Abstract – Recent declines of bee populations have led to great interest in preserving bee species and fuel efforts to develop solitary species for pollination purposes. Xylophilous solitary bees can be easily reared in artificial nest tubes for commercial agricultural as well as wild plant pollination. The impact of the dimensions of these artificial nest tubes on reproduction parameters was studied in the red mason bee, *Osmia bicornis* (L.), in a long-term study. Increasing tube diameter positively affected both progeny sex ratio and body size. Sex ratio, but not progeny body mass, was negatively affected by short tube length. Building costs rose with increasing diameter accompanied by deteriorated efficiency of tube space utilization. Although female bees used a wide spectrum of nest dimensions, artificial nest tubes of 8–10 mm internal diameter and a length of at least 150 mm were optimal.

sex ratio / body size / nest cavity dimensions / diameter / length / *Osmia bicornis*=*O. rufa*

1. INTRODUCTION

Many cavity-nesting solitary bees use existing natural cavities such as hollow plant stems, beetle borer tunnels in dead wood, or empty snail shells to construct their nests within (Michener 2007). In contrast to ground nesting bees or species that build their nests on the surface of hard materials, females of xylophilous species depend on the dimensions of the prebuilt cavities that limit the space for brood cell construction. The internal diameter of the tube may limit brood cell volume and, thereby, progeny body size. Females can compensate for different nest diameters only par-

tially by adapting the length of the brood cell. Both the diameter and the length of the brood cell have to be large enough to allow formation of the provision mass as well as movements of the larva while spinning its cocoon. Moreover, the inner diameter determines the true building costs of nest construction at least by the area that has to be sealed by nesting material, such as mortar or leaf cuttings, to partition brood cells.

Cavity nesting species depend on the size spectrum of suitable cavities to construct nests. Especially in species with a sexual dimorphism in body size, progeny sex ratio can be expected to be influenced by the diameter of the selected cavities. Narrow tunnels force females to construct brood cells of the smaller sex (Longair 1981). Male biased sex ratios in narrow tubes have been reported, e.g., in *Megachile rotundata* (Stephen and Osgood 1965; Gerber and Klostermeyer 1972; O'Neill et al. 2010), *Osmia lignaria* (Torchio and Tepedino 1980; Tepedino and Torchio 1989), and *Osmia bicornis* (Raw 1972; Holm

Electronic supplementary material The online version of this article (doi:10.1007/s13592-015-0380-z) contains supplementary material, which is available to authorized users.

1973; Brechtel 1986). Also, progeny body size might be influenced (*M. rotundata*: O'Neill et al. 2010). Nest length might influence progeny sex ratio if brood cells for the sexes are restricted to particular regions of the linear nest. Short nest cavities should shift the sex ratio toward the sex whose brood cells are located at the entrance of the nest. Thus, the size spectrum of available nest cavities might have an impact on local population structure and stability (Ulbrich and Seidelmann 2001; Roulston and Goodell 2011).

In contrast to natural conditions, the dimensions of artificial nesting cavities can be governed in solitary bee-keepings to control progeny sex ratio and body size. For pollination purposes, it is advisable to maximize the number of females in the progeny and to produce large individuals that have a higher fecundity (e.g., Tepedino and Torchio 1989; Kim 1997; Tomkins et al. 2001; Bosch and Vicens 2006), lower winter mortalities (Tepedino and Torchio 1982; Bosch and Kemp 2004), and can be expected to work at cooler temperatures (Stone and Willmer 1989; Stone 1994). On the other hand, building costs of nest structures such as brood cell lining and partitions have to be minimized. Collection of construction materials consumes activity time that is diverted from time that could be used for provisioning and pollination. Last but not least, the offered cavity space should be sufficiently used by the bees.

The impact of nest tube dimension on reproduction parameters were studied in the red mason bee *Osmia bicornis* (L., syn.: *O. rufá*), a species that is regularly used as an orchard pollinator. Females of this protandric species construct mixed nests containing both sexes. Typically, nests consist of a series of cells for the later emerging sex (daughters) at the back of the tunnel and a series of the earlier emerging sex (sons) at the entrance (Raw 1972; Holm 1973; Maddocks and Paulus 1987). We analyzed nests of predefined dimensions from three consecutive nesting seasons. Several reproduction parameters were studied: progeny sex ratio, number of provisioned brood cells, and progeny body size as well as mortality and economical parameters (e.g., space usage, building efforts, and room efficiency). The aim of our study was first to identify optimal nest tube dimensions for the propagation

of *O. bicornis* for pollination purposes and second to demonstrate the impact of tube dimensions on reproduction parameters in trap nests studies.

2. MATERIAL AND METHODS

Nest material and study design Nest diameter range is limited by the body size of *O. bicornis* to 4 mm at the lower end and, due to the focus on a precise linear nest architecture for this study, to 12 mm at the upper end. At inner diameters above 12 mm, *O. bicornis* females will construct longitudinal walls (Jacob-Remacle 1976; personal observations), thus constructing two cells in parallel. This leads to distorted construction costs that cannot be compared to smaller diameter nests. Artificial nest tubes were made from hollow stems of Japanese knotweed (*Fallopia japonica*, Houttuyn). The stems were cut into segments close to raised nodes to produce naturally sealed tubes. Internodes of 4, 6, 8, 10, and 12 mm inner diameter (\varnothing) were selected by solid diameter gauges and trimmed afterwards to one of the five length classes: 70, 100, 130, 160, and 190 mm (distance between node diaphragm and opening). Five tubes of the same diameter class, one per length class, were combined into one round stalk bundle with all openings in one plane. The position of the length classes in each bundle was random. Ten bundles per diameter were prepared (containing 250 nest tubes in total). These 50 bundles were piled randomly into a cardboard box open to the front so that the tube openings of all bundles were in the same level. The box was then stuffed with styrofoam packing flakes from behind to stabilize the assembly.

Similarly constructed test boxes were offered to nesting females in three consecutive years in a regularly maintained population of *O. bicornis* located in the Botanical Garden of Halle/Saale (Germany, Saxony-Anhalt, 51° 29' 04 N, 11° 56' 07 E). This location provides a high diversity and stable richness of food plants. Effects of resource shortage or extensive traveling costs on maternal investment can be excluded (Kim 1999; Ulbrich and Seidelmann 2001; Ivanov 2006; Peterson and Roitberg 2006).

Beside the test block, additional nesting tubes of Japanese knotweed (various dimensions) and wooden nest blocks (tube dimensions 8×150 mm, 100–120 tubes per block) were offered in one and the same shelter that protected the nest material from rain and direct sunshine. Overwintered cocoons free of parasites were

exposed in the first days of April in the shelter to allow natural emergence. Each year, a total of 800 nest tubes were offered to about 1000 emerging females to correct for a dispersal rate of about 40 % (Seidelmann 2006). After the start of the nesting season, the test box was photographed every 2–3 days to monitor the sealing of the nest tubes. Temperature and humidity were registered by climate loggers (StowAway series; Onset Instruments) every 5 min over the whole nesting period. Mean temperature and relative humidity were calculated for the potential activity period of the bees (700 to 2100 h; see Table S1 for a characterization of weather conditions). In July, all nests were removed from the Botanical Garden and stored in an empty honey bee hive at outdoor temperatures in the courtyard of the institute.

Nest analysis In January, each nest was individually dissected by slitting the stalk with a scalpel on two sides to raise the upper half of the tube. Cocoons were removed and cleaned from feces and debris by hand. For each nest, the length of the vestibulum (empty cell at the entrance of the tube), size and content of every cell, as well as position and size of unused tube areas were recorded. Additionally, the weight of three entire cell partitions was noted. The length of cells was measured by an electronic sliding caliper (Preisser DIGI-MET 150, precision 0.03 mm) correct to 1 mm, and the weight of cleaned cocoons and partitions by an electronic balance (Mettler Toledo ML104/01, precision 0.0001 g) correct to 0.1 mg. To identify the sex of a bee and to check for parasites, cocoons were opened gently at the top. Bees were sexed according to the hair color of the clypeus (males: white; females: black). The sex of bee larvae that were killed by a parasite or perished by unknown reasons was inferred from the cell length and the sex of the bees in the neighboring cells (Raw 1972; Holm 1973; Longair 1981; Maddocks and Paulus 1987; Seidelmann 2006). As not all stalks were used for nest construction by *O. bicornis*, a total of 702 nests containing 5404 cells were analyzed from three nesting periods (2010–2012).

Calculations Sex ratio (proportion of daughters), parasitism rate, and mortality rate were calculated for each nest. Parasitism rate and mortality rate were defined as the number of cells parasitized or with dead siblings, respectively, per total number of provisioned cells of the nest. Usage of tube length was calculated as sum of the

lengths of all provisioned cells per nest divided by the nominal tube length. Room efficiency was calculated per cell as quotient of cocoon mass per cell volume (calculated as cylinder volume from tube diameter and cell length). The estimation of diameter-specific construction costs was based on cell partition mass. The mass of building material per area was indicated as partition index. As the edges of the partitions are thicker than the diaphragm itself, the mass of a partition is a nonlinear function of the diameter:

$$m_p = A \times \pi d + B \times \frac{\pi}{4} d^2 \quad (1)$$

with m_p (mg) being the mass of the partition and d (mm) being the internal diameter of the nest tube. A (mg/mm) and B (mg/mm²) are factors that correct for different mortar expenditure to construct the diaphragm and the thickened edge, respectively. The factors were estimated by SPSS (IBM, ver. 22.0) and are given as estimated value \pm SE.

Statistical analysis Nesting females adapt the progeny sex ratio and progeny body size to their age-specific provisioning capability (Torchio and Tepedino 1980; Ivanov 2006; Seidelmann 2006). To take these shifts into statistical account, the relative season date for each nest was determined as mean of start and closure dates (see [electronic supplementary material](#) for details) and normalized to a total nesting period of 50 days. The normalized date of tube occupation (= start date of construction of the first brood cell) was furthermore used to estimate the attractivity of tubes based on the assumption that bees occupy tubes of preferred dimensions first.

The impact of nest tube dimensions was analyzed by GLM univariate ANOVA in SPSS (IBM, ver. 22.0) with diameter and length as fixed factors, year as random factor, and season date as covariate. Parameters such as progeny sex ratio, cell number, and rate of parasitism were analyzed per nest, while parameters of individual offspring such as cocoon mass, cell volume, and derived values were analyzed on the basis of provisioned brood cells. Due to the sexual size dimorphism in body size, sex was used as additional fixed factor in these analyses. Moreover, to correct for sexual dimorphism effects in the analysis of room efficiency, cocoon mass had to be

used as an additional covariate. Differences between nest dimensions were tested as contrasts against the largest dimension value. Females were assumed to suffer no spatial limitations in nests of the largest dimensions and to be able to provision cells in a manner optimal for their fitness. Values in the text and figures are given as mean±standard deviation unless otherwise stated. The error level was set to $\alpha=0.05$.

3. RESULTS

3.1. General usage of nest tubes

Osmia bicornis females accepted tubes of all supplied dimensions. However, bees used only 57.2 % of the 4-mm tubes, while 100 % of the 6–12-mm tubes were occupied. Tube attractiveness as assessed by the date of occupation did not depend on tube dimensions in general (diameter— $F_{4, 658}=1.98$, $p=0.190$; length— $F_{4, 658}=2.44$, $p=0.129$). However, narrow tubes (4 mm) were occupied later than thicker ones (Figure 1; all Scheffé post hoc test— $|\text{diff}| \geq 9.920$, $SE \geq 1.352$, $p < 0.001$). Tubes of $\varnothing \geq 6$ mm did not differ in the mean occupation date (all

$|\text{diff}| \leq 2.174$, $SE \leq 1.365$, $p \geq 0.459$). Shorter tubes were less attractive to the bees compared with the longest ones (Figure 1; all $|\text{diff}| \geq 5.635$, $SE \geq 1.266$, $p < 0.001$). The three longer tube classes did not differ in occupation date (all $|\text{diff}| \leq 2.446$, $SE \leq 1.290$, $p \geq 0.431$).

3.2. Progeny body size and sex ratio

Mean cocoon mass differed between the sexes (sons— 85.31 ± 27.52 mg, $n=1481$; daughters— 150.02 ± 30.62 mg, $n=3127$; $F_{1, 4608}=114.5$, $p=0.002$) and was influenced by nest tube diameter ($F_{4, 4608}=101.8$, $p < 0.001$), but not by tube length (Figure 2c; $F_{4, 4608}=0.49$, $p=0.742$). The cocoon mass of daughters increased with the diameter up to 10 mm (all $|\text{diff}| \geq 0.008$, $SE \geq 0.001$, $p < 0.001$) and was not further increased in wider tubes (diff=0.002, $SE=0.001$, $p=0.088$). In sons, only cocoons from the two narrowest diameter classes were lighter than the ones from the widest tubes (Figure 2c; both $|\text{diff}| \geq 0.016$, $SE=0.002$, $p < 0.001$; all $\varnothing > 6$ mm, $|\text{diff}| \leq 0.002$, $SE=0.002$, $p \geq 0.311$). Cocoon mass did not differ between years ($F_{2, 4608}=7.26$, $p=0.087$).

The overall sex ratio (proportion of daughters) for all cells including those that were parasitized ranged between 0.608 ± 0.313 in 2010 and 0.538 ± 0.292 in 2012. Sex ratio depended on diameter ($F_{4, 658}=257.8$, $p < 0.001$) but not on nest length ($F_{4, 658}=3.20$, $p=0.074$). In $\varnothing=4$ mm nests, daughter cells were constructed by way of exception only. The proportion of daughters increased with the diameter up to 8 mm (all $|\text{diff}| \geq 0.742$, $SE \geq 0.024$, $p < 0.001$) but was not further increased in wider tubes (Figure 2b; all $|\text{diff}| \leq 0.008$, $SE \leq 0.024$, $p \geq 0.746$). Although sex ratio did not depend on nest tube length in general, nests of 70 mm produced a higher proportion of sons than the longest nests (diff= -0.114 , $SE=0.027$, $p < 0.001$) while all other length classes did not differ ($|\text{diff}| \leq 0.049$, $SE \leq 0.26$, $p \geq 0.059$). The missing general impact of tube length was an unexpected effect of entering “year” as a random factor in the model. Analyzing the years individually, sex ratio increased with length in each individual year (Figure S1; 2010— $F_{2, 212}=5.84$, $p < 0.001$; 2011— $F_{2, 244}=5.40$, $p < 0.001$; 2012— $F_{2,$

$202=3.07, p=0.018$). The outliers found in 2010 and 2011 mask the trend of increasing sex ratios

with lengthened tubes in the general analysis (see [electronic supplementary material](#) for details).

3.3. Brood cell number, space usage, and construction effort

The number of brood cells constructed per nest depended on both nest dimensions (Figure 2a; diameter— $F_{4, 658}=13.34$, $p=0.001$; length— $F_{4, 658}=145.8$, $p<0.001$) and ranged between 2.7 ± 1.1 cells in 4×70 mm² nests and 13.8 ± 3.9 cells in 12×190 mm² tubes. However, the longer tubes were used for a higher number of brood cells in the larger diameter classes only (160 mm nests in $\varnothing \geq 6$ mm, 190 mm nests in $\varnothing \geq 8$ mm; $L\times D$ — $F_{16, 658}=2.85$, $p=0.007$).

In total, $73.3\pm 16.7\%$ ($n=651$) of the available nest tube length was used to construct brood cells, a vestibulum, and a nest plug. The total length used did not depend on nest tube diameter ($F_{4, 651}=0.57$, $p=0.691$) or length ($F_{4, 651}=2.72$, $p=0.101$). However, there was an interaction between diameter and length ($F_{16, 651}=2.09$, $p=0.039$) caused by differences between length classes at $\varnothing \leq 6$ mm (all $F_{4, 73/147} \geq 2.85$, all $p \leq 0.030$). Room efficiency (cocoon mass per brood cell volume, Figure 2d) depended on tube diameter ($F_{4, 4575}=55.99$, $p<0.001$), length ($F_{4, 4575}=7.52$, $p=0.006$), progeny body size ($F_{1, 4575}=2132$, $p<0.001$), but not on size-dimorphism-adjusted sex ($F_{1, 4575}=0.14$, $p=0.734$).

The mean mass of partitions increased with diameter (Figure 3, $F_{4, 1125}=396.5$, $p<0.001$), but did not depend on nest length ($F_{4, 1125}=0.66$, $p=0.630$). The partition index decreased with diameter (Figure 3, $F_{4, 1125}=7.76$, $p=0.006$) and was also independent from nest tube length ($F_{4, 1125}=1.60$, $p=0.242$). However, the mass of the partitions corresponds well to the value expected under a fixed solidity of the edges and diaphragm. The constants of the nonlinear regression (Eq. 1) were estimated to $A=2.22\pm 0.41$ mg/mm as mortar expenditure for the edge and $B=1.30\pm 0.16$ mg/mm² for the diaphragm ($R^2=0.359$).

3.4. Mortality and parasitism

Brood cells were parasitized by *Cacoxenus indagator* (Diptera: Drosophilidae, 6.1 %), *Chaetodactylus osmiae* (Acari: Chaetodactylidae, 1.1 %), *Monodontomerus obscurus*

(Hymenoptera: Torymidae, 1.1 %), and *Anthrax anthrax* (Diptera: Bombyliidae, < 0.1 %), or destroyed by *Aphomia sociella* (Lepidoptera: Pyralidae, 1.0 %). Rate of infestation by parasites and nest destroyers increased with tube diameter (Figure 2e; $F_{4, 658}=7.09$, $p=0.009$, see [electronic supplementary material](#) for details), but was independent from tube length ($F_{4, 658}=1.68$, $p=0.240$). Parasitism by the different species varied from year to year ($\chi^2=448.8$, $df=10$, $p<0.001$). In 51.9 % of the cells infested by *C. indagator* and *Ch. osmiae*, bee larvae survived in spite of the parasitization.

Beside losses from parasitism, 8.0 % of the eggs, larvae, or pupae died without detectable reason. This preimaginal mortality varied between years ($F_{2, 658}=48.22$, $p=0.001$) and was influenced solely by the tube diameter (Figure 2f; $F_{4, 658}=4.18$, $p=0.038$), but not by tube length ($F_{4, 658}=0.65$, $p=0.644$). Both factors, mortality due to parasitism and due to unknown reasons, altered the sex ratio from 0.580 ± 0.332 created by the mother bees to a ratio of 0.611 ± 0.351 of emerging offspring ($t=-6.63$, $df=649$, $p<0.001$). Sons suffered from higher parasitism (13.0 %) than daughters (8.4 %, $\chi^2=22.30$, $df=1$, $p<0.001$). Moreover, mortality due to unknown reasons was also higher in sons (11.3 %) than in daughters (6.2 %, $\chi^2=42.32$, $df=1$, $p<0.001$).

4. DISCUSSION

Solitary bees nesting in pre-existing cavities rely on the supply of appropriate hollows for reproduction. Suitable tube-like cavities in wood or plant stems are limited resources (Roulston and Goodell 2011). Females are forced by the unpredictability of the dimensions of available nest tubes and the limitations by small diameters on the body size of progeny to use any discovered tubes as economically as possible. Especially for a species with a distinctive sex dimorphism in body size, females should adapt the sex ratio of progeny in the nest under construction. If the actual tube does not limit progeny body size, females can be expected to shift their actual investment toward the upper boundary of the projected conditional progeny body size spectrum (Seidelmann et al. 2010). This body size optimization implies also

Figure 3. Partition index and mass of *O. bicornis* cell partitions according to nest tube inner diameter. Stars with dashed line: partition index; diamonds: partition mass; solid line: nonlinear regression of partition mass. Symbols refer to mean \pm SD.

an adjustment of progeny sex ratio in favor of the larger sex. Providing solely nest tubes of large dimensions maintains this shift, but is not able to drive mean body size over the species-specific optimum and Fisherian sex ratio (Tepedino et al. 1984; Seidelmann et al. 2010, 2014). The observed female biased progeny sex ratio and deviations from typical mean body size in our study result from the restricted number of nest tubes leading to an overrepresentation of nests constructed early in the nesting season. Young bees construct more daughter cells and progeny of larger body size (Torchio and Tepedino 1980; Tepedino and Torchio 1982; Tomkins et al. 2001; Seidelmann 2006; this study—Table S2).

A presupposition for the rearing of any solitary bee is the acceptance of the offered nest materials. *Osmia bicornis* females did not prefer a particular internal tube diameter in our study. The lower acceptance of 4 mm tubes could be a body size exclusion phenomenon. In contrast to the low diameter discrimination in our study, *O. bicornis* females preferred in other studies either narrow nest diameters of 5–6 mm (Free and Williams 1970; Tasei 1973; Brechtel 1986) or wider nests of 7–9 mm (Jacob-Remacle 1976; Maddocks and Paulus 1987; Ivanov 2006). This inhomogeneity of preferred diameters reflects the diversity of bee body size found in autochthony and managed populations. In contrast to the diameter, preferences for certain nest tube length likely were not

due to nesting female body size. Although all length classes were used by the bees in our study, the shorter ones (70 and 100 mm) were occupied later than the longer ones, indicating a preference for deeper nest tubes. This result is consistent with increasing frequencies of occupation of reed tubes up to 230 mm depth (Ivanov 2006), but only partly consistent with the preference of 120-mm tubes over both 140- and 100-mm tubes (Maddocks and Paulus 1987).

Both nest tube dimensions were found to influence the reproduction parameters of *O. bicornis* females. The diameter had generally a deeper impact than the tube length. Sex ratio and body mass increased from the smallest diameter towards 8- and 10-mm tubes, respectively, and remained nearly constant afterwards. On the contrary, parameters of economical space usage (e.g., room efficiency) decreased with increasing diameter. Also, the effort to construct cell partitions increased with tube width, although females adhered to their construction principle and did not thicken the structure to support stability. Offspring quality and economy of nest construction form an optimum of productivity at internal nest tube diameters of 8–10 mm.

The expected male biased sex ratio in short nest tubes was restricted to nests of 70 mm length. A general trend of increasing proportions of daughters with increasing nest tube length (Gruber et al. 2011) was not consistently found in our study.

However, the impact of tube length can be expected to diminish above a critical number of brood cells. Females construct a few brood cells for sons at the entrance of the nest (e.g., Raw 1972; Maddocks and Paulus 1987; Ivanov 2006). Therefore, short tubes limit the space left over for the construction of brood cells for daughters. Above a critical length, however, the space is sufficient to realize the sex ratio projected by mother bee's condition, and sex ratio should be unaffected by the nest tube length. Finally, the risk spreading principle (Torchio and Tepedino 1980) should restrict the number of cells produced in a single nest. The resulting decrease of space usage, however, was not found at least in the length range studied by us.

5. CONCLUSION

Osmia bicornis females accept nest tubes of a wide range of diameters and length. Tubes of ≥ 6 mm diameter and ≥ 100 mm length are sufficiently accepted for a commercial propagation. The proportion of daughters and progeny body size reached their maximum at 8–10 mm inner tube diameter. Wider tubes are not recommended because parasitism and building costs increase with diameter. The optimal length of nest tubes for the propagation of *O. bicornis* has to be oriented on the sex ratio shift toward males in tubes shorter than 130 mm, and on practical demands as handling and procurement of nest tubes. Tubes in the range of 8–10 mm diameter and 150 to 200 mm length were found to be optimal. These recommendations apply also for trap nest studies to avoid a male biased sex ratio and a distorted body size spectrum. Nests constructed early in the nesting season are especially valuable for pollination purposes as they contain the highest proportion of daughters and bees of the largest body size.
