microcytic anemia. D-dimer was 478, BNP was 16, and CK-MB was 134. Chest radiograph showed diffuse bilateral reticulonodular pattern. A chest CT chest showed bilateral enlarged axillary lymph nodes, cardiomegaly, scattered ground glass opacities, and traction bronchiectasis throughout the bilateral lungs. Ventilation-perfusion scan was negative for pulmonary embolus. Pulmonary function tests (PFTs) revealed a restrictive pattern and a reduced diffusion capacity, consistent with an interstitial lung disease. Her echocardiogram showed a normal left and right ventricular systolic function and stage I-II left ventricular diastolic dysfunction. Transbronchial lymph node biopsy showed chronic inflammation of the bronchial mucosa. Further lab testing revealed an elevated CPK at 4375, sedimentation rate of 22, and CRP of 2.97. Antibody testing found a positive Anti-SSA and Anti-Jo1. Anti-dsDNA, anti-centromere, anti-Smith, anti-SSB/La, and anti-Scl70 were all negative. An electromyogram (EMG) showed an irritable myopathy. She was diagnosed with antisynthetase syndrome with polymyositis and interstitial lung disease. She was treated with prednisone 30 mg twice daily with a plan to start azathioprine as an outpatient.

DISCUSSION: Antisynthetase syndrome is a rare systemic autoimmune syndrome. It is thought to involve an immune reactivity towards tRNA synthetases that may be involved in the inflammatory response in muscle or lung. Diagnosis requires the presence of antisynthetase antibodies and the presence one or more of characteristic clinical features including interstitial lung disease, inflammatory myopathy, and inflammatory polyarthritis. Initially, interstitial lung disease may be the only manifestation and more severe disease may develop over time. Anti-Jo1 antibody is associated with antisynthetase syndrome. Other helpful tests include CPK, EMG, PFTs and biopsy. In this case, the patient had findings consistent with interstitial lung disease on pulmonary testing. However, other clues including proximal muscle weakness, elevated CPK, and inflammatory biomarkers prompted an evaluation for a systemic autoimmune process. The myopathy on EMG and a positive anti-Jo1 antibody helped confirm the diagnosis. Our case illustrates the crucial role of a thorough history and physical exam. Although this patient's chief complaint was shortness of breath, her functional limitations were due to both dyspnea and weakness. Upon further questioning, she specifically felt weak when rising from a seated position and trying to arrange her hair, classic symptoms of pathologic proximal muscle weakness. Decreased strength on physical exam corroborated that history. It is easy to overlook strength deficits as poor effort or exertional limitations from another disease process. In this case, strength was the key to the diagnosis, which was then confirmed with serologies. Given the heterogeneity of polymyositis and antisynthetase syndrome, it is vital to remember that interstitial lung disease is not always a diagnosis in and of itself; it can also be a sign of a systemic illness that the physical exam can be effective and efficient in helping to diagnose.

MALIGNANT PERITONEAL MESOTHELIOMA PRESENTING AS FEVER OF UNKNOWN ORIGIN Avash Kalra¹; Nate Schomaker¹; Frank W. Merritt². ¹University of Colorado, Denver, CO; ²University of Colorado, Aurora, CO. (*Tracking ID #2199483*)

LEARNING OBJECTIVE #1: Develop an effective clinical approach to fever of unknown origin in the setting of intra-abdominal fibrosis

LEARNING OBJECTIVE #2: Diagnose malignant peritoneal mesothelioma, while recognizing the potential for sampling error associated with surgical biopsy

CASE: A 35-year-old Caucasian male with no significant past medical history presented with a six month history of daily fevers, night sweats, unintentional 40-lb weight loss, fatigue, and constant periumbilical abdominal pain. He reported no risk factors for exposure to tuberculosis or other atypical infections. Evaluation at another hospital was notable for elevated erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP), as well as marked thrombocytosis. Magnetic resonance imaging (MRI) of the abdomen revealed fibrosis in the peritoneal and mesenteric soft tissues, and an upper endoscopy showed mild esophagitis. The patient underwent an exploratory laparotomy that included four tissue biopsies of peritoneum and omentum that all revealed non-specific fibroadipose tissue without evidence of malignancy. At the time of transfer from the outside hospital, the patient appeared cachectic, was febrile to 39.0°C, and tachycardic to 110 beats per minute. His abdomen was soft and mildly tender throughout, with no palpable masses. The patient underwent a thorough evaluation for infectious, rheumatologic, hematologic, and malignant causes. Briefly, autoimmune markers (including auto-antibodies and immunoglobulin levels) and a panel of infectious disease markers were negative. A computerized tomography (CT) scan of the head and chest was also unrevealing, and bone marrow biopsy revealed normal cellularity without dysplasia or abnormalities on flow cytometry. With continuing symptoms, the patient underwent a whole-body positron emission tomography (PET)-CT scan which showed intense uptake of FDG, a radiopharmaceutical that correlates with high metabolic activity, throughout the omental, mesenteric, and peritoneal soft tissues and associated peritoneal calcifications. Subsequently, the patient underwent repeat exploratory laparotomy, with repeat biopsies, which on pathology review were consistent with diffuse malignant peritoneal mesothelioma (MPM). After surgical consultants determined that the extensive abdominal tumor burden would not be amenable to debulking, chemotherapy with carboplatin and pemetrexed was initiated shortly before the patient was discharged home.

DISCUSSION: General internists commonly encounter fever of unknown origin (FUO), a clinical entity defined by fever greater than 38.3 °C for at least three weeks and an unrevealing evaluation over at least one week. Infections, malignancies, and connective tissue disease comprise the majority of diagnosed cases of FUO, but up to 50 % of cases do not reveal a diagnosis. Thorough history-taking, hypothesis-based laboratory testing, and even CT scanning of the chest and abdomen are encouraged diagnostic methods. Data have also suggested that FDG-PET can be a valuable imaging technique, as it was in this case, for the general patient population with FUO and an elevated ESR or CRP. This case describes the presentation of a rare malignancy in a young male who presented with FUO. The initial differential diagnosis included rheumatologic, hematologic, oncologic, and infectious etiologies, and the eventual diagnosis of primary MPM was made only after repeat biopsies of fibrotic peritoneal and omental tissues. Indeed, this FUO case included the added complexity of diffuse intra-abdominal fibrosis, which raised suspicion for malignancy. Malignancies to consider include carcinomatosis, mesothelioma, lymphomatosis, and sarcomatosis. Although these conditions can exhibit some characteristic imaging findings - for instance, presence of hemorrhage (sarcomatosis), significant ascites (carcinomatosis), calcification of plaques (mesothelioma), or focused lymphatic involvement (lymphomatosis) - imaging is rarely diagnostic on its own. When initial biopsy results are non-diagnostic, it is important to consider sampling error. In this case, with diagnostic uncertainty persisting after the first set of biopsy specimens, intense FDG uptake on PET-CT within areas of fibrosis provided objective support for pursuing repeat biopsies. This patient's presentation adds to the current literature of primary MPM, the most frequent malignancy of the peritoneum but a rare malignancy overall that is diagnosed only about 250 times in the U.S each year. Median survival based on cancer registry data suggests a median survival of 10 months. Exposure to asbestos, the most commonly recognized risk factor for this malignancy, was not identified in the patient's history. When debulking surgery is not an option, chemotherapy is carboplatin-based and is usually palliative. This patient's case was typical in that he presented non-specifically and at a late stage of diagnosis, reflecting a need for a high index of suspicion in appropriate circumstances.

MALIGNANT PLEURAL MESOTHELIOMA PRESENTING AS AN ENIGMATIC PLEURAL EFFUSION Priyanka Parekh²; Sujata Bhushan¹. ¹Dallas VA Medical Center, Dallas, TX; ²University of Texas Southwestern, Dallas, TX. (Tracking ID #2189043)

LEARNING OBJECTIVE #1: Diagnose and manage a suspected malignant pleural effusion (MPE). Occasionally fluid studies and cytology are unrevealing and further invasive measures must be taken for definitive diagnosis. Once diagnosed, the management of MPE is usually palliative and chosen based primarily on the the patient's expected survival time.

LEARNING OBJECTIVE #2: Recognize malignant mesothelioma as a rare etiology of malignant pleural effusion (MPE).

CASE: Fifty-two year old Caucasian male with past medical history of COPD, left spontaneous pneumothorax, status post chemical and mechanical pleurodesis with left upper lobe resection, was admitted with a 3 week history of progressive dyspnea on

exertion, left-sided pleuritic chest pain and a nagging dry cough. His occupational history was notable for working in construction in the Navy shipyards, and social history was notable for heavy tobacco use. Physical exam was significant for decreased breath sounds and dullness to percussion of the left lung base. Chest radiography revealed an opacified left lower lobe. Computed tomography confirmed the presence of a large loculated left-sided pleural effusion with rightward mediastinal deviation. The patient underwent thoracentesis with chest tube placement, with subsequent drainage of three liters of grossly bloody fluid, exudative by Light's criteria. Gram stain and culture of the pleural fluid were negative. Cytopathology of the fluid was sent twice, including PAP stain, and was negative for malignant cells. The patient subsequently underwent video-assisted thoracoscopic surgery with pleural biopsy, and placement of a thoracic irrigation system with chest tubes and an indwelling pleural catheter. During the surgery he was noted to have thick pleural studding with tumor. Histopathology revealed a myxoid neoplasm, most consistent with a diagnosis of malignant pleural mesothelioma (MPM).

DISCUSSION: The first step in both diagnosis and management of a suspected malignant pleural effusion (MPE) is thoracentesis for pleural fluid analysis as well as relief of dyspnea. MPEs are typically exudative; the presence of low pH and/or low glucose suggests high tumor burden. MPEs are commonly lymphocyte-predominant, and can be grossly bloody. While these features of pleural fluid analysis are suggestive of MPE, the definitive diagnosis depends on the detection of tumor cells via pleural fluid cytopathology or pleural biopsy histopathology. The sensitivity of pleural fluid cytology to detect malignant cells is suboptimal, estimated at 40–87 %. Serial thoracenteses for repeated cytologic analysis, as well as the addition of immunohistochemistry staining detecting various tumor markers, have both been proposed to increase sensitivity of this diagnostic strategy. However, in many cases, a more invasive diagnostic procedure—such as CT-guided closed pleural biopsy, medical thoracoscopy, or video-assisted thoracoscopic surgery (VATS)—to obtain a histologic biopsy is required to make the diagnosis. The use of medical thoracoscopy in particular raises diagnostic sensitivity to 95 %. The development of MPE implies diffuse metastatic spread of the primary cancer. Prognosis depends on many factors, most notably the underlying tumor type; however, survival typically does not exceed 12 months. Therefore, management strategies are most commonly aimed at symptom relief rather than tumor eradication. Therapeutic options for MPE include observation with as-needed serial thoracenteses, indwelling pleural catheter, chemical pleurodesis, and pleuroperitoneal shunt. The choice of intervention is primarily dependent on the patient's expected survival time, with the goal of treatment being to maximize symptom relief and to minimize hospital days as well as procedure-related pain, discomfort, and complications. Most MPEs are caused by metastases from primary lung, breast, or ovarian cancers, or from lymphomas. A rare but steadily increasing cause of MPE is malignant pleural mesothelioma (MPM), an insidious neoplasm arising from the mesothelial lining of the parietal and visceral pleura. Exposure to asbestos is a well-known important etiologic factor. Pleural fluid cytology has a poor diagnostic yield of 20–33 %. Immunohistochemical markers like calretinin, WT-1, vimentin and cytokeratin 5/6 are routinely employed, but have inadequate sensitivity and specificity. In most cases, pleural biopsy via VATS is required to make the diagnosis, with a reported diagnostic sensitivity of 87 %. Although MPM is uniformly fatal at an average of 9–17 months, promising increases in survival have been reported with the use of aggressive multimodality treatment regimens that combine surgical resection with radiation, chemotherapy, or both. Maintaining a high index of clinical suspicion may result in an earlier diagnosis and a more successful treatment outcome.

MANAGEMENT OF SEVERE HYPERTRIGLYCERIDEMIA IN ACUTE ALCOHOLIC PANCREATITIS Payel J. Roy¹; Robert Lowe². ¹Boston University Medical Center, Boston, MA; ²Boston University School of Medicine, Boston, MA. (Tracking ID #2197430)

LEARNING OBJECTIVE #1: Evaluate the differential diagnosis of acute pancreatitis.

LEARNING OBJECTIVE #2: Assess conventional treatment options for hypertriglyceridemic pancreatitis and their applicability to alcoholic pancreatitis with severe hypertriglyceridemia.

CASE: Mr. S is a 44 year-old male with past medical history significant for uncomplicated acute alcoholic pancreatitis diagnosed 2 months earlier that was medically managed. Mr. S re-presented with severe epigastric pain radiating to the mid-back with associated nausea and vomiting. He endorsed drinking 6–8 beers daily for the last 2 weeks and 10 beers earlier on day of admission. He also endorsed eating multiple cheeseburgers and sausages at a friend's picnic. Examination revealed a pulse of 110 and blood pressure of 164/110. The patient was an alert and oriented middle-aged man in severe distress. He had a tender abdomen without peritoneal signs and no evidence of pleural effusion on lung exam. Initial labs were significant for a normal leukocyte count, BUN, and lactate level, and for a total bilirubin of 0.2 mg/dL and lipase 382 U/L (upper limit of normal 81 on laboratory scale), meeting criteria for acute pancreatitis. His bedside index for predicting severity in acute pancreatitis (BISAP) score was 0. He was initially managed on the medical ward for

alcoholic pancreatitis with bowel rest, normal saline infusion, and intravenous pain control. A lipid panel obtained later revealed a triglyceride level of 1425 mg/dL; repeat was 1605 mg/dL. The patient was started on gemfibrozil and urgently transferred to the MICU for initiation of an insulin drip, with a goal of titrating to a triglyceride level of less than 500 mg/dL.

DISCUSSION: This case highlights the importance of considering a broad differential in acute pancreatitis and of recognizing and managing severe hypertriglyceridemia. Mr. S had a prior presentation for presumed alcoholic pancreatitis without a lipid panel checked at that time. Potential etiologies for acute pancreatitis in Mr. S included gallstones (unlikely with a normal bilirubin) and alcohol ingestion, with hypertriglyceridemia, hypercalcemia, drug-induced, autoimmune, and infection much less likely. It is unclear if Mr. S had alcoholic pancreatitis associated with severe hypertriglyceridemia or if he truly had hypertriglyceridemic pancreatitis, a somewhat rare disease. The management of the former is uncertain, as severe hypertriglyceridemia is not necessarily seen, nor are triglyceride levels always checked, in acute alcoholic pancreatitis. In addition, the management of hypertriglyceridemia in pancreatitis without an insulin drip, apheresis, or heparin infusion is not well-documented in the literature, particularly in patients with alternate possible etiologies for pancreatitis. Mr. S was managed with conventional treatment for hypertriglyceridemic pancreatitis; however his more likely diagnosis was alcoholic pancreatitis complicated by severe hypertriglyceridemia given his lack of a family or personal history of hypertriglyceridemia. Conventional treatment of hypertriglyceridemic pancreatitis includes apheresis, insulin drip, and/or heparin. Apheresis is indicated for patients with lactic acidosis, hypocalcemia, and organ system dysfunction. An insulin drip is indicated where apheresis is not available and if the serum glucose is >500 mg/dL. Heparin infusion is less commonly used, but may be effective in lowering triglyceride levels acutely. Oral antihyperlipidemic medications should be initiated as adjuvant therapy, though their action is significantly slower. Early recognition and management of severe hypertriglyceridemia in pancreatitis is important in order to prevent complications of pancreatitis, including pseudocysts, organ failure, hemorrhage, infection, and necrosis. Mr. S was treated for alcoholic pancreatitis with severe hypertriglyceridemia using an insulin drip; however it is unclear if he had alcoholic pancreatitis as opposed to primary hypertriglyceridemic pancreatitis. More studies will be needed to determine the cost-effectiveness of checking triglyceride levels on all cases of acute pancreatitis and to determine if all cases of severe hypertriglyceridemia in the setting of presumed alcoholic pancreatitis should be managed similarly to hypertriglyceridemic pancreatitis.

MARCHIAFAVA-BIGNAMI DISEASE: A CASE REPORT WITH GOOD PROGNOSIS Michelle Tong; Violetta Laskova. Mount Sinai Beth Israel, New York, NY. (Tracking ID #2197592)

LEARNING OBJECTIVE #1: Recognize clinical features of Marchiafava-Bignami disease

LEARNING OBJECTIVE #2: Broaden differential for neurological deficits in malnourished alcoholics

CASE: Sixty-eight year old male presents with 3–4 days of abrupt onset of generalized weakness, shortness of breath and fever/chills. He has a history of chronic alcohol abuse with 2–5 drinks 3–5 days per week, last used 4 days prior to admission. He denied any prior withdrawal from alcohol, seizures, or loss of consciousness. He is HIV positive on ART with CD4 count 636 and has ischemic cardiomyopathy with EF 48 %. On physical examination, vitals showed temperature 101.3 F, HR 74, BP 121/67, RR 20, oxygen saturation 98 %. He appeared chronically ill and cachectic with temporal wasting. He had soft crackles of the left lower lobe on respiratory exam, regular rate and rhythm without murmurs on cardiac exam, and no edema or JVD. Strength of all extremities was intact with no focal neural deficits. On initial workup, chest X-ray demonstrated left lower lobe infiltrate and CBC was significant for WBC 19.4. Patient was started on antibiotics and admitted for community acquired pneumonia. The second day of admission, patient was found to have acute onset slurred speech, ataxia, and aggressive behavior. He was alert and oriented, with fluent severe dysarthria, able to follow commands, read, repeat, and name objects. Cranial nerves were intact, motor strength and sensation of all extremities were intact and symmetric. Moderate dysmetria of upper extremities was found on finger to nose exam, he was able to perform heel to shin testing bilaterally. Gait was wide-based and unsteady with truncal titubation. Initial differential included cerebrovascular event, and stroke workup was initiated with non-contrast CT head, which was negative. MRI brain found abnormal high T2 signal arising from the splenium of the corpus callosum with no mass effect or surrounding edema. The genu and body of the corpus callosum had relatively normal signal intensity. Based on the brain MRI and physical findings, Marchiafava-Bignami disease (MBD) was diagnosed, and the patient was started on IV thiamine 500 mg TID for 3 days, then 100 mg PO daily until discharge. Patient's gait and speech improved daily on thiamine and he was discharged five days after thiamine was started with full recovery.

DISCUSSION: MBD is defined by demyelination or necrosis of the corpus callosum, first identified post-mortem in three alcoholic men in 1903 by pathologist Marchiafava and Bignami. The disease often features acute or subacute findings of dysarthria, ataxia, and in more severe cases, dementia, seizure and coma. In vivo diagnoses of MBD via MRI have allowed for earlier detection and treatment of this rare disease. By 2001, over 250 cases had been reported since the disease was first documented, mostly as post-mortem diagnoses. Since 2001, less than a hundred cases have been identified in the literature based on a computerized review, mainly diagnosed on imaging. In 2004 Heinrich et al. further subdivided the disease into Type A and Type B based on clinicoradiologic data. Type A involves the entire corpus callosum on MRI and is characterized by severe impairment of consciousness, including coma and seizure, and is associated with poor prognosis. Type B partially involves the corpus callosum on MRI and clinical manifestations include dysarthria and gait disturbance and at most slight impairment of consciousness, associated with good prognosis. Our case is consistent with Type B, as the patient did not have impaired consciousness, MRI revealed partial lesions of the corpus callosum, and he recovered fully during the hospitalization. MBD is most commonly seen in malnourished alcoholics. Alcoholism is associated with several neurological conditions, such as Wernicke encephalopathy, Korsakoff syndrome, cerebellar degeneration, and peripheral neuropathy. MBD is possibly misdiagnosed as this population commonly presents with neurological findings. The specific pathogenesis of MBD remains unclear. MBD has also been found in diabetes, lupus, dermatomyositis, and anorexia nervosa. In some of these cases, especially in settings of diabetes or autoimmune disease, improvement with corticosteroids was seen. High dose thiamine has often been helpful in alcoholic patients with MBD, as with our case. Nevertheless, there is no proven treatment of MBD and degree of responsiveness has been variable. Cortical involvement generally predicts poorer prognosis, with multiple reports of persistent symptoms or vegetative state in spite of treatment with vitamins and corticosteroids. While there are many differentials of altered mental status and neurological findings in chronic alcoholics, it is worth recognizing the signs of MBD, especially since treatment with B complex vitamins and corticosteroids are associated with good response in Type B disease.

MASSIVE LEFT ATRIAL MYXOMA PRESENTING AS PULMONARY HYPERTENSION Darya Rudym^{2,1}; Meng Chen^{2,1}; Andrew Levy^{2,1}; Joshua Denson^{2,1}. ¹New York University School of Medicine, Bellevue Hospital Center, New York, NY; ²NYU Langone Medical Center, New York, NY. (Tracking ID #2199179)

LEARNING OBJECTIVE #1: Recognize a large myxoma as a possible cause of severe pulmonary hypertension and right heart failure

CASE: A 64 year-old woman with hyperthyroidism on methimazole presented with 6 months of worsening dyspnea on exertion. She reported gradually decreasing exercise tolerance from unlimited to less than one block over the course of 6 months. She also noted a 20 lb weight loss over the same time period. Associated symptoms included lower extremity swelling and an uncomfortable sensation in her chest when lying on her left side. Her exam revealed a very thin woman with clubbing of her fingers and toes, jugular venous distention of 14 cm, a parasternal heave, a loud P2, and a diastolic rumble heard best at the apex in the left lateral decubitus position. EKG showed evidence of L atrial enlargement and right heart strain. Transthoracic echocardiogram revealed a severely dilated left atrium with a 7.4 cm by 3.4 cm mass attached to interatrial septum that entered mitral valve orifice in diastole, leading to obstruction of mitral valve orifice and severely elevated transmitral gradient of 16 mm Hg. It also revealed severe pulmonary hypertension with a mean right atrial pressure of 15 mmHg and a pulmonary artery systolic pressure of 87.8 mmHg. Given the classic echocardiographic evidence of myxoma and absence of other systemic tumors, the patient underwent resection, which confirmed the diagnosis by histopathology. Her post-operative course was uneventful, and she was seen in clinic one month later reporting complete resolution of her symptoms.

DISCUSSION: Myxoma is a common primary cardiac tumor, which can affect all four of the chambers but the vast majority are seen in the left atrium¹. It is more commonly reported in women and can present at any age. The typical triad of myxoma presentation are symptoms of mitral valve obstruction, embolic symptoms and constitutional symptoms^{2–4}. Mitral valve obstruction leading to heart failure-like symptoms such as dyspnea on exertion and lower extremity edema are among the most common, reported in 67 % of presentations². Notably, patients do not report symptoms of heart failure until the tumor grows large enough to obstruct the mitral valve. Similarly, severe pulmonary hypertension develops when the myxomatous growth obstructs mitral valve outflow such that its hemodynamics mimic severe mitral valve disease. One of the studies reported pulmonary hypertension in 61 % of myxoma cases and the degree of mean pulmonary artery pressure was noted to increase proportionally with the size of the myxoma⁵. TTE is crucial in diagnosis and raises the suspicion for myxoma but histopathologic findings of scattered cells within mucopolysaccharide stroma seal the diagnosis. Prompt surgical resection is critical to prevent embolic events and post-operative course generally carries low risk of complications. Pulmonary artery pressure decreases immediately post excision and

patients report dramatic improvement in their symptoms^{4,5}. In our case, careful physical examination and early recognition of myxoma were instrumental in assuring a good outcome for the patient. Although an uncommon cause, the astute physician should consider left atrial myxoma in the differential for pulmonary hypertension. References: 1. Keeling IM. MEDICARE 3-DAY RULE: A CASE IN POINT Lauren E. Corona²; Najibah K. Rehman¹; Diane L. Levine¹. ¹Wayne State University, Detroit, MI; ²Wayne State University School of Medicine, Detroit, MI. (Tracking ID #2192742)

LEARNING OBJECTIVE #1: Examine the Medicare 3-day rule and its history

LEARNING OBJECTIVE #2: Recognize the potential adverse consequences of the rule

CASE: Ms. W, a 78-year-old African-American female with dementia was brought to the hospital by her daughter because she was no longer able to manage her care. The daughter was interested in nursing home (NH) placement. Ms. W was oriented to person only. She was admitted to the medical service for medical clearance. This elderly patient, with no acute disease process, would require placement in a NH, however, Medicare would require her to spend 3.0 inpatient days in the hospital to justify/pay for discharge (d/c) to a NH.

DISCUSSION: The Medicare 3-day rule (M3DR) was instituted in 1965 with the primary aim of reducing use of limited, high-cost skilled nursing facilities (SNF) and ensuring appropriate and detailed work-ups for patients needing such care. In 1965, a 3-day inpatient stay was a reasonable time for work-up and development of care and d/c plans. The rule applies to both those coming from the community and the NH provided they will be returning to the NH upon d/c. The mean cost per hospital stay (in 2012) is \$8500. This increases to \$13,000 in the elderly. In comparison, the cost of a one-night stay at a SNF is \$430/day and \$300/day at a NH. It is widely known that with hospitalization comes an increased risk for adverse events (AE) (e.g., hospital-acquired infections, delirium, falls, medical errors). Older adults are particularly at increased risk for AEs. One proponent of the M3DR is the NH itself. The rule allows for NHs to transfer care to a hospital when a resident becomes acutely ill. Thus, the high costs associated with care for acute illness are eliminated. The NH benefits are twofold; the costs for the acute care for that patient are reduced, but also, upon return, the NH will receive higher Medicare payments because of the higher level of SNF care that is needed. Attempts to reassess and permit waivers to the rule have made little headway. Current efforts have focused on treating acute illnesses within these long-term care facilities without transfer to the hospital. Shared savings approaches where all parties are incentivized to keep patients out of the hospital are also being prioritized. Over the course of her hospitalization, Ms. W required no medical services that could not also have been performed in an outpatient or NH setting. On day 3 she began to wander and required a sitter. This increased her LOS as the NH stipulated she be sitter-free for 24 h prior to d/c. Because of the M3DR and subsequent need for a sitter, d/c fell on a Saturday (NHs do not take new patients on weekends). Ms. W was therefore d/c'd on day 6. The M3DR was instituted as a means of filtering admission to NHs and SNFs, and in doing so keeping Medicare costs down. Rather than keeping costs down, it requires unnecessary and lengthier hospitalizations. With the aging of the population and the increasing number of patients that will need these services, efforts should be made to maximize the care within less expensive settings instead of incentivizing admissions and increasing hospital LOS. Reevaluation of the M3DR must be undertaken for patient safety and quality of care to prevail.

MERCURY POISONING: A MIMICKER OF PHEOCHROMOCYTOMA Erin Meierhenry²; Alan Kuo²; Janki D. Amin²; Neveen S. El-Farra¹; Magdalena Ptaszny². ¹David Geffen School of Medicine at UCLA, Los Angeles, CA; ²UCLA, Los Angeles, CA. (Tracking ID #2179014)

LEARNING OBJECTIVE #1: Consider mercury poisoning in the differential diagnosis of hyper-adrenergic state.

LEARNING OBJECTIVE #2: Recognize the importance of obtaining a thorough history of herbal supplement use and alternative medications.

CASE: A 46-year-old man with recently-diagnosed hypertension presented with multiple complaints. He was well until 4 weeks prior to presentation when he noted gradual onset of diffuse weakness, paresthesias, tremor, fatigue and myalgias. He also suffered from new

insomnia, anxiety, subjective fevers and diaphoresis. He reported intermittent use of Chinese herbal medicine over years with increased consumption in the past several weeks. The patient had an extensive drinking history, consuming four alcoholic beverages per night for many years but quit at the onset of his symptoms. On presentation, vital signs were significant for persistently elevated blood pressure up to 218/100 and heart rate up to 100. His exam was significant for an obese habitus, profuse diaphoresis and salivation, and tremulousness. Neurologic exam was notable for poor articulation of speech, 4/5 strength in upper and lower extremities bilaterally, unsteady gait, fine tremor punctuated by course shaking in bilateral upper extremities, and tenderness to palpation of calves bilaterally. A broad differential was considered. CBC and chemistry were within normal limits. Urinalysis was notable for 3+ proteinuria. Neurologic work up including lumbar puncture, electromyography (EMG) of upper and lower extremities and brain and spinal cord imaging were unremarkable. A cortisol stimulation test was within normal limits. The patient was treated empirically for alcohol withdrawal with minimal improvement. The clinical presentation was concerning for pheochromocytoma, however, serum metanephrines and urine catecholamines were only mildly elevated. In addition, CT of abdomen and pelvis showed no evidence of adrenal mass. Toxicologic work up revealed an elevated blood mercury level, twice the upper limit of normal and a urine mercury level 25 times the upper limit of normal. He was started on chelation therapy with penicillamine and had gradual improvement in his symptoms and normalization of blood pressure. Though his hyperadrenergic symptoms improved, he continued to have sequelae from mercury toxicity, including neuropathy, proteinuria, autonomic dysfunction, generalized weakness, and urinary retention.

DISCUSSION: The most common causes of hyperadrenergic state include overdose of sympathomimetic drugs (ex: amphetamines, cocaine, epinephrine, monoamine oxidase (MAO) inhibitors with tyramine-containing foods), panic disorder, and pheochromocytoma. Mercury poisoning is a rare but important mimicker of pheochromocytoma, and should be considered in patients presenting with sympathetic overdrive in the right clinical context. By inactivating catechol-O-methyltransferases (COMT), mercury inhibits the breakdown of catecholamines, resulting in manifestations such as tremulousness, hypertension, and diaphoresis. Other common symptoms of mercury poisoning include weakness, fatigue, paresthesias, excess salivation, gait unsteadiness, and cognitive/emotional difficulties, all of which were present in our patient. Chinese herbal medications have often been associated with high levels of mercury and other heavy metals. Studies estimate that less than 50 % of patients disclose use of herbal medications or supplements. Disclosure of complementary and alternative medicine correlates with a perception of a high quality relationship with the physician. Disclosure may be improved by keeping social and cultural factors in mind and using certain keywords, such as natural products, teas, herbs picked from a garden, when obtaining the history. This case illustrates the importance of obtaining a thorough history of all medication and substance use, including complementary/alternative medications.

MESENTERIC VENOUS THROMBOSIS (MVT) Nathan Punwani¹; Jillian S. Catalanotti²; Richard Brooks¹. ¹George Washington University Hospital, Washington, DC; ²The George Washington University, Washington, DC. (Tracking ID #2201043)

LEARNING OBJECTIVE #1: Identify MVT as a rare cause of abdominal pain

LEARNING OBJECTIVE #2: Describe the thrombophilia and myeloproliferative workup necessary to assess for underlying causes of MVT

CASE: The patient is a 42 year old male with no significant past medical or surgical history who presented to the hospital for evaluation of a 4-day history of abdominal pain. His abdominal pain was concentrated in the epigastric region with no radiation or migration from one site of the abdomen to the other. The patient described the pain as waxing and waning over the course of 4 days, and he characterized it as a burning sensation that was worse after meals. The patient took over-the-counter antacids, which provided some transient relief of symptoms. He denied any nausea, emesis, jaundice, diarrhea, constipation, or GI bleeding. The patient did not regularly take any medications, including non-steroidal anti-inflammatory drugs, proton pump inhibitors, or H2 antagonists. He denied any history of gastroesophageal reflux or peptic ulcer disease. He also reported an unremarkable family history and denied any significant history of tobacco, alcohol, or illicit drug use. The patient initially presented to his primary care doctor on the day of admission and was reported to have a fever of 101.2 F (38.4C); he was then told to go to the emergency room for further evaluation. On admission, the patient was afebrile and all other vital signs were normal. Physical exam was noteworthy for mild tenderness to palpation in the right upper quadrant and epigastric regions with no rebound or guarding, and a negative Murphy's sign. Complete blood cell count, comprehensive metabolic panel, and lipase levels were all within normal limits. Lactate dehydrogenase was elevated at 800. In the emergency room, a CT of the abdomen with contrast was performed; the scan revealed an extensive thrombus within the superior mesenteric vein extending from the most distal branches to the proximal main portal vein. The patient underwent an extensive hypercoagulability and myeloproliferative workup that was

negative for prothrombin gene mutation, factor V Leiden, lupus anticoagulant, anticardiolipin antibodies, protein C and S studies, and JAK2 and BCR-abl genetic mutations. Flow cytometry for paroxysmal nocturnal hemoglobinuria was also negative. However, antithrombin III activity levels were found to be reduced at 40 %. The patient was started on enoxaparin 1 mg/kg SQ BID and was eventually transitioned to warfarin.

DISCUSSION: Mesenteric venous thrombosis (MVT) is a rare diagnosis that represents 1 in 5000 to 15,000 inpatient admissions and 6 to 9 % of cases of acute mesenteric ischemia. Thus, the diagnosis requires a high clinical index of suspicion. The symptomatic presentation of MVT tends to be acute in nature (60–80 % of cases) and usually manifests as evolving abdominal pain over the course of 6 to 14 days. The abdominal pain is often located in the mid-abdomen and occurs out of proportion to physical exam findings. The mean age at presentation is 40 to 60 years, and males are more commonly affected. Symptoms that are typically associated with MVT include nausea, emesis, anorexia, fever, constipation, diarrhea, and—if ischemia is prolonged—gastrointestinal bleeding. Diagnosis is made by abdominal CT imaging with contrast, which has an accuracy of 90 %. Treatment consists of anticoagulation with warfarin after appropriate enoxaparin or heparin bridging. Use of the novel factor Xa anticoagulants have not been evaluated by formal studies of MVT patients. Thrombophilia and malignancy—especially myeloproliferative disorders like polycythemia vera, essential thrombocythemia, and myelofibrosis—collectively account for 40 % of MVT cases. Consequently, a hypercoagulability and malignancy workup is crucial to identify the etiology of MVT. Abdominal imaging should reveal any local abdominal malignancies near the mesenteric veins that could trigger thrombosis. Hypercoagulability testing should consist of assays for prothrombin gene mutation, factor V Leiden, protein C and S, and antithrombin III levels. Ideally, blood should be drawn prior to initiation of anticoagulation for thrombophilia testing. JAK2 and BCR-abl genetic mutations should also be tested for identification of any occult myeloproliferative disease.

METASTATIC PANCREATIC NEUROENDOCRINE TUMOR CAUSING CUSHING-LIKE SYNDROME WITH REFRACTORY HYPERTENSION AND HYPERGLYCEMIA Bilal Shaikh¹; Andrew C. Rettew¹; Asad Jehangir²; Ana Abaroa-Salvatierra³; Kyle M. Bennett⁴. ¹Reading Health System, Wyomissing, PA; ²Reading Health System, West Reading, PA; ³Reading Hospital, West Reading, PA; ⁴The Reading Hospital, Wyomissing, PA. (Tracking ID #2198987)

LEARNING OBJECTIVE #1: Recognize ACTH hypersecretion in patient with symptoms such as new onset hypertension, hyperglycemia, proximal muscle weakness, psychosis, and leg swelling

LEARNING OBJECTIVE #2: Determine underlying cause of ectopic ACTH secretion in order to initiate proper treatment

CASE: A 57-year-old female with previous hypothyroidism evaluated for proteinuria of 2000 mg/dl on urinalysis, new-onset severe hypertension, worsening lower extremity edema, and fatigue. Physical examination revealed a blood pressure of 190/100 mmHg, mild right upper quadrant tenderness without rebound, and normal bowel sounds. Mild bilateral lower extremity pitting edema to the shins was also noted. Laboratory investigation revealed serum sodium of 140 meq/L (range: 135–153 meq/L) potassium of 1.7 meq/L (range: 3.5–5.3 meq/L), glucose of 195 mg/dL (range: 70–99 mg/dL), creatinine of 0.5 mg/dL (range: 0.5–1.5 mg/dL), and magnesium level of 1.7 mg/dL (range: 1.8–2.4 mg/dL). Urinalysis was significant for proteinuria of 30 mg/dL, no ketones, 250 mg/dL of glucose, and no red blood cells. Lower extremity duplex ultrasonography was negative for deep venous thrombosis. Chest computed tomography was negative for pulmonary embolism, but reported multiple iso-dense hepatic lesions. Right upper quadrant ultrasonography and abdominal and pelvic computed tomography confirmed multiple liver lesions without common bile duct dilatation consistent with malignancy, a 1.4 cm pancreatic tail mass, and mild bilateral adrenal hyperplasia. The patient underwent percutaneous liver biopsy and pathology identified a low-grade, well-differentiated neuroendocrine carcinoma. Endocrinology was consulted to evaluate for secondary causes of severe refractory hypertension with hyperglycemia. The patient was found to have a cortisol-producing paraneoplastic syndrome supported by a highly elevated 24 h free urine cortisol at 8911 mcg/24 h (range: 3.5–45 mcg/24 h), elevated morning cortisol of 140.2 mcg/dL (range: 8.7–22.4 mcg/dL), elevated adrenocorticotropic hormone (ACTH) 823 pg/mL (range: 10–60 pg/mL), and chromogranin A 2103 ng/mL (range: <93 ng/mL). The remainder of the secondary hypertension workup was negative including plasma renin activity (PRA), aldosterone, plasma catecholamines, growth hormone, and glucagon. The patient was seen in consultation by gastroenterology, hematology-oncology, and general surgery and started on ketoconazole to help with hyperglycemia and hypertension as well as subcutaneous octreotide. Her hyperglycemia was additionally treated with insulin aspart prior to meals with twice daily insulin glargine. The hypertension was controlled with intravenous hydralazine and lisinopril. She later developed psychosis, which was attributed to hypercortisolism. It was decided that the patient required a higher level of care and was transferred to a tertiary institution.

DISCUSSION: The incidence of ACTH-secreting pancreatic neuroendocrine tumors account for approximately 15 % of all ectopic Cushing syndrome cases and 1.2 % of all functioning pancreatic neuroendocrine carcinomas. Recognition of ACTH-secreting paraneoplastic syndrome is exceedingly difficult and usually requires repeated trips to multiple clinicians before a final diagnosis is made. Causes of ectopic Cushing syndrome include bronchial carcinoid, small cell lung carcinoma, medullary carcinoma of the thyroid, and functioning pancreatic neuroendocrine tumors. The diagnosis should be suspected in patients with sudden onset of hypertension with hyperglycemia, psychosis, proximal muscle weakness, and new onset lower extremity edema. Rapid clinical recognition and prompt initiation of treatment is crucial to good patient outcomes.

METHOTREXATE NEUROTOXICITY: PERSISTENT NEUROLOGICAL DEFICITS IN AN ADULT PATIENT WITH ACUTE LYMPHOBLASTIC LEUKEMIA (ALL) Avnish Dhamija; Michael Elnicki; Jennifer McComb. University of Pittsburgh Medical Center, Pittsburgh, PA. (Tracking ID #2193211)

LEARNING OBJECTIVE #1: Recognize that intrathecal methotrexate therapy can lead to neurotoxicity with persistent neurological deficits.

CASE: The patient is a 55-year-old female with B Cell ALL and no prior neurological deficits who presented for HyperCVAD 3B treatment. Intrathecal methotrexate (MTX) was administered, which was shortly followed by acute kidney injury and toxic serum levels of MTX (defined as >10 mM/L 24 h after administration). MTX levels peaked at 31.35 mM/L (approximately 24 h after administration), and creatinine levels peaked at 3.4 mg/dL. Intravenous cytarabine was discontinued and rescue therapy was initiated with leucovorin and glucarpidase. Despite these measures, the patient developed new onset dysarthria, ataxia and altered mental status. A CT of the head demonstrated no evidence of ischemic or hemorrhagic stroke. An MRI of the brain revealed micro hemorrhages in the deep frontal white matter. An EEG showed moderate to severe slowing with focal areas of cerebral dysfunction superimposed on a diffuse disturbance of cerebral function or encephalopathy. A lumbar puncture was unrevealing. The patient received intravenous immunoglobulin for possible paraneoplastic syndrome, which did not improve her neurological status. Ultimately, she did not recover her neurological function. She underwent tracheostomy and percutaneous endoscopic gastrostomy and was transferred to a skilled nursing facility.

DISCUSSION: Due to the propensity of central nervous system involvement in ALL, MTX is commonly used as intrathecal chemoprophylaxis. MTX neurotoxicity is a grave and rare consequence of chemotherapy in ALL. The pathogenesis is unclear and the data is limited in terms of estimating the magnitude of risk for our patients. Prior studies have proposed various mechanisms of MTX induced neurotoxicity including altered levels of methionine, folate or homocysteine and elevated levels of adenosine. Adenosine is considered to be a central nervous system depressant, which may contribute to its neurotoxic effects. Aminophylline functions as an adenosine receptor antagonist and has been used in several cases to reverse MTX neurotoxicity, with partial and complete resolution of symptoms [1,2]. Currently, treatment of MTX induced neurotoxicity includes rescue therapy with leucovorin and glucarpidase. However, a limited number of cases have suggested that Aminophylline may play a role in treatment of MTX induced neurotoxicity. Further studies are necessary to elucidate the pathogenesis of MTX induced neurotoxicity in adults and treatment modalities. References: 1. Bernini, J. C., et al. "Aminophylline for methotrexate-induced neurotoxicity." *The Lancet* 345.8949 (1995): 544–547. 2. Ganesan, Prasanth, et al. MIRTAZAPINE INDUCED GALACTORRHEA: A RARE ADVERSE EFFECT Hector M. Guzman; Gina Luciano. Baystate Medical Center/Tufts School of Medicine, East Windsor, CT. (Tracking ID #2199253)

LEARNING OBJECTIVE #1: Discuss the potential etiology of mirtazapine-induced galactorrhea as compared to antipsychotics.

LEARNING OBJECTIVE #2: Discuss a cost-conscious workup of hyperprolactinemia

CASE: Galactorrhea is a well-known adverse effect of medications that inhibit dopamine, such as antipsychotics and some antidepressants. Mirtazapine, a non-dopaminergic drug, is a common antidepressant and is not known to generally cause hyperprolactinemia or galactorrhea. We report galactorrhea as a rare side effect of mirtazapine. A 34-year-old female with a history of depression and anxiety presented to the clinic with bilateral breast engorgement and nipple discharge. She denied headaches, visual changes, temperature intolerance, change in libido or any new social stressors. She was not currently or recently breast-feeding and denied a history of nipple manipulation. Her menstrual cycles were monthly without recent changes. She had started mirtazapine therapy 8 weeks prior with

15 mg daily for 4 weeks and 30 mg daily for the subsequent 4 weeks with improvement of her mood. Physical exam revealed a weight gain of 5 kg over 6 weeks, bilateral breast enlargement and clear non-bloody discharge. There were no masses or skin lesions. Laboratory testing revealed an elevated prolactin level of 29.7 ng/mL. TSH of 0.8 mIU/mL, a pregnancy test was negative, serum creatinine was 0.8 mg/dL with a BUN of 8 mg/dL. Endocrinology was consulted for hyperprolactinemia. MRI of the head was not recommended because she had no menstrual abnormalities and no headaches or visual problems to suggest a prolactinoma. As her laboratory testing was also unrevealing for other potential causes of galactorrhea such as renal failure or hypothyroidism, no additional testing was deemed necessary. Although galactorrhea is an unlikely cause of mirtazapine, the time course suggested that this medication was the offending agent. Within two weeks of discontinuation of mirtazapine, the prolactin level decreased to 9.7 ng/mL and her galactorrhea resolved.

DISCUSSION: To our knowledge, this is the second case report in the United States and 3rd in the world in which mirtazapine is associated with galactorrhea. Hyperprolactinemia is often caused by antipsychotics and some antidepressants, but it is rarely caused by mirtazapine. Antipsychotics block dopamine receptors, eliminating the inhibitory effect on prolactin, thereby causing hyperprolactinemia and subsequently galactorrhea. Mirtazapine, in contrast, has no known direct effect on dopamine and is instead known to be a potent antagonist of 5HT₂, 5HT₃ serotonin receptors and alpha 2 receptors. It is unknown if mirtazapine acts on other serotonin receptors such as 5HT₁, which has been found to increase prolactin levels. Serotonin stimulation is thought to indirectly increase prolactin levels but the mechanism is unclear. Another plausible explanation for mirtazapine-induced prolactinemia is the stimulation of GABA neurons in the tuberoinfundibular dopamine cells. These cells have 5HT₁ receptors, which may affect the inhibitory effect of dopamine. Applying the scientific method and careful history taking are fundamental in approaching a common disease caused by an uncommon etiology. Evaluating galactorrhea in a patient requires a comprehensive history in order to avoid unnecessary testing. This can be addressed by exploring the common causes based on clinical signs and symptoms prior to ordering a battery of tests. Patients may present with symptoms of bilateral nipple discharge, menstrual cycle disturbances, low libido and breast tenderness. Bloody discharge is more suggestive of a breast tumor or malignancy and is typically unilateral. Conversely, breast discharge that is bilateral, clear and milky is suggestive of a systemic effect. If the fluid is confirmed to be milky, a prolactin level should be obtained. A normal level may indicate the presence variability in the peptide hormone heterogeneity and further work up may not be necessary. Hyperprolactinemia, however, warrants an assessment of common causes such as medications, stress, chronic breast stimulation, trauma, surgical procedures or anesthesia and illicit drug use such as marijuana. Obtaining this from the history may point towards a specific inciting event or medication. The first step in management should be to stop any offending medications. Secondary causes of hyperprolactinemia such as renal failure and hypothyroidism should be excluded before ordering an MRI to rule out a prolactinoma. An MRI, sophisticated hormone panels, referrals to a breast specialist, and breast ultrasounds without worrisome signs or symptoms and in the presence of other possible causes is not cost effective and can add undue psychological stress. In conclusion, mirtazapine is a commonly prescribed antidepressant, not typically known to cause galactorrhea, which may lead to preventable psychosocial distress and expensive medical costs if not identified early.

MISSED OPPORTUNITIES—A CASE FOR SUSPECTING RHINO-CEREBRAL MUCORMYCOSIS Ruchira Sengupta; Bronwyn L. Small; Niraj M. Patel; Brian Hachey; Jennifer Kaya; Hector Cajigas; Rana Awdish. Henry Ford Hospital, Detroit, MI. (Tracking ID #2196700)

LEARNING OBJECTIVE #1: Recognize the risk factors and clinical presentation in those patients at highest risk of developing invasive fungal infection.

CASE: Introduction: Mucormycosis is a rare human fungal infection that is most common in immune-compromised hosts. Because *Rhizopus* organisms thrive in high glucose, acidic environments, the serum from individuals in diabetic ketoacidosis (DKA), are an ideal milieu for fungi. Rhino-orbital-cerebral infection, in the setting of hyperglycemia with metabolic acidosis, is the most common clinical presentation of mucormycosis, and delayed diagnosis can be devastating. We present the case of a young, poorly controlled diabetic woman who failed outpatient therapy for facial cellulitis and was ultimately found, on surgical debridement, to have advanced orbital mucormycosis. **Case Presentation:** Patient is a 46 year-old woman with a history of poorly controlled insulin dependent diabetes, and recent dental extraction 2 days prior to admission, who presented to the emergency department with left eye swelling and pain. She was initially treated for blepharitis, however she returned shortly afterwards when her symptoms did not improve. She was subsequently prescribed oral klexef and erythromycin ointment for presumed cellulitis. Her symptoms progressed further to facial numbness, ocular pain, nausea and vomiting. CT scan of the face revealed maxillary and ethmoidal sinus disease, with left infraorbital cellulitis. Lab work at this time found her to be in DKA with anion gap 20, beta beta hydroxybutyrate of 4.07 mmol/L, and glucose >500 mg/dL, with the inciting event

presumed to be her orbital cellulitis. Vancomycin and ampicillin/sulbactam were initiated; however she continued to deteriorate with progression of her ophthalmologic exam to downward and lateral gaze restriction. There was suspected involvement of intraorbital neurovascular bundle given her facial hyperesthesia. She was urgently taken to the OR for a joint procedure by ENT and Ophthalmology for orbital wall decompression with left maxillary antrostomy, total ethmoidectomy and sphenoidectomy. Purulent material was removed from the maxillary sinus and culture demonstrated *rhizopus* species. Due to high index of suspicion, patient was empirically initiated on treatment with amphotericin B post-operatively, and subsequently anidulafungin was added for additional coverage.

DISCUSSION: Discussion: Rhino-orbital-cerebral infection is a devastating manifestation of mucormycosis in immunocompromised patients. The infection usually presents as acute sinusitis with requisite fever, nasal congestion, headache, and sinus pain. It spreads rapidly to all of the sinuses, palate, orbit, and brain. Our patient exhibited this pattern of typical spread, with orbital involvement, proptosis, and also facial hyperesthesia, which reflects infarction of the sensory branch of the fifth cranial nerve. Interestingly, our patient did not display a black nasal eschar, which is generally hallmark of infectious spread beyond the sinuses. The preceding dental manipulation may have been causative, reinforcing the importance of sterility during any invasive instrumentation. This case illustrates the importance of maintaining a high index of suspicion for fungal infection, especially in high-risk patients presenting with classic sinusitis symptoms. This is especially critical as prognosis is heavily dependent upon prompt identification, early initiation of antifungals and timely surgical intervention.

MODERN-DAY AWARENESS OF ZOONOTIC DISEASES AND CLINICAL IMPLICATION IN THEIR EARLY DIAGNOSIS Md U. Ali. Capital Health Regional Medical Center, Plainsboro, NJ. (Tracking ID #2198913)

LEARNING OBJECTIVE #1: *Staphylococcus intermedius* associated infections are very rare in human beings but should always be considered among the differential diagnosis in serious invasive infections, especially among patients who are in close contact with dogs

LEARNING OBJECTIVE #2: Canine associated zoonotic disease should always be considered under differential diagnosis especially in patients who are immunocompromised and having intimate contact with dogs

CASE: A 60 year old male with a history of diabetes, hypertension, pituitary mass, hypothyroidism and end stage renal disease on dialysis presented with complaints of fever, transient confusion and lethargy. The patient denied headache, neck pain, change in vision, nausea, vomiting, shortness of breath, recent fall, chest pain or palpitations. Patient has been on long term peritoneal dialysis and recently switched to hemodialysis for which he had tunneled dialysis catheter. There were reports of patient maintaining an intimate contact with his dog, where dog was licking him on several occasion. Patient had temperature of 102 ° F and tachycardia on arrival. Laboratory evaluation showed leukocytosis of 18.4 with 16 % bandemia. CT of head showed no change in pre-existing pituitary mass and chest X-ray was normal. Blood cultures returned positive for *S. intermedius* and therefore transesophageal echocardiogram was done which showed a mobile vegetation which was attached to the posterior mitral leaflet measuring approximately 18 mm. The patient was initially started on nafcillin resulting in a significant improvement in his condition. The patient was eventually discharged on cefazolin during which time he was asymptomatic and repeat blood cultures were negative for the microorganism

DISCUSSION: Zoonotic diseases are those that can be transferred between animals and humans. The CDC estimates that more than 6 out of every 10 infectious diseases in humans are spread from animals; fortunately the numbers are low in North America. The risk in humans becomes greater with immunosuppression. Skin and oral flora of dogs harbor various pathogenic microorganisms including *Staphylococcus intermedius*. Case reports of human infections from this microorganism are relatively rare, but the true incidence is unknown because the pathogen is frequently misidentified as *Staphylococcus aureus*. There are only 16 cases in the literature that have described *S. intermedius* as a cause of infection in humans ranging from soft tissue infections to bacterial endocarditis. Most of these cases have been described in association with exposure to animals, mostly dogs. Above we report a rare case of *S. intermedius* causing bacterial endocarditis in a dialysis patient. The presumed source of infection was the patient's dog. Although very rare in human beings, disease caused by *S. intermedius* should always be considered among the differential diagnosis of serious invasive infections, especially among patients who are in close contact with dogs.

MORE THAN JUST A CRAMP: A RARE CASE OF EXERCISE INDUCED ABDOMINAL PAIN Gregory Constantine; Lee Lu. Baylor College of Medicine, Houston, TX. (Tracking ID #2195053)

LEARNING OBJECTIVE #1: Recognize spontaneous intra-abdominal hematoma as a cause of acute abdominal pain.

LEARNING OBJECTIVE #2: Review spontaneous intra-abdominal hematoma.

CASE: An 18-year-old previously healthy Asian male presented with sudden onset of sharp non-radiating epigastric abdominal pain. Symptoms began after a routine exercise with weight lifting and jogging. The pain was associated with severe nausea without emesis. It was exacerbated in the supine position and improved when seated leaning forward. He denied diarrhea, constipation, dysuria, or trauma. Physical exam was remarkable for a mildly distended and diffusely tender abdomen, most pronounced over the epigastrium. CT scan of the abdomen and pelvis revealed a moderate amount of ascites as well as a large confluence of omental masses measuring up to $11.3 \times 7.5 \times 5$ cm and 45 Hounsfield units (HU). Laboratory values were significant for a drop in hemoglobin from baseline of 13 to 11 g/dL, the remaining studies including coagulation tests were within normal limits. A CT-guided biopsy of the omental mass revealed both fresh and degenerated blood consistent with a hematoma. He was diagnosed with spontaneous omental hematoma and intraperitoneal hemorrhage. Vital signs and hemoglobin remained stable throughout the remainder of the hospital course. His symptoms improved with supportive measures, and he was discharged with instructions to avoid strenuous physical activity until the hematoma resolved. Follow up CT one month later noted absence of the previously seen free peritoneal fluid. The left omentum contained a now smaller and resolving 4.5×3.4 cm non-enhancing lesion measuring 55 Hounsfield units (HU) consistent with an old hematoma.

DISCUSSION: Spontaneous hemoperitoneum is a rare cause of sudden abdominal pain from non-traumatic or iatrogenic events. The incidence and prevalence are not well known due to limited data in the literature. Visceral organs including the liver, spleen, kidneys, and adrenals are common sites of spontaneous intra-abdominal hemorrhage. Rupture of hepatic tumors, particularly hepatic adenomas are responsible for a majority of cases. Additional etiologies and risk factors include the presence of coagulopathy in the form of bleeding diathesis or anticoagulant medications. Reports of spontaneous intra-abdominal hemorrhage have been described involving the epiploic, splenic, and gastric vessels that supply the omentum. The majority of vascular etiologies such as aneurysms, arteriovenous malformations, pseudoaneurysms, mycotic aneurysms, or arterial dissection typically present as a catastrophic event. In this case, the underlying etiology is likely vascular rupture as a result of strenuous physical activity, leading to minor trauma in the setting of increased intra-abdominal pressure. There have been only a few case reports describing spontaneous intra-abdominal hemorrhage, both vascular and visceral occurring with little activity such as running/jogging. Rapid diagnosis is paramount with the initial therapeutic goals aimed at resuscitation. CT is the preferred method of diagnosis as it provides information regarding the area of extravasation. Once an active site of hemorrhage has been identified, further management via embolization or surgery may be pursued. Long term outcome data of exercise induced spontaneous intra-abdominal hemorrhage is not available. Hence, although rare, spontaneous hemoperitoneum should be considered in the differential diagnosis in a young patient presenting with acute abdominal pain after exercise.

MORE THAN JUST A SORE THROAT: A CASE OF PARAINFECTIOUS EPSTEIN-BARR VIRUS (EBV) CEREBELLITIS Irem Nasir. Greenwich Hospital, Greenwich, CT. (Tracking ID #2193986)

LEARNING OBJECTIVE #1: Recognize new ataxic dysarthria and gait as due to EBV cerebellitis.

CASE: A 39 year old healthy EMT worker with a remote history of drug abuse, had presented to his PCP 2 weeks prior to this admit, with sore throat, myalgias, and low grade fever 100.6 F. Pt was diagnosed with infectious mononucleosis with a positive monospot. He returned to our hospital with new progressive dysarthria and difficulty walking x4 days that he was unable to go to work. He was nauseous and vomiting x1 day. He denied headaches, neck stiffness, diplopia, dysphagia, vertigo, tinnitus, or any focal numbness or weakness. He also denied abdominal or chest pain, shortness of breath, dysuria, joint pains, and any rashes. He denied any current drug or alcohol use. He did have sick contacts as an EMT worker but did not recall anyone with similar symptoms. He denied any travel history in the past month. On exam, he was afebrile, with no pharyngeal erythema or exudates, and had mildly swollen anterior cervical nodes. On neurologic exam, he was alert, cranial nerves were intact, no nystagmus, neck was supple, and had no facial droop. He had full strength in all muscle groups, sensation intact, 2+ reflexes throughout, and plantar flexor responses. His exam was significant for severe finger-nose and heel-shin dysmetria, dysidiadochokinesia, guttural dysarthria and he had a wide based gait and needed assistance to even take a few steps. Labs were significant for WBC 7 with 55 % lymphocytes, mildly elevated liver function tests at AST 116, ALT 213, and total bilirubin 0.6. EBV serology was positive for Early Ag IgM and Viral capsid Ag IgM antibodies and serum EBV PCR at 3300, and negative for EBNA antibodies indicating acute EBV infection. Urine drug screen was negative. Vitamin B12 was normal. ASO, CMV, HIV, hepatitis, and Lyme serologies were all negative for acute infection. ANA, SPEP, and celiac serologies were negative. Ceruloplasmin was negative. CT head was negative. MRI brain

w/o contrast was negative. On the lumbar puncture, the WBC at 3, glucose at 68, and protein at 28, were all normal. Further extensive CSF workup followed. CSF was negative for herpes, HHV-6, CMV, enterovirus, varicella, JC virus, and importantly, also negative for EBV PCR. CSF West Nile, Lyme, VDRL serologies and cryptococcal Ag were negative as well. The CSF cytology and B and T cell rearrangements were negative. CSF oligoclonal banding was negative for any monoclonal bands. All blood and CSF cultures were negative. Both the serum and CSF paraneoplastic autoantibody panel were negative. On CT chest, abdomen, pelvis and US scrotum no overt masses were noted. Patient was diagnosed with acute EBV associated parainfectious cerebellitis and started on a combination of high dose IV methylprednisolone and IVIG x5 days. Patient only had mild improvement in his ataxic gait and dysarthria during his admission. He was discharged on no further medications and then followed up with physical and speech therapy. After about 8 weeks, patient was back to baseline and has returned to work as an EMT.

DISCUSSION: EBV, a human herpesvirus, results in a febrile syndrome with a sore throat, cervical adenopathy, and splenomegaly called infectious mononucleosis which is most common in children and young adults. EBV infection can also cause various neurologic disorders including bells palsy, meningitis, encephalitis, guillaine barre, cranial neuropathies, transverse myelitis, and acute cerebellar ataxia, as seen in our patient. Acute cerebellar ataxia is a rare manifestation of EBV and is more common in children. There can be a mild CSF lymphocytic pleocytosis, which was not the case with our patient. It is not clear if neurologic manifestations of EBV result from direct tissue invasion or from a postinfectious autoimmune phenomenon. The ataxia has even preceded the systemic symptoms of EBV by several days in some case reports. Most cases of EBV cerebellitis are benign, as in our patient, but there have been cases of life threatening cerebellar swelling, in which the MRI brain shows cerebellar enhancement, fourth ventricle obstruction with hydrocephalus, needing emergent decompression. High dose iv methylprednisolone and IVIG have been used anecdotally, but with unclear benefits. There are also case reports of some benefits with plasmapheresis suggesting that immunomodulatory therapy may limit the duration of this illness. Parainfectious EBV cerebellitis should be considered in the diagnosis of acute cerebellar ataxia, which will prevent much anxiety in both patient, families, and the clinicians, given the EBV cerebellitis benign course and excellent prognosis.

MORE THAN SKIN DEEP Andrew S. Calzadilla¹; Jessica Zuleta². ¹Jackson Memorial Hospital/ University of Miami Miller School of Medicine, Palmetto Bay, Macao; ²University of Miami, Miami, FL. (Tracking ID #2196101)

LEARNING OBJECTIVE #1: Recognize that scalp primary skin cancers may be aggressive if left untreated.

LEARNING OBJECTIVE #2: Remind physicians of the importance of evaluating the skin as part of a complete physical examination.

CASE: An 89 year Caucasian man living alone with past medical history of hypertension, coronary artery disease, diastolic heart failure and stage IV chronic kidney disease was referred to the hospital for evaluation of worsening renal function. The patient denied dyspnea, headache, fever, change in vision, and edema of the legs. Vital signs were normal. He was an alert man wearing a hat. Physical examination revealed a piece of gauze overlying a 6×5 cm fungating mass with a central defect of 1 cm depth and a foul smelling green discharge. The dura matter was visible on examination. Neurologic examination elicited no focal deficits. Meningeal signs were absent. The patient revealed the mass had been present for the preceding 2 years with progressive growth and also mentioned that he had concealed the lesion from his friends and family. Laboratory data revealed serum potassium 5.4, serum bicarbonate 16, blood urea nitrogen (BUN) 75 mg/dL, creatinine 3.65 mg/dL, NT-pro-brain natriuretic peptide (BNP) 3092 pg/mL. Wound cultures grew methicillin sensitive *Staphylococcus aureus* treated initially with renal-adjusted vancomycin then de-escalated to cefazolin. A renal ultrasound demonstrated no hydronephrosis. Magnetic resonance imaging (MRI) of brain with venogram suggested epidural extension of a soft tissue mass with mild mass effect on the superior sagittal sinus without evidence of dural venous sinus thrombosis. Full body PET scan showed increased FDG activity corresponding to the scalp mass with no lymph node uptake. After medical optimization for his multiple co-morbidities the patient underwent bi-frontal craniotomy with surgical excision of scalp mass and debridement from the dura with subsequent left anterior thigh free flap reconstruction. Pathology reported well-differentiated squamous cell carcinoma with perineural invasion, epidural extension and 1.5 cm disease free peripheral margins. The skin graft healed well and the patient was free of signs of infection or dehiscence two weeks after the surgery. He recovered well from the surgery and was later discharged to an inpatient rehabilitation center. Primary squamous cell carcinoma of the scalp is indolent but may attain aggressive features when it penetrates the periosteum. They are known to extend laterally for considerable distances with subsequent metastasis and possible death. Several case reports have indicated that the aggressive forms of squamous cell carcinoma are immune-histochemically similar to less aggressive scalp

squamous cell carcinomas. [i] Some aggressive cutaneous cancers can be characterized to be at increased risk of developing metastatic disease. The risk factors for metastases include recurrence, large tumors >2 cm, perineural involvement, poor differentiation, infiltration well into the dermis, renal or other solid organ transplant patients, immunosuppressed patients and tumors on the ear, lip or areas of the skin that get no sun exposure. [ii] [i] Unusually Aggressive Squamous Cell Carcinoma of the Scalp Victor Chung, MD1; Louis Insalaco, BS1; Talley Whang, MD2; Arnold Lee, MD1 1Department of Otolaryngology—Head and Neck Surgery, 2Department of Pathology Tufts Medical Center, Tufts University School of Medicine, Boston MA [ii] Bichakjian CK, Alam M, Andersen J, et al. NCCN Clinical Practice Guidelines in Oncology (NCCN Guidelines): Basal Cell and Squamous Cell Skin Cancers, Version 1.2013, National Comprehensive Cancer Network, 2013.

DISCUSSION: Due to the extensive nature of disease at presentation, our patient required a multidisciplinary surgical intervention. Radiation is reserved for patients that are poor surgical candidates or tumors deemed inoperable. Clinical decision making is well informed by a thorough history and physical examination. However, patients with limited health literacy may fail to voluntarily reveal important parts of their history. Regardless of the original reason for medical evaluation, it is incumbent on all healthcare providers to obtain both a complete history and perform a thorough physical examination to aid in their evaluations of patients. Information should be elicited about sun exposure beginning in childhood and potential occupational exposure to ultraviolet light and radiation treatment. A total body examination of the skin is the only screening test available for cutaneous squamous-cell carcinoma.[i] [i] Cutaneous Squamous-Cell Carcinoma Murad Alam, M.D., and Désirée Ratner, M.D. *N Engl J Med* 2001; 344:975–983

MRI? WE DON'T NEED NO STINKING MRI Jason Dinsmoor; Michael P. Smith. University of Nebraska Medical Center, Omaha, NE. (Tracking ID #2200100)

LEARNING OBJECTIVE #1: Diagnose reversible posterior leukoencephalopathic syndrome (RPLS) with clinical factors when magnetic resonance imaging is not available

LEARNING OBJECTIVE #2: Develop a methodical approach to altered mental status

CASE: A 66 year-old man presented with altered mental status. He required intubation and management in the intensive care unit. Due to concern for a stroke, his systolic blood pressure had remained elevated, and due to the patient's implantable cardioverter defibrillator, brain magnetic resonance imaging was not obtained. The patient did undergo two computed tomography scans of his head two days apart that did not reveal findings consistent with a stroke. After stabilization of his clinical status including extubation he was transferred to the general medicine service with continued altered mental status and diplopia. He remained hypertensive, had episodes of confabulation, and continued diplopia with no other physical exam findings. Laboratory and imaging to that point had been unrevealing. His altered mental status and vision changes had slowly improved until on hospital day five when altered mental status, vision changes, and difficulty to control blood pressure returned. A repeat electroencephalogram was ordered at that time. Initially, there were no abnormalities noted, but the patient remained altered. Later during the course of the study, the patient developed status epilepticus by electroencephalogram. He returned to the intensive care unit for intensive blood pressure medication and antiepileptic medication. His condition improved to his baseline by hospital discharge with control of his blood pressure.

DISCUSSION: Altered mental status is a problem commonly encountered by the general Internist. A methodical approach to the problem is essential to making an accurate diagnosis, particularly when a patient's past medical history limits the diagnostic tests that are part of a standard evaluation. In these cases, a clinical diagnosis must be obtained by exclusion of all other reasonable alternatives. A simple starting point would be a thorough evaluation of all the organ systems required to allow a patient's brain to function properly, prioritized by known information and comorbidities, specifically evaluating the heart and lungs, the vessels supplying the brain, what is in the vessels (including the pressure), and the brain itself. Reversible posterior leukoencephalopathic syndrome is a cause of altered mental status that traditionally requires magnetic resonance imaging to diagnose. However, RPLS must be considered in patients who are persistently hypertensive, encephalopathic, and develop visual changes. Patients with RPLS can also frequently develop seizures as part of their clinical picture. As this is often a reversible condition, blood pressure control with titratable agents and prophylactic anti-epileptic medications are essential. When magnetic resonance imaging can be obtained, findings are often vasogenic edema most often localized to the posterior cerebral hemispheres, but not exclusive to this part of the brain. Altered mental status is a problem commonly faced by the general Internist and by its very nature, there are often significant hurdles in obtaining an accurate history. Thus a methodical approach to altered mental status is essential to making an accurate diagnosis, particularly when patient comorbidities limit diagnostic testing.

MUDDIED WATERS—ULCERATIVE COLITIS VS SHIGELLOSIS: DIAGNOSTIC ERRORS IN A PATIENT WITH BLOODY DIARRHEA Jeffrey M. Luk¹; Yi-han Yang¹; Stephen Holt². ¹YNHH, New Haven, CT; ²Yale University, New Haven, CT. (Tracking ID #2198916)

LEARNING OBJECTIVE #1: Recognize common cognitive biases and their contribution to misdiagnosis

LEARNING OBJECTIVE #2: Identify exposures, symptoms, signs and laboratory findings that suggest a diagnosis of shigellosis or inflammatory bowel disease

CASE: A 29-year-old African American male presented with lower abdominal cramping followed by onset of dark brown stool up to 10–15 times a day associated with urgency, tenesmus, nausea, non-bloody, non-bilious emesis, and a reported fever of 101 for 3 days. On day of presentation he developed hematochezia with liquid stools. He denied recent travel, sick contacts, or eating raw food, but endorsed increased stress. Past history is notable for lactose intolerance since adolescence and four years of intermittent, self-resolving abdominal cramps and non-bloody, mucous diarrhea lasting several days, occasionally associated with alcohol, greasy foods or stress. He takes no medications. Family history is significant for a brother with biopsy-proven ulcerative colitis (UC). He works at a breakfast diner, drinks alcohol infrequently, and has a three-pack-year smoking history with recent cessation. He is sexually active with one male partner. Review of systems was negative for significant weight loss, blurry vision, oral ulcers, arthralgia, skin rashes, peri-anal disease, or dysuria in the last four years. On exam, he was afebrile with blood pressure 155/84, heart rate 73. He appeared uncomfortable. There were no oral ulcers. Heart and lung exam were normal. His abdomen was diffusely tender to palpation particularly in the lower quadrants with hyperactive bowel sounds. He had no organomegaly, joint swelling, rashes, or obvious perianal or rectal abnormalities. Laboratory testing revealed a leukocytosis of 12.6 with 87 % neutrophils, normal electrolytes, hemoglobin, LFTs and lipase; CT abdomen demonstrated diffuse thickening of the distal descending colon to the rectum. Work-up upon admission was significant for normalized WBC but positive fecal leukocytes and elevated CRP of 169. He was *C diff* antigen, O&P, HIV and gonorrhea/chlamydia negative. Given his age, family history and recurrent episodes of diarrhea with fecal leukocytes and elevated CRP, inflammatory bowel disease (IBD) was thought to be the most likely cause. He was treated supportively with intravenous hydration, pain medications and anti-emetics. GI performed a colonoscopy that was interpreted as pancolitis thought to be most consistent with UC. With preliminary stool studies yielding normal bowel flora, the patient was started on prednisone 40 mg and mesalamine 2.4 mg daily and he was ultimately sent home with a 10-week steroid taper. However, one day post-discharge, his stool culture yielded *Shigella flexneri*. The patient was informed to stop taking prednisone and to instead start Ciprofloxacin for 7 days. Four days post-discharge, surgical pathology of colonic biopsies were interpreted as most consistent with acute, self-limited colitis.

DISCUSSION: Studies show that diagnostic error is the most common reason for malpractice claims. Flaws in systems design, provider training, and clinical reasoning may all contribute to misdiagnosis. The diagnostic process involves gathering and interpreting information for generating a differential and refining and verifying the diagnosis. The medical literature describes a wide number of cognitive biases that clinicians may experience during this process. Examples of biases include: availability, anchoring, confirmation, framing, premature closure, diagnosis momentum, aggregate, and gambler's fallacy. Acute bacterial colitis and inflammatory bowel disease can present with similar signs and symptoms. The patient's history may help guide diagnosis, but results of stool cultures or endoscopic imaging and biopsies may ultimately be required to confirm the diagnosis. Several biases may have been at play that led to the initial diagnosis of UC in this patient and to his exposure to immunosuppressant drugs. The principle of Occam's Razor suggests that a patient's presenting symptoms are more likely to be caused by one etiology rather than two unrelated problems. Thus, our patient's four year history of intermittent mucous diarrhea and his new, acute bloody diarrhea were often attributed to a single etiology. Framing, confirmation and anchoring biases may have caused providers to place less emphasis on causes of acute inflammatory diarrhea despite the fact that this was the first time the patient experienced bloody diarrhea. The diagnostic momentum of UC as the most likely etiology of this patient's bloody diarrhea was also carried from the primary team to the GI consultants and individual interpreting the colonoscopy. Finally, accepting the diagnosis of UC after colonoscopy but prior to verification with biopsy results and negative stool cultures is an example of premature closure. Awareness of cognitive biases may help providers avoid pitfalls during the diagnostic process.

MUDPILES MADE CRYSTAL CLEAR Aimee E. Hiltbold²; Ahmed Mohiuddin¹. ¹Tulane University, New Orleans, LA; ²Tulane University Medical Center, New Orleans, LA. (Tracking ID #2199229)

LEARNING OBJECTIVE #1: 1. Recognize the presentation of ethylene glycol intoxication.

LEARNING OBJECTIVE #2: 2. Appreciate the pathophysiology and treatment of ethylene glycol toxicology.

CASE: A 20-year-old male college student presents after being found unresponsive. After finishing final exams, he reported considerable weakness, and was unarousable the next morning. His past medical history is significant for premature birth at 23-1/2 weeks and panhypopituitary syndrome. He is intermittently compliant with his thyroid, steroid, and growth hormone regimen. The family denies any history of suicidal ideation or ingestion, and states that the patient does not drink alcohol, smoke tobacco, or endorse any recreational drugs. Initial vital signs are T: 37, P: 55, RR: 17, BP: 120/90, saturating 100 % on RA. His CGS is 8. Pupils are sluggish but reactive. There are no signs of injection sites. His laboratory results are significant for Na: 140, K: 4.7, Cl: 107, Bicarb: 13, for an AG: 20, BUN: 13, Cr: 1.2, and Gluc: 93. Acetaminophen, salicylate, BAL, and UDS are unremarkable. EKG shows sinus bradycardia. Stat CT of the head shows no acute intracranial process. All other labs and imaging are unremarkable. Overnight, he becomes tachycardic and develops a severe metabolic acidosis with a pH of 6.87. Measured serum osmolality is 344, with an osmolal gap of 51. Urinalysis is negative for ketones, has microscopic hematuria and occasional calcium oxalate crystals. Following hemodialysis and correction of his acidosis, he confesses to ingestion of antifreeze in a suicide attempt.

DISCUSSION: Ethylene glycol is a lethal and accessible poison encountered by hospitalists, which can be effectively treated with early recognition. Alcohol dehydrogenase and aldehyde dehydrogenase convert ethylene glycol into glycolic acid and oxalic acid. Oxalic acid binds calcium, leading to calcium oxalate crystals that deposit into kidney, brain, lung, and heart. Initially, serum osmolality may be increased, but acidosis is generally absent. Within hours of ingestion, metabolism to toxic organic acids leads to a high anion gap metabolic acidosis, causing neurological and cardiopulmonary decompensation. Urinalysis will reveal oxalate crystalluria in 50 % of cases, and will usually demonstrate acute renal failure. Treatment of ethylene glycol ingestion depends on the stage of presentation. Within 30–60 min of consumption, nasogastric tube suctioning can be performed. Those patients with significant toxicity, as evidenced by AMS, metabolic acidosis, and increased osmolal gap, should undergo immediate hemodialysis to remove the parent compound and toxic metabolites. Folic acid, thiamine, and pyridoxine may assist in toxic metabolite breakdown. Ethanol has 10 to 20 times greater affinity for alcohol dehydrogenase, and out-competes ethylene glycol as a substrate. This inhibits conversion into toxic metabolic acids. Fomepizole, with 500 to 1000 times greater affinity for ADH, is able to completely inhibit ADH at lower concentrations, is easier to use, and is FDA approved. If acidosis is absent at presentation, Fomepizole may be effective as a sole agent for treatment. Guidance per the toxicology service and regional poison control centers are helpful in developing an appropriate treatment plan.

MUSCLE PAINS FROM A PILL Matthew L. Law, Tulane University Health Sciences Center, New Orleans, LA. (Tracking ID #2198613)

LEARNING OBJECTIVE #1: Recognize the proposed mechanisms of statin-induced myopathy

LEARNING OBJECTIVE #2: Discuss lipid management after statin-induced myopathy

CASE: A 44 year-old man presented with 2 days of diffuse myalgias. The pain started with 10/10 diffuse aching pains in his bilateral lower extremities. That same night he had performed his normal nightly exercises. He called his primary care physician, who encouraged vigorous fluid intake. He drank 2 l of Gatorade with no relief from his symptoms. He was previously diagnosed with hypertension and hyperlipidemia; he had recently changed from pravastatin to atorvastatin due to elevated liver enzymes. Physical exam demonstrated diffuse muscle tenderness but no point tenderness. He exhibited 5/5 strength in bilateral lower extremities. Initial creatinine was 1, with AST of 88 and ALT of 45 (a decrease from previous) and a CK of 2721. After aggressive IV fluid resuscitation, the CK trended to 2386. Due to patient's recent change in statins and slow response of CK to fluids, he was diagnosed with statin-induced myopathy. He was discharged on a 6-week statin holiday and then subsequently started on low-dose rosuvastatin by his primary care physician.

DISCUSSION: Myalgias are a common symptom presented to a general internist. A differential diagnosis for myalgias includes alcohol induced myopathy, connective tissue diseases, electrolyte and endocrine abnormalities, and peripheral neuropathy. It is necessary to acquire an accurate list of medications along with any recent changes and reason for change when taking a patient's history. Due to the increasing risk of polypharmacy, medication side effects should always be considered. The 3-hydroxy-3-methylglutaryl coenzyme A-reductase inhibitors, commonly known as statins, are one of the most common drugs prescribed to help lower cholesterol, and decrease cardiovascular morbidity and mortality by about 25 %. With the recent changes in guidelines, statin therapy is expected to increase as the threshold for statin therapy encompasses a greater patient

population and use of other lipid lowering agents is less supported. Studies have shown that in clinical practice up to 5–10 % of patients receiving statins develop myopathy. This side effect has been underestimated in randomized controlled trials due to exclusion of high-risk patients such as patients with a history of muscle symptoms and omission of mild symptoms in patient interviews. Additionally, most trials focus on the incidence of rhabdomyolysis rather than myalgia, fatigue, or minor muscle complaints. Many causes have been proposed for statin-induced myopathy including metabolic reduction of cholesterol and coenzyme Q10 levels, drugs that interfere with CYP-450 metabolism, and the individual statin characteristics of either being hydrophilic or lipophilic. Hydrophilic statins (pravastatin and rosuvastatin) have theoretically decreased uptake in skeletal muscle and therefore should have less muscular symptoms-though muscle symptoms are still reported in these individuals. Once, statin-myopathy is diagnosed, it is important to initially reassess the lipid goal. If cholesterol therapy is still needed, a 6-week statin holiday should be prescribed to see if symptoms resolve. A physician should then consider a trial of pravastatin or rosuvastatin at lower doses. Statin-induced myopathy is a more common side effect of statin therapy than is often realized. This side effect needs to be considered and reviewed with each individual patient a general internist places on lipid lowering therapy. Special consideration should be given to polypharmacy issues and if a previous history of muscle disease exists. Furthermore, this side effect should be considered and discussed as a possible reason for non-adherence in patients.

MUSCLE TROUBLE: MCARDLE DISEASE DISCLOSED BY STATIN THERAPY Gail M. Pokorney, University of Washington, Soldotna, AK. (Tracking ID #2194157)

LEARNING OBJECTIVE #1: Recognize that statin administration can unmask metabolic myopathy

LEARNING OBJECTIVE #2: Distinguish between statin myopathy and underlying muscle disease

CASE: A 61-year-old woman presented with several weeks of bilateral lower extremity pain and weakness. Her medical history was notable for a transient ischemic attack, which prompted initiation of simvastatin four years earlier. She had no family history of neuromuscular disease. Physical exam demonstrated intact upper extremity strength but reduced strength (4/5) in the proximal lower extremity muscle groups bilaterally. She was noted to rise slowly from a chair without use of her arms. Neurologic exam was otherwise unremarkable. Laboratory work-up was normal except for a creatine kinase (CK) level of 1116 U per liter (normal range 23–143 U per liter). Her muscle weakness and CK elevation were attributed to statin myopathy, and simvastatin was discontinued. Over the next 3 months, the CK level decreased but never normalized. The lower extremity muscle pain and weakness persisted as well. Muscle biopsy was performed and demonstrated absent myophosphorylase activity. Additional history revealed subjective muscle weakness and reduced exercise tolerance dating back to childhood. Surprisingly, there were no clinical episodes of rhabdomyolysis, despite participation in at least one 10-km road race. Muscle symptoms worsened after initiation of simvastatin, but the patient attributed this to aging and deferred seeking medical attention until symptoms became severe. Based on her lifelong muscle weakness, difficulty tolerating exercise, and absent myophosphorylase staining on biopsy, a diagnosis of McArdle disease (myophosphorylase deficiency) was made. The patient and her son received counseling on the management and genetic implications of this diagnosis.

DISCUSSION: Statins are near-ubiquitous medications with myopathic side effects ranging from myalgia to rhabdomyolysis. The reported frequency of statin-associated muscle events is 1–5 % in clinical trials and 11–29 % in observational cohorts; the difference is attributed in part to patient selection in the trials. The onset of muscle symptoms typically occurs within weeks to months of statin initiation but can occur at any point in the treatment course. CK elevation, if present, can range from >3-fold to >50-fold greater than untreated baseline values. Time to recovery from statin myopathy following statin withdrawal likewise can be variable with respect to both symptom resolution and normalization of CK. Numerous conditions can increase the risk for statin-induced muscle toxicity, including age, gender, co-morbid medical conditions, drug-drug interactions, and genetic variants. In patients with previously undiagnosed metabolic myopathy, statins may precipitate or worsen neuromuscular symptoms, as described in the case above. There are several case reports of statin therapy unmasking not only McArdle disease but also CPT II deficiency, myoadenylate deaminase deficiency, and mitochondrial diseases. One cross-sectional study of patients with drug-induced myopathies found a higher prevalence of hereditary metabolic muscle disorders (both homozygote and carrier states) than would be expected in the general population. Another retrospective study of patients who developed chronic muscle diseases after age 50 observed a greater than expected frequency of prior exposure to statins. The precise mechanism by which statins trigger clinical expression of pre-existing myopathy is unknown, but it is postulated that statin effects on energy metabolism couple with genetic susceptibility to produce muscle symptoms in these high-risk patients. In practice, it can be

difficult to distinguish between pure medication-related myotoxicity and latent or subtle muscle disease that becomes clinically manifest after statin administration. Regardless of etiology, it is appropriate to stop a statin in the setting of intolerable symptoms and/or significant CK elevations (>10 times the upper limit of normal). Current literature suggests that patients with muscle symptoms (particularly weakness) and elevated CK levels (>3 times the upper limit of normal) that persist 1–3 months after statin discontinuation should receive diagnostic evaluation for underlying muscle disease. Electromyography can be a useful screening test to determine if muscle biopsy is needed, especially in patients with asymptomatic CK elevations. CK measurement prior to onset of statin therapy, while not necessary in all patients, is recommended in those with baseline muscle complaints. This may lead to earlier identification of underlying primary muscle disease and help mitigate diagnostic uncertainty when a new statin user develops muscle symptoms.

MY-OH-MA... IT TOOK MY BREATH AWAY Jonathan D. Kirsch; Kay L. Ingraham. University of Minnesota, Minneapolis, MN. (Tracking ID #2194007)

LEARNING OBJECTIVE #1: Recognize an abdominal mass as a potential cause of venous stasis, deep vein thrombosis, and pulmonary embolism.

LEARNING OBJECTIVE #2: Review the acquired risk factors and inherited thrombophilias leading to venous thromboembolism.

CASE: A 49 year-old, previously healthy woman presented with one day of progressively worsening right-sided body pain and shortness of breath. She noted her pain started while in bed the previous morning, radiating from her right upper quadrant to her chest and worsening with inspiration. She denied fever or leg swelling and denied any recent surgeries, hospitalizations, or traveling. She had no personal or family history of heart disease or blood clots and did not smoke tobacco or take oral contraceptives. The patient had been told she had a fibroid uterus several months ago and reported experiencing heavy menstrual periods for years. On exam, she was tachycardic and tachypneic, taking shallow breaths. Her abdomen was non-tender to palpation although pain was present in her right upper quadrant with inspiration. She had no lower extremity edema. Due to high suspicion for venous thromboembolic disease and widespread pain, a CT scan of her chest, abdomen and pelvis was ordered. It revealed bilateral pulmonary emboli and a right sided pleural effusion. The abdominal and pelvic CT scan revealed a 20.1×19.4×12.7 cm uterine myoma compressing the inferior vena cava and common iliac veins. A lower extremity venous Doppler ultrasound was negative for deep vein thrombosis. A complete hypercoagulability workup was also negative. The patient was diagnosed with venous thromboembolism due to mass effect from her large uterine myomas. She was treated with enoxaparin and scheduled for a total hysterectomy.

DISCUSSION: Venous thromboembolism is a common problem encountered by internists. They are a result of a culmination of Virchow's triad—venous stasis, vascular endothelial injury, and a hypercoagulable state. When exploring the potential causes of a venous thromboembolism, it is important to take a thorough history before reporting an unprovoked venous thromboembolism. The label of “unprovoked” can lead to longer anticoagulation and further unnecessary, diagnostic workup. As uterine myomas are very common in women over the age of 40, it is important to recognize an enlarged uterus as a potential cause for venous thromboembolism. Definitive treatment for a venous thromboembolism in this case is a total hysterectomy. Venous thromboembolisms are usually classified as being caused by acquired risk factors, inherited thrombophilias or a combination of these. Acquired risk factors for VTE include the following: immobility, hospitalization, surgery, oral contraceptive use, antiphospholipid antibody syndrome, and malignancy. Inherited thrombophilias include Factor V Leiden, Prothrombin, Protein C and S gene mutations as well as Antithrombin deficiency.

MYOCARDIAL INFARCTION: THE FORME FRUSTE OF INFECTIVE ENDOCARDITIS Daniel J. Coffin. Baystate Medical Center, Agawam, MA. (Tracking ID #2196080)

LEARNING OBJECTIVE #1: Recognize ST elevation myocardial infarction as a presentation of infective endocarditis in patients with conventional risk factors for coronary artery disease and bacteremia.

LEARNING OBJECTIVE #2: Recognize risk factors for embolization, and when to consider surgical intervention in addition to medical management.

CASE: MA is a 72 year-old woman with a medical history of acute myelogenous leukemia, hypothyroidism, hypertension, and non-insulin dependent diabetes mellitus who presented with a weeklong history of fatigue and non-specific malaise, with a 1-day history of acute substernal chest pain. Social history significant for 30 pack-year tobacco history, but no alcohol or intravenous drug abuse. Initial workup revealed an obese elderly woman with no fever, and compensated vital signs. Her cardiopulmonary exam did not reveal any new murmurs, and she was euolemic. An initial white blood cell count was noted to be 19.5/k/mm3 without bands, neutrophil predominant. An ECG revealed anterolateral ST elevations

indicative of a STEMI, and she underwent percutaneous transluminal coronary angiography (PTCA) and was found to have a proximal LAD occlusion that was remedied with thrombectomy and a single drug eluting stent, with resolution of chest pain. On her post-myocardial infarction transthoracic echocardiogram, a vegetation was seen surrounding her mitral valve without evidence of valvular insufficiency. This finding was confirmed with a trans-esophageal echocardiogram, which revealed a friable lesion measuring 2.39 cm×1.92 cm×1.8 cm. Blood cultures drawn at that time grew *Viridans streptococci*. As the myocardial infarction was deemed to be a septic embolization event, and with concern of further embolization, the patient underwent mitral valve replacement, with the causative vegetation being confirmed as infective. On further evaluation, the patient claimed to have her chemotherapy port removed for completed chemotherapy one week prior to presentation—inferred to be the initial causative nidus of bacteremia.

DISCUSSION: Native valve endocarditis has known complications associated with embolic phenomenon. One of these, septic coronary embolism, can cause coronary artery occlusion and ST segment myocardial infarction. Although a complication of known bacterial endocarditis, per the best of our knowledge, it is exceedingly rare for the presenting symptom of endocarditis to come in the form of acute ST elevation myocardial infarction. Recognizing risk factors for bacteremia in patients presenting with myocardial infarction would increase suspicion in the clinician to look for endocarditis, and signs of other potential complications such as cerebral vascular accidents, or splenic infarction. Septic coronary embolism is a small fraction of embolic events resulting from vegetations of infective endocarditis, and is often fatal. According to guidelines from the American College of Cardiology and American Heart Association, surgical intervention is indicated with vegetations >10 mm or recurrent emboli despite antibiotic therapy (a grade IIb and IIa recommendation, respectively), as these present the greatest risk for embolization. Medical management of septic coronary embolization includes thrombectomy, percutaneous transluminal coronary angioplasty, or surgical embolectomy. None of these interventions have been studied adequately enough for clear recommendations regarding preferential modality, so selection of intervention is base on clinical scenario and available clinical resources.

NEAR FATAL CASE OF LEGIONNAIRE'S DISEASE WITH RHABDOMYOLYSIS Tatiana McKenna²; Ronnie Mantilla¹. ¹Capital Health Regional Medical Center, Trenton, NJ; ²Capital Health Regional Medical Center, Hopewell, NJ. (Tracking ID #2154102)

LEARNING OBJECTIVE #1: Rhabdomyolysis with acute renal failure (ARF) is a rarely recognized entity and associated with high morbidity and mortality rates. We strongly suggest to monitor CK levels immediately after *Legionella* infection is suspected to prevent renal damage.

LEARNING OBJECTIVE #2: Recognition of this interrelationship (mentioned in #1) can help make an early diagnosis, start timely treatment (including fluids and renal replacement therapy), and prevent fatal consequences.

CASE: A 37-year-old African American male smoker with a medical history of hypertension and asthma presented with 1-week of malaise, night sweats, dry cough and decreased urinary output. There was no diarrhea. Patient worked as a heavy duty cleaner at a local school. Physical exam showed temperature of 97.6 F, blood pressure 110/60 mm Hg, heart rate 98/min, respiratory rate 18/min, dry crackles at the left lung base. Significant laboratory findings on admission were: white blood cell count 17,900/μL, 42 % band, Sodium 133 mEq/L, Potassium 2.7 mEq/L, and Bicarbonate 29 mEq/L, blood urea nitrogen 18 mg/dL, and creatinine 1.57 mg/dL. Creatinine phosphokinase level (CK) 11,583 U/L. Arterial blood gas showed pH 7.22 Units, pCO2 65 mmHg, pO2 25 mm Hg on 100 % FiO2 via non-rebreather mask. Chest XRay revealed entire left lung consolidation. All sets of blood and urine cultures were negative, urine was positive for *Legionella* antigen. Patient was started on parenteral antibiotics. His hospital stay was complicated by development of respiratory failure and several episodes of cardiac arrest requiring multiple resuscitative attempts. He was transferred to the intensive care unit (ICU) on mechanical ventilator, new antibiotics were added. CK levels increased up to 58,586 U/L, and he subsequently developed ARF requiring hemodialysis (HD). In 2 weeks he was extubated, renal function improved and HD was discontinued.

DISCUSSION: *Legionella* infection is among the first four major causes of community acquired pneumonia. Risk factors include male gender, older age, smoking, alcoholism, chronic obstructive lung disease, recent travel, and chronic underlying disease (with or without immunodeficiency). It is worth mentioning that diarrhea is reported in 21–50 % and encephalopathy in 4–53 % of cases. Both are suggestive but not pathognomonic for the *Legionnaire's disease* (LD). Rarer findings in LD are rhabdomyolysis and acute renal failure (ARF). These complications when present can be associated with prolonged hospital stay and increased risk of severe disease progression. We present a case of severe rhabdomyolysis and ARF in the absence of obvious signs of *Legionella* infection. Rhabdomyolysis and ARF in patients with LD are associated cofactors that can predict development of severe complications. Possible mechanism is a direct bacterial invasion or endotoxins which can damage the muscle. Subsequent CK elevation leads to acute interstitial nephritis.

NEUROCYSTICERCOSIS: LIVE WORM NO PROBLEM, DEAD WORM BIG PROBLEM John S. Fleming; Aaron Roberts; Christopher Di Felice. Western Michigan University Homer Stryker MD School of Medicine, Kalamazoo, MI. (Tracking ID #2196537)

LEARNING OBJECTIVE #1: Recognize the clinical features of neurocysticercosis

LEARNING OBJECTIVE #2: Assess the need for treatment in patients with neurocysticercosis

CASE: A 42 year-old male presented after having a generalized tonic-clonic seizure at home. He works as an engineer and is required to travel overseas frequently. He confirmed traveling to China and India multiple times over the past two decades including a weeklong trip to China 2 months prior to admission. Initial labs including CBC, CMP, CPK, and troponin were within normal limits. CT brain demonstrated right parietal calcification and MRI brain showed right parietal cortical calcification with surrounding edema consistent with late stage neurocysticercosis. Patient was admitted and started on IV Dilantin and Decadron. His symptoms improved and he remained seizure-free throughout the rest of his hospitalization. He was discharged home in stable condition on PO Decadron and PO Dilantin for seizure prophylaxis and was referred for follow up with neurology.

DISCUSSION: Cysticercosis is caused by the larval stage of the pork tapeworm *Taenia solium*. It is endemic in most developing countries and while the exact prevalence is unknown, it is estimated that 50 million people living in India, Asia, Africa, and Latin America have the parasite. Transmission is via ingestion of *Taenia solium* eggs which are shed in the stool of humans or pigs harboring the intestinal tapeworm. While the scolex is alive it produces a number of substances that surround it and prevent normal host immunologic reaction. However, once the scolex is dead it no longer produces this protective coating and host immunologic response ensues resulting in inflammation. It is this inflammation, edema and calcification that result in adult onset seizures that characterize many cases of neurocysticercosis. Neurocysticercosis can be asymptomatic for many years after infection during the time that the scolex is alive. The typical asymptomatic period lasts between 10 and 20 years after initial infection until death of the scolex and subsequent symptoms. Clinical manifestations depend on the location of the cysts, but are generally associated with seizures and headaches. Our patient was most likely infected while in India and thus it is likely that the *Taenia solium* scolex was present in his brain for many years before dying and causing symptoms. When a single lesion that contains a nonliving parasite is found then no anti-parasitic medications are indicated as was the case with our patient. However, if multiple lesions in different stages are found then initiation of Albendazole or Praziquantel is appropriate. Concomitant treatment with steroids to prevent or reduce inflammation from the death of a scolex will help reduce the risk of seizure, mass effect, and other symptoms.

NEW ON THE DIFFERENTIAL FOR KIDNEY FAILURE: CANNABINOID HYPEREMESIS SYNDROME Julie Caplow; David J. Aizenberg. University of Pennsylvania, Philadelphia, PA. (Tracking ID #2197404)

LEARNING OBJECTIVE #1: Recognize cannabinoid hyperemesis syndrome and renal failure as potential complications of longstanding marijuana use.

LEARNING OBJECTIVE #2: Obtain a thorough social history in patients presenting with acute kidney injury.

CASE: A 49 year old previously healthy man presented to the emergency room with a 2 day history of incessant vomiting associated with muscle cramps and oliguria. He had started after doing roof work on a hot summer day. He denied taking any medications but endorsed longstanding daily marijuana use, which he continued during his illness with transient relief in symptoms. On presentation he appeared dry and was found to have a creatinine of 7.6 mg/dL. Retroperitoneal ultrasound was unremarkable and urine sediment showed granular casts. He was treated with intravenous fluids with return of normal urine output, but his nausea was refractory to anti-emetics and his creatinine continued to rise. He subsequently underwent kidney biopsy which showed only mild acute tubular injury. Serum creatinine peaked at 10.4 mg/dL on day 3 of hospitalization and then trended down to 3.9 mg/dL by day 8, at which point the patient was asymptomatic and was discharged to home. Within one week as an outpatient creatinine normalized to 1.1 mg/dL.

DISCUSSION: Cannabinoid hyperemesis syndrome (CHS) is an increasingly recognized condition in which longstanding marijuana users experience bouts of intractable vomiting. While anti-emetic medications are generally ineffective for this condition, hot showers tend to provide temporary symptom relief and marijuana cessation is the definitive cure. There have been at least 6 recent case reports of acute kidney injury secondary to CHS, in which patients presented with creatinine levels ranging from 3 to 10 mg/dL which normalized within 1 to 5 days of fluid resuscitation. This entity, recently termed Cannabinoid Hyperemesis Acute Renal Failure, is thought to result from severe volume depletion from a combination of cyclic vomiting and frequent hot showers. Though our

patient denied taking hot showers, he suffered additional dehydration from doing roof work under very hot conditions. With a growing prevalence of marijuana use in this country, it is important to take a thorough social history with all patients, recognize CHS and renal failure as serious risks of long-term marijuana use, and counsel patients accordingly.

NEW ONSET ASCITES OF NON PORTAL HYPERTENSION ORIGIN: WHAT SHOULD WE BE THINKING? Raktim K. Ghosh¹; Kulsoom Fatima¹; Sakthiraj Subramanian². ¹St. Vincent Charity Medical Center, An affiliate of Case Western Reserve University, Cleveland, OH; ²st vincent charity medical center, Cleveland, OH. (Tracking ID #2159147)

LEARNING OBJECTIVE #1: Serum ascites albumin gradient (SAAG) value <1.1 g/dL identifies ascites of non portal hypertension origin. Some of the common etiologies of low gradient ascites include tuberculous peritonitis-induced ascites, malignancy-induced ascites, pancreatic ascites, renal ascites and serositis-induced ascites

LEARNING OBJECTIVE #2: TB peritonitis and malignant ascites may not be detected in the initial ascitic fluid analysis. Often diagnosis of peritoneal metastases or TB peritonitis can only be obtained by laparoscopy, which provides a direct view of the lesions and biopsy samples of the peritoneal lesions.

CASE: A 55 years old male patient with PMH of pulmonary TB 15 years ago, was admitted with complaints of abdominal distension and occasional vague pain at the flanks for last 3 months. He also reported night sweats, low grade fever and mild nausea for similar duration. He denied any recent history of vomiting, loss of appetite, weight loss, jaundice, change in bowel habit, recent exposure to an active TB patient, HIV, prison confinement, chronic cough and chest pain. Review of system was negative for PMH of chronic alcoholism, pancreatitis, heart disease, hepatitis and venous thrombosis. The pertinent physical examination findings included distended abdomen with fullness at the flanks and positive shifting dullness. There was no stigmata of chronic liver disease. Initial labs including CBC, electrolytes, liver enzymes, bilirubin, INR, amylase and lipase were unremarkable. The computed tomography scan showed abdominal and pelvic ascites and enhancement of mesentery suggestive of infectious process. The patient underwent diagnostic peritoneal tap and fluid analysis showed total white count of 2500, PMN count of 1 %, low adenosine deaminase, high protein 5.3 gm/dL and high albumin 3.1 gm/dL. The serum albumin was 3.3 gm/dL, suggesting a non portal hypertension origin of ascites as SAAG was <1.1 g/dL. Cytology analysis of fluid showed reactive mesothelial cells, macrophages, lymphocytes but no evidence of malignancy. The fluid was sent for AFB culture which was reported negative after 6 weeks. T spot was negative. Laproscopic biopsy of omentum was consistent with adenocarcinoma of stomach. The patient also underwent EGD which showed deep serpiginous appearing ulcer in the pre-pyloric area. Histopathological examination showed adenocarcinoma of stomach with signet ring.

DISCUSSION: Accumulation of fluid within the peritoneal cavity results in ascites. In the United States, ascites is most often due to portal hypertension resulting from cirrhosis which accounts for approximately 80 % of cases. Some of the common etiologies of low gradient ascites (SAAG <1.1 g/dL) include tuberculous peritonitis-induced ascites, malignancy-induced ascites, pancreatic ascites, renal ascites and serositis-induced ascites. Ascites with low gradient SAAG can often become a diagnostic challenge as two commonest etiologies i.e. TB peritonitis and malignant ascites may not be detected in the initial ascitic fluid analysis. The neoplasms most frequently associated with ascites are ovarian, breast, colon, stomach and pancreatic adenocarcinomas. Overall sensitivity of cytology smears for the detection of malignant ascites is 58 to 75 % which increases to more than 90 % after 2nd or 3rd fluid analysis. However, our patient did not have any peritoneal fluid after initial tap for reanalysis. Almost all patients with peritoneal carcinomatosis have positive ascitic fluid cytology due to the presence of viable malignant cells exfoliating into the ascitic fluid but only two third of the cases of malignant ascites are due to peritoneal carcinomatosis. Malignant ascites from other mechanisms including lymphatic vessel obstruction, portal hypertension from metastases or heart failure will have negative fluid cytology. TB peritonitis and malignant ascites when associated with portal HTN from liver metastases or cirrhosis may have a SAAG >1.1 g/dL making it more of a diagnostic challenge in which case history and high degree of suspicion is required to make the diagnosis. The early use of upper endoscopy in patients presenting with gastrointestinal complaints may be associated with a higher rate of detection of early gastric cancers. Examination of AFB smear and peritoneal fluid AFB culture have very low diagnostic yield. Often diagnosis of peritoneal metastases or TB peritonitis can only be obtained by laparoscopy, which provides a direct view of the lesions and biopsy samples of the peritoneal lesions.

NEW ONSET SEIZURE SECONDARY TO ENERGY DRINK CONSUMPTION

Kiruba Vembu; Diane Book. Medical College of Wisconsin, Milwaukee, WI. (Tracking ID #2199370)

LEARNING OBJECTIVE #1: Recognize rare causes of new onset seizures, including overconsumption of energy drinks

LEARNING OBJECTIVE #2: Identify the clinical presentation and toxicity associated with caffeine use

CASE: A 21 year old male presented to the ED after a sudden loss of consciousness and two minutes of tonic clonic seizure activity witnessed by his colleagues; the episode lasted approximately two minutes. Vitals on admission were as follows: blood pressure 152/72, heart rate 103, temperature 98.1 degrees F, respiratory rate 18 and oxygen saturation of 98%. Upon arrival, he was found to have post ictal symptoms including disorientation and slowed speech. Further history obtained from the patient revealed that he had consumed two bottles of a commercial energy drink immediately prior to the onset of seizure activity. Upon arrival to the ED, he received 2 mg lorazepam with noted improvement in mental status. A CT of the head was performed and was negative. The basic chemistry panel was significant for a sodium level of 134 mEq only. Complete blood count showed an elevated white blood count of 12.6. Lactic acid was elevated at 4.5 mmol/L. He was then admitted, but had no further seizures during the hospitalization. MRI was performed, and was negative. Urine toxicology screening was negative. Additional questioning on admission revealed that he had no significant medical history, including seizure or mental health history. He also denied a family history significant for seizures.

DISCUSSION: Since energy drinks first came to the market in 1997, sales growth has increased substantially, with billions of beverages sold a year. Since their introduction, these products have been reported to be associated with neurological events, including seizures. We report the case of a new onset seizure in the adult population, most likely secondary to rapid energy drink consumption. Since energy drinks are classified as dietary supplements, ingredients are not regulated by the Food and Drug Administration (FDA). Literature search shows that cases of new onset seizure have been associated with common energy drink ingredients including caffeine, guarana, and taurine; all of these have been considered as potential seizure triggers. Caffeine is the primary psychoactive ingredient in the majority of energy drinks; by increasing catecholaminergic tone, it can have proconvulsant effects. Since caffeine follows zero order kinetics, seizures can arise in a dose dependent manner. The initial effects of caffeine toxicity are non specific and include tachycardia and headache, both of which our patient experienced. These symptoms can be followed by altered mental status, seizure, hypotension and arrhythmia. Ingredients such as guarana, a natural caffeine additive derived from a plant known to have the highest concentration of caffeine in the world, also increase the caffeine content in these beverages. However, heavy consumption of energy drinks are commonly associated with other behaviors that also lower the seizure threshold such as concurrent alcohol use or sleep deprivation; thus, a direct link between new onset seizure and energy drink use is difficult to establish. Further studies will be required to elucidate the risk of seizure precipitation in otherwise healthy adults that consume more than the recommended amount of energy beverages.

NON-TUBERCULOSIS MYCOBACTERIAL (NTM) RENAL INFECTION
Jeremiah K. Sisay, M.D.; Venkata Ghanta, M.D., M.S.; Raymond Munoz, M.D..
Methodist Dallas Medical Center, Dalllas, TX. (Tracking ID #2198954)

LEARNING OBJECTIVE #1: Recognize NTM renal infection presenting as unexplained hematuria in an immunocompetent patient

CASE: A 45 year old, morbidly obese, Hispanic man presented to the hospital complaining of bilateral flank pain and gross hematuria, which began the night prior to admission. He described the pain as 10/10 in severity, constant, with radiation to the inguinal region and partially relieved with pain medications. He also complained of dysuria, frequency and urgency of 1 week duration. He presented with similar symptoms (bilateral flank pain, hematuria) to another hospital 1 year prior to admission and was treated with antibiotics for pyelonephritis, although neither his urinalysis nor urine culture showed evidence of infection. Following discharge, the patient remained asymptomatic until the described episode. The patient did not take medications, denied tobacco, alcohol and substance abuse, worked as a truck driver and lived with his wife and children. He immigrated to the US from Mexico many years prior to presentation and denied recent travel. He reported a family history of "heart problems." Review of systems was significant for fever, chills, night sweats, and a 30 lb unintentional weight loss over the past year. Physical examination was significant for tachycardia, and fever to 101.6 °F. Otherwise, he was in no acute distress and had a benign physical exam except for an enlarged prostate on rectal examination. Pertinent laboratory data included leukocytosis to 22,000/uL with 88 % neutrophilia and hematuria. CT abdomen/pelvis with contrast revealed pelvic, inguinal and abdominal lymphadenopathy, seen on a previous CT scan approximately 1.5 years prior, with noted enlargement of the left pelvic lymph nodes. Evaluation included urine and blood cultures which showed no growth, left inguinal lymph nodal biopsies which showed benign, reactive features, PPD test with controls and Quantiferon gold test which were negative. Urine was submitted for AFB smears and cultures. The

patient was treated empirically with vancomycin and piperacillin/tazobactam and his symptoms resolved. Several weeks following discharge, his mycobacterial cultures grew *Mycobacterium avium* complex (MAC). The patient was seen post-discharge in the outpatient clinic with complete resolution of his symptoms and was scheduled for cystoscopy.

DISCUSSION: Genitourinary infections caused by NTM are rarely reported. Among the expected risk factors for NTM disease, it is commonly believed that preexisting pulmonary conditions are most common. However, many cases of NTM disease occur in patients with concurrent illnesses or in patients taking immunosuppressive medications (1). Several studies have shown that MAC is the most common pathogen causing post-transplant NTM disease (1, 2, 3). Notably, one fourth of patients with NTM disease from a study in New York City did not have a known risk factor, which suggests the possibility of a unique genetic susceptibility or environmental exposure in immunocompetent patients (1). In a retrospective review of genitourinary infections caused by NTM conducted in the University Hospital of Taiwan from 1996 to 2008, 15 patients were identified and 11/15 had underlying co-morbid conditions, with the most common being chronic renal disease. Only one patient had AIDS while three had malignancy. The majority of these patients presented with fever, followed by characteristic symptoms of urinary inflammation (dysuria, frequency or urgency) (4). A case report described NTM infection causing acute kidney injury in a patient with CKD stage 3. The patient was treated with levofloxacin for 2 weeks with clinical improvement and serum creatinine returned to baseline (5). The pathogenesis and optimal treatment regimen of genitourinary NTM in immunocompetent patients remains poorly understood. However, case reports and series are emerging and should encourage clinicians to consider NTM in their differential diagnosis of both immunocompromised and immunocompetent patients presenting with genitourinary symptoms. **References:** 1. NOT ALL CHEST PAINS ARE THE SAME Vassiliki Pravodelov. Boston University Medical Center, Boston, MA. (Tracking ID #2199336)

LEARNING OBJECTIVE #1: Recall the clinical signs, diagnostic approach, and treatment of Graves' disease.

LEARNING OBJECTIVE #2: Identify non-cardiac causes of chest pain.

CASE: A 55 year old woman with history of hypercholesterolemia presented with chest pain. Three days prior to presentation, while sitting in her office, she had three episodes of 3/10 chest discomfort associated with palpitations and dyspnea. On the evening prior to admission she had a 3/10, non-radiating mid-sternal chest pain "like a brick on the chest" that was constant and worsened to 10/10 through the night. Associated symptoms included dizziness, diaphoresis that felt like a hot flash, and dyspnea. Upon further questioning, she reported having worsening knee pain and swelling by the end of the day bilaterally, hot flashes, palpitations, and hand tremors over the past three weeks. She also noted voice hoarseness, sore throat sensation, and odynophagia. She had been taking a daily herbal laxative for constipation. She denied any history of radiation. Family history was unremarkable. The patient was hemodynamically stable and not in distress. Exam was notable for mild proptosis, lid lag, and restricted right lateral gaze without prominent exophthalmos. She had mild tremor on arm extension and her deep tendon reflexes were 2+ throughout. Her thyroid exam showed a non-tender mildly enlarged thyroid without palpable nodules. Her skin exam was normal. Laboratory studies were significant for normal cardiac enzymes thrice, hypercalcemia with corrected calcium level 10.9 mg/dL, mild normocytic anemia with hemoglobin 11.4 g/dL, and normal kidney and liver function. The thyroid panel indicated primary hyperthyroid state with thyroid stimulating hormone (TSH) below detectable levels, and elevated total Triiodothyronine (T3) >400 ng/dL (above assay) and total Thyroxine (T4) 15.6 ng/dL. Parathyroid hormone (PTH) and Vitamin D levels were normal. Thyroid peroxidase antibodies and thyroid stimulating immunoglobulins were both present and elevated. Hemoglobin A1c was 5.5 % and lipid panel showed LDL 89 mg/dL, HDL 29 mg/dL, and total cholesterol 132 mg/dL. Her ECG showed normal sinus rhythm without ischemic changes and the patient had no events on cardiac telemetry. She was started on propranolol to decrease sympathetic stimulation. Her clinical picture was not consistent with thyroid storm as she was hemodynamically stable. She had a thyroid radioactive iodine uptake scan (RAIU) that showed diffuse homogeneous radiotracer uptake at 4 h and 24 h consistent with Graves' disease. She was started on methimazole and was seen in endocrinology clinic. Long-term treatment options were discussed with the patient, including methimazole,

radioactive iodine ablation, and thyroidectomy. The patient remained on methimazole and was referred to ophthalmology for evaluation of Graves' orbitopathy.

DISCUSSION: This patient was admitted to the medical floor as a "typical chest pain rule out". However, by carefully taking the patient's history and performing a full physical exam, we were able to soon identify her underlying medical problem, which was thyrotoxicosis. Chest pain rule-outs are one of the most common reasons for hospital admission. It is important to constantly remind ourselves that chest pain may be a manifestation of many different conditions, especially in patients at low risk for cardiac disease. Graves' disease is one of the most common autoimmune disorders affecting the thyroid gland. It is characterized by the presence of circulating antibodies that bind and stimulate TSH receptors, resulting in hyperthyroidism and diffuse enlargement of the thyroid gland (goiter). Graves' disease has multiple extra-thyroid manifestations, the most common of which is ophthalmopathy. The diagnostic hallmark of thyrotoxicosis is elevated T3 and T4 with undetectable TSH. Symptoms of thyrotoxicosis include chest pain, tachycardia, palpitations, tremors, anxiety, weight loss, and hypercalcemia. The diagnostic criteria for Graves' disease are thyrotoxicosis with at least one of the following: detectable serum TSH receptor antibodies, evidence of ophthalmopathy and/or dermopathy, diffuse and increased RAIU. In our patient, her laboratory findings, history, and physical exam all supported thyrotoxicosis and Graves' disease was confirmed with evidence of proptosis on exam and increased RAIU. Treatment usually starts with the use of anti-thyroid medications (methimazole or propylthiouracil) with goal to restore euthyroidism. Methimazole is used more often due to its better side effect profile compared to propylthiouracil. Once euthyroidism is achieved, multiple options exist, including long-term anti-thyroid drugs, radioactive iodine ablation, or surgery. Our patient remained on methimazole as about 30 % of patients on this medication remain in remission. Beta-blockers can be used to alleviate symptoms of thyrotoxicosis, such as palpitations and tremors, before euthyroid state is achieved, something that our patient benefited from.

NOT ALL VALVE VEGETATIONS ARE ENDOCARDITIS Christopher M. Begley; Akshay Amarani; Andrew Whipple. Western Michigan University Homer Stryker M.D. School of Medicine, Kalamazoo, MI. (Tracking ID #2198817)

LEARNING OBJECTIVE #1: Recognize that cardiac papillary fibroelastomas may result in serious complications including stroke, valvular dysfunction or sudden cardiac death

CASE: A 56-year-old man was brought in to the hospital for a 3-week history of intermittent confusion. According to family, his symptoms consisted of short-term memory impairment. No focal sensory or motor deficits were reported. Past medical history was significant for diabetes mellitus, hypertension and coronary artery disease. Physical exam, including vital signs and neurological exam, was unremarkable. Laboratory data showed no abnormalities other than mild hyperglycemia. Computed Tomography (CT) of the head revealed a small ischemic focus in the right pons, with recommended Magnetic Resonance Imaging (MRI) for further characterization. MRI of the brain confirmed this finding and additionally showed small remote lacunar infarcts in right brainstem and left thalamus. On day one of hospitalization, a transthoracic echocardiography (TTE) was performed as an embolic source was suspected. A small to moderate sized mobile mass versus vegetation was visualized on the aortic valve, and transesophageal echocardiography (TEE) was recommended. TEE was performed on day two of hospitalization; findings revealed a pedunculated moderate sized mobile mass on the non-coronary cusp leaflet measuring 0.6×0.9 cm. The mass was thought to be suggestive of a cardiac papillary fibroelastoma. The patient underwent excision of the mass, which was attached to the free margin of the leaflet on a thin stalk, and thus 1×3 mm edge was removed. The patient tolerated the procedure well and was discharged after recovery from surgery. Pathology confirmed papillary fibroelastoma.

DISCUSSION: Primary tumors of the heart are a rare entity, with prevalence estimated to be less than 0.1 %. Papillary fibroelastomas are the second most common primary cardiac tumor behind myxomas. The mean age of patients who develop fibroelastomas is 60 years, with a male predominance. Prior to echocardiography, most tumors were diagnosed post-mortem. Despite the fact that many are found incidentally and are considered pathologically benign tumors, there is great potential for serious morbidity and mortality. Patients may present with stroke secondary to embolism, caused by the tumor itself or subsequent thrombus, valvular dysfunction and possibly sudden cardiac death. Surgery is indicated in patients who are thought to have embolic events related to mobility and for those greater than or equal to 1 cm in size. Grossly, papillary fibroelastomas have been described to have a sea anemone like appearance with multiple papillary fronds attached to the endocardium by a short stalk. The majority of resections do not require valvular repair or replacement. Recurrence following resection has not been reported.

OLD MAN, OLD PROBLEM, OLD MEDICATION, NEW SOLUTION: INNOVATIVE TREATMENT FOR POST-BLADDER CATHETERIZATION PELVIC DISCOMFORT Michelle Devor; Marc Tzorfas. SDVAHCS, San Diego, CA, CA. (Tracking ID #2199407)

LEARNING OBJECTIVE #1: Recognize a treatment option for post-catheterization discomfort in catheter-dependent elders.

LEARNING OBJECTIVE #2: Consider the complexities of treatment decision-making in interventions in the old-old.

CASE: A 94 yo man presented with post-Foley catheterization pelvic and urethral discomfort. Initially diagnosed with BPH in August 2001, he failed medical management and had persistent post-void residuals of 350–450 ccs; urodynamics showed poor detrusor function. Declining indwelling catheterization, chronic intermittent catheterization tid was initiated in June 2008. After suffering 2 symptomatic UTIs in 2013, felt related to his decline in dexterity and vision and his accelerating fixation on catheterization (performing the procedure more than 10 x per day), indwelling catheterization was initiated in January 2014. Following catheterization, the patient complained of urethral pain, urgency and pelvic discomfort particularly at night. Mechanical manipulations and in-home education failed to alleviate symptoms. At day 14 post-catheterization, Pyridium® 95 mg tid was started; symptoms improved within 24 h. The dose was decreased to 95 mg qhs, which maintained the good response, and was then changed to PRN. By early March 2014, he was no longer needing the medication and has not needed it since. He has had one symptomatic multiorganism UTI within the first month felt related to sterile technique during a catheter change.

DISCUSSION: Phenazopyridine (Pyridium® is an azo (R-N=N-R') dye, with an unknown mechanism of action, used as an oral urinary tract analgesic, adjunctive to antimicrobial therapy for cystitis. Adverse drug events include discoloration of the urine, GI disturbance, rash, pruritus and, most concerning, anaphylactic reactions, hepatotoxicity, methemoglobinemia, hemolytic anemia, renal and hepatic toxicity, though those the latter are dose-dependent and seen primarily in overdose situations. There is scant clinical data for efficacy and safety as a urinary tract analgesic or for any of the indications listed in the Pyridium® insert, and no published studies trialing phenazopyridine in patients who have difficulty tolerating the discomfort of chronic indwelling Foley catheters. Urologists employ it for endoscopic procedures, one of the insert's indications. One study of women undergoing GYN surgery showed no effect of phenazopyridine on post-operative pain care (1). As might be expected, there are no studies or reports of its use in nonagenarians. The decision to initiate a chronic indwelling Foley in this elder was reached after considerable thought and discussion as his functional status and quality of life was excellent despite several limiting conditions. Disturbing his status quo was risky and the resultant discomfort was trying. Phenazopyridine offered palliative treatment for his discomfort with no adverse consequences and was able to be weaned off after a period of adjustment to the catheter. Any intervention in a nonagenarian must be undertaken with caution weighing the proposed benefits against potential complications and impacts on quality of life. There is little "precedence" in this population since, just by virtue of their age, they represent unique physiology that permits such longevity. We contend that clinicians consider the use of phenazopyridine in elders who suffer from post-catheter urinary tract pain and urgency, though caution must be taken as this one case report cannot be generalized to all elders, and others may experience adverse consequences from this poorly studied medication. Reference: 1. Anderson C, Chimhanda, M, Sloan J et al. Phenazopyridine does not improve catheter discomfort following gynecologic surgery. Am J Obstet Gynecol 2011; 204–267. e1-3.

ONE ADMITTING DIAGNOSIS LEADS TO A SECOND DIAGNOSIS Kanapa Kornsawad²; Sadie Trammell Velasquez¹. ¹University of TX Health Science Center at San Antonio, San Antonio, TX; ²University of Texas Health Science Center, San Antonio, TX. (Tracking ID #2188592)

LEARNING OBJECTIVE #1: Identify unusual causes of hemolytic anemia

LEARNING OBJECTIVE #2: Identify the high value of Vitamin B12 testing in patients with anemia

CASE: A 34-year-old woman presented with 2 months of generalized fatigue and was found to be in Diabetic Ketoacidosis. She has a history of Type I Diabetes Mellitus. Review of systems was notable for malaise, dizziness and dyspnea on exertion. She was diagnosed with gastroparesis and anemia one month ago without a clear etiology. Physical examination revealed pale conjunctiva. Laboratory data was significant for a white blood cell count (WBC) 7.5 K/uL, hemoglobin 6.0 G/dL, Mean Corpus Volume (MCV) 102 fL and platelets 67,000 K/uL. Peripheral blood smear showed evidence of hemolysis with schistocytes with hypersegmented neutrophils, thrombocytopenia and teardrop cells (see picture). Other significant labs included vitamin B12 68 pg/mL, low reticulocyte count, total bilirubin 2.3 mg/dL, lactate dehydrogenase (LDH) level 7642 IU/L and haptoglobin <8. The patient was given two units of packed red blood cells with minimal response. She was started on intramuscular B12 supplementation with subsequent improvement of her anemia, thrombocytopenia and normalized of the LDH and transaminase levels. Work up for the etiology of her Vitamin B12 deficiency revealed positive anti-intrinsic factor (IF) antibody, specific for a diagnosis of pernicious anemia.

DISCUSSION: Hematological findings in cobalamin or vitamin B12 deficiency include anemia, leukopenia, thrombocytopenia, macrocytosis and hyperpigmented neutrophils. Approximately 10 % of the patients have life-threatening hematological manifestations with symptomatic pancytopenia, “pseudo” thrombotic microangiopathy and hemolytic anemia. In our patient, she met criteria for “pseudo” thrombotic microangiopathy with hemolytic anemia (elevated LDH, low haptoglobin), thrombocytopenia and schistocytosis in the setting of low B12 level. Patients with pseudo-TMA are found to have a very high LDH, low reticulocyte count and thrombocytopenia. The patient’s low Vitamin B12 and a positive anti-intrinsic factor antibody demonstrated she had Vitamin B12 deficiency due to pernicious anemia which resulted in severe intramedullary hemolysis and ineffective erythropoiesis. General Internists should be aware and consider vitamin B12 deficiency in a patient with anemia, which can present as mechanical hemolysis and thrombocytopenia.

PAIN IN THE NECK: RECOGNIZING THE SIDE EFFECTS OF INTRAARTICULAR CORTICOSTEROID INJECTIONS Michael Weinreich¹; Joseph Conigliaro². ¹North Shore - LIJ School of Medicine, Manhasset, NY; ²North Shore LIJ Health System, New Hyde Park, NY. (Tracking ID #2196710)

LEARNING OBJECTIVE #1: Diagnose adrenal suppression in patients receiving intraarticular corticosteroid injections.

LEARNING OBJECTIVE #2: Recognize risk factors for adrenal suppression.

CASE: A 57-year-old female with a history of chronic neck pain from a motor vehicle accident presented to our office after a syncopal episode. For the past 9 years she has received steroid injections for her chronic neck pain. During the evaluation of the etiology of her syncope, she was found to have a sodium of 118 mmol/L and orthostatic hypotension with a 45 point increase in her heart rate as she moved from lying to standing. The remainder of her evaluation revealed negative intracranial imaging, normal echocardiogram, absence of arrhythmias on EKG and telemetry, and a normal electroencephalogram. She was found to have a serum AM cortisol level of 0.9 ug/dL and her serum ACTH was < 5 pg/mL, consistent with secondary adrenal insufficiency believed to be as a result of chronic steroid injections. She was treated with oral corticosteroids with resolution of her hyponatremia and symptoms.

DISCUSSION: Corticosteroid injections are a common treatment for a variety of articular pathologies. Intraarticular (IA) steroids, are systemically absorbed and cause negative feedback on the production of ACTH by the anterior pituitary. This results in decreased cortisol production by the adrenal cortex, which can precipitate an adrenal crisis. While this mechanism is a well described phenomenon in the use of oral steroids, it has been poorly described in the IA injection literature. A small case series of 25 patients with rheumatic joint disease noted that corticosteroid injections resulted in suppression of the pituitary-adrenal axis for up to two weeks following a single injection. Other case reports have also noted seizures, syncope, and adrenal insufficiency post IA injections, not to mention local side effects and joint degeneration. There is scant data on the long-term side effects among patients receiving chronic steroid injections. The American College of Rheumatology recommends joint injections at intervals of no more than once every 3 months. The steroids most commonly utilized, listed in order of decreasing popularity of use, are methylprednisolone acetate, triamcinolone hexacetonide, and triamcinolone acetonide. Triamcinolone hexacetonide has the lowest level of systemic absorption but is not widely utilized. Patients with IA corticosteroid joint injections can experience a reduction in serum cortisol level by 21.5 % for 3 days after injection. Those at highest risk for adrenal-pituitary axis suppression include pediatric patients, the elderly, those with steroid injections at intervals greater than every 3 weeks, and those with a long-term history IA injection. As joint pain is a common ailment managed by General Internists, awareness of this therapeutic side effect is vital to recognizing adrenal suppression in patients with a history of chronic IA corticosteroid injections.

PANCREATIC PARESIS: A CASE OF PARANEOPlastic WEAKNESS Nehal Patel¹; Bartley J. Gill¹; Christina Otterness¹; Zaven Sargsyan^{1, 2}. ¹Baylor College of Medicine, Houston, TX; ²Michael E DeBakey VA Medical Center, Houston, TX. (Tracking ID #2199183)

LEARNING OBJECTIVE #1: Recognize necrotizing autoimmune myopathy (NAM) as a cause of sudden-onset proximal muscle weakness and creatinine kinase (CK) elevation in cancer patients

LEARNING OBJECTIVE #2: Prevent the contribution of statin therapy to muscle injury in the hospitalized patient

CASE: A 53-year-old man admitted for work-up of a pancreatic mass began reporting significant weakness during his hospital stay. Prior to admission, he had experienced 6 months of epigastric pain, 40-lb weight loss, and fatigue. A 2×2 cm pancreatic head mass was discovered on abdominal CT. His admission exam was notable for jaundice,

epigastric tenderness, and a normal neurological exam including strength. Initial laboratory studies included an AST of 786 U/L, ALT of 681 U/L, alkaline phosphatase of 1135 U/L, and total bilirubin of 19 mg/dL. CA 19-9 was 2274 U/mL. Several EGDs with EUS were performed, as fine needle aspirations of the mass were initially non-diagnostic. Pathology eventually reported atypical cells suggestive of adenocarcinoma. While undergoing this work-up, the patient developed rapidly worsening proximal muscle weakness over several days. Proximal strength had worsened to 2/5 in his legs and 4/5 in his arms. Distal muscle strength remained normal, along with sensation, reflexes, and bulbar muscle function. The patient had been on atorvastatin, which was immediately discontinued, but careful review of new medications revealed none that affected its metabolism. Laboratory workup showed a creatinine kinase (CK) of 3068 U/L, which ultimately peaked at 44,000 U/L. Anti-Jo and ANA were normal. Electromyogram showed myotonic discharges consistent with myositis. Muscle biopsy of the left quadriceps revealed degenerating and regenerating myofibers without fiber type grouping or perivascular inflammation, as well as focal endomysial capillary dropout. These features were consistent with necrotizing autoimmune myopathy (NAM) with minimal inflammation. The patient was treated with high-dose steroids and intravenous immunoglobulin (IVIg), with a subsequent normalization of CK levels and moderate improvement in proximal lower extremity weakness. He is currently preparing for chemoradiation therapy.

DISCUSSION: Weakness is a common symptom encountered by the general internist, and inflammatory myopathies must be considered in its differential. This group of disorders encompasses polymyositis, dermatomyositis, inclusion body myositis, and the recently recognized necrotizing autoimmune myopathy (NAM). The symptoms of NAM are similar to those of polymyositis: progressive, symmetric proximal muscle weakness and elevated CK levels. The key distinguishing pathologic feature of NAM is necrosis of muscle fibers with absent or minimal inflammation. Similar to polymyositis and dermatomyositis, NAM has also been associated with malignancy. NAM can also be triggered by statins, but with a rare prevalence of 1 in 100,000. In this patient’s case, we believe the etiology of NAM was paraneoplastic, with a possible exacerbation by atorvastatin use. No standardized guidelines are available for the treatment of NAM. Expert opinion supports a trial of oral prednisone 1 mg/kg as first-line treatment, with addition of methotrexate, azathioprine, or IVIg in refractory cases. Response to treatment varies from partial to full functional recovery. This case highlights the importance of considering paraneoplastic myopathy as a cause of proximal muscle weakness in a patient with malignancy, and to utilize muscle biopsy to distinguish NAM from other autoimmune myositides. Furthermore, the possible contribution of statin therapy to our patient’s myopathic processes emphasizes the importance of early discontinuation of statins in acute settings of suspected muscle or liver injury.

PE WITH 0 WELLS CRITERIA Gen Yamada²; Christine Kwan¹. ¹Teine Keijinkai Hospital, Arlington, TX; ²Teine Keijinkai Hospital, Sapporo, Japan. (Tracking ID #2194452)

LEARNING OBJECTIVE #1: Diagnose pulmonary embolism (PE) when Wells criteria is 0

CASE: A 65-year-old Asian man presents with 4 months’ acute-onset, worsening chest pain ever since hospital discharge following his cervical cord injury. Initially, the intermittent right chest pain lasts a few minutes and occurs once/week, but it has gradually worsened to 30–60 min/episode for 3–5 times/day with bilateral involvement. The pain is squeezing, radiating to his back and shoulders, 10/10, not improved by anything, and worsened by deep breaths. He also reports low-grade fever ($T_m=38$), palpitations, dry cough, dyspnea, and left>right leg heaviness. Other review of systems is within normal limits. The patient’s past medical history includes constipation and cervical cord injury from a fall while he is drunk 7 months ago; he has been hospitalized for 3 months for rehabilitation after which he can now walk. He takes magnesium dioxide, baclofen, and dantrolene; he has no allergies. He has smoked 3 packs/day for 40 years and drunk 5 cans of beer/day but quit both 7 months ago. He has no family history of cardiovascular disease. On physical exam, vital signs include temperature 36.5, blood pressure 101/50, heart rate 77, respiratory rate 18, and oxygen saturation 98 % room air. Heart exam shows regular S1 and S2 with no tenderness to palpation, murmurs, gallops, or rubs. Lungs are clear to auscultation bilaterally. His extremities show no edema or palpable cords. On neurological exam, his motor strength is 4/5 except for 2/5 dorsiflexion of the bilateral feet. The rest of his exam shows no abnormalities. On labs, the patient’s complete blood counts, chemistry panel, and cardiac enzymes show no abnormalities except for increased CRP at 19.4 mg/dL (normal: 0–0.3) and D-dimer at 5.8 mcg/mL (normal: <1). His chest x-ray and electrocardiogram demonstrate no irregularities. Enhanced chest computed tomography (CT) is obtained, which reveals large clots in the right common iliac vein and bilateral pulmonary arteries with infarction. For his PE, he is started on heparin with transition to warfarin; a hypercoagulability panel, including protein C and S, antinuclear antibody, anticardiolipin antibody, and antithrombin III are negative. His chest pain improves within several days.

DISCUSSION: Because of nonspecific symptoms and signs, PE is difficult to diagnose and can mimic other diseases, such as acute coronary syndrome, pericarditis, and pneumonia. Typical symptoms include dyspnea (73 %), pleuritic chest pain (66 %), cough (37 %), and leg swelling/pain (28 %), some of which occur in the above patient. The sensitivity, unfortunately, of some PE signs of tachycardia and tachypnea are only 30 and 20 %, respectively, with specificity of 70 and 90 %. When using Wells criteria to assess the clinical probability of PE, the above patient has no clinical symptoms of a deep venous thrombosis (DVT), and heart rate is <100/min. While he does have a history of immobilization, it is >4 weeks ago; he also has no previous DVT/PE, hemoptysis, or malignancy. His Wells score is, thus, 0, denoting a low (6 %) probability of PE, as opposed to a high (>6) Wells score with a 49 % chance of PE. In fact, 16 % of patients have a false negative result on Wells criteria. While D-dimer is also non-specific (46 %), it can, however, be meaningful when no alternative diagnosis better explains the patient's illness, like the above.

PECULIAR CASE OF CEREBROVASCULAR ACCIDENT PRESENTING AS HEMIBALLISMUS Muhammad Sarfraz Nawaz¹; Gaurav Goyal¹; Toufik Mahfoud Haddad¹; Pranathi R. Sundaragiri¹; Temple Brannan². ¹Creighton University School of Medicine, Omaha, NE; ²Nebraska-Western Iowa Veterans Affairs Medical Center, Omaha, NE. (Tracking ID #2191582)

LEARNING OBJECTIVE #1: Recognize hemiballismus as initial presentation of acute cerebrovascular accident (CVA)

LEARNING OBJECTIVE #2: Highlight management of movement disorders in the setting of acute CVA

CASE: A 72-year-old Caucasian male with past history of ischemic CVA, hypertension, diabetes mellitus, peripheral vascular disease and nicotine dependence presented with frequent involuntary jerking movements of the right upper and lower extremities for 1 week duration. The symptoms initially started as twitching of right shoulder and progressively worsened. The symptoms were absent during sleep but were prominent during the day and interfered with his activities of daily living. The patient denied numbness, tingling, limb weakness, loss of consciousness, seizure-like activity, headaches or visual changes. He had no family history of seizure or movement disorders. Physical examination revealed an elderly male, oriented and alert with elevated blood pressure of 206/111 mm Hg with uncoordinated and unintentional movements of the right upper and lower extremities causing him to have a limp during ambulation. Muscle strength was 4/5 in left biceps, triceps and hip flexors and 5/5 in other muscle groups, normal muscle tone and sensations, and absence of atrophy. Patellar reflexes and Babinski's sign were negative bilaterally. Routine laboratory parameters were normal except for a hemoglobin A1C of 11.8 %. Computed tomography (CT) scan of the head showed chronic right-sided thalamic lacunar infarct. Magnetic resonance imaging (MRI) of the brain confirmed chronic right thalamic infarct and new small sub-acute infarcts in left lentiform nucleus. MR angiogram of the head was limited by severe motion artefacts but did not demonstrate any obvious vascular stenosis or cessation of flow. The patient was medically optimized on aspirin, simvastatin, haloperidol and lorazepam. The hemiballismus was attributed to the lentiform nuclear infarction. Patient's hyperkinetic movements dramatically reduced in intensity over the next 3 days and he was asymptomatic with no residual neurological issues at 3 month follow-up.

DISCUSSION: Hyperkinetic disorders like chorea and hemiballismus are rare manifestations of an acute CVA (0.5–1 %).¹ However, CVAs are the most common cause of acquired chorea and hemiballismus in adults. Other causes of non-genetic hemiballismus include non-ketotic hyperglycemia, encephalitis and vasculitis.² Movement disorders secondary to cerebral ischemia most commonly involve the contralateral lentiform nucleus, followed by the contralateral cortical, thalamic and subthalamic regions, although rare cases of ipsilateral subthalamic lesions with ipsilateral hemiballismus/hemichorea have been reported as well.^{2–3} Diagnosis involves the use of CT scan and/or MRI, the diagnostic yield of which can be improved by using MR angiography.⁵ Treatment of CVA-related hemiballismus follows conventional stroke guidelines with additional therapy for prevention of movement-disorder related injury.² Both neuroleptics and benzodiazepines have been shown to be successful in managing symptoms of excessive involuntary movements.⁴ Hemiballismus usually resolves within 2–3 months, but can take up to 1 year in some cases.² In rare refractory cases, stereotactic surgery and deep brain stimulation can be very successful in managing the symptoms.² Presence of such symptoms may delay the diagnosis of an acute stroke and the subsequent therapy. This case report underscores the need for a high level of suspicion for such cases to ensure timely and appropriate management. **References:** 1. Handley A, Medcalf P, Hellier K, Dutta D. PENILE PAIN: A PERPLEXING PRESENTATION Joshua Feuerstein²; Hao Feng¹. ¹Yale University, New Haven, CT; ²Yale-New Haven Hospital, New Haven, CT. (Tracking ID #2191729)

LEARNING OBJECTIVE #1: Recognize the presentation of metastatic cancer to the penis

LEARNING OBJECTIVE #2: Identify causes of penile pain

CASE: This is an 86 year-old male with a history of high grade recurrent bladder cancer and chronic urinary retention who presented to the hospital with intractable penile pain. In June 2013, he was incidentally noted to have high grade T1 bladder cancer during a TURP for BPH with two recurrences over the following year. In October 2014, he began having pelvic pain for which he made multiple visits to the Urology clinic and the Emergency Room. The pain was located on the ventral shaft of his penis without radiation. It was associated with hardening of the penis which progressively worsened over the next 2 months. He denied any fevers, chills, masses, skin changes, penile discharge, or new medications. Aspiration of the penis was attempted on two separate occasions to rule out priapism, however only scant blood was obtained. Imaging included an MRI of the pelvis which showed no evidence of penile fibrosis (although limited due to motion) and a penile ultrasound with dopplers which demonstrated mild skin thickening around the penile shaft with normal blood flow. No etiology was found and so he was prescribed acetaminophen/codeine and asked to follow with his primary care doctor for pain management. In late November he again presented to the ER for intractable penile pain, not responsive to IV medications, and was admitted to the medicine service for pain management. His medical history was significant for mild dementia and significant medications included trazodone. His exam was notable for a semi-erect and engorged penis, but was not painful to palpation. There was no skin change, rash, lymphadenopathy, discharge, or abnormal shape. Lab work was unremarkable, with a normal creatinine and normal urinalysis. A CT of the pelvis was obtained which showed left hydroureter, thickened bladder wall, and minimal subcutaneous edema of the penis without focal mass or drainable collection. Given the unclear diagnosis and intractable pain, the decision was made to do an exploration of the penis. Cystoscopy was unrevealing and exploration showed the spongiosum was enlarged and firm. However, biopsies of the periurethral and corporal tissue revealed high grade papillary urothelial carcinoma and FNA of an inguinal lymph node showed the same, providing the likely etiology of his pain. Body CT revealed metastatic disease to the bone and lung, along with enlarged pelvic and inguinal lymph nodes. The decision was made not to treat, but rather proceed with hospice care.

DISCUSSION: The differential diagnosis for penile pain should include emergencies such as priapism, fracture, and paraphimosis, along with less urgent conditions such as Peyronies disease, infection, neuropathy, and chronic pain syndrome. Malignancy must always be on the differential as well. Malignancy typically presents as a single or multiple infiltrative nodules, ulcerative lesions, induration, malignant priapism, and swelling of the penis. Other less common presentations include pain, hematuria, obstructive voiding symptoms, and pseudophimosis. Our patient presented with swelling and pain, without the typical skin changes or masses, illustrating the high index of suspicion needed for diagnosis. Penile metastatic lesions are rare, with approximately 400 cases reported as of 2006. Metastases to the penis are usually associated with disseminated neoplasm, and commonly affect the shaft or glans of the penis more than the prepuce. The most common primary tumors are urothelial bladder cancer and prostate adenocarcinoma, mainly spread via the retrograde venous route. The highest concern in our patient was for priapism. Malignant priapism, which presents as edema and rigidity, has been reported in between 20 and 53 % of patients with penile metastasis. The pathogenesis is due to infiltrative tumor cells causing venous occlusion or cavernosal thrombosis. This is different than true priapism, where there is actual tumescence of the corpora cavernosa. Treatment for malignant priapism is mainly restricted to surgery or radiation. As in our patient, metastatic penile lesions are usually associated with disseminated neoplasm, and unfortunately carry a poor prognosis (average life expectancy of 9 months). Our patient had presented to many different providers with complaints of pain with the actual diagnosis remaining elusive for months. It required exhausting all diagnostic tests and even proceeding to surgery before the etiology of his pain was eventually found.

PERSISTENT FEVER IN AN IMMUNOCOMPETENT PATIENT WITH A VENTRICULOPERITONEAL SHUNT Heidi Alvey¹; Sagger Mawri²; Jainil Shah². ¹Henry Ford Health System, Southgate, MI; ²Henry Ford Hospital, Detroit, MI. (Tracking ID #2198858)

LEARNING OBJECTIVE #1: Diagnosis and treatment of fungal meningitis in an immunocompetent patient

CASE: Patient is a 52 year old male presenting with a chief complaint of persistent fever. Patient has a past medical history of hypertension, hyperlipidemia, diabetes, coronary artery disease, and gender reassignment surgery (female to male) 30 years ago with testosterone supplementation. He initially presented to an outside facility 1 month prior with complaint of headache and dizziness. Imaging showed a cerebellar infarct, which subsequently developed significant hemorrhagic conversion. He underwent a suboccipital craniotomy for elevated intracerebral pressures with impending herniation. His course was complicated by obstructive hydrocephalus, which required the placement of a ventriculoperitoneal shunt, and vent dependent respiratory failure requiring a tracheostomy and gastrostomy tube placement. Through patient's course at the outside facility, he was persistently febrile, but had negative blood, urine, and respiratory cultures. Multiple courses of broad spectrum antibiotics were given without defervescence. Fever was thought to be of central origin. He was then transferred to a long term care facility. After transfer, patient was persistently febrile, and began to have worsening tachycardia, tachypnea, and hypotension. He was transferred from the care facility to the intensive care unit with concern of sepsis. On arrival, patient was afebrile, mildly tachycardic, and hypotensive. He was oxygenating well on minimal vent settings. Examination revealed rhonchi with thick tracheostomy secretions, regular heart sounds without murmur, non-tender and non-distended abdomen with clean and dry gastrostomy site. He was unresponsive, with only minimal flexion in his upper extremities to pain. A urinary catheter and upper extremity central venous catheter were in place with no signs of infection. Over the next 24 h, patient became persistently febrile and increasingly tachycardic. Cultures were taken from multiple sites and the patient was started on empiric broad spectrum antibiotics with vancomycin, cefepime, and metronidazole. Blood cultures were negative; urine culture grew candida that persisted even after catheter exchange. Respiratory cultures grew only commensal flora. Imaging of the chest, abdomen and pelvis did not show any evidence of pulmonary embolism or fluid collections. Imaging of the head showed an intact ventriculoperitoneal shunt and evidence of his previous stroke. Neurosurgery was consulted, and a lumbar puncture and tap of the shunt reservoir was done. The cerebrospinal fluid was xanthochromic with elevated protein, low glucose, and a leukocytosis with neutrophilic predominance. Both lumbar puncture and ventriculoperitoneal shunt cultures grew yeast, with negative viral and bacterial cultures. He was empirically started on amphotericin B and flucytosine, which was deescalated to high dose fluconazole after the organism was speciated to a pan-sensitive *Candida parapsilosis*. A retinal exam showed candida retinitis without vitritis. Echocardiography was negative for vegetations. HIV testing was negative. Repeat cerebrospinal fluid studies showed persistence of the candida species, so the patient was taken to the operating room for externalization of the shunt on hospital day 10. The patient did well postoperatively, and the external drain was clamped and subsequently removed on hospital day 16. Repeat cerebrospinal fluid specimens demonstrated clearing of the organism. Over the hospital course, patient became more alert and was moving extremities spontaneously. His fevers subsided after initiation of appropriate antimicrobial coverage. He was discharged to a nursing facility to complete an 8 week course of intravenous fluconazole.

DISCUSSION: *Candida parapsilosis* is an uncommon cause of meningitis in immunocompetent patient, usually affecting neonates, only rarely causing central nervous infections in adults. Risk factors for development of candidal meningitis include immunosuppression, malignancy, AIDS, corticosteroid use, prolonged usage of central venous catheter, and previous or current VP shunt. Studies in neonates have shown prolonged usage of externalized central devices like catheters or ventricular drains significantly increase the risk of candidal meningitis. *C. parapsilosis* is commonly found on the hands of healthcare workers, with one study showing colonization of up to 25 % staff. Consensus is lacking regarding treatment agents and duration. Several case reports indicate success using amphotericin B, flucytosine, and/or fluconazole. In the case of this patient, removal of the devices (central catheter and shunt) in addition to appropriate antimicrobial therapy lead to improvement in the patient's clinical status. It is important to keep a high index of suspicion for fungal infectious etiologies in the critically ill patient, especially when artificial devices are present.

PERSISTENT HYPOGLYCEMIA IN A YOUNG PATIENT WITH METASTATIC MALIGNANT PHEOCHROMOCYTOMA Farrell Tobolowsky. University of Texas at Houston, Houston, TX. (Tracking ID #2199636)

LEARNING OBJECTIVE #1: To recognize that pheochromocytoma can cause hypoglycemia in rare cases

CASE: C.W. is a 42 year-old male with no past medical history who presented to the hospital with worsening abdominal pain. The patient stated that the pain was located on the right side of the abdomen with radiation to the mid-back and right shoulder blade. Review of systems was positive for diaphoresis, night sweats, fatigue, facial swelling, intermittent headaches, palpitations, enlarged lymph nodes of the neck, decreased appetite and a 7-lb unintentional weight loss for the past 2 months. Family history was notable for prostate cancer and diabetes in his father. Physical examination showed facial edema,

bilateral submandibular lymphadenopathy, tachycardia, and tenderness to palpation in the right lower and upper quadrants. C.W. was admitted to the medicine team, and abdominal computed tomography showed a large right adrenal mass with areas of necrosis and cystic change as well as multiple lesions in the liver and retroperitoneal lymphadenopathy. Further investigation revealed extremely elevated urine metanephrines (1082 ug/24 h), confirming a diagnosis of pheochromocytoma. C.W.'s hospital course was complicated by persistent hypoglycemia despite nutrition supplementation, with postprandial glucose as low as 43. He was subsequently transferred to the intensive care unit (ICU) for higher level of care. While in the ICU, C.W. was started on a D10NS infusion, total parenteral nutrition, and tube feeds via a Dobhoff. Although the patient was eventually able to wean off the D10 infusion, he continued to rely on total parenteral nutrition to maintain normal glucose levels. Further workup for the etiology of C.W.'s hypoglycemia revealed low insulin (<0.5 uIU/mL), low c-peptide levels (0.19 ng/mL), and normal cortisol (19.3 ug/dL). Patient had an insulin-like growth factor II of 409 ng/mL and growth hormone level of 0.3 ng/mL, both values in the reference range. Preactalbumin was also found to be decreased at 11.7 mg/dL. The patient was started on prednisone per endocrinology recommendations, which helped to increase the patient's appetite. Symptomatic management of the pheochromocytoma was initiated with metoprolol, doxazosin, and diltiazem to control heart rate and blood pressure. The patient underwent three cycles of chemotherapy with cyclophosphamide, vincristine, and dacarbazine, unfortunately with minimal response.

DISCUSSION: According to the literature, patients with pheochromocytoma often have hyperglycemia due to excess catecholamine production. Additionally, 26 to 50 % of patients develop diabetes mellitus from impaired insulin release (Nove Press Med, 1981). However, some patients with a pheochromocytoma can instead have hypoglycemia after surgical removal of the tumor as catecholamines are decreased. Consequently, alpha and beta adrenoreceptors are no longer stimulated to increase glycogenolysis, gluconeogenesis, and inhibit insulin release (J Clin Invest, 1967). Few case reports have been published that illustrate hypoglycemia in these patients, even before resection of the tumor. In general, cancer patients are more likely to have hypoglycemia, with the most common mechanism being overproduction of insulin-like growth factor 2 (IGF-2) (Horm Res, 1994). Our patient had normal levels of serum IGF-2, making this mechanism an unlikely cause of hypoglycemia. Furthermore it is expected that low insulin and c-peptide levels would have predisposed the patient to hyperglycemia due to impaired uptake of circulating glucose. C.W.'s persistent hypoglycemia was thought to be secondary to poor oral intake for the two months before admission (as evidenced by low prealbumin), local effects of the tumor in the liver, and a large adrenal tumor burden. These patients often have a "limited hepatic glucose reserve secondary to tumor burden in the liver" as our patient did with his multiple liver lesions (Endocr, 2010). In one published case report, the use of F-2-fluoro-2-deoxy-D-glucose positron emission tomography/computed tomography (PET/CT) imaging illustrated increased direct uptake of glucose due to the metabolic activity of the tumor extensively infiltrating the body. Although our patient's hypoglycemia appears to be multifactorial and this imaging was not available in our facility, it would be useful in determining the cause of hypoglycemia in these patients with metastatic malignant pheochromocytoma. Although this case is rare, it is important to recognize that both local and metastatic pheochromocytoma can present with hypoglycemia instead of hyperglycemia.

PERSISTENT MYCOBACTERIUM ABSCESSUS INFECTION SECONDARY TO INTERFERON GAMMA AUTOANTIBODIES Roshni Naik; Jose A. Cortes. Beth Israel Medical Center, New York, NY. (Tracking ID #2200235)

LEARNING OBJECTIVE #1: Recognize that persistent nontuberculous mycobacteria infections may be due to an acquired immunodeficiency such as interferon gamma autoantibodies.

LEARNING OBJECTIVE #2: Recognize the prevalence of interferon gamma autoantibodies among the Asian population.

CASE: A 78 year old female of Filipino descent with chronic hepatitis C initially presented with back pain. Thorough evaluation of back pain revealed chronic thoracic osteomyelitis with bone biopsy culture growing *Mycobacterium abscessus*. The patient developed bacteremia despite several antimicrobial therapies including amikacin, azithromycin, ciprofloxacin, ertapenem, ethambutol, isoniazid, linezolid, meropenem, pyrazinamide, rifampin, and tigecycline. The patient underwent surgical removal of T11/12 vertebral body with titanium cage placement but remained persistently bacteremic. Given her multi-drug resistance, the patient was sent to National Institutes of Health for further evaluation, and was found to have interferon gamma autoantibodies. The patient received immunotherapy including rituximab and interferon alpha for five years, and consequently bacteremia cleared. The patient clinically improved and since then she has not had any nontuberculous mycobacteria infection.

DISCUSSION: Interferon gamma is important in providing protection against intracellular organisms such as mycobacteria, salmonella, and dimorphic mold. This cytokine stimulates

monocytes/macrophages, specifically by increasing their microbicidal activity, promoting antigen presentation function, and stimulating the production of proinflammatory cytokines on contact with microbial stimuli. There have been 29 case reports that described nontuberculous mycobacteria infection in non-HIV adult patients with interferon gamma autoantibodies. Majority of the cases involved patients of East and South East Asian descent, including Thai and Taiwanese population. These patients presented with severe disseminated infections, involving the lymph nodes, lungs, skin, bone marrows, bone, and/or soft tissue. The most commonly isolated mycobacterium were *Mycobacterium chelonae* and *Mycobacterium avium* complex. Other reported opportunistic organisms cited include Cytomegalovirus, *Burkholderia coccovenans*, *Aspergillus*, *Candida*, *Salmonella*, *Streptococcus pyogenes*, and *Mycobacterium tuberculosis*. These patients may have severe disease with prolonged course despite multiple antibiotics treatment. Studies have reported that treatment with interferon gamma, immune globulin, and plasmapheresis has been unsuccessful. This patient was included in a study in which rituximab was administered and resulted in the clearance of the infection, reduction in antibody titer, and improvement in interferon-gamma signaling. The activation for the production of interferon gamma autoantibodies is unknown, which warrants further investigation.

PITUITARY APOPLEXY: A RARE CLINICAL PRESENTATION OF RHABDOMYOLYSIS AND ALTERED MENTAL STATUS Nilsa M. Jimenez², Prashant Grover¹. ¹St.Francis Hospital and Medical Center, Hartford, CT; ²University of Connecticut Health Center, Manchester, CT. (Tracking ID #2198691)

LEARNING OBJECTIVE #1: Recognize an uncommon but life threatening cause of severe hyponatremia.

CASE: A 45 year-old orthodontist male with past medical history of hypertension presented to the emergency department with 1 day history of altered mental status and 10 days history of positional headache, fatigue, problem with manual dexterity and lower extremity muscle pain. Physical examination was unremarkable except for a temperature of 100.0 F, blood pressure of 173/57, and waxing waning mental status. Initial investigation revealed serum sodium of 108 mmol/L (135–145 mmol/L), which was likely the cause for the altered mental status and an elevated creatinine kinase (CK) at 4094 U/L (30–170 mosmo/kg). During hospitalization his CKs peaked to 16,000 associated with renal failure. He was initially treated with hypertonic saline which slightly raised his serum sodium and improved his mental status. A CT scan of the brain done to rule out other causes of altered mental status showed a small hypodensity in the right basal ganglia region. A follow up MRI of the brain showed a pituitary adenoma with increase signal intensity consistent with hemorrhage confirming the diagnosis of pituitary apoplexy. Endocrinological evaluation revealed a low TSH, ACTH, cortisol, FSH, LH and GH consistent with hypopituitarism and secondary adrenal insufficiency due to apoplexy. He was immediately started on stress dose steroid, hydrocortisone 100 mg every 6 h until his sodium remained above 120 mmol/L as well as thyroid replacement with dramatic return to baseline. He was seen by neurosurgery as an outpatient and underwent a transnasal endoscopic resection of the pituitary adenoma. Pathology revealed a macroadenoma with fresh hemorrhage.

DISCUSSION: Pituitary apoplexy is uncommon but is life-threatening condition if overlooked. More uncommon is to see rhabdomyolysis in pituitary apoplexy. It is not unusual to see hyponatremia in hypopituitarism; this could be a form of secondary syndrome of inappropriate antidiuretic hormone (SIADH) or it could be secondary to subnormal secretion of aldosterone. However, it is a rare presentation to see rhabdomyolysis in patients with hypopituitarism and to date there is very limited data on this topic. There have been isolated case reports linking hypothyroidism with spontaneous rhabdomyolysis due to hypothyroid myopathy. Another explanation could be water intoxication due to cortisol deficiency in hypopituitarism. Cortisol has a significant effect on body water regulation by regulating the extra cellular fluid preventing the water moving into cells. Once this process is inhibited, water intoxication causes cellular edema and lysis of the muscle cells. Hence, serum chemistry, cortisol, and creatinine kinase level should be checked to prevent organ damage such as acute kidney injury. Remembering the patient with hypopituitarism and adrenal insufficiency secondary to pituitary apoplexy can present with rhabdomyolysis and hyponatremia is important and timely management is crucial to reduce mortality.

PLEURAL MYCOBACTERIUM AVIUM COMPLEX INFECTION IN AN IMMUNOCOMPETENT YOUNG FEMALE WITH NO RISK FACTORS Ravi P. Mangani; MIsbahuddin Khaja; Karen Hennessey; Omonuwa Kennedy. Lincoln Medical Center, New York, NY. (Tracking ID #2198030)

LEARNING OBJECTIVE #1: Lymphocytic Predominant Pleural Effusions Must raise suspicion of Mycobacterial Disease

LEARNING OBJECTIVE #2: In case of Mycobacterial Lung disease, If preliminary Investigations are unyielding, Pleural Biopsy Must be Pursued to make the diagnosis. Yield from Cultures of PLeural Fluid are not always reliable.

CASE: *Mycobacterium Avium* Complex (MAC) infections rarely affects the pleura, accounting for 5-15 % of pulmonary MAC. There is paucity of reports of pleural MAC infection in the immunocompetent population. We report a case of MAC pleurisy and pleural effusion in an otherwise immunocompetent young patient with no predisposing factors. Our case is a 37 year old healthy female with no past medical history who was admitted to the hospital with 2 weeks of right sided pleuritic chest pain, productive cough and fever after a trip to Algeria. She denied history of ill contact. On exam she was febrile, tachycardic, tachypneic with signs of right sided pleural effusion which were confirmed by Chest X-ray and chest CT. Thoracentesis revealed lymphocytic predominant exudative fluid. The patient was placed on respiratory isolation for suspicion of mycobacterial tuberculosis infection until ruled out, three days later. The patient underwent pleural biopsy, Bronchoscopy with Broncho-Alveolar Lavage and Video Assisted Thoracoscopic Surgery (VATS), all of which failed to identify the causative organism. Six weeks later, MAC was identified in the pleural fluid and pleural biopsy samples. Based on these results, patient was started on clarithromycin, ethambutol, rifampin and isoniazid. After 6 months of treatment, she was asymptomatic with complete resolution of the right pleural effusion. She continues to have therapy to complete a 12 month regimen and has remained asymptomatic to date.

DISCUSSION: Pleurisy and pleural effusion caused by MAC in an immunocompetent host is rare and can prove to be a diagnostic challenge for physicians. The presence of lymphocytic effusion should raise the suspicion for both tuberculous and nontuberculous mycobacterial disease and pleural biopsy must be considered to make the diagnosis. The exact pathogenesis of MAC pleurisy remains obscure and possibilities include entry of MAC into the pleural fluid through a transient bacteremia, or contiguous spread from a sub-pleural focus. Clinicians should have a high index of suspicion of MAC infection in an otherwise immunocompetent patient presenting with a unilateral lymphocytic exudative effusion.

POETRY IN DIAGNOSIS: A CASE OF POEMS SYNDROME Simeng Sun; Carolina Bernabe; Matthew Harrington. Mount Sinai Beth Israel, New York, NY. (Tracking ID #2200340)

LEARNING OBJECTIVE #1: Recognizing POEMS syndrome in patients with multiorgan dysfunction

CASE: Seventy-seven year-old male with systolic heart failure (EF 28 %), hypothyroidism, and CKD stage 3 presented with dyspnea on exertion and paresthesias in all four extremities. Physical exam revealed anasarca. CT scan of chest/abdomen/pelvis revealed large volume ascites, pericardial and pleural effusions. Transthoracic echocardiogram revealed large pericardial effusion without evidence of tamponade physiology. Initial labs revealed hemoglobin 12.4 g/dL, BUN 54 mg/dL, Cr 4.01 mg/dL, Albumin 3.6 g/dL. Paracentesis was performed and 10 l of ascites was removed; SAAG of 1.8 indicated portal hypertension to be the etiology of the ascites. Abdominal ultrasound revealed hepatic steatosis, normal kidneys, and patent portal vein. Viral hepatitis panel and HIV screen were negative. Serum immunofixation revealed monoclonal gammopathy with IgM lambda spike. Serum free kappa/lambda ratio was normal. Abdominal fat pad biopsy ruled out amyloidosis. Bone marrow biopsy demonstrated no plasma cell dyscrasia. Serum vascular endothelial growth factor (VEGF) level was found to be elevated on ELISA (120). The patient fulfilled criteria for POEMS syndrome (polyneuropathy, organomegaly, endocrinopathy, monoclonal protein, skin changes) based on polyneuropathy, monoclonal IgM lambda gammopathy, elevated serum VEGF and volume overload. The patient's hospital course was complicated by perforated cholecystitis, peritonitis, and liver abscess, which was treated with drainage and antibiotics.

DISCUSSION: POEMS syndrome is a rare multisystem disorder with unclear etiology and variable clinical presentation. Diagnosis of POEMS syndrome is challenging. The Mayo Clinic criteria for diagnosis of POEMS syndrome require peripheral neuropathy and monoclonal plasma cell disorder. In addition, patients must fulfill 1 of 3 major criteria (osteosclerotic bone lesions, elevated VEGF or Castleman's disease), and 1 of 6 minor criteria (endocrinopathy, skin changes, organomegaly, extravascular volume overload, thrombocytosis/polycythemia or papilledema). Although no standard treatment currently exists for POEMS syndrome, early therapy may begin upon diagnosis, ideally prior to multi-organ involvement. Treatment may include hematopoietic stem cell transplant, radiation, and chemotherapy (i.e. Melphalan plus dexamethasone or agents such as Lenalidomide, Thalidomide or Bortezomib). Unfortunately, our patient's disease was advanced on presentation; he agreed only to supportive therapy. POEMS syndrome is often misdiagnosed or under-diagnosed due to its rarity and complexity. This diagnosis should be considered in patients with multi-organ system dysfunction of unclear etiology.

POLYARTICULAR GOUT FLARE MASQUERADING AS SEPSIS Deep Shah¹; Gopi Mohan¹; Peter Fleuckiger²; Frank Corrigan¹; Doyt Conn¹. ¹Emory University School of Medicine, Atlanta, GA; ²Wake Forest School of Medicine, Winston-Salem, NC. (Tracking ID #2154169)

LEARNING OBJECTIVE #1: Recognize that acute gout may trigger a non-infectious systemic inflammatory response syndrome

LEARNING OBJECTIVE #2: Identify the clinical pitfalls in distinguishing between acute and chronic gouty arthritis

CASE: A 64-year-old African American man with a history of chronic tophaceous gouty arthropathy, hypertension, and stage 3 chronic kidney disease presented with 4 days of severe pain in his left foot and ankle associated with fevers, fatigue, and weakness. He denied a history of recent trauma, illness, sexual activity, or new medications. The patient reported recently completing two courses of corticosteroids for acute gout flares. On physical exam, he was uncomfortable and diaphoretic. His vitals showed a temperature 38 °C, pulse 126 beats per minute, blood pressure 141/86 mmHg, and respiratory rate 14 breaths per minute. Purulent-appearing material drained from open wounds on the first and fourth toes of the left foot. The whitish exudate and soft tissue swelling obscured a probe-to-bone test. In addition to the left foot and ankle, his left metatarsophalangeal joints, left ankle, right ankle, and several proximal interphalangeal joints were warm and mildly tender to palpation. Bilateral olecranon-bursa nodules were appreciated. Laboratory findings revealed a white blood cell count 18,700/ μ L (16.5 K/ μ L bands), CRP 42.5 mg/L, and ESR 120 mm/hr. Plain film radiography of the left foot was concerning for osteomyelitis of the first toe. The patient was initially managed for sepsis secondary to osteomyelitis and a possible superimposed cellulitis. Despite broad-spectrum antibiotics and intravenous fluid resuscitation, the patient remained febrile and tachycardic with a persistent leukocytosis. General surgery was consulted for potential operative intervention given the presumed diagnosis of left great toe osteomyelitis. Further evaluation with magnetic resonance imaging of his left foot and ankle showed nonspecific inflammatory changes without clear evidence of osteomyelitis. In addition, gram stain and culture of the exudate from his open wounds was negative for microorganisms. Examination of the purulent-appearing material under polarized light microscopy revealed copious negatively birefringent urate crystals. Oral prednisone was initiated and antibiotic therapy discontinued. The patient's fever, tachycardia, and pain in all affected joints improved rapidly. Blood and wound cultures remained sterile.

DISCUSSION: The differential diagnosis for acute polyarthritis associated with constitutional symptoms and abnormal vital signs is fairly narrow. Our patient's presentation was not consistent with a viral infection triggering a reactive arthritis or a new drug exposure precipitating serum sickness. Crystal-induced arthritis may present with pain in multiple joints; however, in patients with a history of poorly controlled gout, distinguishing acute and chronic features of their disease process is challenging and fraught with clinical pitfalls. This case illustrates an acute polyarticular gout attack with systemic inflammatory response syndrome (SIRS) masquerading as sepsis. Distinguishing these two entities, which often present with similar findings, is challenging for several reasons. First, our patient's previous flares were not associated with abnormal vital signs, drainage of purulent-appearing material, or radiography suggestive of osteomyelitis. Polyarticular gout flares, though, may present as pseudosepsis, characterized as a systemic inflammatory response due to a non-infectious etiology. In mouse models, it has been demonstrated that monosodium urate crystals, serving as danger signals, can activate the intracellular inflammasome complex. This triggers release of cytokines and ultimately a sterile systemic inflammatory response. A similar mechanism has been postulated for pseudogout-induced SIRS. In addition, on physical exam, liquefied monosodium urate crystals may be mistaken for purulent exudate as seen in this case. Finally, chronic tophaceous gout leads to nonspecific inflammatory changes in bones and joint spaces that may appear similar to osteomyelitis on plain film radiography and mimic a source of infection. In patients suffering from chronic tophaceous gout, it is important to recognize that polyarticular gout attacks can induce a SIRS response without an associated infection. As exam and imaging findings may be unreliable, microscopic examination of exudates or synovial fluid with both polarized light microscopy and gram stain is necessary to distinguish this entity from sepsis due to osteomyelitis or other infectious sources. Early recognition may prompt a trial of corticosteroids, thereby avoiding unnecessary antibiotic therapy or surgical intervention. Finally, while both gout and infectious etiologies may initially respond to corticosteroids, sustained improvement off antibiotics with sterile wound and blood cultures indicates a non-infectious process driven by crystal-induced inflammation.

POLYARTICULAR SEPTIC ARTHRITIS AND SELECTIVE IGM DEFICIENCY Tareq Khader; Keyvan Ravakhah. SVCMC, Cleveland, OH. (Tracking ID #2199317)

LEARNING OBJECTIVE #1: Recognize polyarticular septic arthritis

LEARNING OBJECTIVE #2: Diagnose underlying immunodeficiencies in patients with unusual infections

CASE: A 70-year-old lady came to our facility with a painful swollen left knee associated with fever for the past 4 days. She had a history of severe osteoarthritis for which she underwent bilateral knee replacement several years ago. Upon first encounter her

temperature was recorded at 37.7. Her left knee was swollen, erythematous and severely tender with restricted range of motion. Her examination was also remarkable for decreased air entry on the left side with dry basal crackles. No murmurs were appreciated. Arthrocentesis of the left knee revealed 174,000 nucleated cells, and gram positive cocci in pairs. She was started on Ceftriaxone and Vancomycin immediately after the arthrocentesis. The following day she experienced right knee pain, swelling and redness and left shoulder tenderness with restricted range of motion. Both joints were drained. The fluid analysis in the right knee showed a total number of nucleated cell of 197,000, and the left shoulder fluid showed a total number of 79,000 nucleated cells. Both fluids showed gram positive cocci in pairs. The three fluid samples and blood cultures grew streptococcus pneumoniae, sensitive to ceftriaxone. Antibiotics were changed to ceftriaxone. We conducted a search for the source of the streptococcus pneumoniae. A chest CT scan showed chronic, unchanged emphysematous changes on the left lung, but no consolidation was noted. The spleen was clearly seen at the lower cuts of the scan. A trans-esophageal echocardiogram did not reveal any vegetations. Further more, we decided to assess her immune system. She was HIV negative. Her immunoglobulin profile showed normal IgG 1 and IgG 2 and slightly elevated IgG 3 and IgA. Her IgM was significantly reduced at 5. A diagnosis of selective IgM deficiency which put her at a higher risk of unusual gram positive infections was made. She was treated with extensive debridement and prolonged antibiotic therapy. Patient continued to improve and was discharged on ceftriaxone for a total of 6 weeks.

DISCUSSION: Polyarticular septic arthritis has 3 times more mortality risk than myocardial infarction, and the survivor frequently ends up with severe disabilities. It was well known that about 50 % of the cases have an obvious source of their infection. In one case series of 25 patients with polyseptic arthritis which accounted for about 16 % of the total cases of septic arthritis, mortality rate was 30 %, compared to 4 % with monoarticular septic arthritis. Selective IgM deficiency is a rare, mainly acquired and not congenital in adults. Our patient denied any history of recurrent infections of any type during childhood. Majority of acquired selective IgM deficiency are associated with another condition, including hematological and solid malignancies and certain immunological disorders like SLE and RA. Our patient did not have any known history of above disorders but she was recommended to undergo cancer screening as an outpatient.

POLYMICROBIAL FECULENT EMPYEMA: AN UNUSUAL COMPLICATION OF COLON CANCER Dov Shalman; Randall Edson. California Pacific Medical Center, San Francisco, CA. (Tracking ID #2192334)

LEARNING OBJECTIVE #1: Diagnose the underlying cause of polymicrobial empyema.

LEARNING OBJECTIVE #2: Recognize colo-pleural fistula as a possible complication of bowel perforation due to colon cancer, IBD, or other colonic pathology.

CASE: A 72-year-old man with a long history of alcohol abuse but minimal previous contact with health care professionals was brought to the emergency department with progressive left chest and abdominal pain and diarrhea following a fall that occurred 1 week before admission. On admission, he was found to have a loculated pleural effusion with mediastinal shift on chest X-ray and CT chest, concerning for either hematoma or empyema. A thoracentesis was attempted under ultrasound guidance without success, so a chest tube was placed by interventional radiology. Pleural fluid culture was positive for Escherichia coli (pan-sensitive) and Streptococcus constellatus, and the patient was treated initially with 16 days of piperacillin/tazobactam, then 10 days of Penicillin G, and then an additional 8 days of piperacillin/tazobactam. Abdominal CT scan demonstrated thickening of the splenic flexure wall as well as a lobular mass within the splenic flexure of the colon suggesting a carcinoma of the colon with perforation. Colonoscopy was performed, and biopsy confirmed the diagnosis of adenocarcinoma at the splenic flexure. The patient was taken to surgery for extended left colon and partial sigmoid resection, and the surgery team noted near-complete luminal obstruction and perforation. The patient had a prolonged recovery from this procedure, but ultimately underwent decortication of his left lung. At the time of decortication he was noted to have a feculent empyema, which the cardiothoracic surgeons determined was due to colo-pleural fistula. He had a prolonged recovery in the hospital and was ultimately transferred to a skilled nursing facility.

DISCUSSION: Colon cancer is most often diagnosed on routine screening or as a result of evaluation for GI bleeding or obstructive symptoms. This case illustrates an unusual presentation of complicated colon cancer, with perforation at the splenic flexure and contiguous involvement of the pleura via a colo-pleural fistula, resulting in a polymicrobial empyema. A major clue to the diagnosis was the finding of enteric flora in the pleural space, which should always prompt clinicians to search for an intraabdominal source.

PREGNANCY, A STRESS TEST FOR THE THYROID Amy Chen. UCSF, San Francisco, CA. (Tracking ID #2199778)

LEARNING OBJECTIVE #1: Manage subclinical hypothyroidism in adults, during pregnancy, and recognize the relationship of subclinical hypothyroidism with infertility

LEARNING OBJECTIVE #2: Diagnose the different stages of postpartum thyroidism and recognize the need to screen for permanent hypothyroidism after resolution of thyroiditis

CASE: The patient is a previously healthy 34 year-old woman who presented to clinic with palpitations. She was 5 months postpartum and noticed intermittent palpitations for the past month. She denied feeling anxious, tremor, sweating, heat intolerance, or diarrhea. Her exam was only notable for a mild tachycardia with a heart rate of 100 with no thyromegaly, nodules, or lid lag, skin or eye changes. Her initial workup revealed a low TSH <0.03 and elevated free T4. Her thyroid receptor antibodies (both TSI and TBII) were negative and thyroperoxidase (TPO) antibodies were positive. Two months later, her palpitations have completely resolved and a repeat TSH was now elevated to 6.6 and the free T4 was low. She was prescribed thyroid hormone replacement but because she was feeling well, she did not start the medication. Another month passed, and her TSH is higher at 10.7, free T4 at the low end of normal, but TPO antibodies were even higher. At this point, she started thyroid hormone replacement and one month later, both her TSH and free T4 had normalized.

DISCUSSION: Subclinical hypothyroidism is defined as an elevated TSH but normal free T3 and T4 levels. It is currently recommended to treat this condition, which is usually asymptomatic, when the TSH is greater than 10, in patients who have a high risk of progressing to overt hypothyroidism (for example, individuals with a family history of thyroid disease or with a positive TPO antibody), during pregnancy, and in women who are desiring pregnancy with a TSH greater than 2.5. A TSH greater than 2.5 has been associated with decreased fertility and there have been studies to suggest the optimal TSH range for achieving pregnancy is between 0.5 to 2.5. Therefore, it is recommended to screen for subclinical hypothyroidism when working up infertility. At this time universal TSH screening is controversial and there is insufficient evidence for universal screening of women preconception or during pregnancy. Hypothyroidism during pregnancy is associated with both maternal (preeclampsia, maternal hypertension, postpartum hemorrhage, placental abruption) and fetal (low birth weight, fetal demise, preterm delivery, impaired development) complications. If a woman has been diagnosed with subclinical hypothyroidism prior to pregnancy, she is at higher risk for developing overt hypothyroidism during her pregnancy and she should be treated if her TSH is greater than 2.5. Experts recommend a narrower TSH range during pregnancy with trimester specific goals (0.1 to 2.5 during the first trimester, 0.2–3.0 in the second trimester, and 0.3–3.0 during the third trimester). If a woman is already on thyroid hormone replacement prior to pregnancy, more than half of these women will need to increase their dosing and may need a 30 to 50 % in their medication. Women with limited thyroid reserve, iodine deficiency, or underlying Hashimoto's thyroiditis but are euthyroid prior to conception may develop hypothyroidism during their pregnancy. This patient initially presents with symptoms and laboratory data consistent with thyrotoxicosis. Postpartum thyroiditis is the most common form of thyrotoxicosis in the postpartum period. A hyperthyroid phase occurs in the first 6 months and usually resolves spontaneously and is followed by hypothyroidism. The American Thyroid Association recommends screening women who are diagnosed with postpartum thyroiditis in the hyperthyroidism phase with a TSH every 2 months to diagnose the hypothyroidism phase. The majority of women return to euthyroidism 1 year post partum. However, 10 to 20 % of women who return to euthyroidism will eventually develop permanent hypothyroidism. Therefore, experts recommend that women who recover from postpartum thyroiditis be screened yearly with a TSH to evaluate for permanent hypothyroidism.

PREVENTING A PRION PROBLEM: DIAGNOSING AND LIMITING TRANSMISSIBILITY OF CJD IN THE HOSPITAL SETTING Sheena Mathew. NYP Cornell, New York, NY. (Tracking ID #2193686)

LEARNING OBJECTIVE #1: Diagnose patients with dementia and motor deficits with Creutzfeldt-Jakob disease

LEARNING OBJECTIVE #2: Prevent transmission of CJD disease in the hospital setting

CASE: Sixty-six year old female without any past medical history presents with 2 months of progressive gait instability, confusion and memory loss. Her inability to concentrate forced her to leave her job, and new leg weakness and numbness lead to two falls without prodromal symptoms or loss of consciousness. She reported new depression, insomnia and urinary incontinence. She denied fevers, recent travel history, or sick contacts. Her family was concerned about her worsening functional status and brought her into the ED after a negative outpatient workup. She was not taking medications, and has no family history of neurodegenerative diseases. On admission she was afebrile with normal vital signs, a well-nourished female with normal cardiopulmonary and abdominal exam. Strength was 5/5 in all extremities with cogwheel rigidity in bilateral upper extremities and increased tone. Proprioception and cranial nerves were intact, but gait was unsteady, falling backwards when attempting to walk. She was oriented to herself and place, but unable to state the date. Labs found a normal CBC, BMP, folate, copper, TSH ESR, CRP,

negative RPR and borderline low thiamine and vitamin B12. Blood and urine cultures negative. Head CT did not find hydrocephalus, mass, or midline shift. CT chest abdomen and pelvis was negative for malignancy. MRI of the brain found abnormal diffusion gradient in the deep grey matter, and the cerebellum. EEG showed frontotemporal slowing. Lumbar Puncture with special precautions was positive for 14-3-3 and tau protein. She continued to decline during the hospitalization and was bedbound and mute after 2 weeks with new myoclonus. Brain biopsy found vacuolar changes and western blot was positive for PrPsc confirming the diagnosis of CJD. Patient was discharged home with hospice services

DISCUSSION: Creutzfeldt-Jakob disease is a progressive and fatal neurodegenerative disorder that affects approximately one in a million patients per year. This spongiform encephalopathy is due to accumulation of a misfolded prion protein, PrPsc. In the majority of cases there is no identifiable exposure and is considered to be sporadic CJD. Although rare, CJD should be kept in the differential when evaluating patients, particularly age 50s to 60s with a rapid decline in functional status. Patients will exhibit a progressive dementia with one or many of the following symptoms: myoclonus, visual or cerebellar signs, pyramidal/extrapyramidal symptoms, and akinetic mutism. Workup should include a MRI, EEG, and also a lumbar puncture. Typical MRI findings include T2 intensity of the basal ganglia, cerebellum and cortex and restricted diffusion in those areas on DWI. EEG will show spike and wave complexes and possible diffuse slowing, while the CSF fluid will be positive for 14-3-3 and tau protein. According to the CDC criteria, a brain biopsy is the gold standard for diagnosis. However probable CJD can be established with two out of four of classic symptoms and one of three of the above tests positive for CJD. When caring for patient with suspected CJD all caretakers need to be educated on the potential risk of iatrogenic transmission, but only standard universal precautions are required for routine care of these patients. This includes phlebotomy as blood is considered a low infectivity fluid. Corneal tissue, CSF, and brain tissue are considered higher infectivity fluids and do require extra precautions because prion proteins are not killed by standard chemical and antibacterial methods. The WHO has guidelines for sterilizing materials contaminated with high infectivity fluids. No cases of CSF transmission have been reported. The highest rates of iatrogenic transmission actually are found in dural transplant grafts and cadaveric pituitary hormones recipients. Awareness and abiding by protocols make transmission in the hospital setting highly unlikely but caution should be taken when dealing with high infectivity fluids to mitigate risk.

PRIMARILY SUSPECT CHOLANGIOCARCINOMA Allison L. Ramsey¹; Maria Otazo¹; Andrew Caruso¹; Jeffrey T. Bates². ¹Baylor College of Medicine, Houston, TX; ²VA Medical Center, Houston, TX. (Tracking ID #2200185)

LEARNING OBJECTIVE #1: Recognize common malignancies associated with Ulcerative Colitis and Primary Sclerosing Cholangitis

LEARNING OBJECTIVE #2: Understand disease screening protocols for patients with Ulcerative Colitis and Primary Sclerosing Cholangitis

CASE: A 30 year old female with well controlled Ulcerative Colitis (UC) on Mesalamine and Azathioprine presented with 1-week history of right upper quadrant abdominal pain, subjective fevers, nausea and emesis. She denied diarrhea, change in pain with food intake, and no medications helped with her symptoms. She was afebrile (99.6 F) upon presentation with physical exam notable for an ill appearing, jaundiced woman with positive Murphy's sign and severe tenderness in the right upper quadrant. Lab abnormalities included elevated Alkaline Phosphatase (522), ALT (266), AST (144), Total/Direct Bilirubin (4.1/3.6) with no leukocytosis (8.8). Abdominal ultrasound showed a hydropic gallbladder with MRCP significant for beading and narrowing of the common bile duct to 1.2 cm with adjacent soft tissue mass. Further imaging with CT abdomen revealed a 1.6×2.1×2.3 hypodense soft tissue prominence surrounding the extrahepatic common bile duct. These findings were consistent with Primary Sclerosing Cholangitis (PSC) and possible extrahepatic Cholangiocarcinoma (CCA). For diagnosis and relief of her biliary obstruction, ERCP was subsequently performed with biliary stent placement. Fine needle aspiration of the mass revealed adenocarcinoma, consistent with CCA. Her hospital stay was complicated by cholangitis secondary to Extended Spectrum Beta Lactamase (ESBL) E. coli, which delayed further treatment of her malignancy. Follow up CT abdomen 3 weeks later showed increased size of the mass to 3.2×2.6×4.4 cm, with encasement of the portal vein and infiltration of the pancreas. Given the proximity of her tumor to these critical structures, the patient was not a surgical candidate. She was started on induction chemotherapy with Cisplatin and Gemcitabine upon completion of 14 days of Meropenem treatment for her cholangitis

DISCUSSION: This case highlights the importance of suspecting complications such as PSC in patients with UC as well as understanding cancer surveillance recommendations for this population. About 5 % of patients with UC will develop PSC, with associated increased risk of malignancies, such as cholangiocarcinoma and colorectal cancer. Although there is no screening protocol for PSC in patients with UC, PSC can be expected in

individuals with raised alkaline phosphatase, positive pANCA, and the classic “beading” of the common bile duct on MRCP. Colorectal surveillance for patients with UC is established with a screening colonoscopy and extensive biopsies within 8 years of diagnosis. In UC patients who also develop PSC, colonoscopy should be done at the time of diagnosis and annually thereafter. Unfortunately, CCA surveillance is limited, with no currently recommended biochemical marker or imaging modality. ERCP with brush cytology/biopsy sampling has been suggested along with certain serum biomarkers (CA-19-9), but none have been validated, as malignancy is often missed with these methods. Treatment of CCA includes liver transplantation in those with early stage disease, as well as chemotherapy and radiation before surgery to reduce the tumor size.

PRIMARY CARE PEARLS AND PERILS: FIBER SUPPLEMENTATION AND RETROGRADE ENEMAS IN AN ELDERLY PATIENT WITH CHRONIC CONSTIPATION Denzil Etienne; Osei Whyte. SUNY Upstate Hospital, Syracuse, NY. (Tracking ID #2189777)

LEARNING OBJECTIVE #1: Assess constipation—a commonly encountered problem in the elderly—and its management, particularly the indication and perils of fiber supplementation and retrograde enemas in this population.

CASE: A 91 year old Caucasian male was transferred from an outside hospital for rectal bleeding. His past medical history was significant for chronic constipation, hypertension, hyperlipidemia and benign prostatic hyperplasia. The patient reported that he was constipated for the past 3 weeks despite taking daily fiber (polycarbophil) supplementation prescribed by his primary care physician (PCP). He also complained of poor oral intake during this time. His constipation progressively became worse leading his PCP to recommend an over the counter bisacodyl enema which was self-administered. This was the first time the patient had used a retrograde cleansing enema. Self-administration of the enema was followed by bright red blood per rectum as well as severe rectal pain. The patient was brought to the ED where CT of the abdomen and pelvis demonstrated evidence of rectal perforation. He subsequently underwent laparoscopic transverse colectomy. Further clinical course of the patient was uneventful and he was discharged after an 8-day inpatient stay.

DISCUSSION: In the primary care setting, chronic constipation is the second most common digestive complaint particularly in older adults greater than 65 years and is associated with lower quality of life and poorer health outcomes in this population. Fiber supplementation (organic polysaccharides) such as psyllium (eg. Metamucil), methylcellulose (eg. Citrucel), polycarbophil (FiberCon) and wheat dextrin (Benefiber) is frequently prescribed by primary care physicians for the initial treatment of chronic constipation. Fiber supplements generally increase the stools ability to absorb water, but if consistently taken by constipated patients with inadequate fluid intake, they are unable to effectively increase intraluminal volume via water retention and may paradoxically lead to inspissated or hardened stool. Moreover, it has been shown that fiber supplements may worsen symptoms of constipation in patients with slow transit constipation or dyssynergic defecation. Rectal perforation due to self-administration of retrograde enemas is a rarely reported but potentially life-threatening phenomenon. Even in the absence of disease, the rectal wall can be perforated by introduction of a rubber catheter tip for the purpose of administering a cleansing enema. Primary care providers may consider tailoring individualized instructions (eg. video/in-office demonstration) for elderly patients or recommending assistance from a family member/health aide—as this population is more likely to lack the dexterity to self administer enemas in a safe and effective manner

PRIMARY MALIGNANT MELANOMA OF UTERINE CERVIX SIMULATING CERVICAL CARCINOMA Shourya Tadisina¹; Joseph Ramzy¹; Anteneh Tesfaye²; Phani Akella¹; Ujwala Koduru¹; Orimisan Adekolujo¹; Susan J. Smith¹; Radhika Kakarala¹; Madan Arora¹. ¹McLaren Flint, Michigan State University, Flint, MI; ²Medstar Georgetown University Hospital, Washington, DC. (Tracking ID #2199368)

LEARNING OBJECTIVE #1: Recognize the possibility of a primary malignant melanoma of the uterine cervix in patients presenting with postmenopausal vaginal bleeding and a cervical mass.

CASE: A 71 year old Caucasian female, para-4, with no significant past medical history presented with postmenopausal vaginal bleeding for 1 week. Pelvic examination and ultrasound revealed a 3.5×3.4×2.6 cm cervical mass. Biopsy was initially reported as invasive, poorly differentiated carcinoma consistent with non-keratinizing squamous cell carcinoma of the cervix. CT abdomen and pelvis revealed no pelvic lymphadenopathy. She underwent a robotic radical hysterectomy and bilateral salpingo-oophorectomy with resection of parametrium and pelvic lymph nodes. Surgical pathology report was consistent with primary malignant melanoma of the cervix with immunostains strongly positive for vimentin, S-100 and MART-1 with no involvement of the resected lymph nodes. BRAF mutation was negative. A second review of the previous biopsy slides confirmed

malignant melanoma. Post-operative PET scan, brain MRI and CT chest were negative for metastasis. Final diagnosis was primary malignant melanoma of the cervix, FIGO stage IIB. She was followed with regularly scheduled pelvic examinations and PET scans every 3 months with no additional treatment. After 7 months of follow-up, she developed urinary incontinence; cystoscopy revealed a vesico-vaginal fistula. At exploratory laparotomy she was found to have multiple pelvic masses involving the small bowel, omentum, bladder wall and vaginal cuff. The histopathology of the resected masses was consistent with metastatic malignant melanoma. She was treated with 4 cycles of ipilimumab and she remained in complete remission for 32 months.

DISCUSSION: Primary mucosal melanomas arise from melanocytes located in the mucosal lining of respiratory, urogenital and gastrointestinal tract and account for 1 % of all melanoma. About 2 % of these lesions originate in the female genital tract, of which cervical melanomas are extremely rare. Primary malignant melanoma of the cervix is more aggressive with a worse prognosis than cervical carcinoma. It is seen in postmenopausal women who commonly present with vaginal bleeding or vaginal discharge similar to cervical carcinoma. In our patient, an initial histology was erroneously reported as poorly-differentiated squamous cell carcinoma of the cervix. Though rare, physicians must include primary malignant melanoma of the cervix in their differential because its behavior, treatment options and follow-up are extremely different than cervical carcinoma. The prognosis of primary malignant melanoma of the cervix is dismal regardless of the stage at diagnosis and treatment; mean overall survival was 22.9 months for cases reported in the literature. Our patient remained in complete remission for 32 months after treatment of her recurrent metastatic disease with ipilimumab, highlighting the benefit of immunotherapy in a subset of patients with primary mucosal melanoma.

PROCTITIS AMONG MSM: EXPANDING THE DIFFERENTIAL DIAGNOSIS

Sarah J. Knish. UCSF, San Francisco, CA. (Tracking ID #2199558)

LEARNING OBJECTIVE #1: Explore the differential diagnosis for proctitis in men who have sex with men (MSM)

LEARNING OBJECTIVE #2: Diagnose and treat patients presenting with lymphogranuloma venereum

CASE: A 35yo man presented to clinic complaining of bloody rectal discharge for approximately 1 month, consisting of streaks of blood with bowel movements. He reported mild rectal discomfort with defecation. He reports no fevers or chills, no abdominal pain, no nausea, vomiting, diarrhea or constipation. He has a prior history of syphilis, gonococcal (GC) urethritis and Chlamydia trachomatis (CT), all with documented treatment and clearance at the time of presentation. He has no family history of inflammatory bowel disease or cancer. He endorses no recent travel or camping. He is sexually active with men; he reports receptive and insertive anal intercourse as well as oral sex. He has had 7 partners in the last 3 months and rarely uses condoms. On exam, his vital signs were normal; rectal examination revealed no external ulcerations or fissure, no hemorrhoids, induration or fluctuance. He experienced severe pain with insertion of anoscope, but no ulcerations or active bleeding was seen. The patient was treated empirically for rectal GC/CT with 250 mg IM ceftriaxone and 1 g oral azithromycin; laboratory testing returned the following day with a positive result from rectal swab transcription-mediated amplification (TMA) testing for Chlamydia. The patient returned 5 weeks later, now reporting severe, constant rectal pain and purulent, foul rectal discharge. Additionally, he had developed a deep aching pain that had moved up from the pelvic floor into the low back over the last week. Rectal exam now revealed peri-anal tender induration and mucopurulent and bloody discharge as well as a nearly pathognomonic finding of a lymphorrhoid. The patient was treated empirically for GC with 250 mg IM ceftriaxone and was given a 21-day course of doxycycline 100 mg BID given high suspicion for lymphogranuloma venereum (LGV). Testing returned 2 days later; TMA from a rectal swab was positive for gonorrhea and chlamydia, and PCR was positive for lymphogranuloma venereum (LGV).

DISCUSSION: On the differential for proctitis among men who have sex with men, STDs are prominent; these range from ulcerating genital infections (HSV, syphilis) to rectal gonorrhea, rectal Chlamydia trachomatis (D-K serotypes) and lymphogranuloma venereum (LGV). Apart from STDs, diagnoses to consider include food-borne or water-borne infectious diarrhea (E. coli, Salmonella, etc.); opportunistic infections (e.g. CMV colitis) should be considered in immunosuppressed patients. Other gastrointestinal disorders to consider are inflammatory bowel disease, colorectal cancer and lymphoma. Lymphogranuloma venereum (LGV) is a disease that is caused by infection with specific serotypes (L1, L2, L3) of Chlamydia trachomatis. Although these infections are endemic in Africa, southern Asia, and parts of the Caribbean, outbreaks have also been described in developed nations since 2003 among MSM. While the endemic form of the disease is typically manifest as the ‘inguinal syndrome’ with predominant lymphadenopathy, buboes, necrosis and draining tracts, proctitis is the most common presentation during outbreaks among MSM. Rectal LGV presents with anal or rectal pain, discharge,

tenesmus, rectal bleeding and sometimes constipation; systemic symptoms (fever, malaise) may be present. Anoscopic findings may include mucosal friability, ulcerations, masses or polyps, and mucopurulent exudate. The diagnosis of LGV proctitis is made by LGV-specific PCR from a rectal sample; standard TMA testing for Chlamydia will also be positive, but will not distinguish between LGV infection and other CT serotypes. While Chlamydia serotypes D-K may be treated with one dose of azithromycin or one week of doxycycline, LGV requires a 3-week course of doxycycline. If buboes are present, they should be drained. Partner testing should be offered as well. Patients presenting with LGV are at high risk for other sexually-transmitted infections and should be screened at regular intervals and offered counseling on reducing the risk of infection.

PROFUSE DIARRHEA IN A PATIENT WITH METASTATIC INVASIVE LOBULAR CARCINOMA Anthony T. Fojo. Washington University, Saint Louis, MO. (Tracking ID #2199284)

LEARNING OBJECTIVE #1: Recognize that malignant metastases to the colonic mucosa can cause secretory diarrhea

CASE: A 65-year-old female with a history of recurrent invasive lobular carcinoma of the breast (ER-positive, PR-positive, and HER2-negative) with signet-ring features and liver metastases was directly admitted from clinic for several weeks of progressive confusion, 30-lb weight loss, and diarrhea. Her family reported four to eight bowel movements daily, including at night, with associated nausea and intermittent vomiting. The diarrhea was watery, moderate volume, and had turned bloody over the past week. Physical exam was notable for marked confusion and frankly bloody stool; vital signs and abdominal exam were unremarkable. Initial labs were significant for a sodium of 148 mmol/L, bicarbonate of 7 mmol/L with an anion gap of 17 mmol/L, and creatinine of 1.99 mg/dl (baseline of 0.9 mg/dl), with normal potassium; these abnormalities resolved with aggressive hydration, as did her mental status changes. Stool osmolar gap was 51 mmol/L, infectious studies and fecal leukocytes were negative, and fecal fat was elevated at 27 %. Serum Chromogranin A and VIP and urine 5-HIAA were within normal limits; gastrin was slightly elevated at 290 pg/ml. A colonoscopy was performed which showed thousands of 3 to 5 mm sessile polyps throughout the entire colon. Biopsy demonstrated poorly-differentiated carcinoma with signet rings that was ER-positive, PR-negative, and HER2-negative. This carcinoma was felt to be consistent with her breast primary.

DISCUSSION: Malignant metastases to the mucosa of the GI tract are rare. After melanoma, breast cancer is the second most likely primary to metastasize to the GI tract, and is more common in lobular than ductal carcinoma. While usually solitary or few in number, when diffuse, such metastases can cause significant diarrhea.

PROTON PUMP INHIBITOR INDUCED ACUTE INTERSTITIAL NEPHRITIS—REMAINING MINDFUL OF THE MEDICATION RECONCILIATION Dr. Jasdeep S. Badwal¹; Dilpreet K. Singh². ¹Baystate Medical Center/ Tufts School of Medicine, Springfield, MA; ²Baystate Medical Center/Tufts School of Medicine, Springfield, MA. (Tracking ID #2199814)

LEARNING OBJECTIVE #1: Recognize that proton pump inhibitors (PPIs) can be implicated in acute interstitial nephritis (AIN).

LEARNING OBJECTIVE #2: Recognize the importance of assessing for new medications on a patient's medication list.

CASE: A 62 year old female with a medical history significant for congestive heart failure on bumetanide, paroxysmal atrial fibrillation on flecainide, and gastroesophageal reflux disease on omeprazole, presented with a 5 day history of fevers, chills, myalgias, weakness, poor oral intake, and lower abdominal pain. Her vital signs and physical examination were unrevealing apart from slight suprapubic tenderness and dry mucous membranes. Laboratory analysis revealed a normal complete blood count (CBC), a marked acute kidney injury (AKI) with a blood urea nitrogen (BUN) of 41, and a creatinine (Cr) of 4.0 (baseline 1.0), urine analysis with 13 white blood cells, 5 % eosinophils, no casts, and urine electrolytes revealing a fractional excretion of urea (FeUrea) of 0.05 % consistent with pre-renal azotemia due to volume depletion. She was commenced on intravenous fluids (IVF) with resolution of her urinary eosinophils within 24 h. However her renal function remained unchanged throughout her course. Nephrology was consulted and the patient underwent a computed tomography (CT) scan of her abdomen that revealed mild perinephric fat stranding of the right kidney. She underwent a negative autoimmune workup including complement, anti-nuclear antibody, anti-glomerular basement membrane antibody, anti-neutrophil cytoplasmic antibodies, immunoglobulin's, and hepatitis panel. A renal biopsy was subsequently performed given her unremitting renal failure and the patient was discharged with instructions for close nephrology follow up for the results. However, she returned two days later with nausea and vomiting, was found to be mildly hyperkalemic and her renal function gradually worsened with a Cr trending to a maximum of 6.9. Her biopsy results revealed acute

interstitial nephritis for which a throughout review of her medication history revealed that she had been commenced on omeprazole a few weeks prior to her initial presentation. In the absence of exposure to other drugs associated with AIN, her presentation was attributed to her new PPI. She was commenced on prednisone, her PPI was discontinued, underwent transient hemodialysis in the acute setting, and had gradual normalization of her renal function over a span of 4 months.

DISCUSSION: Proton pump inhibitors are among the most widely prescribed classes of drugs in the United States, accounting for greater than 112 million prescriptions in 2009. They are generally well tolerated with some data suggesting an increased risk for such conditions as community-acquired pneumonia, clostridium difficile diarrhea, fractures, and magnesium deficiency. Less commonly however, PPIs have also been implicated in AIN, mainly reported as case reports and case series without apparent predilection for any one particular PPI. AIN commonly arises in the setting of drug allergy, autoimmunity, or idiopathically. Typically, renal function deteriorates more indolently in AIN than in comparison to the more acute worsening as seen in acute tubular necrosis (ATN), and without obvious abnormalities on urine analysis as are seen in ATN (e.g. muddy brown casts). Providers should remain cognizant about their patients' medications and recognize the importance of obtaining a throughout medication history including onset of therapy in particular cases similar to this, where the clinical course is unresponsive to conventional therapy.

PSA: PROSTATE SERVICE ANNOUNCEMENT Allison L. Ramsey¹; Crear Gail¹; Jeffrey T. Bates²; Andrew Caruso¹. ¹Baylor College of Medicine, Houston, TX; ²VA Houston Medical Center, Houston, TX. (Tracking ID #2200229)

LEARNING OBJECTIVE #1: Recognize that following PSA levels are not reliable screening tests for small cell variant prostate cancer.

LEARNING OBJECTIVE #2: Recognize that small cell prostate cancer is a rare but aggressive variant of prostate malignancy.

CASE: A 75-year-old man with a history of a partially-resected prostate was admitted with a 2-day history of hematuria and difficulty with urination. Five years ago, he underwent a partial prostatectomy for benign prostatic hypertrophy (BPH) with pathology negative for malignancy; his only medications are tamsulosin and finasteride. This current episode was associated with suprapubic pain, bilateral lower extremity swelling, and facial swelling. On physical examination, he had an elevated blood pressure at 171/100 mmHg, periorbital edema, and a left lower lung field which was dull to percussion. His abdomen was distended with suprapubic tenderness; his prostate was hard, nontender, and had irregular contours, and he had left inguinal lymphadenopathy. Urinalysis showed pyuria and hematuria, and a subsequent computed tomography (CT) scan was notable for a large lobulated prostate mass, bilateral hydronephrosis, and multiple liver and lung lesions with a left-sided pleural effusion. Creatinine was elevated to 2.8 mg/dL and a prostate-specific antigen (PSA) was normal. A prostate biopsy showed poorly-differentiated carcinoma with focal areas of neuroendocrine differentiation; positive staining for the markers PSA, PSAP, CK7, synaptophysin, and CD56; and negative staining for chromogranin and CK20. He was diagnosed with small cell prostate cancer. The patient was initiated on carboplatin and etoposide and had bilateral nephrostomy tubes placed. He completed four cycles of chemotherapy before opting to pursue palliative measures.

DISCUSSION: Historically, prostate cancers have been detected using PSA, and even after diagnosis, this one test has essentially replaced digital rectal examinations (DRE) and imaging as the mode of surveillance both during and after treatment. For the majority of patients, PSA testing is sufficient, due to its specificity to prostate tissue. However, in a subset of patients, PSA levels cannot be reliably used for surveillance. Small cell neuroendocrine carcinoma is an extremely aggressive and rare histological variant which occurs in 0.5–2 % of all prostate cancers. About one-half of cases are pure small cell while the other half are admixed with adenocarcinoma. There is no clear histogenetic origin for small cell prostate cancer, but one theory hypothesizes that this malignancy arises from stem cells. Since these stem cells are not specialized, they do not have the capacity to produce PSA. In contrast to patients with adenocarcinoma, PSA is usually normal in patients with small cell prostate cancer, even in those with metastatic disease. However, other tumor markers consistent with embryonal or neuroendocrine cells, such as CEA or chromogranin A, will be elevated. With these patterns in mind, patients with small cell prostate cancer may merit more thorough surveillance with imaging and DRE. Because of the rarity of the condition, no standard therapeutic regimen has been developed. Platinum based chemotherapy regimens have been attempted in case reports, but small cell prostate cancer is often aggressive and diagnosed in a late metastatic stage which hinders the therapeutic opportunity.

PSYCHOSIS NOS Elisa H. Ignatius. Emory University School of Medicine, Atlanta, GA. (Tracking ID #2199446)

LEARNING OBJECTIVE #1: Identify features of clinical history and exam which suggest non-psychiatric causes for psychosis

LEARNING OBJECTIVE #2: Recognize a rare but potentially reversible cause of new onset psychosis: anti-NMDA receptor (NMDAR) encephalitis

CASE: A 34 year old male with no prior medical history was transferred from a psychiatric facility due to disorientation and tachycardia. He was first evaluated 10 days prior with complaints of "delayed response," right hand paresthesias, and "hearing echoes." Recent stressors included longer hours at work, brief homelessness, increased marijuana use, and a sinus infection for which he had taken amoxicillin. ER work-up showed only THC positive urine and he was discharged home with stress management techniques. He returned 4 days later with command hallucinations and insomnia; labs showed mild leukocytosis (11) and he was discharged with hydroxyzine. Two days later he returned under police custody after attacking his mother. In the ER he was wandering the halls naked, responding to hallucinations and perseverating on religious delusions. CT head was normal and labs were notable for leukocytosis (16), urine positive for THC and CPK 4900 (attributed to police Taser). Neurology and psychiatry agreed this represented new onset psychosis and he received Ativan, Haldol, Benadryl, Risperdal and Thorazine prior to psychiatric admission. Once admitted, he demonstrated aggressive and self-injurious behavior refractory to medications and was quickly brought back to the ER for worsening agitation. In the ED he alternated between relative lucidity (able to answer basic questions) and periods of unresponsiveness, rigidity, diaphoresis, and urinary incontinence. Given the numerous anti-psychotics recently administered plus the elevated CPK, there was initial concern for neuroleptic malignant syndrome versus infectious encephalitis/meningitis. Lumbar puncture showed mild lymphocytic pleocytosis and he was empirically started on broad meningitis coverage and PRN Ativan. Over the next 48 h, the patient developed increasingly frequent periods of autonomic instability characterized by diaphoresis, fevers, hypertension, tachycardia, apnea, rigidity, tearfulness and unresponsiveness. Between episodes he demonstrated repetitive orofacial dyskinesias and cyclical motions of his legs or arms but was initially able to follow commands and answer questions; as the days progressed he drifted further from that baseline. EEG showed global dysfunction, MRI was normal and LP non-revealing so antibiotics were discontinued; recovery time was accelerated by Ativan so this was continued. After conferring with consulting services, NMDA receptor antibody was added onto prior CSF studies. While awaiting results, his autonomic dysregulation became more severe with intermittent tachypnea and hypoxia so he was transferred to MICU, initiated on high-dose steroids and intubated. NMDA receptor antibody subsequently returned positive and patient received 4 days plasmapheresis and 2 days IVIg with gradual improvement. Broad testing for precipitating malignancies including testicular ultrasound, CT chest/abdomen/pelvis, tumor markers were unremarkable. He was extubated and is able to follow commands but continues to exhibit milder intermittent autonomic instability.

DISCUSSION: Anti-NMDA receptor (NMDAR) encephalitis is more common in women and symptoms include memory difficulties, dyskinesia, catatonia, anxiety, mania, social withdrawal and psychosis. Numerous psychiatric journals recommend considering this diagnosis in patients with new-onset psychosis plus any of these cardinal features. Brain imaging is often normal but can show increased FLAIR/T2 signaling in the cortex or medial temporal lobes; EEG is often non-specific and CSF studies show only mild leukocytosis with lymphocytic pleocytosis. Presentation mimics phencyclidine ingestion (which antagonizes the NMDA receptor) as well as schizophrenia, further complicating the diagnosis. Despite exhaustive work-ups, men less commonly have an underlying malignancy (8 % versus 41 % in females); among women, ovarian teratomas are associated. Treatment includes high-dose steroids, IVIg, plasmapheresis and occasionally second line immunosuppressants such as rituximab and cyclophosphamide; long-term treatment to prevent relapses among patients without obvious inciting malignancy may include mycophenolate mofetil or azathioprine. Some reports suggest a correlation between NMDAR and HSV encephalitis; a non-specific viral prodrome is common in many cases. There are currently no links between illicit drug use and NMDAR encephalitis. Internal Medicine doctors are often tasked with identifying the "organic" causes of altered mental status. Though it would be low yield to consider work-up for NMDAR encephalitis in all men in their 30s with new onset psychosis, it is nonetheless an important disease to consider early in the differential given the potential for meaningful neurologic recovery with prompt treatment.

PULMONARY ARTERY SARCOMA: A RARE PULMONARY ARTERY FILLING DEFECT Demetra Gibson¹; Neda Laiteerapong². ¹University of Chicago Medical Center, Chicago, IL; ²University of Chicago, Chicago, IL. (Tracking ID #2193451)

LEARNING OBJECTIVE #1: Recognize the clinical features of pulmonary artery sarcomas

CASE: A 71-year-old woman presented with 6 months of progressively worsening dyspnea on exertion. She had just driven over 100 miles to a Thanksgiving celebration. Her history included hypertension, hyperlipidemia and deep venous thrombosis one year ago status post inferior vena cava (IVC) filter placement. Her medications were metoprolol and warfarin, and her international normalized ratio (INR) was 2.8. She did not use

tobacco, alcohol or illicit drugs, and her family history was unremarkable. Review of systems was positive for cough, shortness of breath, and swelling. She had no chest pain or orthopnea. Physical exam was notable for tachycardia, tachypnea, jugular venous distension, systolic murmur and 2+ bilateral lower extremity edema. She was normotensive with clear breath sounds and extremities were warm and well-perfused. CT scan showed a main pulmonary artery defect, flattening of the interventricular septum suggestive of elevated right-sided pressures, and scattered bilateral lung nodules. Echocardiogram confirmed signs of right heart failure. She was diagnosed with a massive pulmonary embolism (PE) and received emergent systemic tissue plasminogen activator. She had no significant response, so she underwent catheter-directed lytic therapy and aspiration thrombectomy, which provided minimal improvement in the size of her pulmonary artery mass. After a 2-week hospital stay, she reported feeling back to normal and was anxious for discharge. She was discharged on enoxaparin with follow-up. Biopsy of lung nodules was deferred given the need for anticoagulation. Ten days later, she was admitted from clinic due to progressive dyspnea. Physical exam was unchanged and consistent with volume overload. On echocardiogram, the pulmonary artery defect was larger and extending into her right and left pulmonary artery, and her right ventricular function had worsened. She was started on a continuous heparin infusion. CT surgery was consulted for possible thrombectomy, and hematology was consulted to evaluate for hypercoagulability. At this time, alternative diagnoses were entertained. A PET scan was ordered, which showed hypermetabolic activity within the pulmonary artery and lung nodules. CT-guided biopsy of a lung nodule was performed, and pathology was consistent with a pulmonary artery sarcoma (PAS). She was treated with doxorubicin, but she became progressively symptomatic with worsening performance status. After discussion with the patient and family, she was transitioned to hospice care and passed away.

DISCUSSION: This case illustrates the diagnostic challenge of PAS. PAS is a malignant tumor predominantly arising from the intima of the vessel, leading to progressive intraluminal growth of the tumor, right ventricular outflow tract obstruction and right ventricular failure. The differential diagnosis for a pulmonary artery filling defect includes PE, PAS, tumor embolism, locally invasive or compressive lung or mediastinal tumor, fibrosing mediastinitis and pulmonary infections. PAS are extremely rare and less than 250 cases have been reported. They are often misdiagnosed as PE, leading to a delay in diagnosis and unnecessary anticoagulation. PAS presents similarly to PE but can be distinguished by the presence of a systolic murmur which represents the outflow tract obstruction. PAS and PE also have similar appearances on CT and can only be distinguished with PET scan or gadolinium-enhanced MRI. Biopsy is often difficult due to the risk of hemorrhage. Limited data exists to the optimal treatment of PAS; thus, treatment is usually multimodal and includes radiation, chemotherapy or surgical excision, depending on the size of tumor, presence of metastases, and patient hemodynamics. Early recognition of this rare and aggressive malignancy has the potential to improve survival. Surgical excision can be curative if discovered before metastasis. Prognosis is poor with a mean survival of 1.5 months without excision, which only extends to a few years if excised. While PE is a highly prevalent condition, the key clinical features in this case that should prompt the consideration of an alternative diagnosis include: symptoms in the presence of a therapeutic INR and IVC filter, lack of response to thrombolytics and embolectomy; the presence of a systolic murmur and pulmonary nodules, and the enlargement of the pulmonary artery defect.

PULMONARY HYPOPLASIA IN ADULTS SRINATH YADLAPALLI¹; Mohammed Al-Deen¹; Kishore Yalamanchili¹; Mashrafi Ahmed². ¹TEXAS TECH UNIVERSITY-AMARILLO, Amarillo, TX; ²Texas Tech University, Amarillo, TX. (Tracking ID #2197852)

LEARNING OBJECTIVE #1: Distinguish pulmonary hypoplasia from other common causes of shortness of breath in adults.

LEARNING OBJECTIVE #2: Diagnose COPD by using objective evidence.

CASE: A 49 year old female presented with acute worsening of her shortness of breath. She had to be intubated by emergency medical service because of low oxygen saturation. She had a past medical history of diabetes mellitus type-2, hypertension, obesity, systolic heart failure, obstructive sleep apnea and COPD. She had never smoked and had no family history of emphysema. She was born full term but very low body weight. She used albuterol, budesonide and formoterol inhalers and regular oxygen two liters via nasal cannula throughout the day and CPAP at night. On physical examination, she had decreased breath sounds bilaterally, no wheezes, crackles, jugular venous distension or pedal edema. She was extubated after 24 h. She had orthodeoxia with oxygen saturations 96 % on supine position and 88 % on standing. Her oxygen saturation with and without oxygen were 96 and 84 %. Arterial blood gas showed Ph-7.25/PCO2-84/PO2-83/HCO3-37. CT-scan showed very small lungs with no emphysematous changes. COPD was ruled out as pulmonary function tests showed restrictive picture (FEV1/FVC 108 %, FEV1 29 %, FVC 27 %, DLCO 51 %, TLC 71 %). CHF exacerbation was ruled out as there was no jugular venous distension or crackles on examination. Chest x ray did not show any

pulmonary edema. Orthodeoxia could be due to intra-cardiac or intra-pulmonary shunts. CT-Angio which was done for A-V malformations was negative and 2D-Echocardiogram did not reveal any septal defects. Neuro-muscular causes were ruled out as she did not have any weakness in her extremities and negative inspiratory force was normal. The probable cause of her symptoms is congenitally hypo-plastic lungs. CT-scan showed small sized lungs with small lung cavities.

DISCUSSION: Pulmonary hypoplasia, often associated with other congenital anomalies is usually diagnosed during infancy. The incidence of congenital hypoplasia may range from 9 to 11 per 10,000 live births. Less severe cases of hypoplasia can present in adults. There have been very few case reports of pulmonary hypoplasia diagnosed in adults. It is important that we distinguish it from other common causes of shortness of breath. The patient had shortness of breath for many years. She was incorrectly diagnosed with COPD without pulmonary function tests. She did not smoke and had no family history of emphysema. The CT-scan did not show any emphysematous changes, which makes COPD or α_1 -anti-trypsin deficiency less likely. Moreover, pulmonary function tests showed restrictive picture. The treatment of COPD is beta agonists, oxygen, steroids which are different from the treatment of pulmonary hypoplasia. Diagnosing pulmonary hypoplasia earlier in life could have avoided unnecessary inhalers, steroids and early referral for lung transplant. This emphasizes the importance of diagnosing COPD using objective evidence on clinical suspicion. Lung transplant is considered as a treatment option for this condition.

PULMONARY NODULE—HOW OLD SHOULD YOUR PATIENT BE FOR YOU TO CONSIDER LUNG CANCER? Dipti Baral¹; Birendra Sah¹; Bishma Pokhrel². ¹SUNY Upstate Medical University, Syracuse, NY; ²National Academy of Medical Sciences, Kathmandu, Nepal. (Tracking ID #2199114)

LEARNING OBJECTIVE #1: Suspect lung cancer even in younger age patients with lung nodule

LEARNING OBJECTIVE #2: Recognize the importance of follow up in lung nodules

CASE: A healthy, 26 year-old-male, immigrant from South America, with no recent travel history, tested positive on tuberculin skin test during his pre-employment check-up. He reported being negative a year ago. He had smoked half pack a day for a year. There was no family history of cancer. Chest X-ray showed a right lung nodule. Acid fast bacillus smear and culture of sputum, quantiferon tuberculosis test and fungal serology came negative. Computed tomography of chest revealed an 11 mm spiculated nodule in the superior segment of right lower lobe with mild hypermetabolic activity on Positron Emission Tomography (PET) scan. Navigational bronchoscopy guided transbronchial biopsy of the nodule showed respiratory bronchiolitis. He was empirically treated with a course of antibiotics. As the nodule persisted on repeat CT scan after 2 months, CT guided needle biopsy was performed which revealed adenocarcinoma of lung. Immunohistochemical studies showed expression of CDX-2, cytokeratin 7, 19 and 20 with no expression of thyroid transcription factor-1 or napsin, which is unusual for lung adenocarcinoma. Epidermal growth factor receptor gene deletion or point mutation and anaplastic lymphoma kinase gene rearrangement were negative. He underwent right middle and lower lobe lobectomy; final diagnosis was moderately differentiated adenocarcinoma stage IA (T1aN0M0). Patient is in clinical and radiological remission at 3 months follow up.

DISCUSSION: For any incidentally found lung nodule, risk factors for cancer are evaluated; increasing patient age being one. As lung cancer is rare in younger than 30 years, diagnosis can be delayed. Lung cancer, the leading cause of cancer mortality in industrialized countries, commonly occurs in the 6th decade and with significant smoking history. But lung carcinoma should be included in differential diagnosis of any incidentally discovered lung nodules even in younger population. Adenocarcinoma is the most frequent lung cancer in this population and has been found to be more common in female and in non-smokers; hence suggesting increased genetic role. Recent researches have shown favorable outcome with surgery in young due to less co-morbidities, especially in earlier stages. Extensive researches are however needed to investigate the risk factors, genetics, prognosis and treatment options for lung cancer in this population. It is imperative that lung nodules be followed up regardless of patient's age.

PURE SENSORY VARIANT OF GUILLAIN BARRE SYNDROME WITH NORMAL REFLEXES—A VERY RARE PHENOMENON Sourabh Aggarwal²; Devin B. Malik²; Akshay Amaraneni²; Andrew Whipple¹; yashwant Agrawal². ¹Western Michigan University Homer Stryker M.D. School of Medicine, Kalamazoo, MI; ²Western Michigan University School of Medicine, Kalamazoo, MI. (Tracking ID #2197584)

LEARNING OBJECTIVE #1: GB is characterized by acute, progressive, muscle weakness.

LEARNING OBJECTIVE #2: GBS can rarely present in pure sensory form. GBS can present with normal reflexes.

CASE: Guillain Barre syndrome (GBS) is a peripheral neuropathy characterized by acute, progressive, muscle weakness and is the most important cause of acute flaccid paralysis in the United States. One of the hallmark of diagnosis is areflexia. We present an interesting and very rare variant of GBS. A 60 year old gentleman with known medical history of hyperlipidemia presented to ED with acute onset of bilateral lower extremity sensory loss mainly in his feet. It was progressive in nature, started in left leg and over next 5–6 h progressed to his right leg and was unable to walk not because of weakness, but because of loss of sensations. Sensory loss later progressed to his perianal area including his penis. He denied any other complains. There was no history of any fever, chills, sick contacts, trauma or falls. He denied any breathing difficulties, diarrhea and incontinence. His past medical history, surgical history, social and family history were otherwise unremarkable. On examination vitals were unremarkable. On neuro exam, he had a complete loss of vibratory sense, sense of position, hot and cold perception, and perception in space in his feet and bilateral legs. Muscle strength was 5/5 in both upper and lower extremities, flexors and extensors group of muscles. All deep tendon reflexes, even contralateral reflexes were normal and Babinski's sign were down-going bilaterally. Initial lab evaluation including complete metabolic profile was unremarkable. MRI of the back was done without contrast and was unremarkable. Lumbar puncture was done in the ER and showed no white cells or red cells but elevated protein. Provisional diagnosis of acute ascending sensory polyneuropathy was made and EMG was done which confirmed the diagnosis of atypical sensory variant of Guillain Barre syndrome. He was started on IVIG therapy and recovered with next 5 days to his baseline activity with resolution of sensory symptoms.

DISCUSSION: Guillain Barre syndrome is most common cause of acute flaccid paralysis in US. Sensory variant of GBS is a very rare variant. Areflexia used to be hallmark of GBS, but recent studies have pointed towards GBS variants with normal reflexes. Our patient was unique to have two atypical features of GBS. He recovered well with IVIG therapy and has not had a recurrence of symptoms till date. Physicians should have high index of suspicion for diagnosis of sensory variant of GBS in appropriate setting as early diagnosis can help prevent complications.

PUSTULE PUZZLE: A PUSTULAR RASH WITH SYSTEMIC SYMPTOMS Margaret Lowenstein¹; Ivy Nguyen¹; Priyanka Agarwal². ¹University of California San Francisco, San Francisco, CA; ²University of California, San Francisco, San Francisco, CA. (Tracking ID #2194249)

LEARNING OBJECTIVE #1: Recognize the clinical manifestations of acute generalized exanthematous pustulosis (AGEP), a rare drug eruption.

LEARNING OBJECTIVE #2: Distinguish AGEP and acute generalized pustular psoriasis.

CASE: A 93-year-old woman with a history of diabetes presented with 3 days of a full body rash. The patient had been started on ceftriaxone 3 weeks prior after being diagnosed with Klebsiella osteomyelitis of the tibia secondary to a non-healing ulcer. She reported the development of a milder rash 2 weeks prior, shortly after starting ceftriaxone, and was treated with 5 days of prednisone. The rash resolved with steroid treatment but then recurred, worsening over several days along with associated somnolence and generalized weakness. On admission, she had a temperature of 100.2, heart rate of 129, blood pressure of 102/57, with normal respirations and oxygen saturation. The patient was uncomfortable with a diffuse rash covering 60–70 % of her body surface area. The rash manifested as broad areas of erythema and pink plaques studded with innumerable pustules, some of which coalesced and ruptured leading to desquamation. She had no bullous or necrotic lesions and no mucosal involvement. White blood cells were 18 g/dl with a neutrophilic predominance and a normal eosinophil count. BUN was 115 mg/dL, creatinine was 1.2 mg/dL, and glucose was 230 mg/dL; other electrolytes and liver function tests were within normal limits. Infectious workup was negative. On skin biopsy, the patient was found to have subcorneal pustular dermatitis, consistent with acute generalized exanthematous pustulosis (AGEP) or pustular psoriasis. Her symptoms resolved rapidly with discontinuation of ceftriaxone, more consistent with a diagnosis of AGEP, as pustular psoriasis would not resolve quickly in the absence of immunomodulatory treatment. The patient was discharged with an aggressive skin care regimen. Beta lactams were added as a severe drug allergy.

DISCUSSION: Drug eruptions are an issue commonly encountered by internists, with many commonly prescribed drugs as culprits. Reactions range from a simple morbilliform rash to life-threatening reactions with systemic manifestations that can mimic septic shock. The presence of a diffuse pustular rash with systemic symptoms should point towards two important diagnoses: acute generalized exanthematous pustulosis (AGEP) and acute generalized pustular psoriasis. AGEP is a rare, acute drug eruption with a characteristic appearance of diffuse sterile pustules on a background of erythema and edema. Systemic manifestations, including fever, are usually present, and patients can develop a systemic inflammatory response leading to hypotension and shock. Lab abnormalities include a

neutrophil-predominant leukocytosis. Common precipitants include antibiotics (particularly penicillins, quinolones, sulfonamides), anti-malarials, and calcium channel blockers (particularly diltiazem), though a wide variety of drugs have been implicated. Onset is within hours to days of exposure. Treatment involves identifying and withdrawing the culprit agent, as well as supportive care with topical steroids and emollients as patients may desquamate later in their course. Patients often require admission for fluid resuscitation, infection rule-out, and intensive skin care. Pustular psoriasis is also associated with a generalized eruption of pustules and erythematous plaques, and can have systemic symptoms of fever and malaise. Lab abnormalities commonly include a leukocytosis and elevated sedimentation rate, as well as electrolyte abnormalities and elevated liver enzymes. Notably, pustular psoriasis may present in patients without a prior diagnosis of psoriasis. First line treatment for pustular psoriasis is retinoids or methotrexate, with other immunomodulatory agents such as cyclosporine or infliximab used in severe cases. AGEF and pustular psoriasis appear similar both clinically and histologically, and a thorough medication exposure history is essential to differentiating these two entities. AGEF is generally secondary to new medications as above, while pustular psoriasis flares are usually associated with withdrawal of systemic glucocorticoids (although other medications or infections have been implicated). For this reason, providers should be cautious about treating patients with known psoriasis with systemic steroids unless absolutely necessary. Although rare, both AGEF and pustular psoriasis are life-threatening rashes related to a number of commonly prescribed medications. Swift recognition and dermatologic consultation are essential to prevent serious complications.

PYOGENIC LIVER ABSCESS IN A SPLENECTOMIZED DIABETIC: A CASE STUDY Anupam Kotwal; Candace Shanks; Kevin Abraham; Maria M. Garcia. University of Massachusetts Medical School, Worcester, MA. (*Tracking ID #2190979*)

LEARNING OBJECTIVE #1: Recognize the risk factors and clinical features of a pyogenic liver abscess (PLA).

LEARNING OBJECTIVE #2: Understand the management of a PLA caused by resistant organisms.

CASE: A 75 year old lady was admitted for intermittent fevers of 1 week duration associated with chills, rigors, fatigue and myalgia. She did not report abdominal pain, dysuria, rash, vomiting or diarrhea. Her medical history was significant for Whipple's procedure (pancreatectomy, splenectomy, cholecystectomy and pylorus-sparing duodenectomy) for Intraductal Papillary Mucinous Neoplasm (IPMN) 10 years ago, type 1 diabetes mellitus, mitral regurgitation, atrial fibrillation and diverticulosis. On presentation, she was febrile at 38.6 °C and had tachycardia, conjunctival icterus, jaundice and a grade 3/6 holosystolic murmur at the cardiac apex, but no ascites, abdominal tenderness, lymphadenopathy or hepatomegaly. Laboratory workup was significant for low Hemoglobin of 11.7 mg/dL, elevated WBC of 37,200/mm³ (94% neutrophils), low albumin of 2.8 g/dL (3.5–4.8), high AST of 220 IU/L (10–40), high ALT of 125 IU/L (10–40), high total bilirubin of 17 mg/dL (0.3–1.2), direct bilirubin of 5.6 mg/dL (0.0–0.4) and high alkaline phosphatase (ALP) of 354 IU/L (30–115). The neutrophilic leukocytosis and hepato-cellular pattern of jaundice suggested an infectious hepatic process. Blood cultures were drawn and CT scan of the abdomen was performed which revealed a fluid and gas containing 6×6 cm collection in the right hepatic lobe. This was concerning for a PLA, so empiric coverage with Piperacillin/Tazobactam was initiated. Ultrasound guided drainage of the abscess was performed after which a pigtail catheter was inserted. A transthoracic echocardiogram showed moderate mitral regurgitation but no vegetations. Initial blood cultures resulted positive for *Klebsiella pneumoniae* (KP), *E. coli* and *Clostridium perfringens* (CP), following which antibiotic regimen was changed to Ampicillin/Sulbactam. Cultures of the drainage from the PLA grew *Enterococcus fecalis*, *Streptococcus bovis* and *E. coli*. Stool and urine culture remained negative. Her WBC slowly decreased to 13,400 / mm³, and liver enzymes and bilirubin normalized. Repeat blood cultures remained negative for 5 days. She was then transitioned to oral Amoxicillin/Clavulanate and remained afebrile without any chills or rigors. A week later, she again developed fever, leukocytosis and elevated ALP. Appearance of the abscess on CT scan changed to multiloculated which was further confirmed by MRCP representing a complicated abscess with a hemorrhagic component, along with mild intrahepatic biliary duct dilatation. A percutaneous biliary drain was placed, and Piperacillin/Tazobactam and Clindamycin were initiated. Blood cultures this time resulted positive for extended-spectrum beta-lactamase (ESBL) producing KP, so the antibiotic regimen was changed to Ertapenem. We checked tumor markers, of which CA 19–9, CA 125 and Carcinoembryonic antigen were mildly elevated, and Alpha-fetoprotein was normal. She was also found to have a right sided pleural effusion, which was exudative without features of complicated effusion. The culture and cytology analyses were negative. She underwent a biopsy of the liver parenchyma surrounding the PLA which demonstrated histological features of inflammation but not malignancy. The abscess fluid was also negative for malignant cells. Blood cultures drawn 2 days and 7 days later did not grow any organisms. Within 2 weeks, her laboratory abnormalities normalized, she remained afebrile and jaundice resolved. She was discharged

from the hospital on Ertapenem for a proposed duration of 4 weeks and a plan to remove the pigtail catheter and biliary drain at a later date.

DISCUSSION: PLA is the most common type of visceral abscess, and is caused mainly by enteric bacteria. Our patient's history of poorly controlled diabetes, IPMN and abdominal surgery were potential risk factors. Splenectomy increased her susceptibility to encapsulated organisms like KP and diabetes increased her susceptibility to CP. The absence of abdominal pain or tenderness and the different organisms growing from the PLA versus the blood were unusual features in this case. Management of PLA incorporates antibiotic therapy and abscess drainage. Percutaneous drainage has been shown to be effective for single as well as multiloculated abscesses, with surgical drainage being used as a last resort. Studies have evaluated the correlation between PLA and visceral malignancies. In particular, PLA due to KP is correlated with increased incidence of colorectal malignancy. Our patient's KP bacteremia suggests hematogenous spread from her abscess. In the absence of histological evidence of malignancy, the elevation of tumor markers was attributed to an inflammatory state caused by the PLA which would also explain the exudative pleural effusion.

PYOGENIC LIVER ABSCESS PRESENTING WITH A MIGRATORY RASH Timothy C. Beer¹; Michael Foltzer². ¹Geisinger Medical Center, Danville, PA; ²Geisinger Medical System, Danville, PA. (*Tracking ID #2153897*)

LEARNING OBJECTIVE #1: Learn the appropriate management strategies for pyogenic liver abscess based on size and clinical characteristics

LEARNING OBJECTIVE #2: Recognize referred shoulder pain as a sign of intra-abdominal pathology

CASE: A previously healthy 27-year-old man presented to the ED for evaluation of two days of fevers, right shoulder pain and a migratory erythematous rash on his chest. He worked in a meat-processing plant, was sexually active and monogamous with his fiancé and denied recent shoulder injury, tick bites or travel. He had undergone a tooth extraction 5 months prior. In the ED, exam revealed a temperature of 101.5 °F, heart rate of 122 and right shoulder tenderness exacerbated by active movement and reclining. A non-tender, erythematous rash extended in a band from shoulder-to-shoulder across his chest. He had widespread tooth decay, but no sign of acute oral infection. The remainder of his exam was unremarkable. Laboratory results were remarkable for a leukocytosis of 14,300 and ESR of 51 mm per hour. The remainder of his labs, including renal function tests, serum electrolytes, liver function tests, hepatitis panel, ANA, RF, EBV and Lyme serologies were all normal. Radiographs of the right shoulder were unremarkable. Blood and urine cultures were drawn, antibiotic therapy with Ertapenem was initiated, and he was admitted to the hospital. Within 3 h of admission, the patient had defervesced, his shoulder pain had resolved and his rash had completely disappeared. CT and MRI of the abdomen and pelvis revealed a 6.1×5.7×5.5-cm multiseptated lesion within the hepatic dome, concerning for liver abscess. (2 figures) The location of his liver abscess was felt to be poorly amenable to percutaneous drainage. Since his symptoms seemed to have improved dramatically with antibiotics alone, the decision was made to manage him non-invasively unless his status worsened. He remained clinically stable for the next several days, however, on the fourth day of hospitalization, he became febrile to 104.5 °F and both his rash and right shoulder pain returned. Within a span of several hours, a rash appeared near his right shoulder, migrated across his chest to his left shoulder, disappeared altogether, and then reappeared once again. (3 figures) Shortly thereafter, he developed right upper quadrant abdominal pain. His clinical condition continued to deteriorate rapidly and emergent surgical drainage of the abscess was performed. Cultures of his purulent liver abscess drainage grew many *Fusobacterium* species. Antibiotics were continued for 2 weeks postoperatively. At follow-up 1 month after discharge, he denied any recurrence of fever, rash or shoulder pain and repeat imaging revealed near complete resolution of his liver abscess.

DISCUSSION: This case provides multiple interesting clinical features and prompts several useful teaching points. It appears to be the first published report of pyogenic liver abscess presenting with a migratory rash. When considered in isolation, such an unusual clinical phenomenon could potentially send a clinician on a wild goose chase for various exotic infectious, rheumatologic and neoplastic etiologies. However, the additional physical exam finding of right shoulder pain in the absence of trauma subtly but importantly pointed toward an intra-abdominal pathology. Pain signals from abdominal viscera, especially the liver and gallbladder, are often referred to the right shoulder via the phrenic nerve. Such referred pain is particularly common when there is irritation of the diaphragm, such as in this case, where the abscess was located in the hepatic dome. Our patient was a healthy 27-year-old without any history of underlying hepatobiliary pathology, diabetes, cancer, immunosuppression or any of the other major risk factors classically associated with pyogenic liver abscess. However, a likely source of infection could be identified upon careful consideration of his reported history in light of the organism isolated from his liver abscess. *Fusobacterium* is commonly implicated in infections involving periodontal tissues and our patient had poor dentition and had undergone dental extraction just several months prior to his presentation. This case therefore highlights that, in the absence of

known hepatobiliary pathology or immunosuppressing condition, a thorough dental history and examination may help identify the underlying source of pyogenic liver abscess. Finally, this case reinforces the general expert consensus that successful definitive treatment of large pyogenic liver abscesses essentially always requires percutaneous or surgical drainage. Several large retrospective reviews have demonstrated high failures rates with medical therapy alone for pyogenic abscesses above 5-cm in greatest dimension. Clinicians should therefore not wait for clinical deterioration to develop before taking these patients for either percutaneous or surgical drainage.

RADIATION RECALL: A RARE CASE OF ORAL MUCOSITIS AFTER PEMETREXED CHEMOTHERAPY Mashooque Dahar; Justin Vranic; Venu M. Ganipiseti; Venu Pararath Gopalakrishnan; Ubaid Sherwani. Presence Saint Francis Hospital, Evanston, IL. (Tracking ID #2198449)

LEARNING OBJECTIVE #1: Recognize a rare complication of mucositis after chemotherapy in a patient who had radiation of the involved area in remote past.

CASE: An 82 year-old Caucasian male was admitted to our hospital with severe odynophagia, hoarseness of voice and poor oral intake for 2 days. He denied fevers, chills, cough, shortness of breath, orthopnea, diarrhea, nausea, vomiting or skin rash. The patient was recently diagnosed with stage IVA poorly differentiated adenocarcinoma of the lung with bilateral lung nodules and malignant pleural effusions. He received his first cycle of chemotherapy with Pemetrexed (after appropriate premedications) and carboplatin 3 days prior to admission. The patient's past medical history was significant for squamous cell carcinoma of left tonsil that was treated in 2001 with targeted radiotherapy and stage III CKD. He had a 30 pack-year smoking history but quit 30 years ago. On physical examination he was hemodynamically stable. He had severe swelling and erythema of the oral mucosa overlying his left tonsillar fossa in the area that was previously irradiated. No thrush or lymph node enlargement was noted. His labs showed mild leukocytosis of 11,000 k/mm cu and mild elevation of BUN to 51 mg/dL and Cr to 1.85 mg/dL from his baseline likely due to poor oral intake and dehydration. His CT scan of soft tissues of the neck was unremarkable. Upper GI endoscopy (EGD) showed nothing significant except severe oral mucositis of the prior irradiated area. He was treated conservatively with local Lidocaine lozenges and short course of systemic corticosteroids. His condition improved gradually and future cycles of Pemetrexed were avoided.

DISCUSSION: Radiation recall is a rare and unpredictable phenomenon that is characterized by an acute inflammatory reaction confined to previously irradiated tissues. It is posited that following radiotherapy, molecular and microvascular changes occur within the irradiated tissue bed, leaving it unable to tolerate cytotoxic medications. When systemic cytotoxic therapies are administered, localized inflammation results in a dermatitis-like reaction. Anticancer agents are most likely to precipitate radiation recall, but it is also believed that certain antibiotics, antituberculosis drugs, and statins can also lead to this phenomenon. The median interval between radiotherapy completion and clinical presentation of radiation recall is approximately 40 days; however, there are case reports of radiation recall occurring years after the completion of radiotherapy. Skin reactions comprise approximately two-thirds of radiation recall cases, but in rare cases soft tissue necrosis, mucositis, and solid organ involvement have also been reported. Pemetrexed is a multi-targeted, anti-folate drug approved as a single agent or in combination with cisplatin for the treatment of a small number of malignancies, including metastatic non-small cell lung cancer and malignant pleural mesothelioma. Although it has been associated with skin toxicity, there is a paucity of cases demonstrating radiation recall dermatitis in the published literature. Here, we report the first case of severe radiation recall mucositis following Pemetrexed chemotherapy exposure. The patient in this case received radiotherapy to his left tonsil 14 years prior to his first exposure to Pemetrexed. This was an especially early presentation for mucositis 2 days following administration of Pemetrexed as compared to the typical onset of mucositis as side effect chemotherapeutic agents. We suspect radiation therapy predisposed the patient to premature onset of severe mucositis of previously irradiated area. This clinical case demonstrates that Pemetrexed can trigger severe radiation recall mucositis in select patients. Additionally, this highlights a rare complication that can occur years after the successful completion of radiation therapy. Clinicians must be cognizant of this possible side effect when caring for patients with prior radiation exposure, and they need to be vigilant for signs of localized dermatitis, mucositis, and soft-tissue necrosis in patients who were recently started on chemotherapeutics or antibiotics after the completion of radiotherapy.

RAPIDLY PROGRESSIVE FATAL GAS GANGRENE DUE TO CLOSTRIDIUM SEPTICUM IN A PATIENT WITH COLON CANCER REVEALED BY AUTOPSY Haruka Kuno¹; Harumi Gomi²; Kazutaka Fukushima²; Yukiko Matsumoto²; Taijiro Shirokawa²; Kousei Miura³; Shijima Taguchi³; Norio Takayashiki³; Takao Kanai². ¹University of Tsukuba Hospital, Tsukuba, Japan; ²Mito Kyodo General Hospital, University of Tsukuba, Mito, Japan; ³Mito Kyodo General Hospital, Mito, Japan. (Tracking ID #2181014)

LEARNING OBJECTIVE #1: To promote awareness of patients with gas gangrene due to *Clostridium septicum*

LEARNING OBJECTIVE #2: To diagnose and treat patients with gas gangrene by early recognition and aggressive debridement

CASE: A 73 year-old man with well controlled type II diabetes mellitus and hypertension presented to our hospital with a 2-day history of left upper arm pain and 4-h history of left lower back pain. He had no history of trauma or surgery. On admission, he was afebrile and vital signs were unremarkable except for respiratory rate of 26 per minute. The left lower back showed severe pain, wide range of discoloration, and palpable gas under the skin. There was no tenderness or warmth. X-ray of the trunk showed extensive gas in the soft tissues of the left lateral thoracic dorsal region extending to the pelvis. A diagnosis of necrotizing soft tissue infection was made and treatment was started with intravenous fluids and antibiotics. The patient deteriorated rapidly, and within 7 h he demonstrated signs of severe sepsis and septic shock with systolic blood pressure of 60 mmHg and a pulse rate of 110 beats per minute. The patient was taken immediately to the operating room for urgent surgical debridement. Initial incisions revealed extensive myonecrosis with gas formation in the soft tissues and liquefied muscles. Gram stain of the necrotic tissues revealed an abundance of spore-forming gram-positive bacilli. After the operation the patient was admitted to the intensive care unit for treatment of multi organ dysfunction. Wide-spectrum antibiotics including meropenem, vancomycin, and clindamycin were urgently administered together with crystalloid rehydration. The patient died of overwhelming sepsis 6 days later despite rigorous and intensive medical therapy. The infecting organism was isolated but not identified by routine methods of tissue samples and blood cultures. Genetic sequence analysis identified the organism as *Clostridium septicum*. Then the final diagnosis of Clostridial myonecrosis, i.e. gas gangrene was made. An autopsy discovered ascending colon cancer in the patient which had not been noted before.

DISCUSSION: Gas gangrene is a rare, life-threatening infection of deep skin and soft tissues. It is typically associated with contaminated wounds but may also occur in the absence of any trauma or surgery. Non-traumatic gas gangrene due to *Clostridium* spp. is most commonly caused by *Clostridium septicum* [1]. *C. septicum* is part of normal gastrointestinal tract flora but when infection occurs, it is often fatal. *C. septicum* is capable of infecting normal tissue and thought to gain access to the bloodstream through the gastrointestinal mucosa. It is critically important that this highly fatal condition is considered early. A comprehensive approach using a careful history-taking and physical examinations along with microscopic analysis such as Gram stain of the tissues can confirm the diagnosis and associated complications [2]. Treatments should include aggressive surgical debridement and appropriate combination antibiotics, as well as general supportive medical care. A multidisciplinary team approach is necessary to manage these patients pre- and post-operatively. In conclusion, we report a case of traumatic gas gangrene due to *C. septicum* with colon cancer revealed by autopsy. It is important that primary care providers maintaining recognition of gas gangrene provide prompt and appropriate management for patients with skin and soft tissue infections in order to improve their clinical outcomes. 1. RARE CASE OF RENAL CELL CARCINOMA METASTASIS 15 YEARS AFTER RESECTION TO PAROTID GLAND AND EXTERNAL JUGULAR VEIN Karthik Kannegolla¹; Rakshita Chandrashekar¹; Abhishek Seth¹; Juraj zahatansky¹; sree chandana². ¹Western Michigan University Homer Stryker M.D. School of Medicine, Kalamazoo, MI; ²west michigan cancer centre, Kalamazoo, MI. (Tracking ID #2199699)

LEARNING OBJECTIVE #1: There have been case reports of unusual sites of metastasis of RCC to main pancreatic duct, biliary thrombus, superior sagittal sinus. However, unusual metastatic sites like head and neck region with late metachronous metastases (>10 years) are extremely rare. Hence metastasis from RCC must always be in the differential for any vascular presentation in a patient with a history of RCC.

CASE: Eighty-three year old Caucasian man with past medical history of hypertension, hyperlipidemia, left RCC 15 years back status post left nephrectomy presented with a 2 cm×2 cm painless left parotid swelling which gradually progressed over 4 months. Ultrasound revealed tumor thrombus in the left external jugular vein with extension in to other branches. CT soft tissue of neck revealed asymmetric contrast enhancement in the left masticator, retromandibular and external jugular vein. Fine needle aspiration cytology was consistent with metastatic RCC. He underwent partial left parotidectomy and excision of left external jugular vein with dissection of cranial nerve VII. Gross Pathology showed the 2.2×1.0×1.0 cm mass extending into the lumen of the vein. Given his age and extent of tumor, he was treated also with radiation therapy. He was started on Pazopanib and switched to VOTRIENT. Patient is being followed at the cancer center regularly and has been doing well for 2 years.

DISCUSSION: Renal cell carcinoma(RCC) is the most common primary neoplasm of the kidney. Common metastasis sites include lungs, liver and brain. Late metastasis 10 years after the curative nephrectomy is very rare. Vascular invasion into the external jugular vein is also very rare with less than 20 cases reported in literature. Renal cell carcinoma, especially clear cell, gains access to the venous system as the initial route of extrarenal spread. Intravenous growth can involve extrarenal veins or renal veins but it is extremely rare to metastasize and involve the head and neck veins. Considering the fact that kidneys receive 25 % of circulating blood volume, they are hypervascular tumours associated with multiple arteriovenous shunt, with a high expression of vascular endothelial growth factor(VEGF), the platelet-derived growth factor receptor and basic fibroblast growth factor(bFGF), good adaptive potential in a diverse array of microenvironments, RCC has a high hematogenous spreading potential. However, an alternative theory postulates that tumor emboli may spread through Batson's paraspinal venous plexus, bypassing pulmonary vascular filtration and reaching head and neck. There have been case reports of unusual sites of metastasis of RCC to main pancreatic duct, biliary thrombus, superior sagittal sinus. However, unusual metastatic sites like head and neck region with late metachronous metastases (>10 years) are extremely rare. Hence metastasis from RCC must always be in the differential for any vascular presentation in a patient with a history of RCC.

RECURRENT BENIGN LYMPHOCYTIC MENINGITIS- A CASE REPORT
Mayssam A. Nehme; Karolyn Teufel. George Washington University, Arlington, VA.
(Tracking ID #2159104)

LEARNING OBJECTIVE #1: Recognize benign recurrent lymphocytic meningitis

LEARNING OBJECTIVE #2: Prevent prolonged hospitalizations, unnecessary testing and treatment with associated costs.

CASE: A 33-year-old woman presented to the emergency department with headache, meningismus, subjective fever and vomiting of 3 days duration. She was overall healthy except for two previous hospitalizations for viral meningitis in 2006 and 2011, and possible bacterial meningitis in 2002. At the time of presentation, she denied any recent infections or sick contacts. She also denied any new neurologic symptoms including hallucinations, diplopia, photophobia, seizure activity or focal deficits. The patient recently traveled to Europe for business, but was not exposed to unpasteurized products, ticks or mosquito bites. She was in a monogamous relationship and did not have any history of genital or oral herpetic lesions. The physical exam revealed positive meningeal signs and was otherwise unremarkable. The patient was admitted to the hospital and a lumbar puncture revealed lymphocytic pleocytosis with CSF WBC 164, lymphocytes 99 %, glucose 55, total protein 90, RBC 23. We treated her with intravenous Acyclovir and her symptoms improved markedly within 24 h. The following day, HSV2 PCR result was positive and the patient was diagnosed with recurrent benign lymphocytic meningitis. She was discharged on oral Valacyclovir with a plan to consider suppressive therapy at outpatient follow up with an infectious disease specialist.

DISCUSSION: Recurrent benign lymphocytic meningitis was first described by Pierre Mollaret in 1944. It is a rare disease that manifests with recurrent episodes of aseptic meningitis followed by spontaneous recovery. The disease is most commonly seen in young adults, especially women. Patients generally present with acute headache, meningismus, fever and photophobia. They can also exhibit focal neurologic deficits, including cranial nerve palsies, seizures, hallucinations, diplopia and altered mental status. Most cases are associated with HSV2 infection and careful assessment including sexual history should be obtained. Patients do not always have a history of genital or oral herpes infection and analysis of CSF for HSV DNA is the gold standard for diagnosis. Once confirmed, patients can be treated with Acyclovir which may also be used as suppressive therapy. Recurrent benign lymphocytic meningitis should be considered in healthy patients with repeated episodes of meningitis. Early diagnosis may prevent prolonged hospitalizations along with the iatrogenic risks of inappropriate treatment, unnecessary testing and the associated costs

RECURRENT DAPSONE HYPERSENSITIVITY SYNDROME IN AN HLA-B*13:01-POSTIVE INDIVIDUAL WITH OCCULT MYCOBACTERIUM MARINUM INFECTION David M. Levine; Matthew Akiyama; Xian Jie (Cindy) Chen; Diana Esaiian; Neha Jindal; Vinh Pham; Patrick M. Cocks. New York University School of Medicine, New York, NY. (Tracking ID #2195193)

LEARNING OBJECTIVE #1: Describe the diagnosis and management of dapsone hypersensitivity syndrome.

LEARNING OBJECTIVE #2: Formulate a differential diagnosis for nodular lymphangitis.

CASE: A 60 year-old Chinese male with history of hypertension, diabetes, dyslipidemia, and coronary artery disease initially presented 6 months prior with a right fourth finger

lesion present for several months. A biopsy showed a diffuse dermal infiltrate of neutrophils and histiocytes; special stains were negative. Six weeks prior, the patient started fluconazole and dapsone, resulting in mild improvement, but upon discontinuing (1 month of dapsone), 6 days later he noticed the onset of a rash. His face was edematous with confluent erythematous patches, while his abdomen, chest, and upper extremities contained erythematous macules coalescing into patches with scattered foci of punctate crusts. His bilateral inguinal folds and proximal thighs demonstrated purpuric and erythematous macules, respectively. His lower legs, feet, and oral mucosa were spared. The rash was accompanied by new onset cough, diarrhea, fever (39.1 C), tachycardia, and tachypnea. Initial lab work was significant for venous lactate 3.28, AST 115, ALT 213, hypokalemia, anemia (hemoglobin 10.4, MCV 90), but no eosinophilia (later noted at 10 %). His initial RegiSCAR of 5 indicated probable DRESS which trended up to 6 (definitive DRESS) after eosinophilia was noted. Infectious and rheumatologic workups were negative. Treatment was initiated with IV methylprednisolone 80 mg every 6 h for 2 days, then 40 mg every 12 h for 2 days, with defervescence and slight improvement in rash. He was subsequently discharged on PO prednisone 30 mg daily. One day later he represented with recrudescence of fever (39.8 C), venous lactate, hepatitis, and leukocytosis with eosinophilia. He again received steroids with improvement. As an outpatient, he was slowly tapered, but upon tapering to 30 mg daily (day 25), the patient noted recurrent rash at his wrists and ankles and so prednisone 40 mg daily was reinstated with subsequent improvement. Another slow taper over months was successful. Subsequent HLA typing revealed heterozygosity for the HLA-B*13:01. Approximately 4 months after discharge, due to a lack of improvement in his finger lesion, another biopsy was sent, this time to the CDC, which tested positive for *Mycobacterium marinum* by PCR. *M. marinum* was treated with clarithromycin and rifampin with good effect.

DISCUSSION: Our case illustrates a classic presentation of Dapsone Hypersensitivity Syndrome (DHS) with a previously undescribed feature: recurrent relapse and clinical deterioration in the setting of steroid taper. Rapid steroid taper associated with drug hypersensitivity relapse has previously been reported in phenytoin, vancomycin, carbamazepine, leflunomide, and allopurinol. DHS requires two of four criteria: fever, generalized rash, hepatitis, and lymphadenopathy. Other findings might include mucosal involvement, exfoliative dermatitis, adenopathy, hemolytic anemia, and cholangitis. DHS onset ranges from 6 h to 21 weeks (mean 28 days) and resolves within 7 days to several months (mean 27 days). Persons that possess the HLA-B*13:01 allele are at increased risk for DHS. The initial discharge dose of 30 mg daily was likely inadequate, yet there are few guidelines to inform this decision. Prednisone dosing recommendations range from 0.8 to 2 mg/kg/d followed by a gradual taper over 3–6 months. This case also highlights the importance of identifying the etiologic agent for nodular lymphangitis in a timely fashion so that directed antimicrobial therapy may be initiated and adverse events from empiric agents may be prevented. Common etiologies include *Sporothrix schenckii*, *Nocardia* (most often *N. brasiliensis*), *M. marinum*, leishmaniasis, tularemia, and systemic mycoses. While *M. marinum* often eludes diagnosis due to poor growth on culture media, pathologic and molecular techniques are important in establishing the diagnosis. This was one of the first cases in the 2013 outbreak in New York City. Here we present a case of DHS in an HLA-B*13:01 positive individual with recurrent relapse and clinical decline after steroid taper in the setting of occult *M. marinum* infection. It is important for practitioners to remain cognizant of steroid dosing and taper during DHS treatment. Our case demonstrates that gradual, lengthy steroid taper may be crucial in preventing recurrent DHS, although more investigation is needed. It also demonstrates the utility of directed diagnostics for nodular lymphangitis.

RECURRENT DEBILITATING COMPARTMENT SYNDROME IN ASSOCIATION WITH UNDIAGNOSED HYPOTHYROIDISM Tatvam T. Choksi²; Abha Patel²; Richard Plotzker¹; Ravindra Hallur². ¹Mercy Catholic Medical Center, Philadelphia, PA; ²Mercy Catholic Medical Center, Darby, PA. (Tracking ID #2199276)

LEARNING OBJECTIVE #1: Major osseous or vascular limb trauma, crush injury, ischemia, burns etc. are well known causes of acute compartment syndrome (ACS). However, ACS can be an extremely rare and serious manifestation of underlying thyroid disease. Our review of the literature revealed at least three cases of compartment syndrome primarily associated with hypothyroidism. Here we describe a unique case of recurrent bilateral compartment syndrome in a young man with previously undiagnosed hypothyroidism.

CASE: A 30 year old African American male with history of hypertension presented to the emergency department with increasing pain, swelling and numbness of his right leg over 1 week. Symptoms were localized to his anterior right shin down to the dorsum of his right foot. He was recently diagnosed with compartment syndrome in the same extremity 2 months prior, at which time he underwent fasciotomy at an outside institution. On further review, he described an earlier episode of compartment syndrome of his left lower extremity 7 years prior that was also treated with fasciotomy. He denied any trauma, illicit

drug use, excessive exertion or alcoholism. He did experience fatigue and mild extensor calf pain. On exam, he was afebrile with a blood pressure of 160/80 mm Hg and a HR of 104 beats per minute. Examination of his right extremity revealed a tense, tender area over the right shin and exquisite pain with passive stretch and dorsi-flexion of the foot. His dorsalis pedis pulse on right was palpable, but diminished. Duplex ultrasound was negative for deep vein thrombosis. Due to the high suspicion of compartment syndrome, a Stryker needle was introduced revealing a compartment pressure of 35 mm Hg, confirming compartment syndrome. He underwent emergent four compartment fasciotomies of the right lower extremity. Vascular work up was negative for ischemia and the etiology remained unknown. From the records, it was noted that he had persistently elevated CPK (creatine phosphokinase) levels in the past, and that they continued to remain elevated post procedure with a peak level of 1002 U/L. Therefore, a thyroid panel was sent, which showed a TSH of 33.98 uIU/mL and T_4 of 0.66 ng/DL. He was started on 100 mcg of Levothyroxine at that time and eventually had a split thickness skin graft placed over the fasciotomy site. On subsequent follow up, the TSH had normalized.

DISCUSSION: Acute compartment syndrome is a clinical emergency characterized by increased intra-compartmental pressure that can result from any condition that decreases the capacity of or increases the volume of fluid within a defined fascial envelope, resulting in self-perpetuating ischemia, edema and myo-neural injury. Despite having a typical acute onset following the inciting event, in many cases no etiology can be identified. Hypothyroidism is an unusual and highly under-recognized etiology of compartment syndrome. Hypothyroidism causes increased deposition of glycosaminoglycan (GAG), primarily hyaluronic acid, in the dermis and epidermis, as well as in skeletal and smooth muscles. Moreover, thyroid hormone deficiency stimulates fibroblast GAG synthesis and inhibits its degradation. Hyaluronic acid deposition is associated with retention of fluid and an increase in vascular permeability to large molecules. Therefore, hypothyroidism can result in muscle enlargement, increased extravasation of plasma protein in the interstitial space, and impaired compensatory lymph flow and protein return rate. All of these mechanisms can contribute to an increase in compartment volume, predisposing an individual to develop compartment syndrome. Also, patients with hypothyroidism may have underlying myopathy suggested by stiffness or non-specific muscle ache, extensor calf pain and persistently elevated CPK levels, as in our patient. After initiation of treatment with Levothyroxine, over the last 18 months our patient has not had any recurrence of compartment syndrome. Thus, we conclude that hypothyroidism can result in the development of ACS especially in those with anatomical predisposition. Association between hypothyroidism and the development of compartment syndrome, though extremely rare, should not be overlooked. One should always consider undiagnosed or inadequately treated hypothyroidism as a potential cause of ACS when other common etiologies have been ruled out and history or records are suggestive of unexplained myopathy.

RECURRENT NON-OCCLUSIVE MESENTERIC ISCHEMIA DURING DIALYSIS Anene Ukaigwe²; Oluwaseun Shogbesan²; Opeyemi Fadahunsi²; Adetokunbo Oluwasanjo²; Anthony Donato¹. ¹Reading Health System, W. Reading, PA; ²Reading Health System, West Reading, PA. (Tracking ID #2199352)

LEARNING OBJECTIVE #1: Diagnose mesenteric ischemia

LEARNING OBJECTIVE #2: Recognize dialysis as a precipitant of non-occlusive mesenteric ischemia

CASE: Sixty-nine year old man presented to the emergency room with a 2 week history of postprandial abdominal pain, leading to food fear (sitophobia) and 12 lb weight loss over 2 weeks. His past medical history was significant for coronary and femoro-popliteal artery bypass grafting with multiple stents, for coronary and peripheral artery disease; hypertension, type II diabetes mellitus and chronic kidney disease (CKD) on peritoneal dialysis. His symptoms started after his peritoneal dialysate was changed to a more concentrated solution. His medications included carvedilol and isosorbide mononitrate. Physical examination revealed positive orthostatic vital signs, BP 147/83 mmHg; HR 58/min, sitting; 125/54 mmHg, HR 76/min, standing. His abdomen was soft, non-tender without inflammation or purulent drainage from his peritoneal dialysis port. The rest of his physical examination was unremarkable. Complete blood count revealed leukocytosis of 15.1 c/mm³ with chemistries at his baseline. Lactate was 2.5 mg/dl. CT scan of the abdomen revealed small-bowel ischemia with evidence of gas within mesenteric and hepatic portal veins. CT angiography of abdomen subsequently revealed diffuse atherosclerotic disease resulting in areas of moderate stenosis within the ostium of the superior mesenteric artery as well as within the abdominal aorta. His anti-hypertensives were held, however he remained unable to eat without pain. He therefore underwent percutaneous angioplasty of his celiac and superior mesenteric arteries with complete resolution of his symptoms. He was subsequently discharged without any further episodes of mesenteric ischemia.

DISCUSSION: Non-occlusive mesenteric ischemia (NOMI) is increasingly being recognized as a potentially lethal complication of dialysis in patients with CKD. It occurs in 2 % of dialysis patients vs 0.2 % of non-dialysis patients. During dialysis, the need to remove

large amounts of fluid leads to intravascular volume depletion, relative hypovolemia and hypotension. With repeated episodes, this may lead to NOMI as occurred in our patient. The clinical features include postprandial abdominal pain, sitophobia, nausea, vomiting with weight loss, which may be followed by guarding, fever, leukocytosis, metabolic acidosis and elevated lactate levels. The abdominal pain is usually out of proportion to the abdominal examination findings. When these symptoms and signs occur in a patient with ASCVD or risk factors for ASCVD, in the setting of intravascular volume depletion, drugs that reduce splanchnic flow e.g. digoxin, epinephrine, NOMI should be suspected. The diagnosis is reportedly missed up to 90 % of cases, therefore a high index of suspicion is needed. Prompt recognition and intervention is key to initiating appropriate management to prevent morbidity and mortality.

RECURRENT PERICARDITIS NOT RESPONSIVE TO NSAID THERAPY Kathryn Wakmundzki. Penn State University, Hershey, PA. (Tracking ID #2200125)

LEARNING OBJECTIVE #1: Recognize purulent pericarditis as a possible diagnosis when standard treatment fails.

LEARNING OBJECTIVE #2: Recognize diagnostic challenges in purulent pericarditis.

CASE: A previously healthy 37-year-old African American woman with recurrent episodes of presumed viral pericarditis unresponsive to NSAIDs presented with a fourth episode of pericarditis and fevers. She had a large pericardial effusion on echocardiogram with evidence of tamponade. Pericardiocentesis yielded 300 mL of purulent fluid (26,000 nucleated cells, 96 % neutrophils, greater than 100,000 RBCs). Blood and pericardial fluid cultures were negative. She required a pericardial window due to fluid re-accumulation. Empiric piperacillin-tazobactam led to symptom resolution within 24 h of initiation. Rheumatologic workup was negative, as was Tuberculosis and HIV testing. Two separate tissue specimens obtained during her window grew *Propionibacterium*. She was treated with 4 weeks of IV ceftriaxone with complete resolution.

DISCUSSION: Purulent pericarditis carries a mortality of up to 40 % with treatment and 100 % if untreated. It is, for this reason, important to suspect purulent pericarditis in refractory pericarditis or with suspicious pericardial fluid analysis because delay of treatment can have fatal consequences. Risk factors for bacterial pericarditis include pericardial effusion, chest surgery or trauma, immunosuppression, and chronic disease. Fluid analysis poses a challenge because, unlike Light's criteria for pulmonary effusions, there are no standard criteria for exudative, transudative, or purulent pericardial effusions. Typically, pericardial fluid with neutrophil-predominant leukocytosis, low glucose, and elevated protein and lactate dehydrogenase suggests purulence. Fluid culture should be performed but is often unrevealing for a specific cause or pathogen with diagnostic yield as low as 5–35 % of the time. While *Propionibacterium* has only been documented rarely as a causative agent, it is just one of many potential pathogens that will not respond to standard therapy with NSAIDs or colchicine. The most common bacterial pathogens include *Staphylococcus aureus* (36 %), *Streptococcus pneumoniae* (21 %), and *Hemophilus influenza* (12 %). Recommendations for empiric therapy are an antistaphylococcal antibiotic plus an aminoglycoside to cover these pathogens. With high clinical suspicion, purulent pericarditis should be drained immediately and treated empirically with antibiotics due to its challenging diagnostics and high mortality.

RENAL INFARCTION SECONDARY TO SPONTANEOUS RENAL ARTERY DISSECTION: A CASE REPORT Zijing Wu¹; Zeshan Siddiqui²; Christopher Smith¹. ¹Queen's University, Kingston, ON, Canada; ²University of Limerick, Limerick, Ireland. (Tracking ID #2192835)

LEARNING OBJECTIVE #1: To recognize spontaneous renal artery dissection as an important cause of renal infarction

CASE: A 52-year-old man with a history of gout and perforated diverticulitis presented to the hospital with acute onset left flank pain that developed 3 days prior to admission. He reported radiation of the pain to the left anterior abdomen as well as subjective fevers, chills and sweats. There was no diarrhea, nausea, vomiting, hematochezia, hematuria, urinary symptoms, rashes nor any rheumatological symptoms. He was a non-smoker and had no history of hypertension, atherosclerotic disease, cardiac arrhythmias, connective tissue disease, nephrolithiasis, recent abdominal trauma or risk factors for endocarditis. Blood pressure was 136/80 mmHg with a regular pulse rate of 106 beats per minute. Tympanic temperature was normal. Heart sounds were normal without murmurs or extra heart sounds. There were no peripheral stigmata of endocarditis and a fundoscopic exam was normal. The abdomen was soft and non-tender without organomegaly. There was mild tenderness to percussion in the left costovertebral angle. An electrocardiogram showed sinus tachycardia. Abnormal laboratory results included a white blood cell count of $18.8 \times 10^9/L$, lactate dehydrogenase (LDH) of 577 U/L, C-reactive protein (CRP) of 268 mg/L and a creatinine of 102 umol/L compared to a baseline of 62 umol/L. Urinalysis was negative. A computed topography (CT) of the abdomen and pelvis was performed.

The scan was negative for renal stones and recurrent diverticulitis. However, a large cortical infarct involving the upper pole of the left kidney was seen. An echocardiogram, blood cultures, antiphospholipid antibodies, and vasculitis panel were ordered. A CT angiogram performed subsequently showed acute dissection of the superior branch of the left renal artery. Anticoagulation with low molecular weight heparin was commenced with bridging to warfarin and the patient was discharged the following day in a stable condition with a creatinine level of 97 $\mu\text{mol/L}$. Results of thromboembolic and vasculitis workup all returned negative.

DISCUSSION: Renal infarction is a rare condition that is infrequently encountered by the general internist. It is often misdiagnosed initially as it mimics many other diseases. The clinical hallmarks include acute onset abdominal and/or flank pain, often accompanied by nausea, vomiting and macroscopic hematuria. Laboratory investigations may show microscopic hematuria, elevated creatinine levels, leukocytosis, elevated CRP as well as a high LDH. The most common identifiable etiologies of renal infarction include thromboembolic events originating from the heart (atrial fibrillation and endocarditis being the most common), renal artery injury and hypercoagulable states. In approximately 30 % of patients the etiology remains unclear even after an extensive workup for the aforementioned causes. Together with underlying arterial diseases, such as fibromuscular dysplasia and Ehlers-Danlos syndrome, renal artery dissection is among the leading causes of renal infarction caused by renal artery injury. Spontaneous renal artery dissection (SRAD) is a rare entity that occurs in the absence of an extension from an aortic dissection, abdominal trauma or surgical interventions, such as percutaneous angioplasty. Similar to our patient, SRAD typically afflicts men in their fourth to sixth decade of life, who are otherwise healthy, without any clear identifiable risk factors for dissection, such as hypertension or inherited collagen tissue disease. The CT angiogram plays a pivotal role in the diagnosis of SRAD and it is part of the workup that must be considered for a patient in whom the probability of a thromboembolic or hypercoagulable event is low. Although there is no high quality data to guide the treatment of SRAD, most published cases advocate for anticoagulation therapy, using heparin with bridge to warfarin for a typical duration of 3 months. Patients should be monitored for the development of renal failure and hypertension, while revascularization therapy should be considered for patients who develop complications from SRAD.

RHEUM SERVICE PLEASE! THE CASE OF AN UNUSUAL RASH Muneza Muhammad; Min Ji Kim; Maulin Shah. Baylor College of Medicine, Houston, TX. (Tracking ID #2199472)

LEARNING OBJECTIVE #1: Recognize need for histopathologic work-up in connective tissue diseases.

LEARNING OBJECTIVE #2: Understand higher risk of malignancy associated with dermatomyositis.

CASE: A 54 year old African American male with history of hypertension presented with a 4 week history of centrifugally spreading painful, pruritic, rash, myalgias, arthralgias, odynophagia, dysphagia, fatigue and malaise. He previously went to an outside hospital where he was diagnosed with contact dermatitis and prescribed a short course of oral steroids with no relief of his symptoms. On admission, he appeared to have erythematous and hyperpigmented, scaly patches and papules on the bilateral upper extremities, back, chest, periumbilical area, neck, ears and thighs. The bilateral periorbital skin, MCP, PIP, and DIP joints also appeared to have fine scale, erythema, and hyperpigmentation. He had 3/5 strength in the shoulders and hips bilaterally along with joint edema in the wrists and fingers. He was found to have AKI with granular and WBC casts; elevated CK in the 5000 s; and transaminitis. He was initially thought to have discoid or systemic lupus erythematosus or psoriatic arthritis. Rheumatologic workup was largely negative except for mildly elevated rheumatoid factor, ESR, CRP, and Aldolase. Skin biopsy was consistent with dermatomyositis and muscle biopsy was consistent with inflammatory myopathy. The patient was diagnosed with dermatomyositis and started on high dose steroids with improvement in his symptoms. AKI resolved with IV fluids and transaminitis improved after initiation of steroid therapy.

DISCUSSION: Dermatomyositis is a rare, idiopathic, inflammatory myopathy associated with skin manifestations. Classic skin findings like Gottron's papules, shawl sign, and heliotrope rash may aid in diagnosis, but are not always present. In this patient with dark skin, his rash and symptoms were a diagnostic mystery as his skin findings were not typical for dermatomyositis. He was misdiagnosed with contact dermatitis, DLE/SLE, and psoriatic arthritis before skin biopsy was done. It was only in hindsight, reviewing pictures of his initial presentation, that subtle skin manifestations were identified (like the heliotrope rash and Gottron's sign). Inflammation in darker skin can appear more violaceous and hyperpigmented, causing the clinician to miss subtleties in physical exam findings and misdiagnose the patient as it happened in this case. Thus, histopathologic diagnosis is crucial and necessary in any patient with rash and systemic symptoms even if serologic workup is negative or indeterminate. However, the work doesn't stop at diagnosis. Patients with dermatomyositis have a five to seven times higher incidence of cancer as compared to

the general population. Age-appropriate cancer screening should be initiated at time of diagnosis as peak incidence of malignancy diagnosis occurs within the 2 years before and after diagnosis. Tumor markers in our patient were negative and subsequent CT of the chest, abdomen, and pelvis did not reveal any malignancy. Diagnosing connective tissue diseases, like dermatomyositis, can be difficult given the rarity of the condition. This case highlights the need for histopathologic workup in patients with pigmented skin in which classic skin manifestations may not be as obvious. Additionally, it is always important to recognize the need for cancer screening in patients with these rare connective tissue diseases.

RIGHT UNDER HER NOSE Justin D. Kaner¹; Lauren Shapiro². ¹Einstein/Montefiore Medical Center, New York, NY; ²Montefiore Medical Center, Bronx, NY, NY. (Tracking ID #2198573)

LEARNING OBJECTIVE #1: Recognize the challenges of cancer diagnosis in an obese patient

LEARNING OBJECTIVE #2: Learn the basics of epidemiology, diagnosis, and prognosis of nasopharyngeal carcinoma

CASE: A 39 year old woman with a medical history significant for morbid obesity, presented with complaints of constipation, lower extremity weakness and severe leg and back pain for 3 months. Exam was significant for hypoactive bowel sounds, pain to palpation along the lumbar spine and the right femur and 4/5 muscle strength in the right lower extremity. Lymph node exam was unremarkable although limited due to her body habitus. Labs obtained at presentation were significant for a serum calcium of 19.2 mg/dL, creatinine of 4.4 mg/dL, BUN of 37 mg/dL, hemoglobin of 8.8 g/dL, white blood cell count of 16.4 k/u, lactate dehydrogenase of 506 U/L, parathyroid hormone of 10.2 pg/mL. SPEP showed two faint monoclonal bands. CT-scan with contrast as well as an MRI of the cervical/lumbar/thoracic spine showed extensive lytic bony lesions. There was no abdominal or pelvic adenopathy. The patient was treated for her hypercalcemia and her renal failure improved. Diagnosis had been presumed to be multiple myeloma given the constellation of above findings. Bone marrow biopsy was obtained and showed infiltrating poorly differentiated carcinoma. In addition, she had a negative UPEP and a normal kappa/lambda ratio, so we began a search for a primary tumor. Of note the patient informed us that she had told her primary care doctor about a cyst in her neck about 1 year prior, and that to this point it hadn't been evaluated further. A more extensive lymph node exam with better positioning revealed an enlarged cervical lymph node. Further imaging including an MRI with contrast of the face and neck as well as PET-CT showed a soft tissue thickening of the left adenoid in addition to extensive bilateral cervical and left sided retropharyngeal lymphadenopathy. Serum epstein-barr virus DNA pcr was obtained and was 51,800 copies/mL. Biopsy of the left adenoid soft tissue mass was performed and diagnosis was confirmed as metastatic epstein-barr virus positive undifferentiated non-keratinizing nasopharyngeal carcinoma.

DISCUSSION: Many studies have shown a strong association between body-mass index and cancer related mortality. In particular, obese non-smoking women seem to have the greatest association between mortality and body mass index. The risk extends to many common cancers in women including uterine, cervical and breast, but also includes cancers of the pancreas, kidneys and esophagus. The published data on the subject suggests that there are several possible explanations for this phenomenon, including that obese individuals are screened less and thus are diagnosed with a later stage of cancer. Several studies have shown that obese women are screened roughly 5 % less than their normal body-mass index counterparts for cancers of the breast and cervix. Other factors related to the association between body-mass index and cancer related mortality include poor functional and nutritional status, as well as the possibility that obesity itself can induce carcinogenesis. This highlights the importance of being aware of the challenges associated with obesity and cancer diagnosis. Nasopharyngeal carcinoma is an uncommon entity in the western world with an incidence of 0.5/100,000 people. In endemic areas such as southern China, incidence is as high as 25/100,000. In the US, common risk factors for nasopharyngeal carcinoma are smoking and alcohol use, similar to other head and neck cancers. Diagnosis requires a high clinical suspicion and should include a very thorough exam focusing on the lymph nodes of the head and neck. When patients present with early disease, they usually have local symptoms including headache, nasal congestion, bloody nose, ear infections and sometimes a patient may find a swollen lymph node in their neck. Nasopharyngeal carcinoma often mimics other more common conditions due to the type of symptoms it causes as well as its relatively "hidden" location. Distant metastases are decidedly uncommon and only represent a small percentage of presentations. In epstein-barr virus positive nasopharyngeal carcinoma, viral DNA can be demonstrated in the serum via a pcr test. This has been shown to have significant prognostic value, and can be used to evaluate for early signs of recurrence. Recurrence after successful treatment has been shown to occur from 3 to as many as 10 years after treatment, so monitoring is vital.

RITUXIMAB INDUCED SERUM SICKNESS Paras Karmacharya⁴; DILLI R. POUDEL⁴; Ranjan Pathak⁴; Sushil Ghimire⁴; Pragya Shrestha¹; Shawn Potteiger⁴; Madan R. Aryal³; Anthony Donato². ¹Nanjing MEdical College, Nanjing, China; ²Reading Health System, W. LEARNING OBJECTIVE #1: Recognize Rituximab Induced Serum Sickness (RISS) clinically as it may mimic exacerbation of various rheumatologic conditions

LEARNING OBJECTIVE #2: Avoid further infusions of rituximab in patients with a history of RISS as it may provoke more severe symptoms

CASE: A 57-year-old female with longstanding seropositive (rheumatoid factor positive, cyclic citrullinated peptide antibody negative) rheumatoid arthritis (RA) presented to the emergency department with a 1-day history of low-grade fever, pruritic rash all over her body and diffuse joint pains. It did not involve her mucous membranes or her palms and soles. She did not have any dyspnea, chest pain, angioedema, abdominal pain or loose stools. She noted receiving the first dose of rituximab 7 days prior and had mild rigors during infusion which was relieved with benadryl. She received pretreatment with acetaminophen and antihistamines however she had not received corticosteroids. Her medications included methotrexate 25 mg oral once weekly and hydroxychloroquine 200 mg twice daily for her treatment of active, refractory RA. She had failed multiple tumor necrosis factor (TNF) inhibitors previously and had undergone multiple joint replacements and arthrodeses. She noted no history of adverse reactions related to TNF inhibitors. Physical examination revealed temperature of 38.4 °C, heart rate 87 beats / minute and blood pressure 123/69 mm Hg. There was maculopapular skin eruption located face, scalp, trunk and both upper and lower extremities. There was no parotid gland enlargement or lymphadenopathy. Her musculoskeletal examination revealed active synovitis in the metacarpophalangeal and proximal interphalangeal joints. Laboratory parameters revealed a white blood cell count of 9710/mm³, hemoglobin 8.9 g/dL (baseline: 9.0 g/dL) and platelet count 25,000/mm³ (baseline: 30,000/mm³). ESR and CRP were elevated at 54 mm/h and 9.6 mg/L respectively. Blood chemistries and liver function tests were within the normal range. Complement levels were low with C3 level of 57 mg/dL (79–152 mg/dL), C4 level 8 mg/dL (12–42 mg/dL) and CH50 40 U/mL (31–60 mg/dL). Immunoglobulin (Ig) M level was decreased with a value of 43 mg/dL (46–30) while other immunoglobulin levels were within the reference range with IgG of 1470 mg/dL (751–1560 mg/dL) and IgA 647 mg/dL (82–453 mg/dL), IgM 43 mg/dL (46–304 mg/dL). Urinalysis did not reveal proteinuria or hematuria. Blood culture and urine cultures were negative. Diagnosis of rituximab-induced serum sickness was made on the basis of her classic clinical triad of fever, rash and arthralgia following rituximab infusion. Her symptoms resolved spontaneously over the next 2 days and she did not require corticosteroids at the time of discharge. She was advised to avoid further therapy with rituximab.

DISCUSSION: Serum sickness is a classic immune-complex(IC) mediated Type III delayed hypersensitivity reaction. The deposition of IC into the target tissues causes activation of the complement cascade and recruitment of mast cells and phagocytes. It usually occurs 10–14 days following antigen exposure or within a few days of secondary antigen exposure. Rituximab is a chimeric murine-human monoclonal antibody directed against CD20 antigen on the surface of B lymphocytes. Most commonly, it is associated with infusion reaction at the time of infusion which is thought to be related to immediate host cytokine release. RISS presents as a typical Type 3 hypersensitivity reaction with the classic triad of fever, rash and arthralgia. Other symptoms reported include myalgia, malaise, fatigue, conjunctival hyperemia and purpura. It has been reported in different rheumatologic (mostly Sjogren's syndrome) and hematological conditions. Most commonly it has been reported to occur following the second dose of the first cycle. The pathogenesis of RISS remains elusive. It has been found to be associated with conditions with concomitant hypergammaglobulinemia and rheumatoid factor positivity, leading some to speculate about the potential pathogenic role of elevated RF, immunoglobulins and human antichimeric antibody. Corticosteroids are the mainstay of management and symptoms are usually self-limited in mild cases. Repeat infusion of rituximab after RISS may not be appropriate, as patients have been reported to have more severe symptoms following a second exposure.

ROUND AND ROUND WE GO—WHERE THE WORMS STOP, ONLY THE ASTUTE CLINICIAN WILL KNOW Adrienne D. Workman¹; Josh Evans¹; Leigh K. Hunter². ¹Methodist Dallas Medical Center, Dallas, TX; ²Methodist Hospitals of Dallas, Dallas, TX. (*Tracking ID #2193145*)

LEARNING OBJECTIVE #1: Review *Strongyloides stercoralis*' complex life cycle and its impact on clinical presentation, symptomatology, complications and potentially delayed diagnosis

LEARNING OBJECTIVE #2: Recognize the hyperinfection syndrome of strongyloidiasis, its predisposing factors and manifestations, and review preventive and therapeutic strategies

CASE: A 55 year old Laotian man with past medical history significant for systemic lupus erythematosus complicated by stage IV-V nephritis, recurring pruritic skin rash, waxing and waning abdominal pain, diarrhea, and intermittent respiratory symptoms (with several "pneumonias") presented to the emergency department (ED) with significant worsening of these symptoms for approximately 1 week. Six months prior to his admission, he was hospitalized for respiratory failure necessitating intubation and worsened renal function requiring intensified immunosuppression with cyclophosphamide, high dose steroids and temporary hemodialysis. Since that time, the recurring GI, respiratory and dermatologic symptoms had intensified to the point of bloody diarrhea, dyspnea, hemoptysis, and pleuritic chest pain prompting his ED visit. Physical examination revealed the patient to be alert and oriented at time of admission. He was afebrile, tachycardic, tachypneic, and hypotensive with oxygen saturation of 96 % on 2 L oxygen. His lungs were clear to auscultation, heart was without gallop or rub, abdomen was mildly tender to palpation, rectal exam was notable for bloody stool, and skin exam demonstrated a papular, serpiginous, exanthem over his trunk, thighs and back. He had no joint tenderness or swelling and his cognitive function was intact. Laboratory values were significant for renal insufficiency, anemia, and mild elevation of transaminases. Chest radiograph demonstrated numerous bilateral lung nodules approximately 5 mm in diameter not observed on prior imaging. Extensive evaluation for infectious etiologies was undertaken and empiric antibiotic therapy with vancomycin, meropenem, moxifloxacin and trimethoprim/sulfamethoxazole was initiated. The patient rapidly deteriorated with progressive pulmonary infiltrates and hemorrhage, refractory shock, multiple organ failure and gastrointestinal bleeding. He subsequently expired and postmortem sputum specimen demonstrated a helminthic parasite confirmed as *Strongyloides stercoralis*.

DISCUSSION: *Strongyloides stercoralis* is a parasitic nematode endemic in tropical and subtropical regions around the world. Derived from the Greek word strongylos meaning round, the name *Strongyloides* appropriately refers to this roundworm endemic in Vietnam, Laos, and Cambodia where its prevalence is as high as 10 %. The highest rates in the US occur in residents of the southeastern portion of the country and in travelers to or immigrants from endemic areas. Infections have been reported to persist for more than 40 years in individuals secondary to *Strongyloides*' ability to autoinfect its host. Following infection, symptoms occur as the result of either the adult worm residing in the small bowel or by parasitic penetration and migration to distant tissues such as skin and lung. Gut symptoms are usually secondary to parasite-induced duodenitis resulting in abdominal pain, dyspepsia, diarrhea, nausea, or vomiting. Transpulmonary migration of larvae may manifest as dry cough, dyspnea, hemoptysis, recurrent fever, pneumonitis resembling bacterial pneumonia, acute respiratory failure, pulmonary embolism or asthma that paradoxically worsens with steroid use. Dermal migration produces distinctive, migratory eruptions with raised erythematous tracks known as larva currens. Presence of eosinophilia is not predictable and may be infrequent with the more serious hyperinfection syndrome. The diagnostic gold standard is serial stool exams, but sensitivity of a single stool sample is less than 50 % due to larvae being excreted intermittently and requires up to 7 stool exams to approach a sensitivity of 100 %. Duodenal aspirates and serologies may also be utilized. First line treatment is ivermectin with duration based on the patient's response and should be given until symptoms resolve with negative stool tests for two weeks. In conclusion, our patient succumbed to chronic strongyloidiasis, which transitioned to hyperinfection syndrome with intensified immunosuppression. This is an example of the importance of obtaining a complete and correct epidemiologic history in securing a prompt and accurate diagnosis. We will review *Strongyloides*' epidemiology, life cycle, predisposing conditions, common and uncommon presentations, complications, therapeutic options and prognosis.

SARCOMA SPOUT: A RARE CASE OF BILATERAL CHYLOTHORAX IN HIV/AIDS PATIENT WITH A HISTORY OF CUTANEOUS KAPOSI'S SARCOMA Kerri M. Lydon; Ali F. Yousif; Ricardo E. Nuila. Baylor College of Medicine, Houston, TX. (*Tracking ID #2200284*)

LEARNING OBJECTIVE #1: Recognize Kaposi's sarcoma as a cause of chylothorax

LEARNING OBJECTIVE #2: Chemotherapy should be considered in patient's with KS related chylous pleural effusion

CASE: A 25-year-old male with history of HIV/AIDS and Kaposi's Sarcoma (KS), who presented with two days of fever, left chest wall pain, and increasing shortness of breath. Denied productive cough, night sweats, or weight loss. Patient was diagnosed with HIV 2 years prior, developed cutaneous KS lesions on trunk and extremities few months later. Upon admission he has been compliant with highly active anti-retroviral therapy (HAART) for over 1 year with CD4 count of 316, and a viral load of 10,300. He received a total of 7 cycles of Doxorubicin for the KS with significant regression of cutaneous lesions. Exam was remarkable for temperature of 101.80 F, respiratory rate of 40 with normal oxygen saturation. Lung examination revealed absent breath sounds on the left. Few scattered Kaposi's skin lesions were observed on the right lateral chest wall. No oropharyngeal lesions or lymphadenopathy noted. CT chest showed areas of loculated

empyema in the left pleural space and an enlarging right pleural effusion. Left-sided thoracentesis and chest tube insertion yielded 2.3 Liters (L) of milky appearing fluid with analysis revealing triglycerides 2283 mg/dL, LDH 1073 U/L, Protein 6.5 g/dL, WBC 26.5 K/uL with neutrophilic predominance. Vital signs and respiratory status improved after thoracentesis. Cultures from the pleural fluid grew *Streptococcus mitis*. A chest tube inserted on the right also yielded milky fluid and studies consistent with a chylous effusion. In addition to antibiotics, patient was started on octreotide drip and low fat diet. He continued to have 4–5 L of chylous drainage daily and eventually underwent a left thoracotomy for decortication of the loculated empyema. Intraoperatively, a chyle leak was observed where a Kaposi's lesion was seen invading the thoracic duct. Surgical ligation of the duct was attempted. Given chest tubes continued to drain postoperatively greater than 2 L of chyle daily, one cycle of liposomal Doxorubicin was administered with significant reduction in output to <500 cc daily.

DISCUSSION: Kaposi's Sarcoma (KS) remains one of the most common AIDS-associated neoplasm, it is a highly vascular, usually mucocutaneous neoplasm caused by HHV8. An important distinction of the AIDS related KS is its increased propensity to involve visceral organs and lymphatics. Pulmonary manifestations of AIDS-related Kaposi's sarcoma include endobronchial, parenchymal, and pleural involvement. Chylothorax is a rare complication of pleural KS. It is associated with significant morbidity and mortality hence requiring prompt recognition. KS can metastasize to the thoracic duct (TD) as seen in our patient leading to obstruction of lymphatic drainage leading to chylothorax development. The management of chylothorax in AIDS-associated KS is often challenging since this is a rare presentation and lack of standard treatment algorithm. Most evidence-based studies for conservative management with octreotide infusions and low-fat diet are obtained from studies on pediatric populations and traumatic thoracic duct injuries. After failed conservative approaches and thoracic duct ligation, we initiated liposomal Doxorubicin infusion with notable reduction of chylous pleural effusion output. In addition to conservative management, early initiation of chemotherapy should be considered in patients with high output chylothorax secondary to KS.

SAVED MY CD4 CELLS; LOST MY PROXIMAL TUBULAR CELLS Marianna Sargsyan²; Sathish Krishnan²; Harsimran S. Sekhon¹. ¹Presence Saint Francis Hospital, Evanston, IL, Evanston, IL; ²Saint Francis Hospital, Evanston, IL. (Tracking ID #2198260)

LEARNING OBJECTIVE #1: Acute kidney injury (AKI) and Fanconi syndrome (FS) are infrequent complications of tenofovir. The pathogenesis underlying these adverse effects remains elusive. Tenofovir is primarily excreted by the proximal renal tubular cells. It is believed that the adverse effects are due to tenofovir-induced mitochondrial DNA depletion and direct cytotoxicity of the proximal tubular cells.

CASE: A 45 year old female was admitted with 3-day-history of lethargy and confusion. She had a past medical history of HIV, hypertension and schizoaffective disorder. Her medications included atazanavir, lamivudine, emtricitabine, tenofovir, metoprolol, quetiapine and sertraline. She did not have fever, chills, headache, cough, vomiting, diarrhea or dysuria. Her vital signs were within normal limits. On physical examination, she was lethargic and confused. No focal weakness was demonstrated. Laboratory work-up showed WBC 8600/mm cu, hemoglobin 12.6 g/dL, platelets 144,000/mm cu, serum glucose 108 mg/dL, creatinine 3.68 mg/dL, BUN 74 mg/dL, potassium 3.1 mEq/L, sodium 145 mEq/L, chloride 120 mEq/L, bicarbonate 16 mmol/L, albumin 3.1 mg/dL and phosphorus 1.6 mg/L. Her BUN and creatinine levels were normal 2 months prior to the admission. Despite continued replacement, her potassium and phosphorus levels remained low, and her hyperchloremic non-anion gap acidosis worsened. The fractional excretion of sodium was 3.2 % and trans-tubular potassium gradient was 8.4 consistent with intrinsic renal etiology for AKI and potassium wasting in urine respectively. Serum uric acid level was 1.9 mg/dL (2.4–7.1 mg/dL), urine pH was 5.4, and urinalysis showed glycosuria, proteinuria and aminoaciduria. A detailed review of her medications revealed that she was taking tenofovir in two forms: one as viread and another as truvada. She was diagnosed with tenofovir associated AKI and Fanconi syndrome. She was switched to a non-tenofovir containing regimen for HIV, and was treated with intravenous normal saline and potassium phosphate. Her lethargy and confusion resolved. At one month follow-up, her creatinine was 1.15 mg/dL, potassium was 4.6 mEq/dL and phosphorus was 3.0 mg/dL.

DISCUSSION: Proximal renal tubular dysfunction resulting from the tenofovir can cause impaired reabsorption of amino acids, glucose, uric acid, bicarbonate and phosphate. As a consequence, patients develop AKI, hypokalemia, hypophosphatemia, hypouricemia and non-anion gap metabolic acidosis. It usually occurs during the first year of the therapy but, can occur at any stage of the treatment. And the risk increases with higher doses and concomitant usage of other nephrotoxic drugs. AKI and FS usually resolve with the discontinuation of the drug, but occasionally, can result in irreversible renal injury. So, it is important that clinicians be aware of the potential adverse effects so that it can be recognized early and patients can be switched to alternate antiretroviral regimen. It is vital

to monitor renal function, serum electrolyte levels and urinalysis periodically in these patients.

SECONDARY HEMOPHAGOCYTIC LYMPHOHISTIOCYTOSIS: RARE ETIOLOGY OF HEPATIC FAILURE AND REFRACTORY BLEEDING IN ADULTS Mahpara Khaliq¹; Roderick Go². ¹Stony Brook University Medical Center, Bay Shore, NY; ²Stony Brook University Medical Center, Stony Brook, NY. (Tracking ID #2199445)

LEARNING OBJECTIVE #1: Recognize the clinical features of Hemophagocytic Lymphohistiocytosis (HLH) in an adult patient

LEARNING OBJECTIVE #2: Understand the aggressive nature and need of rapid escalation of therapy in HLH
