ABSTRACT

Introduction: Although depression is often associated with poor glycemic control in patients with type 2 diabetes mellitus (T2DM), this observation has been inconsistent. This exploratory, post hoc analysis investigated associations between depression parameters and glycemic control using data from a 24-month, prospective, observational, non-interventional study evaluating glycemic response following insulin initiation for T2DM.

Methods: We analyzed data from a 24-month, prospective, observational study that evaluated glycemic response in patients with T2DM who initiated insulin therapy ($N = 985$) in 5 European countries. Secondary measures included patient-reported diagnosis of depression at baseline, severity of depressed/anxious mood (EuroQol (EQ)-5D item) and diabetes-related distress (Psychological Distress domain of the Diabetes Health Profile, DHP-18). The latter two measures were assessed at baseline and 5 time points throughout the study. Glycemic control was measured by glycated hemoglobin (HbA1c) at these same time points. Analyses employed t tests to assess the unadjusted baseline difference in HbA1c between patients with and without the respective depression parameter. The potential effect of demographic and clinical confounding variables was controlled through a linear model structure. Patient HbA1c levels were analyzed by presence/absence of a history of diagnosed depression, depressed mood, and diabetes-related distress.

Results: Patients with higher depression parameters or distress at baseline had significantly higher rates of microvascular

complications at baseline. Patients with a history of diagnosed depression or high diabetes-related distress had higher HbA1c than patients without. HbA1c of patients with or without depressed mood was not significantly different at baseline. The proportion of patients with depressed mood declined after insulin initiation, whereas the proportion of patients with high diabetes-related distress did not significantly change. HbA1c improved following insulin initiation, regardless of presence/absence of studied depression/distress parameters at baseline.

Conclusion: History of diagnosed depression, diabetes-related distress, and depressed mood were associated with a higher rate of microvascular complications. Diagnosed depression and diabetes-related distress also showed higher HbA1c at baseline when insulin was initiated. Insulin therapy improved glycemic control, while preexisting depressed mood declined and diabetes-related distress remained unchanged.

INTRODUCTION

Depression affects approximately 20–25% of patients with diabetes [1], with rates of major depressive disorder estimated at 12% and depressive symptoms at 15–35% [2]. The presence of depressive symptoms is associated with a poorer quality of life in patients with diabetes and has been shown to be associated with poorer glycemic control and diabetes complications [3–7]. Similar associations have been reported with subthreshold depression [7].

The relationship between glycemic control and depression is likely bidirectional, but the

causal pathways remain incompletely understood [8]. Although poorer self-care among diabetes patients (e.g., adherence to lifestyle recommendations and glucose monitoring) is regarded as a potential contributor to poor glycemic control over time, it cannot fully account for poor control, as depression may also impact stress pathways which in turn can affect glycosylated hemoglobin (HbA1c) levels [9, 10]. However, interventions aimed at reducing depression among patients with diabetes have not led to the reduction in HbA1c or improvements in self-care behaviors, and conversely, an intervention trial to improve diabetes self-care and glycemic control in elderly patients with diabetes did not lead to reduction in depression [11, 12].

Although major depressive disorder and depressive symptoms have generally been considered to be associated with poor glycemic control in type 2 diabetes mellitus (T2DM), the available data from cross-sectional studies on this association are inconsistent and methodological approaches vary across studies [2, 9, 13–25].

Diabetes-related distress refers to the emotional burden that may be an aspect of managing a chronic illness, and can be found in both those with diabetes and their caregivers [26]. It is different from the clinical experience of depression [27–30], as it may manifest more in emotional reactions to diabetes and its treatment. High levels of distress have been significantly linked to elevated HbA1c [29, 31]. Importantly, a prospective, observational, non-interventional study by Fisher and colleagues [8] concluded that diabetes distress, but not clinical depression or depressive symptoms, is associated with poorer glycemic control in both cross-sectional and longitudinal analyses. That 18-month study included a relatively homogeneous group of patients with T2DM

who participated in diabetes education programs and had a reasonable level of glycemic control (average HbA1c of 7.2%). It is important to replicate these findings in a more heterogeneous group of patients to fully understand the relationships between affective parameters and glycemic control in patients with T2DM. It is also important to study the association between HbA1c and depression or distress parameters prior to and following patients' transition to insulin therapy. Barriers to timely intensification of treatment to insulin therapy in patients with poor glycemic control also encompass patients' psychological insulin resistance [32, 33], which contributes to long delays in the start of insulin therapy [34–37]. Psychological resistance to insulin is a multifaceted, encompassing fear of insulin and the potential side effects of hypoglycemia and weight gain, complexity of insulin treatment and regimens, need to self-monitor blood glucose to adapt doses, and emotional factors such as anxiety or depression symptoms [32, 33, 38–41].

Inconsistencies in our understanding regarding the link between glycemic control and depression may be due, in part, to the reliance on diverse measures of depression. These include a previous depression diagnosis (either from claims data, medical records, or self-reported), results from depression diagnostic screening tools (e.g., the Center for Epidemiologic Studies-Depression scale, the Patient Health Questionnaire) or full batteries, e.g., the Structured Clinical Interview for DSM-IV [Diagnostic and Statistical Manual of Mental Disorders, 4th Edition] Diagnosis, scores from clinical assessments of depression symptoms (e.g., the Quick Inventory of Depressive Symptomatology, the Montgomery-Asberg Depression Rating Scale) or measures of diabetes-related distress [27, 42]. A report from the National Institute of Diabetes, Digestive and

Kidney Diseases on diabetes and depression points out that the definition of depression varies across studies due to the variability of measurement and use of undefined terminology [43].

To help clarify the link between glycemic control and depression, this study investigated the association between three types of depression/diabetes distress parameters (depression diagnosis, depressed mood, and diabetes-related distress) over 24 months in patients with T2DM initiating insulin in a large, observational, non-interventional trial.

METHODS

Data from the TREAT study [44] were utilized to conduct an exploratory, post hoc analysis of the association between depression and glycemic control over 24 months in patients with T2DM initiating insulin treatment. The TREAT study was a 24-month, prospective, observational, non-interventional study that evaluated glycemic response in patients with T2DM who were initiated on insulin therapy ($N = 985$) in five European countries (Greece, Portugal, Romania, Sweden, and Turkey). Insulin-naïve patients with T2DM who presented within the normal course of care and initiated insulin under the investigator's supervision or that of a referred physician were enrolled. Enrolled patients at each site had characteristics typical of patient demographics and physician specialty (primary care or specialist) for each country. Further details of the study design and clinical outcomes are available in the primary publication [44].

The TREAT study included secondary measures that are pertinent to depression and distress, including a history of diagnosis of depression, severity of depressed/anxious

mood (EuroQol [EQ]-5D item, hereafter referred to as “depressed mood”), and diabetes-related distress (Psychological Distress domain of the Diabetes Health Profile [DHP-18]). The latter two patient-reported measures were assessed at baseline and five time points thereafter (3, 6, 12, 18, and 24 months) along with HbA1c, thus enabling a cross-sectional and longitudinal evaluation of the potential link between glycemic control, depressive mood, history of diagnosed depression, and diabetes-related distress. Using these three proxy measures of depression/distress the current study assessed: (1) at the time of insulin initiation (cross sectionally), whether depression is associated with higher HbA1c values; (2) during the 24 months following insulin initiation (longitudinally), whether depression is associated with higher HbA1c values; and (3) the relationships between the three studied proxy measures of depression/distress.

This analysis evaluated depression in three ways:

1. History of depression diagnosis—a history of depression diagnosis was recorded by the investigator at baseline (“Has the patient ever been diagnosed with any significant diagnosis other than diabetes: depression?”).
2. Depressed mood—severity of depressed mood was assessed per patient self-report on the EQ-5D depression/anxiety item (“I am not anxious or depressed.”; “I am moderately anxious or depressed.”; “I am extremely anxious or depressed.”) scored as 0 (not), 1 (moderately), or 2 (extremely). Presence of depressed mood was defined as a score of 1 or 2.
3. Diabetes distress—diabetes-related distress was assessed by the Psychological Distress domain of the DHP-18, which included six items that asked the patients about the

impact of diabetes on their mood (e.g., getting depressed, losing temper, or becoming upset, argumentative or moody), with each item being scored as 0 (never), 1 (sometimes), 2 (often), or 3 (very often).

Patient characteristics, use of oral glucose-lowering medications, and diabetes disease history over the previous 12 months were recorded at baseline along with the presence of microvascular complications (diabetic retinopathy, diabetic nephropathy, diabetic neuropathy, erectile dysfunction, and amputation) and macrovascular complications (coronary heart disease, previous myocardial infarct, stroke, transient ischemic attack, peripheral arterial occlusive disease, chronic heart failure, and previous coronary artery bypass graft). Insulin type at initiation was defined as long/intermediate only, mixture only, basal/bolus, or short acting only.

Two-sample *t* tests and Fisher’s exact test were used to compare baseline patient characteristics. Group comparisons on HbA1c were performed with two-sample *t* tests at each time point (unadjusted analysis). An adjusted analysis was also performed to adjust for the effect of potential confounding variables and estimate the association that would be seen should the comparison groups (depressed vs. not depressed) be at the same level for the adjusted covariates. For depressed mood and diabetes distress, group comparisons for HbA1c were performed using analysis of covariance at each time point to control for the potential confounding effect of age, gender, body mass index (BMI), education, duration of diabetes, initiated insulin type, and microvascular and macrovascular complications. For comparison of HbA1c between groups with and without a history of diagnosed depression, a longitudinal, likelihood-based repeated measures mixed model analysis was used, controlling for age,

gender, BMI, education, duration of diabetes, initiated insulin type, and microvascular and macrovascular complications. Analyses were exploratory in that they were not planned as part of the analyses supporting the original publication for this study. However, the analyses and the hypotheses they address were planned and prespecified prior to their being conducted. Results for all analyses were considered statistically significant for $p < 0.05$. SAS version 9.2 (Cary, NC, USA) was used for all analyses.

Compliance with Ethics

Within the TREAT study, all treatment decisions were made between the physician and patient, and care was provided at the discretion of the physician and according to local standards of medical care. All patients provided written informed consent according to local regulations. Local requirements for ethical review and regulatory notifications, as appropriate, were met for each participating country.

The present article does not contain any new studies with human subjects performed by the authors.

RESULTS

A total of 985 patients were enrolled with a mean age of 60.39 years, mean HbA1c 9.55%, and mean duration of 9.96 years since diagnosis of T2DM. Overall, 50.1% of patients were initiated on long/intermediate insulin, 39.3% on mixtures, 7.8% on basal/bolus regimens, and 2.8% on short-acting insulin. Patient characteristics at baseline are summarized in Table 1. Depressed mood was reported by 49.9% of patients (43.9% moderate, 6.1% severe) and history of depression diagnosis by 12.4%. Using the cut-point of those with scores ≥ 75 th

percentile of the distribution on the DHP-18, 29.9% of patients reported high levels of diabetes-related distress at baseline.

Table 1 also shows that regardless of the depression parameter, patients with depressive symptoms were significantly more likely than patients without the depression parameter to be female, to have a higher BMI, and to have microvascular complications. In addition, patients with depressed mood had a significantly longer duration of diabetes than patients without depressed mood.

Most study participants (752; 76.3%) have completed the 24-month study. Reasons for discontinuations (n ; %) included: lost to follow-up (70; 7.1%); physician decision (70; 7.1%); subject decision (63; 6.4%); death (22; 2.2%); missing (7; 0.7%); and sponsor decision (2; 0.2%). Using a comparative analysis stratified by country, the 752 study completers were not found to significantly differ from the 234 study dropouts on any of the studied baseline characteristics. There was, however, one baseline characteristic with a marginally significant difference between the completers and dropouts. There were a lower percentage of dropouts with a history of depression diagnosis at baseline compared to study completers. (9.2% vs. 13.9%, $p = 0.054$).

Cross-Sectional Analysis at Baseline

HbA1c was significantly (adjusted and unadjusted, $p \leq 0.001$) higher in patients with a history of diagnosed depression than in patients without (10.77% vs. 9.36%). HbA1c was similar in patients with depressed mood compared to those without depressed mood (Table 1). HbA1c was significantly higher (unadjusted, $p \leq 0.001$) in patients with high diabetes distress compared to patients with low distress (9.91% vs. 9.39%). Differences were not

statistically significant in the adjusted analysis ($p = 0.701$).

Longitudinal Analysis

The proportion of patients with depressed mood declined over time (from 49.9% to 37.0%, $p < 0.001$; Fig. 1a), while the proportion of patients with high diabetes distress did not decline significantly over time (from 29.9% to 26.7%, $p = 0.098$; Fig. 1b).

Over the 24 months following insulin initiation, glycemic control (as measured by mean HbA1c) improved, regardless of the presence or absence of depression defined by each parameter as shown in Fig. 2. Patients with a history of diagnosed depression had significantly higher HbA1c values during the first 6 months following insulin initiation (HbA1c values decreased over time from

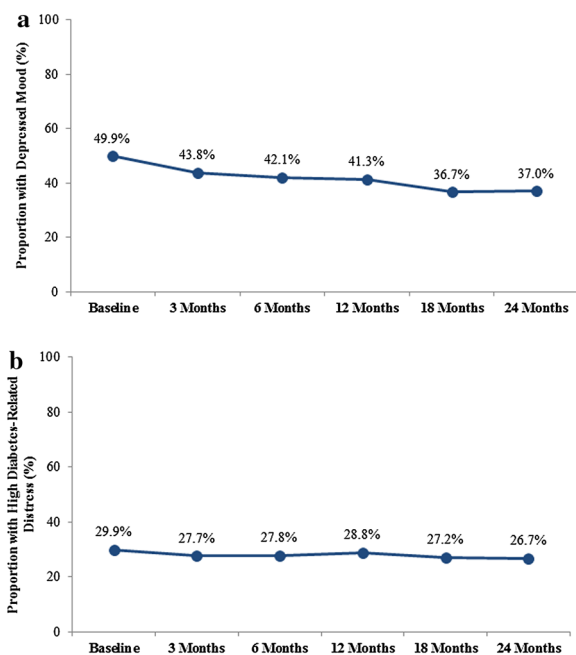

Fig. 1 a Decline over time in proportion of patients with depressed mood [$p < 0.001$ for linear trend test by Generalized Estimating Equation (GEE)]. b No significant change over time ($p = 0.098$ for linear trend test by GEE) in proportion of patients with high diabetes distress

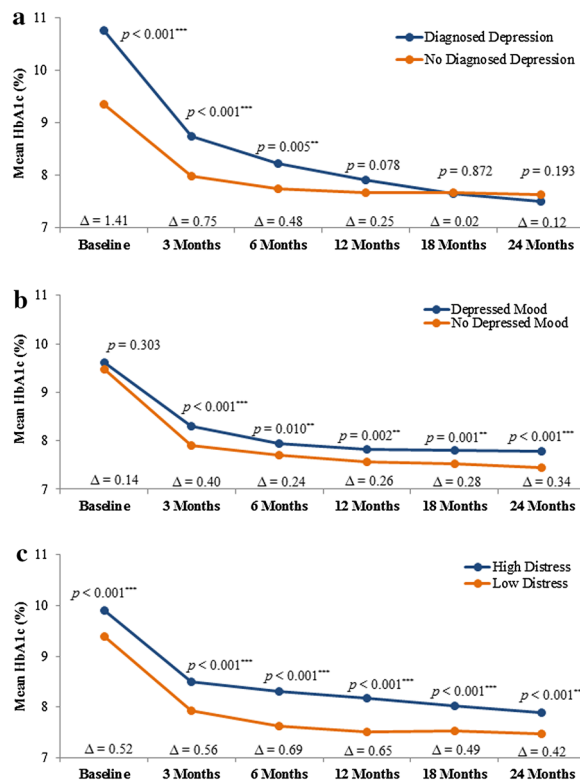

Fig. 2 a Mean HbA1c over 24 months by history of diagnosed depression at baseline. Presented results are from the unadjusted analysis. Results from the adjusted analysis showed a similar pattern as the unadjusted analysis. Group differences were, however, no longer statistically significant at 6 months and became significant in the opposite direction at 18 and 24 months. b Mean HbA1c over 24 months by depressed mood. Presented results are from the unadjusted analysis. Results from the adjusted analysis showed the same pattern as the unadjusted analysis. Group differences were, however, no longer statistically significant at 3 and 6 months. c Mean HbA1c over 24 months by diabetes distress. High diabetes distress is defined as a score ≥ 75 th percentile on the DHP-18 Psychological Distress domain score at each assessment. Results are presented from the unadjusted analysis. Results from the adjusted analysis showed the same pattern as the unadjusted analysis. Group differences were, however, no longer statistically significant at baseline. *DHP-18* Psychological Distress domain of the Diabetes Health Profile, *HbA1c* glycated hemoglobin. *Significant difference between the groups with vs. without the depression parameter at $p \leq 0.05$. **Significant difference between the groups with vs. without the depression parameter at $p \leq 0.01$. ***Significant difference between the groups with vs. without the depression parameter at $p \leq 0.001$. Δ = Difference between groups

10.77% to 8.22%) than those without a history of diagnosis (HbA1c values decreased from 9.36% to 7.74%) (unadjusted $p < 0.01$; Fig. 2a), but not at subsequent time points (12 months, $p = 0.078$; 18 months, $p = 0.872$; 24 months, $p = 0.193$). Over the 24 months, patients with depressed mood continued to have higher HbA1c (HbA1c values decreased from 9.62% to 7.79%) compared to patients without depressed mood (HbA1c values decreased from 9.48% to 7.45%) (unadjusted $p \leq 0.01$; Fig. 2b). Higher HbA1c values were consistently observed in patients with high diabetes distress (HbA1c values decreased from 9.91% to 7.90%) compared to patient without high diabetes distress (HbA1c values decreased from 9.39% to 7.48%) throughout the study period (unadjusted $p < 0.001$; Fig. 2c). Results from the adjusted analysis showed similar patterns (results not shown).

Correlations Between Depression and Distress Measures

Table 2 presents the correlations between the three depression and distress parameters over the 24 months following insulin initiation. The three measures were positively and significantly

Table 2 Correlations between the depression parameters at baseline

Depression/distress parameter	Correlation coefficient (p value)
Depressed mood and history of diagnosed depression	0.194 ($p < 0.001$) ^a
Depressed mood and diabetes distress	0.396 ($p < 0.001$) ^b
Diabetes distress and history of diagnosed depression	0.137 ($p < 0.001$) ^a

^b Pearson correlation

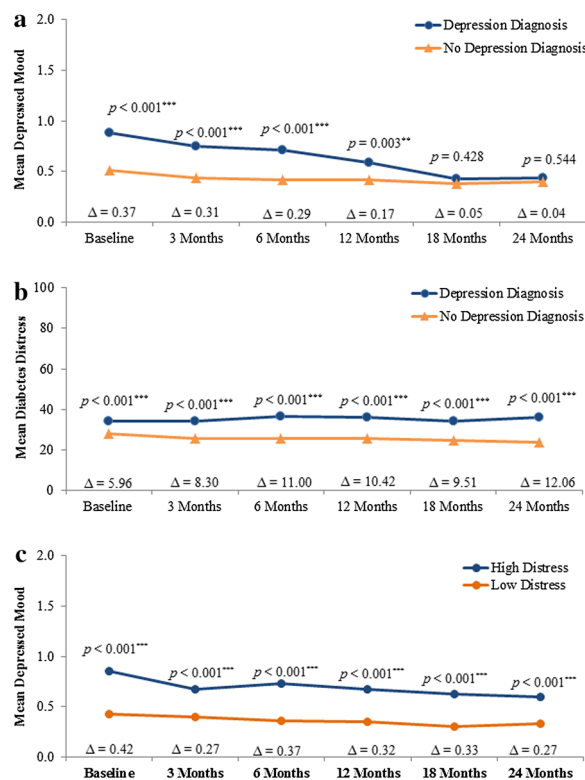

Fig. 3 **a** Depressed mood scores over 24 months by history of depression diagnosis at baseline. Results are presented from the unadjusted analysis. Results from the adjusted analysis showed the same pattern as the unadjusted analysis. Group differences were, however, no longer statistically significant at 12 months. **b** Diabetes distress scores over 24 months by history of depression diagnosis at baseline. Results are presented from the unadjusted analysis. Results from the adjusted analysis showed the same pattern as the unadjusted analysis. Group differences were, however, no longer statistically significant at baseline. **c** Depressed mood scores over 24 months by diabetes distress. Results are presented from the unadjusted analysis. Results from the adjusted analysis showed the same pattern as the unadjusted analysis. *Significant difference between the groups with vs. without the depression parameter at $p \leq 0.05$. **Significant difference between the groups with vs. without the depression parameter at $p \leq 0.01$. ***Significant difference between the groups with vs. without the depression parameter at $p \leq 0.001$. Δ = Difference between groups

correlated at baseline, although the magnitude of the associations was relatively low, with the higher correlation observed between depressed mood and diabetes distress ($r = 0.396$). Figure 3

shows the longitudinal relationships between the depression parameters. In the first 12 months post-initiation of insulin therapy, patients with a history of diagnosed depression had significantly higher mean scores on the depressive mood item compared to patients without a history of diagnosed depression (Fig. 3a). Similarly, Fig. 3b and c shows relationships between diabetes distress and history of diagnosed depression, and depressed mood by baseline diabetes-related distress. In all cases, the presence of depression at baseline is associated with the presence of more symptoms over time. Results from the adjusted analysis showed essentially the same pattern (results not shown).

Sensitivity Analyses

As study participants were enrolled from five European countries (Greece, Portugal, Romania, Sweden, and Turkey), we also assessed—as a sensitivity analysis—the potential impact of country on the current results by repeating the original analyses in two ways: we first reanalyzed the findings while stratifying by country and then repeated the original analysis while adding country to the covariates in the model. Results (not shown) were essentially unchanged when stratifying by country and when adding country to the covariate list. There were, however, four changes from the original *p* values (out of 36 new comparisons): two previously significant comparisons became non-significant and two previously non-significant comparisons became significant.

DISCUSSION

This exploratory, post hoc analysis found consistent and significant associations between poorer glycemic control and each of the three

depression and distress parameters: history of depression diagnosis, depressed mood, and diabetes distress in T2DM patients who initiated insulin therapy. This analysis also demonstrated that patients with higher depression parameters or distress at baseline had significantly higher rates of microvascular complications. Poor glycemic control has indeed been associated with development of diabetic complications [45], and these complications are probably a more direct cause of depressive mood in patients with higher HbA1c than HbA1c alone. In addition, these results show that initiation of insulin therapy was associated with improved glycemic control, and the proportion of patients with preexisting depressed mood decreased significantly (by 13% overall from 49.9% to 37.0%) and resulted in numerically, but not statistically significant, reductions in the proportion of patients with preexisting high diabetes distress (from 29.9% to 26.7%, $p = 0.098$).

Consistent with prior research, a substantial proportion of patients with T2DM in this cohort were experiencing depression or emotional distress, as measured by the three proxy measures of depression. History of depression diagnosis was present in 12.4% of the patients, a finding congruent with previous studies that estimated the prevalence of major depression in diabetes to be around 12% (ranging from 8% to 18%) [2, 46, 47]. Depressed mood was reported by 50% of patients and diabetes-related distress by 30%.

Although the positive associations between poorer glycemic control and depression parameters were observed at baseline for only two of the three depression parameters (history of depression diagnosis and diabetes distress), there was a higher rate of microvascular complications for all three parameters. While the mean HbA1c values improved for patients

during the 24 months following insulin initiation, glycemic control was poorer for patients with, compared to without, the depressive parameters. A higher HbA1c at baseline is, however, associated with a higher HbA1c at endpoint after insulin treatment, although the decrease in HbA1c is higher [48, 49]. A higher HbA1c at baseline was also associated with higher HbA1c at endpoint in the TREAT study [44]. In this analysis, insulin regimens were similar between groups with or without depressive parameters, and thus a higher HbA1c at endpoint is not unexpected and probably more linked to the difficulty and need of more complex insulin regimens in patients with worse glycemic control at insulin initiation than to depressive parameters.

The consistent findings may be due, at least in part, to the positive and significant interrelationships between the depression parameters. Although the correlations were relatively small in magnitude, the correlation between diabetes distress and depressed mood was higher ($r = 0.396$). This is consistent with prior research [28], which reported a correlation of $r = 0.48$ between depressed mood and diabetes distress. Therefore, current findings suggest that the different depression parameters may capture a different but interrelated condition that may require additional assessment and management to optimize glycemic control in patients with T2DM.

In addition, the importance of identifying a history of depression diagnosis has been highlighted by the finding that patients with a history of depression diagnosis had higher levels of depressed mood and diabetes distress not only at baseline, but also during the follow-up period. Interestingly, this differentiation persisted over the 24-month study for diabetes

distress but did not persist for depressed mood beyond the 12-month assessment. Patients with or without a history of depression diagnosis no longer differed on their level of depressed mood after 12 months of insulin therapy, suggesting that those with a preexisting depression diagnosis may have achieved remission, as their levels of depressive symptoms did not differ from patients without a history of depression diagnosis.

This exploratory, post hoc analysis has a number of potential limitations. First is the post hoc nature of the analysis, as the TREAT study was originally designed to assess glycemic response in T2DM patients initiating insulin. Another limitation is the proxy nature of the studied depression parameters. None of the measures used in the analysis were developed or validated for use as a stand-alone measure of depression, thus the psychometric properties of these depression parameters for this use are unknown. A third limitation relates to the history of depression diagnosis at baseline, which does not offer information regarding the specific type of depression diagnosis or when the diagnosis was made. Moreover, no information was available on patients' use of antidepressants at baseline during the study follow-up period, and the use of antidepressants would be expected to impact patients' level of depression and anxiety. Furthermore, high versus low diabetes distress was distinguished by a threshold score of $\geq 75\%$ in the psychological distress score distribution. We chose this threshold based on the statistical distribution and not on any concurrent validation with other measures of distress.

An additional limitation of the study is that we conducted analyses using observed data. It is not possible to rule out that the missing data

(through dropouts and missing visits) show informative missingness and that the results may be different if we had complete data on every subject that entered the study.

The study strengths include the longitudinal measurement of HbA1c and multiple affective measures available at six time points over a 24-month period, which enabled the assessment of both cross-sectional and longitudinal relationships between glycemic control and affective parameters. Reported results reflected adjusted as well as unadjusted analyses, which helped address a number of core baseline differences between those with and without the affective measure. Another strength is the focus on patients initiating insulin.

CONCLUSIONS

Current findings of a decline in the proportion of patients with depressive mood from pre-initiation to post-initiation of insulin therapy may suggest that once the barriers associated with insulin treatment have been addressed, depressed mood improves with better glycemic control. A better understanding of the relationship between glycemic control, diabetic complications, and specific affective parameters may help clinicians to focus more attention on screening for affective conditions and provide information that may lead to more timely treatment or referrals to both mental health and diabetes professionals. In addition to the potential beneficial impact on clinical practice and patients' outcomes, such information may also be useful for diabetes research, as it may help highlight the need to evaluate specific potential affective confounders when assessing glycemic control among patients with T2DM, in either cross-sectional or longitudinal manner.
