Abstract

This research explores how television viewers' online program engagement (OPE)—engagement in social media conversations about television programs—relates to audience size during ads in those programs. We leverage a multisource dataset of 8417 ad instances, volume and deviation measures of OPE activity (program-related Twitter mentions), and audience size during ads. We show that increases in OPE volume and positive deviations from the episode's average level of OPE before an ad relate to higher ad audience size. To explain, we argue that OPE reflects viewers' program involvement which attenuates their channel-changing behavior during ads. Positive OPE deviations moreover relate to higher ad audience sizes most strongly for earlier ads in a break. Our results help television networks and advertisers strategically determine ad placements for increased ad audience size by highlighting social episodes (characterized by high OPE volume) and social moments (characterized by positive OPE deviations) as attractive advertising environments.

Keywords Television advertising · Audience size · Online word-of-mouth · Social TV

Introduction

Watching live television is currently the most popular form of media consumption, to which the average U.S. consumer devotes about four hours per day (Nielsen 2019). Given the abundance of television content available, viewers typically engage in substantial channel switching once screened content, such as ads, ceases to meet their preferences (Wilbur 2016). Since audience size—the number of households watching a program at a specific time—is the core performance metric for the television industry, understanding what drives dynamics in viewership over the course of an episode

and especially during ads is important to networks and advertisers.

In this research, we leverage the continued megatrend of mobile devices becoming an integral part of consumers' lives to shed light on this issue. In particular, 85% of U.S. consumers use their mobile devices while watching television (eMarketer 2017; Nielsen 2015a). Moreover, online program engagement (OPE)—viewers' engagement in social media conversations about television programs, also known as social TV activity (Benton and Hill 2012)—is among the most widespread multiscreen behaviors in which nearly 40% of U.S. multiscreeners engage (IAB 2015). Given that OPE has recently drawn interest as a readily observable indicator for viewers' program involvement, a measure that is typically difficult to obtain (Nielsen 2015b), we propose that observing viewers' OPE during live television episodes can help explain audience size during ads.

Prior research has begun to investigate how OPE before and after a program's airing relates to aggregate¹ episode viewership. While the results indicate a link between OPE and consumers' television consumption, the findings are ambivalent as some studies suggest that episode audience size may rise with increasing volumes of OPE prior to that

¹ We use the term “aggregate” to indicate an episode-level measure of audience size, as opposed to a more granular, within-episode measure of audience size.

program's airing (e.g., Gong et al. 2017; Liu et al. 2016), while others find that post-program OPE is more important (Seiler et al. 2017). However, so far research has not examined within-episode fluctuations in audience size and thus offers little guidance in explaining audience size during individual ads. We thus expand prior work by investigating how viewers' OPE during television episodes relates to ad audience size in these episodes. Investigating this relationship is important because it provides advertisers and networks with insights on how to strategically place ads to increase ad audience size. Such insights are valuable because (1) ad audience size is vitally important to the television advertising industry and (2) viewers' channel-changing renders aggregate episode viewership not representative of ad audience size, as explored in previous research.

Regarding the former point, audience size during individual ads is the core determining factor for pricing in television ad buys, a thriving industry with about \$70 billion in annual revenues in the U.S. (e.g., Crupi 2019; Friedman 2019; Katz 2013; Lafayette 2018a; Statista 2019). In addition, ad audience size is regarded as a fundamental measure of ad effectiveness (e.g., Danaher 1995; Schweidel et al. 2014; Teixeira et al. 2010; Wilbur et al. 2013) and is directly related to brand sales (Tuchman et al. 2018). Yet, regarding the latter point, aggregate measures of episode audience size—those employed in previous research on OPE and often reported to advertisers (e.g., Crupi 2019; Friedman 2012; Lafayette 2018b; Schwarz 2019; Story 2007; see also interviews with industry experts in [Web Appendix 1](#))—are not representative of actual audience size during ads. Since viewers frequently switch channels while watching television programs, audience sizes may vary substantially throughout an episode. Indeed, declines by as much as 20% within the beginning of an ad break are common (Schweidel et al. 2014), and some households skip more than 60% of the ads they are exposed to (Tuchman et al. 2018). In this research, we thus extend recent investigations by examining the relationship between viewers' OPE and audience size during ads.

To investigate this relationship, we bridge extant work on viewers' channel-changing behavior during television advertising (e.g., Schweidel et al. 2014; Teixeira et al. 2010; Wilbur 2016) with the emerging research stream on OPE (e.g., Fossen and Schweidel 2019; Liu et al. 2016; Seiler et al. 2017). In line with past work (Fossen and Schweidel 2019), we treat OPE as a measure of viewers' program involvement, which we posit may attenuate their channel-changing behavior during advertisements, leading to higher audience size during ads. In this way, we seek to answer the primary research question: how does viewers' OPE relate to audience size during television advertisements? We explore two measures of OPE: (1) volume, referring to the relative volume of program-

related online word-of-mouth (WOM) in an episode leading up to an ad's airing, and (2) deviation, referring to the deviation in OPE from the episode's average level of OPE, measured as the difference between OPE volume right before an ad airs and the average per-minute OPE volume in an episode leading up to the ad's airing. We also supplement our analyses with a large set of ad and program characteristics. This allows us to explore our secondary research question: how do ad and program characteristics influence ad audience size in the age of multiscreening consumers?

To answer our research questions, we build a multisource dataset including second-level data on national primetime television ad instances, audience size during these ads, OPE, that is, social media conversations mentioning the programs in which the ads air, and a rich set of ad and program characteristics. Altogether, the data comprise 8417 ad instances for 248 brands that aired on 83 television programs during the fall 2013 television season.

The results show that OPE significantly relates to audience size during television ads over and above conventionally studied ad and program characteristics. We find that increases in OPE volume and positive OPE deviations prior to the airing of an ad relate to higher audience size for that ad. We argue that these relationships exist because OPE reflects viewers' program involvement, which attenuates their channel-changing behavior leading to heightened audience size during the ad. Moreover, we identify ad position as an important moderator of the relationship between OPE deviation and ad audience size. Specifically, positive OPE deviations relate to improved ad audience size most strongly for ads airing earlier in a break. Overall, we find that airing ads in social episodes (characterized by high OPE volume) and after social moments (characterized by positive OPE deviations), especially when ads air early in an ad break, results in larger ad audience sizes. These insights provide managers with important guidance to strategically determine ad placements for increased ad audience size.

Our research contributes to the literature in three key ways. First, previous research shows that OPE can relate to aggregate audience size of television programs (e.g., Gong et al. 2017; Liu et al. 2016; Seiler et al. 2017) but has not accounted for changes in audience size over the course of an episode. Building on this work, we present the first examination of the relationship between OPE and audience size during individual ads. Leveraging OPE as an observable measure of viewers' involvement with an ongoing program, we provide an enhanced understanding of how OPE can serve as an indicator of viewers' ad response at specific moments of an episode. These results extend insights from extant work on OPE and provide television networks and advertisers with actionable insights on determining ad placements (within social episodes and after social moments) to improve ad audience size.

Second, we enrich the growing debate on whether or not social episodes are beneficial for advertisers (e.g., Nielsen 2015b; Nielsen 2015c). Specifically, we extend Fossen and Schweidel (2017, 2019), who find that airing ads during social episodes impacts the volume of online WOM about the ad and increases online shopping behavior on the advertiser's website, by showing that ads airing during social episodes see heightened audience size. We further contribute to this research by showing that OPE volume and deviation are distinct measures (correlation $r = -.001$) to identify social episodes and social moments in episodes. To the best of our knowledge, we are the first to distinguish between these two measures and show that both are individually important to identifying attractive ad opportunities.

Third, technological advances of the evolving digital economy have created opportunities for viewers to engage with programs online and for firms to leverage this data to learn about consumer preferences and markets with unprecedented degrees of accuracy. In this regard, we further emerging research efforts that examine how firms can listen in on social media to generate cost-effective insights about consumer behavior in real-time (e.g., Lamberton and Stephen 2016; Schweidel and Moe 2014). Based on publicly available OPE data (Tweets), we gain a better understanding of audience size dynamics during television episodes and individual ads, information that is currently slow and costly for firms to obtain (e.g., Friedman 2012; Tuchman et al. 2018; expert interviews in Web Appendix 1). As the ongoing process of digitalization will continue to push the frontier on what firms can achieve by leveraging social media data, we hope this research fuels further exploration of innovative approaches for learning about consumer preferences at scale.

We proceed as follows. In the next section, we review relevant extant work on online WOM, OPE, and television advertising as a foundation for our research. We then describe the data and discuss our modeling approach. Last, we present the results of our empirical investigation, discuss corresponding implications, and provide directions for further research.

Background

Related research on the relationship between OPE and audience size

Previous research has investigated the relationship between OPE and aggregate measures of audience size at the episode level. We extend this work, as summarized in Table 1, by (1) investigating audience size during individual ads rather than aggregate audience size at the episode level, (2) considering OPE during, instead of before or after, programs, and (3) examining OPE volume and deviation as two distinct measures to identify promising advertising opportunities.

Previous research finds mixed results regarding the relationship between OPE before or after an episode and aggregate episode audience size, as shown in Table 1. Some studies indicate a positive relationship, such as Lovett and Staelin (2016) and Gong et al. (2017), who show that customer-driven offline and online WOM as well as firm-initiated Tweets, respectively, have positive impacts on aggregate program audience size. Also, Liu et al. (2016) find that the volume of Tweets about a program prior to its airing predicts aggregate program audience size better than other online data such as search trends or reviews.

Yet, other studies point to a less clear relationship. Cadario (2015), for instance, shows that online program WOM volume affects aggregate program audience size only for episodes in the middle of a program's lifetime, while Godes and Mayzlin (2004) and Seiler et al. (2017) find no effect of pre-program online WOM volume on aggregate program audience size. However, Seiler and coauthors show that online program WOM levels *after* the airing of a program exert positive effects on aggregate program audience size, as viewers anticipate positive utility from post-show online WOM and therefore tune in. Thus, extant work is ambivalent about the relationship between OPE volume and aggregate episode audience size. Yet, since this research is based on aggregated data at the program episode level, insights may be limited. In our study, we further explore this relationship and are the first to investigate how OPE volume and deviation, as observable proxies of viewers' program involvement, relate to ad audience size and thereby viewers' channel-changing behavior over the course of an episode.

Conceptual framework

We propose that OPE is a measurable representation of viewers' involvement with television programs. We then build on extant research about how program involvement influences viewers' response to ensuing advertisements to explain the relationship between OPE and audience size during ads. Involvement is a motivational state elicited by one's interest in and arousal caused by a specific subject in a particular situation (e.g., Bloch and Richins 1983; Celsi and Olson 1988; Richins et al. 1992). Television viewing is regarded as an involving experience where viewers' program involvement represents an active, motivated state (Moorman et al. 2007). Overall, involvement is comprised of two core components: (1) enduring involvement, a general sustained care or concern with a subject, and (2) situational involvement, an ephemeral involvement with a subject in a given moment (Houston and Rothschild 1978; Richins et al. 1992). We next present support for OPE as a measure of viewers' program involvement and then explain how such involvement influences viewers' response to ensuing advertisements.

Table 1 Summary of research on the relationship between OPE and audience size

Study	Measures of OPE	Level of analysis	Dependent variable	Main findings
Cadario (2015)	Post-program volume (measured through IMDb votes) and valence (measured through IMDb reviews)	Episode	Aggregate audience size at episode level	Program WOM volume does not significantly relate to DV for early episodes but does increase over time, eventually declining for later episodes; valence of program WOM is not significant
Godes and Mayzlin (2004)	Pre-program volume and dispersion (measured through blog conversations)	Episode	Aggregate audience size at episode level	Dispersion of program WOM is associated with higher DV levels; volume of program WOM is not significant
Gong et al. (2017)	Pre-program volume (measured through media company's Tweets about programs and influentials' Retweets on Sina Weibo)	Episode	Aggregate audience size at episode level	Program WOM volume of company Tweets and influentials' Retweets before a program's airing increase program viewership
Liu et al. (2016)	Pre-program volume, sentiment, and content (measured using program-related Tweets)	Episode	Aggregate audience size at episode level	Program WOM Volume and sentiment improve prediction of DV minimally while content significantly improves prediction of DV
Lovett and Staelin (2016)	Pre- and post-program volume (measured through self-reported exposure to online conversations)	Episode	Aggregate audience size at episode level	Program WOM Volume increases DV
Seiler et al. (2017)	Pre- and post-program volume (measured through Sina Weibo comments about the program)	Episode	Aggregate audience size at episode level	Post-program WOM volume increases DV while pre-program volume is not significant
<i>This research</i>	<i>Volume and deviation during episode (measured using program-related Tweets)</i>	<i>Advertisement</i>	<i>Audience size during individual advertisements</i>	<i>OPE volume and positive OPE deviation are associated with increases in DV; stronger relationship between OPE deviation and DV for earlier ads in an ad break</i>

Program involvement and OPE Our argumentation about the relationship between OPE and ad audience size rests on the notion that OPE reflects viewers' program involvement. We provide two key arguments for this. First, and most importantly, viewers' neurological involvement with a television program exhibits a substantial positive correlation with the volume of program-related Tweets for the program's general audience (Nielsen 2015b). That is, increases in neurological involvement of non-Tweeting viewers accurately predict increases in OPE. Building on this, prior research has employed OPE as a measurable operationalization of viewer involvement with a television program (Fossen and Schweidel 2019). Extant work thus supports using OPE as a publicly available metric for an audience's program involvement.

Second, we find further evidence for the relationship between program involvement and OPE in prior research that shows how involvement relates to WOM. For example, involvement motivates consumers to share their personal experience with others (Richins and Root-Shafer 1988). This

notion aligns with Dichter's (1966) observation that involvement in an experience can produce a tension that must be channeled by way of talking about it. Moreover, involvement can determine the extent to which customer satisfaction translates into WOM (Von Wangenheim and Bayón 2007). Research on WOM activity provides further support for the involvement-OPE link. Specifically, several studies show that interest and arousal, factors that directly relate to involvement (e.g., Bloch and Richins 1983; Celsi and Olson 1988; Richins et al. 1992), drive WOM activities. For example, more interesting products, news, and subjects generate more WOM (Berger and Iyengar 2013; Berger and Milkman 2012; Berger and Schwartz 2011). Similarly, several investigations illustrate that topics are more likely to be discussed if they are more arousing (e.g., Berger 2011, 2014; Huang et al. 2017; Ladhari 2007; Luminet et al. 2000).

To accurately capture involvement as the key mechanism underlying the relationship between OPE and ad audience size, we investigate the effects of two focal OPE measures:

(1) volume, referring to the relative volume of program-related online WOM in an episode leading up to an ad's airing and (2) deviation, referring to the difference between OPE volume right before an ad airs and the average per-minute OPE volume in an episode leading up to the ad's airing. These two measures follow previous work showing that involvement comprises an enduring and a situational component (Houston and Rothschild 1978; Richins et al. 1992). We detail each OPE measure in turn and visually summarize our conceptual framework and corresponding hypotheses in Fig. 1.

OPE volume and audience size during ads We argue that a higher volume of OPE leading up to an ad's airing reflects a heightened level of viewers' general, or enduring, involvement with an ongoing episode. Moreover, we propose that such heightened program involvement relates to less channel-changing during an ad, and thus higher ad audience size, because it increases viewers' desires to not miss any part of the program upon its restart after an ad break. This logic is in line with McSherry (1985) who notes that viewers switch channels less when they fear missing any part of a high-quality program. This argument is also consistent with Moorman et al. (2007) who argue that higher program involvement increases viewers' likelihood of exposing themselves to ads. Research on program involvement has moreover found positive relationships between viewers' involvement with a program and their attitudes toward subsequent ads (Feltham and Arnold 1994; Kilger and Romer 2007; Norris and Colman 1993). Thus, as program involvement increases, viewers should be more inclined to stay with a channel during an ad break and thus engage in less channel switching during an ad. With OPE as a measure for program involvement, we thus expect a positive relationship between OPE volume in an episode leading up to an ad's airing and audience size during that ad.

H1a: OPE volume leading up to an ad relates positively to ad audience size.

Ample research has further identified ad position as an important driver of viewers' channel-changing behavior and response to advertisements (e.g., Danaher 1995; Kent and Schweidel 2011; Schweidel et al. 2014; Siddarth and

Chattopadhyay 1998; Wilbur et al. 2013). In general, findings show that viewers tend to tune out more during earlier compared to later ads in an ad break. A likely reason for this is that the exact length of an ad break is unknown to viewers, so they can only estimate when the program will restart. Tuning out during later ads increases the probability of missing program content as the show recommences (Wilbur 2016). While more involved viewers should be more likely to stay with a channel during ads, this relationship should be especially strong for ads airing later in an ad break, when tuning out further increases the risk of missing program content. We thus expect the hypothesized positive relationship between OPE volume leading up to an ad's airing and ad audience size to intensify for later ad positions in an ad break.

H1b: The positive relationship between OPE volume and ad audience size strengthens as ad position increases.

OPE deviation and audience size during ads In addition to a general, enduring level of involvement with a program, particular moments of a show may elicit a sudden situational deviation in involvement. Such ephemeral deviations may constitute an increase in involvement, that is, a positive deviation (e.g., following unexpected, happy, or controversial events) or a decrease in involvement, that is, a negative deviation (e.g., following uneventful or foreseeable events). Building on past involvement research which is typically concerned with the effects of ephemeral *surges* in involvement (e.g., Feltham and Arnold 1994; Richins et al. 1992; Zaichkowsky 1985), we focus on positive deviations of involvement in our conceptual framework.

Research on the excitation-transfer paradigm proposes that sudden increases in involvement in one situation can influence consumers' behavior in a subsequent situation. This occurs due to a short-term misattribution of involvement across situations until an individual returns to a normal, baseline level of involvement (Zillmann 1971). Research has investigated this phenomenon in the television context. For instance, Mattes and Cantor (1982) find that viewers perceive ads following highly involving moments of a television program as more enjoyable than the same ads following less involving program content. Further studies find that surges in television viewers' involvement improve attention to and response toward ads in

Fig. 1 Illustration of relationship between OPE and ad audience size

the short term (e.g., McGrath and Mahood 2004; Wang and Lang 2012). A key aspect to these findings is the short-lived nature of the observed deviations in situational involvement which only persist until an individual returns to a normal, baseline level of involvement or arousal, a process that does not take long to occur (Zillman 1971).

In line with this research, we pose that a sudden increase in situational involvement right before the airing of an ad² will positively impact viewers' response to the ad, leading them to more readily stay with the ad instead of changing the channel. We thus expect that positive OPE deviations, reflecting heightened situational involvement, will associate with less viewers changing the channel during a subsequent ad and, thus, higher ad audience size.

H2a: Positive OPE deviations prior to an ad relate positively to ad audience size.

We further anticipate the relationship between positive OPE deviations and audience size to also be moderated by ad position. Specifically, the effects of a sudden positive deviation in program-induced interest and/or arousal are likely to decrease over the course of an ad break (Mattes and Cantor 1982; Zillmann 1971). Wang and Lang (2012), for instance, show attitudinal responses toward ads that air after an increase in program involvement to be more positive for ads that air earlier in an ad break. This may occur because the activating effects of a sudden burst in involvement from program content are likely to decay over time, as the temporal distance from the program content increases, and will thus exert less influence on viewers' response to ads that air later in the ad break. Accordingly, we expect the relationship between positive OPE deviation and ad audience size to be more pronounced for earlier ads in an ad break.

H2b: The positive relationship between positive OPE deviation and audience size during ads weakens as ad position increases.

Data and measures

Advertising data

To investigate the relationship between OPE and audience size during ads, we collect data on television advertising from

Kantar Media's Strategy database. In particular, we examine national primetime (8:00 PM–11:00 PM), broadcast (ABC, CBS, CW, FOX, and NBC) advertisements that aired during the fall 2013 television season on the initial airing of recurring programs.³ Strategy provides data on the start and end times of each ad at the second level, program the ad airs in, ad position, and position of the ad break in the program (i.e., break position). Altogether, our data include 8417 ad instances for 248 brands that aired on 83 different programs.

Audience size data

We obtain data on audience size during ads from Comscore, Inc.'s TV Essentials database (Comscore 2020), which includes set-top box tuning data from more than 30 million U.S. households. We use the most granular measure of audience size provided, which is the estimated average number of televisions in U.S. households (extrapolated from the Comscore panel to the U.S. population of TV households) tuned into a given telecast throughout a 30-second interval. For example, this measure provides the number of U.S. households tuned into *Dancing with the Stars* on a given date from 8:00:00 PM to 8:00:30 PM, 8:00:30 PM to 8:01:00 PM, etc.

While these data provide a granular measure of audience size, the 30-second intervals do not always line up exactly with an ad's airing. As a remedy, we determine ad audience size using three different approaches. We estimate our model with each of these approaches and find consistent results. For our primary approach, we treat the audience size measures from the data as constant such that viewership for a given episode recorded at 8:00:00 PM would be used to represent the number of households tuned into that episode from 8:00:00 PM–8:00:29 PM. We detail the two alternative approaches to measuring audience size and the corresponding analyses in [Web Appendix 3.1](#).

OPE data

We supplement these data with Tweets referring to the programs that the ads air in. We focus on Twitter mentions because the vast majority of public social media conversations about television programming occurs on this platform (Schreiner 2013). For the 83 television programs in our data, we collect the volume of Twitter mentions via Topsy Pro at

² We detail our operationalization of OPE deviation in the next section. Furthermore, we explore several alternative operationalization of this measure, including varying the time window relative to the focal ad, in [Web Appendix 3.6](#).

³ The advertising data contains only live programming in the Eastern and Central Time Zones, which accounts for 76% of the U.S. population (based on U.S. Census Bureau 2013 State Population Estimates). Programming in the Pacific Time Zone is not deemed an initial broadcasting since it airs three hours after Eastern/Central programming. The granular level of the audience size and social media data, discussed next, allows us to attribute these measures to the Eastern/Central Time Zone programming.

the minute-level (the most granular level provided by Topsy Pro).⁴ We collect program-related Twitter mentions by tallying the number of Tweets that contain a program's name or nickname (e.g., *Dancing with the Stars* or *DWTS*), hashtag(s) with a program's name or nickname, and/or the program's Twitter handle.

We utilize this data to construct our two OPE measures: volume and deviation. We operationalize OPE volume by first dividing the number of program-related Tweets between the start of the episode and the beginning of the focal ad's airing by the minutes in the episode up until the ad airs. This creates the average per-minute volume of Tweets about the program. We then divide this number by the number of viewers at the beginning of the focal ad to create a relative measure of volume.⁵ For example, if the focal ad begins airing 10 min into an episode with 200 viewers and received 100 program-related Tweets during those 10 min, our OPE volume measure would equal .05 ($(100/10)/200 = .05$).

Following our arguments in the conceptual framework, we construct our deviation measure by focusing on the deviation in OPE right before the airing of the focal ad. As such, we operationalize deviation as the difference between the volume of program-related Tweets in the minute before a focal ad airs and the average number of per-minute program-related Tweets between the start of the episode and the airing of the focal ad. For example, if the focal ad airs 10 min into an episode that received 100 Tweets in those 10 min (10 Tweets per minute on average) and received 40 Tweets in the minute before the focal ad airs, OPE deviation would be 30 ($40 - 10 = 30$). As noted, OPE deviation can be positive or negative where positive (negative) values indicate that the one-minute period prior to the focal ad received more (less) OPE relative to the average per-minute OPE leading up to the ad's airing. A positive OPE deviation therefore reflects a moment in the episode that is more "social" than the average moment in the episode. As a positive OPE deviation increases to higher values, this increase captures the magnitude of the social moment that has occurred.

Table 2 summarizes our primary operationalizations of OPE. We moreover illustrate the robustness of our findings by exploring 23 alternative operationalizations of our OPE measures, as detailed in Web Appendices 3.5 and 3.6. Furthermore, while we focus on OPE volume and deviation

in our main analysis, we explore OPE valence in the *Additional analyses* section.

Data on advertising and program characteristics

We further supplement our data with ad and program characteristics that previous research has found to influence audience size (e.g., Deng and Mela 2017; Gustafson and Siddarth 2007; Schweidel and Kent 2010; Schweidel et al. 2014; Siddarth and Chattopadhyay 1998; Wilbur 2016). For ad characteristics, we capture the ad creative, ad length, day of the week and time of day an ad airs, ad position, break position, whether the ad airs near a half-hour interval (e.g., 8:28 PM or 9:02 PM), and whether the ad runs concurrently with another ad break on a different broadcast network. We gather these data from the Strategy database. Additionally, we construct two same-day ad stock measures to account for previous advertising activity for a given brand on the same network as well as other networks, respectively.

We also collect data on program characteristics that can impact viewers' channel-changing behavior (e.g., Deng and Mela 2017; Schweidel et al. 2014; Schweidel and Kent 2010; Wilbur 2016). In particular, we capture the program the ad airs in, season premieres, fall finales, and viewers' ratings of episodes on IMDb (henceforth referred to as viewer episode ratings).

Table 2 summarizes the variables in our empirical analysis. We present the correlations between these variables in Web Appendix 2. Importantly, we find no correlation between our two measures of OPE ($r = -.001$).

Descriptive statistics

Our data include 8417 ad instances that aired during 817 episodes of 83 programs. Each episode contains on average 4.95 ad breaks. As shown in Table 3, ads begin on average with 4.63 million viewers and end with 4.59 million viewers, equivalent to an average 1% decline in audience size; although, changes vary between -12% to 6%. Changes in audience size over the course of an ad also vary across ad position, with earlier ads seeing higher audience losses than those airing later in the ad break. Specifically, the first ad sees an average audience size decline of 4%, four times that of the average ad. In Fig. 2, Panel (A), we visualize the average audience size at the beginning of an ad and average percentage change in audience size during an ad across ad positions. While the average audience size at the beginning of an ad shows a U-shaped relationship over the course of an ad break, the average percentage change in ad audience size is lowest early in the break and then increases before quickly flattening out. Overall, in line with past research (e.g., Danaher 1995; Schweidel et al. 2014; Wilbur et al. 2013), these descriptive

⁴ Topsy Pro was a certified Twitter partner with comprehensive access to the public firehose of Twitter posts at the time of data collection. It was later acquired by Apple.

⁵ Using a relative volume measure allows us to investigate changes in OPE intensity, as our volume measure is not simply driven by changes in audience size during the episode which would naturally relate positively to ad audience size. Yet, a relative volume measure may create difficulties for practitioners trying to use our approach since audience size data is not available in real-time. We thus also explore an alternative operationalization of volume where we do not divide by the number of viewers at the beginning of the focal ad and find consistent results (see Web Appendix 3.5).

Table 2 Summary of variables

Variable	Description	Freq.(%)	Mean	SD	Min	Max
<i>AudienceSizeBeg_i</i>	Audience size at the beginning of ad <i>i</i>		4,632,236	2,409,515	561,563	12,603,068
<i>AudienceSizeEnd_i</i>	Audience size at the end of ad <i>i</i>		4,585,324	2,380,155	561,563	12,190,214
OPE	<i>ProgramWOMVolume_i</i> is the number of Tweets about the program in which ad <i>i</i> airs from start of episode until ad <i>i</i> airs divided by the minutes in episode up until ad <i>i</i> airs. We then divide <i>ProgramWOMVolume_i</i> by the number of viewers at the beginning of ad <i>i</i> to create our relative volume measure. We take the log of this measure plus one to create <i>LogProgramWOMVolume_i</i> (descriptives are shown for <i>ProgramWOMVolume_i</i>).		266.59	510.48	.00	8778.50
	<i>ProgramWOMDeviation_i</i> is the difference between the number of Tweets about the program between one minute before ad <i>i</i> airs until ad <i>i</i> airs and <i>ProgramWOMVolume_i</i> . We take the log of this measure plus one (see table notes for log transformation) to create <i>LogProgramWOMDeviation_i</i> (descriptives are shown for <i>ProgramWOMDeviation_i</i>).		23.91	667.86	−2271.52	32,690.37
Ad position	Position of the ad in ad break		3.53	1.94	1.00	12.00
Ad creative	Fixed effects for the ad creative in ad <i>i</i>					
Ad length	Ad length in seconds		25.33	8.17	5.00	120.00
Ads on other networks	Ad runs simultaneously with another ad break on a different broadcast network	62.10%				
Ad stock	Number of ads aired by the brand in ad <i>i</i> in primetime on the same network and day ad <i>i</i> airs before ad <i>i</i> airs		.27	.62	.00	5.00
	Number of ads aired by the brand in ad <i>i</i> in primetime on different broadcast network and the same day ad <i>i</i> airs before ad <i>i</i> airs		.88	1.54	.00	13.00
Break position	Relative ad break position in episode, calculated as (position of the ad break in episode)/(number of ad breaks in episode)		.59	.29	.07	1.00
Day (Baseline: Sunday)	Ad airs on a Monday	19.26%				
	Ad airs on a Tuesday	19.18%				
	Ad airs on a Wednesday	16.94%				
	Ad airs on a Thursday	19.39%				
	Ad airs on a Friday	14.30%				
	Ad airs on a Saturday	.10%				
Viewer episode rating	IMDb rating for the episode in which the ad airs		7.69	.88	3.70	9.80
Half-hour break	Ad airs within two minutes of a half-hour break	13.24%				
Program	Fixed effects for the program ad <i>i</i> airs in					
Special episode	Ad airs on a season premiere	9.43%				
	Ad airs on fall finale	10.57%				
Time	Fixed effects for time ad <i>i</i> airs (5-min intervals)					
Model interactions	<i>LogProgramWOMVolume_i</i> and ad position					
	<i>LogProgramWOMDeviation_i</i> and ad position					

Notes: For the log transformation of OPE deviation, if OPE deviation is negative, we take the log of the absolute value of *ProgramWOMDeviation_i* plus 1 and then multiply this value by −1

Table 3 Descriptive statistics for audience size during ads

Variable	Mean	SD	Min	1st quartile	Median	3rd quartile	Max
$AudienceSizeBeg_i$	4,632,236	2,409,515	561,563	2,853,649	4,589,262	6,272,361	12,603,068
$AudienceSizeEnd_i$	4,585,324	2,380,155	561,563	2,837,303	4,552,178	6,213,937	12,190,214
Absolute change in audience size during ad	-46,912	120,460	-1,205,684	-49,177	-1133	4327	256,571
Percentage change in audience size during ad	-.95%	1.99%	-12.10%	-1.39%	-.04%	.14%	5.67%
Percentage change in audience size during ad by ad position							
1	-4.19%	1.90%	-12.10%	-5.29%	-4.05%	-2.98%	1.60%
2	-1.40%	1.55%	-9.15%	-2.00%	-1.03%	-.27%	3.08%
3	-.26%	.63%	-5.58%	-.50%	-.13%	.00%	4.20%
4	.05%	.53%	-3.67%	-.13%	.00%	.21%	5.67%
5	.23%	.45%	-4.78%	.00%	.13%	.41%	3.29%
6	.35%	.51%	-1.70%	.00%	.24%	.53%	3.72%
7+	.39%	.60%	-4.76%	.00%	.30%	.65%	3.12%

Notes: $AudienceSizeBeg_i$ ($AudienceSizeEnd_i$) is the audience size at the beginning (end) of ad i . Absolute change in audience size is calculated as $(AudienceSizeEnd_i - AudienceSizeBeg_i)$; percentage change in audience size is calculated as $(AudienceSizeEnd_i - AudienceSizeBeg_i)/(AudienceSizeBeg_i)$

statistics highlight the relevance of ad position as an explanatory factor of viewers' channel-changing behavior.

Table 4 shows the key descriptive statistics for OPE. The average ad airs in a program that receives 267 Twitter mentions per minute prior to its airing; yet, some ads appear in programs that average as many as 8779 program mentions per minute prior to their airing. We also observe substantial variation in OPE deviation. While the average ad sees an increase

of 24 program-related Tweets in the minute before its airing relative to average per-minute program-related Tweets in the episode up until the ad airs, some ads see Tweets increase in the tens of thousands. We further illustrate average OPE volume and average OPE deviation across ad positions in Panel (B) of Fig. 2. While the volume measure generally increases over the break until around the last ad positions, the deviation measure shows an inverted U-shaped relationship that starts

Fig. 2 Average measures of audience size and OPE by ad position. Notes: This figure plots the average value of each variable by ad position. $AudienceSizeBeg_i$ ($AudienceSizeEnd_i$) is the audience size at the beginning (end) of ad i . Percentage change in audience size from

the beginning to the end of ad i is calculated as $(AudienceSizeEnd_i - AudienceSizeBeg_i)/(AudienceSizeBeg_i)*100$. See Table 2 for other variable definitions and operationalizations

Table 4 Descriptive statistics for OPE

Notes: See Table 2 for variable descriptions

low, increases steadily to the midpoint of the break, and then decreases.

We next develop our empirical model to examine how OPE relates to audience size.

Model

To investigate the relationship between OPE and audience size during ads, we model the log of audience size at the end of ad instance i ($\text{LogAudienceSizeEnd}_i$) as follows⁶:

$$\begin{aligned}
 \text{LogAudienceSizeEnd}_i = & \beta_0 + \beta_1 \text{LogAudienceSizeBeg}_i \\
 & + \beta_2 \text{LogProgramWOMVolume}_i \\
 & + \beta_3 \text{LogProgramWOMDeviation}_i \\
 & + \beta_4 \text{AdPosition}_i \\
 & + \beta_5 \text{LogProgramWOMVolume}_i \\
 & \times \text{AdPosition}_i \\
 & + \beta_6 \text{LogProgramWOMDeviation}_i \\
 & \times \text{AdPosition}_i + \gamma X_i + \varepsilon_i,
 \end{aligned} \quad (1)$$

⁶ For robustness, we test 5 alternative dependent variables, all of which present consistent results. We detail these analyses in Web Appendix 3.2.

where $\text{LogAudienceSizeBeg}_i$ is the log of audience size at the beginning of ad i . We assess the relationship between OPE and $\text{LogAudienceSizeEnd}_i$ by considering both OPE volume ($\text{LogProgramWOMVolume}_i$) and OPE deviation ($\text{LogProgramWOMDeviation}_i$), as defined in the previous section and in Table 2. We also explore the interactions of our two OPE measures with ad position (AdPosition_i). Importantly, our data show that both OPE measures exhibit substantial variation across episodes of a program as well as across programs and are, thus, not solely driven by fixed program or episode characteristics (see Web Appendix 2). This suggests sufficient variation to identify the relationships between our OPE measures and ad audience size.

To further rule out that ad, program, or episode characteristics drive the key relationships in our data, we include several corresponding fixed effects in a vector of control variables (X_i), as discussed in the *Data and measures* section and summarized in Table 2. Notably, we capture further potential influences on viewers' channel-changing behavior by accounting for the specific ad creative used in ad i , the program in which ad i airs, the day of the week and time of day ad i airs, ad position of ad i , and break position of the ad break in which ad i airs. The ad creative and program fixed effects control for any ad-specific factors (e.g., brand advertised, ad content) or program-specific factors (e.g., program, show popularity, genre, audience characteristics like demographics) that may influence viewers' channel-changing behavior above and

beyond other model variables. The day, time, and ad break position fixed effects control for time-relevant factors that may impact channel-changing behavior, apart from other model variables, such as differences in audience composition at different points during a program's airing.

Key identification arguments

Given that we control for the audience size at the beginning of ad i ($LogAudienceSizeBeg_i$), any relationship between OPE and $LogAudienceSizeEnd_i$ is above and beyond the effect of $LogAudienceSizeBeg_i$. In this way, $LogAudienceSizeBeg_i$ functions as a strong predictor that allows us to control for the factors not captured by our model variables that influence audience size prior to ad i 's airing. This approach of using very narrow time windows to investigate our focal relationships leverages an identification strategy employed in extant research to study the causal effects of television advertising (e.g., Fossen and Schweidel 2017; Liaukonyte et al. 2015). The core argument of this identification strategy is that the use of granular time windows makes it unlikely that variables outside the model will impact the outcome measure in such a short time window. Thus, provided a strong and appropriate set of model controls is employed (e.g., relevant and granular fixed effects), the relationship between a predictor and an outcome can be examined during the granular time window. In our setting, we leverage $LogAudienceSizeBeg_i$ and the fixed effects in X_i , discussed above, as our set of strong model controls.

Given our interest in ad position as a key moderator of the relationship between OPE and ad audience size, the television industry's common practice to position ads non-systematically (e.g., Fossen and Schweidel 2017; Wilbur et al. 2013) is also important to our identification strategy. Specifically, advertisers currently buy the majority of their ad time in the upfront market several months before the ads air. Typically, the most granular ad airing time window that advertisers can negotiate is at the quarter-hour level, but most often, the airing time and program in which an ad will appear are not specified (Katz 2013; Liaukonyte et al. 2015). Other common ad buy practices such as "make-good" policies further complicate the ad sequencing process. As such, networks commonly schedule ads in random order across and within programs (Wilbur et al. 2013). We leverage this exogenous nature of an ad's position in its break to explore how it may moderate the relationship between OPE and audience size during ads.

Model estimation

Endogeneity may arise if one or both of our OPE measures is correlated with the error term in Eq. (1). One reason this may occur is from omitted variable bias. Specifically, if our OPE

measures are not strong operationalizations of viewer involvement, the portion of viewer involvement not captured by our measures—or our other model variables—would be correlated with the error term. To help avoid this concern, we (1) construct our OPE measures using data (program-related Tweets) that accurately measure viewers' neurological involvement with a program (Nielsen 2015b) and (2) include a rich set of model controls as noted above.

Nevertheless, to also formally rule out this potential endogeneity concern and to provide a robust test of our hypothesized relationships, we estimate our model using two different estimation procedures: OLS and Gaussian copulas. The latter is an endogeneity-correcting estimation approach that does not require instrumental variables (Park and Gupta 2012). Instead, this approach explicitly estimates and models the correlation between potentially endogenous variables and the error term by building on their joint distribution function. We leverage the control function approach in which an additional variable is added to the model based on the Gaussian copulas for each suspected endogenous regressor. This approach has been used in recent marketing studies to test and adjust for endogeneity if necessary (e.g., Bornemann et al. 2020; Guitart et al. 2018; Mathys et al. 2016; Wetzel et al. 2018).

Utilizing Gaussian copulas estimation, we test if either or both of our OPE measures are subject to significant endogeneity. For this, we estimate Eq. (1) with the Gaussian copulas approach using bootstrapped standard errors with 1000 replications and find that neither OPE measure is endogenous as the copula terms for both OPE measures, which test the correlations between the measures and the error term, are not significant (copula term for $LogProgramWOMVolume_i$ (SE) .002 (.001) with 95% confidence interval [−.000, .005]; copula term for $LogProgramWOMDeviation_i$ (SE) .002 (.001) with 95% confidence interval [−.001, .004]). Since endogeneity correction is not needed in our model, we estimate our main analysis of Eq. (1) using OLS and present the results from this estimation in the next section.

Results

Table 5 presents the relationship between OPE and ad audience size. A positive (negative) coefficient indicates that a variable is associated with higher (lower) audience size at the end of the ad. As our data are not at the individual viewer level, we do not observe whether a viewer tunes into or out of a program. Thus, if a variable (e.g., variable X) relates positively to audience size at the ad's end, this reflects either (1) attenuated channel-changing behavior and/or (2) more individuals tuning into the program. Note that (2) is an improbable explanation given the short time frame of ads. Indeed, it would be very unlikely for anyone not watching a show, let alone enough individuals for

Table 5 Relationship between OPE, ad characteristics, and program characteristics with audience size during ads

Notes: Measures for OPE and ad position are mean-centered for ease of interpretation

* $p < .10$, ** $p < .05$

an effect to become significant, to become aware of X occurring and then tune into the show due to X before the ad completes. Thus, as our data show that audience size typically drops over the course of an ad (see Table 3), a finding supported by the literature (e.g., Danaher 1995; Fossen et al. 2021; Schweidel and Kent 2010), we argue that a variable's positive relationships with ad audience size likely stems from viewers' attenuated channel-changing behavior. This argument further aligns with recent research on the effects of television advertising characteristics on ad audience size (Fossen et al. 2021).

For ease of interpretation, we mean-center the variables that are part of our key interactions, namely OPE volume and deviation and ad position. The effects of these three measures in Table 5 are thus estimated at the mean levels of the variables they interact with.

Relationship between OPE and audience size during ads

The results indicate that OPE significantly relates to ad audience size, over and above conventional ad and program

characteristics. Specifically, for ads with average OPE deviation prior to airing and ad position, higher OPE volumes leading up to their airing associate with higher ad audience size ($\beta = 9.482$, $p = .002$), supporting H1a. Similarly, for ads with average OPE volume leading up to their airing and ad position, more positive OPE deviations right before the ad's airing also relate to higher ad audience size ($\beta = .001$, $p < .001$), supporting H2a. For ads with average levels of OPE volume and deviation, we moreover find that later ad positions relate to increased audience size ($\beta = .007$, $p < .001$).

We only find support for one of our hypotheses about the moderating role of ad position. Specifically, H1b is not supported, as OPE volume leading up to an ad's airing relates positively to audience size during that ad, regardless of ad position ($\beta = -.358$, $p = .637$). By contrast, the interaction between OPE deviation prior to an ad's airing and ad position is negative and significant ($\beta = -.000$, $p < .001$), supporting H2b. Positive OPE deviations are thus more strongly associated with increased audience size for ads that air earlier in an ad break.

To illustrate the effect sizes of the key relationships between OPE and ad audience size, Fig. 3 presents the estimated audience size at the end of a given ad at different values of OPE and ad position, while holding all other model variables constant at their median values. Three key findings emerge. First, Panel (A) illustrates that, for an ad at the median ad position, increases in OPE volume prior to its airing can associate with increases in audience size for the ad as large as 63,949 viewers. For an ad airing earlier in an ad break (ad position at 1st quartile), higher OPE volume can associate with increases in audience size as large as 65,852 viewers. Second, Panel (B) shows that, for an ad at the median ad position, more positive OPE deviations prior to the ad's airing can relate to increases in audience size as large as 53,184 viewers. For an ad airing earlier in an ad break (ad position at 1st quartile), more positive OPE deviations can associate with increases in audience size as large as 68,637 viewers. Third, both Panels (A) and (B) demonstrate a positive relationship between OPE and ad audience size regardless of ad position. The results therefore provide substantial evidence that increases in OPE volume and positive OPE deviations relate positively to audience size during ads.

Relationship between ad and program characteristics and audience size during ads

Table 5 also shows the relationship between ad and program characteristics and audience size during ads. Of note, consistent with Gustafson and Siddarth (2007), longer ads are associated with lower audience sizes ($\beta = -.000$, $p = .003$). Furthermore, we find marginal evidence that ads in ad breaks that air later in an episode see lower ad audience sizes ($\beta = -.003$, $p = .080$). This may occur due to competition from outside viewing options (e.g., episodes reaching their

Fig. 3 Estimated ad audience size at different values of OPE and ad position. *Notes:* This figure illustrates the estimated audience size of ad i at different values of $\text{LogProgramWOMVolume}_i$ and ad position (Panel

A) and at different values of $\text{LogProgramWOMDeviation}_i$ and ad position (Panel B), while holding constant all other model variables at their median values

conclusion) that may encourage viewers to change the channel. Corroborating this notion, higher audience size occurs when an ad airs simultaneously with another ad break on a different network ($\beta = .001$, $p = .045$). We also see some evidence of ad wear-out as more ads aired on a different network by the brand in ad i prior to ad i relate to lower ad audience size ($\beta = -.000$, $p = .004$). Last, we find that ads airing in season premiere episodes are associated with higher ad audience sizes ($\beta = .002$, $p = .003$) which may be driven by the characteristics of such episodes.

Additional analyses

Exploration of viewer involvement mechanism

The results provide strong evidence that increases in OPE volume and positive OPE deviations relate positively to audience size during ads. In our conceptual framework, we propose that viewers' program involvement may be the key mechanism underlying these relationships. As such, we might anticipate that OPE would have a weaker (stronger) relationship with audience size in programming conditions where viewer involvement is generally lower (higher) and OPE might be less (more) reflective of true involvement. To investigate this proposal, we use three alternative operationalizations of viewer involvement beyond OPE based on three external programming contexts with lower- and

higher-involvement conditions. We re-estimate our model in each context separately for the lower- and higher-involvement conditions, and then compare the respective results.

In the first context, following Nielsen (2011), we argue that viewers' program involvement may be higher during peak primetime (9 PM–10 PM; higher-involvement condition) compared to other times (lower-involvement condition). In the second context, we propose that viewers may be more involved toward the end of an episode as the show approaches its conclusion (higher-involvement condition) than at its beginning (lower-involvement condition) (e.g., Page 2017). In the third context, we argue that viewers may be more involved with programs that have been on air longer (higher-involvement condition) than newer programs (lower-involvement condition) (e.g., Derrick 2013; Russell and Levy 2012). Consistent with our proposal, we find weaker associations between OPE and audience size during ads in all three lower-involvement conditions than in the corresponding higher-involvement conditions. We present the key results from these analyses in Web Appendix 3.3.

Might results differ depending on OPE valence?

Research has extensively analyzed WOM valence, producing mixed results on its effects (e.g., Babić Rosario et al. 2016). In the context of movie sales, for example, Chintagunta et al. (2010) show the importance of accounting for valence information when predicting box office movie sales. By contrast,

Liu (2006) finds valence to be less important to this end. In an extension of our main analysis, we thus explore the valence of viewers' OPE. We obtain valence data for each program-related Tweet in our sample from Topsy Pro. Topsy Pro codes Tweets as either positive, neutral, or negative by analyzing the weighted sentiment of words and phrases.

We estimate two alternative specifications of our main model where we operationalize our OPE measures using (1) only non-negative Tweets (positive and neutral Tweets) and (2) only negative Tweets. These analyses allow us to determine whether negatively-valenced versus non-negatively-valenced OPE exhibits a different relationship with ad audience size. The key results, shown in Table 6, are consistent with our main findings and illustrate that, regardless of valence, increases in OPE volume and positive OPE deviations relate positively to ad audience size.⁷ Thus, in line with Liu (2006), valence plays only a limited role in the relationship between OPE and audience size during ads. Moreover, these findings also align with research showing benefits of both positive and negative WOM (Berger et al. 2010; Han et al. 2020).

Do consumers pay less attention to ads when OPE is high?

The results provide convincing evidence that increases in OPE volume and positive OPE deviations relate positively to ad audience size. While a higher audience size is crucial to advertisers and television networks, viewers' attention to ads is also important. That is, while OPE relates to increased ad audience size, these additional viewers may also ignore the television in favor of their second screens.

To probe this concern, we explore a further, more active ad response metric. We collect additional data on viewers' involvement with ads. From this data, we compute an *ad WOM* measure as the change in the relative WOM volume about an advertised brand by audience size after its ad was aired compared to before it was aired. If high OPE activity would indeed reflect viewers focusing on devices other than the television during ads, it should relate to ads eliciting less ad WOM activity. However, in contrast to such concerns, OPE volume exhibits a marginally significant positive relationship with ad WOM activity. Thus, OPE not only relates to improved ad audience size, but

also to more WOM about the advertised brand. We present this analysis in [Web Appendix 3.4](#).

Discussion

This research contributes to extant literature on television advertising and online WOM by presenting the first examination of the relationship between OPE and audience size during ads. We use a multisource dataset of national primetime television ads, audience size during these ads, and social media conversations mentioning the programs in which the ads air. The results show that OPE has a meaningful relationship with ad audience size over and above conventionally studied ad and program characteristics. In particular, we find that increases in OPE volume and positive OPE deviations associate positively with ad audience size and that ad position is an important moderator of the deviation-audience size relationship.

Managerial implications

Social episodes create attractive advertising environments A lively debate in research and practice evolves around whether or not social episodes—episodes with high OPE volume—provide attractive ad inventory. This question is relevant for advertisers and networks alike, with important implications for their ad buy negotiations. On the one hand, social episodes may offer attractive ad inventory because they provide more engaged, tuned-in audiences that may respond more favorably to subsequent ads (e.g., Feltham and Arnold 1994; Flomenbaum 2016; Fossen and Schweidel 2019; Mattes and Cantor 1982; Nielsen 2015b). By contrast, increased involvement with social episodes may also hurt viewers' ad response, thereby resulting in an inferior attractiveness of corresponding ad inventory (e.g., Norris and Colman 1993; Pavelchak et al. 1988; Tavassoli et al. 1995; Teixeira et al. 2014).

Altogether, our research provides evidence in favor of airing ads during social episodes. Specifically, we find that episodes with higher levels of OPE volume prior to the airing of ads yield improved ad audience sizes. Armed with these insights, networks may be better able to negotiate higher rates for ad inventory in their programs that generate social episodes, in both the upfront advertising market, which occurs before the start of the television season, and in the scatter advertising market, which occurs throughout the television season. The results may also help networks incorporate program engagement metrics into the ad buy process, which has proven difficult thus far due to remaining uncertainty about the value of social episodes as worthwhile ad environments (e.g., Calder et al. 2009; Fossen and Schweidel 2019).

For advertisers, our results suggest that buying ad inventory in programs that generate social episodes may be a promising strategy for improved audience size. Even though current

⁷ In addition, consistent with our main analysis, for only non-negative Tweets, we find no significant interaction between ad position and OPE volume and a significant negative interaction between ad position and OPE deviation. However, for only negative Tweets, both the OPE volume-ad position interaction and the OPE deviation-ad position interaction are negative and significant. While these results largely align with our main findings, as we explain in the discussion section, we believe that further analyses of OPE content are an important area of future research.

Table 6 Key results on the relationship between valence of OPE and audience size during ads

Variable	Non-negative WOM			Negative WOM		
	Estimate (SE)			Estimate (SE)		
Ad position	.007	(.000)	**	.007	(.000)	**
OPE						
<i>LogProgramWOMVolume_i</i>	10.480	(3.689)	**	38.540	(11.550)	**
<i>LogProgramWOMDeviation_i</i>	.001	(.000)	**	.001	(.000)	**
Interaction with ad position						
<i>LogProgramWOMVolume_i × Ad position</i>	.250	(.929)		−8.974	(3.304)	**
<i>LogProgramWOMDeviation_i × Ad position</i>	−.000	(.000)	**	−.000	(.000)	*
Adjusted R-squared	.9995	.9995				

Notes: Measures for OPE and ad position are mean-centered for ease of interpretation

* $p < .10$, ** $p < .05$

television ad buying practice restricts ad placements requests to the quarter-hour-level of granularity at best, if desired, advertisers can negotiate ad placements in specific programs (e.g., Katz 2013) and, thus, implement this strategy immediately. A helpful resource to identify programs that create social episodes is Nielsen's (2020) Social Content Ratings, a weekly listing of the best-performing programs with respect to the total OPE activity generated across different social networks.

Social moments create attractive advertising environments

Our results further show that ads airing after social moments, characterized by positive OPE deviations, see higher audience sizes, especially when those ads air early in an ad break. These results help television networks and advertisers determine the most attractive ad placements in episodes for improved ad audience size. These findings can moreover guide networks to strategically initiate ad breaks following social moments for instance during live events where the timing of ad breaks is typically more flexible.

Social episodes and social moments represent distinct constructs, and social moments can occur in any episode at any time. As such, important additional questions evolve around how to identify episodes that generate social moments and how to predict social moments in specific episodes. To probe these questions, we regress our OPE deviation measure on several program characteristics. The results, shown in Web Appendix 3.7, underscore the independence of social episodes and social moments⁸ and illustrate two key takeaways. First, several fixed episode characteristics relate to OPE deviation. Specifically, fall final episodes, episodes that air on Tuesdays (relative to Fridays), and episodes with higher viewer episode ratings associate with positive OPE deviations and may thus generate more social moments. By contrast, season premiere episodes, episodes that air

on Wednesdays (relative to Fridays), and programs of the drama/adventure, suspense/mystery, or comedy genre (relative to slice-of-life genre) associate with negative OPE deviations and may thus produce fewer social moments.

Second, several within-episode characteristics relate to OPE deviations. For instance, social moments are more likely to occur close to half-hour breaks as well as later in an episode, especially during episodes of the drama/adventure and suspense/mystery genre (relative to slice-of-life genre). By contrast, earlier moments in an episode, especially in episodes of the comedy genre (relative to slice-of-life genre), exhibit comparably less potential to be social.

While, as discussed, television networks currently rely mostly on non-systematic ad sequencing (Katz 2013; Wilbur et al. 2013), our findings may help them extract more value from attractive ad slots, for instance through more systematic ad sequencing and differential pricing strategies. For systematic ad sequencing, networks may exploit our insights to form audience size expectations on short notice which they can leverage in their “make-good” policies or to reward advertisers by placing their ads after social moments. They may also advance differential pricing schemes by charging more for ad opportunities that follow social moments. Networks can leverage these strategies immediately in programs in which differential ad pricing and systematic ad sequencing are easy to implement – such as in large television events and for the share of ad inventory that is currently sold programmatically – and will further benefit from these strategies as such programming becomes more widespread, a point we elaborate on below.

While such practices also bear advantages for advertisers, they currently have limited power to negotiate over ad positions. Yet, our results may help advertisers advocate for the inclusion of this aspect in ad buys and, specifically, negotiate for ad inventory based on social moments expectations. In addition, advertisers may leverage our insights on fixed episode characteristics that associate with social moments to

⁸ That is, OPE volume does not exhibit a significant relationship with OPE deviation.

guide their ad buy strategies and place ads in contexts that are more prone to generating social moments.

Reducing information asymmetry during ad buy negotiations

This research further provides advertisers with an improved understanding of viewership dynamics during television episodes in the age of multiscreening consumers. In particular, our results suggest that advertisers can leverage publicly available data (Tweets) to learn more about audience size during television ads. Such information can help level the playing field during ad buy negotiations with networks where information asymmetry is a common problem (Phalen 1998). This benefit is especially heightened because data on viewership dynamics during individual ads is currently hard and costly for firms to obtain (e.g., Tuchman et al. 2018). Our interviews with experts from the television advertising industry (see Web Appendix 1) provide further evidence of the considerable imprecision and lag with which advertisers currently receive information about the audience size of their ad airings. An enhanced ability to judge the fairness of ad prices should allow advertisers to better identify attractive programs with improved audience size during ads (such as social episodes) as well as negotiate more favorable ad prices in programs with less online engagement.

Program content strategies Our findings may moreover help television networks to more strategically manage the creation of new program content and ad opportunities. We show when in an ad break positive OPE deviation most strongly associates with higher ad audience size. These results should allow networks to more purposefully experiment with and optimize program content strategies, such as how to pace program content and/or time ad breaks to viewers' involvement levels at relevant points during an episode.

Implications for the future of television advertising in a programmatic world Our results highlight that OPE as an observable proxy of program involvement can help identify attractive advertising opportunities across and within episodes. In this way, we show how firms can listen in on social media to gain cost-effective insights into consumer behavior in real-time (e.g., Lamberton and Stephen 2016; Schweidel and Moe 2014). While, as explained, these insights may be useful to television networks and advertisers under the current ad buying model, they may also prove valuable in years to come as the industry will continue to shift to programmatic ad buying models where advertisers can bid not only on quarter-hour time windows, but on specific ad slots in real-time similar to online advertising. While currently only about 13% of U.S. television ad inventory can be sold programmatically (Peterson 2019), this approach is rapidly gaining popularity with networks' programmatic ad inventory and advertisers' spending on this inventory increasing year-to-year (eMarketer 2018).

Our research has important implications for the programmatic future of the television ad buy industry. For example, as discussed, advertisers currently do not have precise or timely access to audience size data (e.g., Crupi 2019; Friedman 2012; Lafayette 2018b; Schwarz 2019; Story 2007; expert interviews in Web Appendix 1). This is even the case for programmatic ad buys, where advertisers are not typically supplied with audience size information and, rather, rely on information on audience characteristics (e.g., demographics) and program characteristics (e.g., program genre) to purchase impressions programmatically (e.g., Chordia 2018; Peterson 2019; expert interviews in Web Appendix 1). Our approach of leveraging readily accessible OPE data can thus provide live insights about audience sizes that can help advertisers improve their real-time bidding strategies. As such, in line with our findings, advertisers could monitor OPE across and within specific episodes to create expectations about audience sizes during ad slots, and then adjust their bidding on slots accordingly. Given that programmatic ad buy models rely on real-time auctioning mechanisms, implementing our results can lend advertisers a competitive edge over competitors interested in similar advertising opportunities but with inferior tools to inform their bid values.

Limitations and directions for future research

Our study uses OPE as a scalable measure of program involvement to help explain audience size during ads. Future work may build on our results to overcome its limitations. First, while we focus on how OPE volume and deviation relate to ad audience size, future work may delve more deeply into OPE content. In supplementary analyses, we show that our key results are consistent after considering OPE valence. Yet, further research could investigate under which conditions positive versus negative OPE may relate differently to viewer behavior. Additional dimensions of OPE content could also be the subject of future work. For example, researchers could extract topics that viewers discuss related to a program and see how they relate to ad audience size or other measures of ad effectiveness. Investigating characteristics of the poster of OPE (e.g., number of followers, network centrality, user- versus firm-generated content⁹) might also be worthwhile. Relatedly, future research may explore the relationship of OPE with other important outcomes in the short- and long-term, such as viewers' loyalty to specific programs, or explore OPE in non-linear television viewing contexts.

⁹ The OPE data we gathered from Topsy Pro does not allow us to distinguish user- from firm-generated content. For one of the programs in our data, we thus re-collected this data for every episode from a second data source—Crimson Hexagon—to probe the ratio of user-generated content versus firm-generated content. We find that firm-generated content makes up only a very small share of program-related Tweets (4.7% on average) during its airing.

Second, our data do not allow for the direct observation of both an individual viewer's OPE and channel-changing behavior. Such individual-level data could allow examination of viewer characteristics and within-viewer variation of OPE with channel-changing. Moreover, while we provide evidence for program involvement as the key driver of our investigated relationships, individual-level data as well as lab experiments could allow further exploration of the psychological processes behind the key relationships we investigate.

Last, future research could also expand our exploration of what spurs social moments in episodes. For this, researchers could obtain videos of the episodes and employ manual coding or image/audio recognition technology to identify important content aspects. Such research could also complement our findings by helping television networks produce more involving shows which should also see higher audience size during ad breaks.
