Abstract

The sludge generated by wet scrubbing the off-gas from a silicomanganese plant in Norway represents a significant loss in silicon and manganese values. This work seeks to extract these values in the production of ferroalloys and slags that can be utilized by alternative industries. Carbothermic smelting the sludge together with iron or iron scraps at 1600 °C produced FeSiMn alloys consisting of 57–64 wt.% Mn, 16–22 wt.% Si and 18–25 wt.% Fe. The low level of phosphorus in the sludge allowed for beneficial phosphorus concentrations as low as 500 ppmw in the metal alloys. The addition of lime to the material mix resulted in increased evaporation of alkalis, capture of sulfur in the slags as calcium sulfides and slag compositions similar to conventional steel-making slags that can be recycled accordingly.

Introduction

Metallurgical dust fractions generated during metal production are commonly captured through wet scrubbing of the off-gas, and these sludges may contain significant metal values. However, due to high conversion costs and properties not compatible with the daily operations of the furnace, they are rarely recycled by the plants. Instead, the sludges are collected in landfills for inexpedient storage. The significant

material losses, environmental impact of such landfills, and establishment of circular principles have at the same time parked interest among industrial actors, lawmakers, and the general public to develop new strategies and technologies for recycling of sludges. Stricter regulations like the Extractive Waste Directive (2006/21/EC) and the European Waste Legislation put new constraints on landfilling and increase the pressure on the industry to find alternative and more sustainable solution for handling their wastes [1]. The Norwegian Waste-to-Value project was a part of an ambitious plan to develop technologies for better utilization of waste products from industrial partners.

local settling ponds. The plant generates approximately 10 000 metric tons of sludge annually and has been subject to various studies over the years [2, 3]. Direct recycling into the submerged arc furnace (SAF) has proven to be challenging, due to the high tar and water content, and the presence of alkalis and unwanted circulation of volatiles proved to have negative consequences for the daily operations and energy consumption of the furnace. The authors suggested that the most suitable option was to calcine the sludge, for evaporation of volatiles, followed by smelting in an open bath arc furnace. The generated slag would contain most of the Mn, for reintroduction into the SAF, while alkalis would be removed through the off-gas. Experiments were to be performed at a later stage, but any public literature remains absent. An alternative use of the sludge, which acts as the basis for this work, is the possibility of using it as a raw material for direct production of ferromanganese instead. Manganese is an essential component in steelmaking, with varying concentrations of 0.25–30%, where its primary role is to increase the hardenability of the steel and prevent formation of iron sulfides [4]. The low melting point of iron sulfides degrades the high-temperature properties of the steel and may lead to hot shortness. Minimization of sulfur has been prioritized by steel producers for years, and most plants are able to remove small concentrations as a part of their daily routine. However, certain steel products have restrictive specifications on other impurities as well, such as phosphorus, and the demand for such specialized steels is increasing. Conventional steels typically contain 0.05% P, but concentrations as low as 0.005% and as high as 0.1% are also not uncommon. Steels containing manganese, silicon, and titanium are particularly susceptible to embrittlement in the presence of P, especially in corrosive and low-temperature environments. This group of very low-phosphorus steels require phosphorus levels below 0.02%. Dephosphorization is not a trivial process and can be both challenging and costly, emphasizing the importance of locating raw materials that are natively low in phosphorus. However, producers may find themselves in a situation where it becomes necessary to adapt to alternative raw materials as high-grade ores are depleted.

The current work seeks to investigate the possibility of using the SiMn sludge together with iron sources for producing ferromanganese (FeMn) alloys and slags that can be utilized by alternative industries. The low phosphorus level of the sludge, which is comparable to typical high-grade manganese ores, may also prove to be especially useful for producing low-phosphorus alloys [2, 4].

Materials and Methods

Thermochemical Calculations

Equilibrium calculations were performed using FactSage 7.2 thermochemical software in order to design and evaluate the experimental work [5]. Input species are taken from Table 1 and normalized to 100 g of SiMn sludge. Descriptions of oxide solution, such as liquid slag (SLAG), monoxide (MeO), and calcium silicate solid solution (ac2SA), were taken from the FToxide database. Thermodynamic properties of pure substances and gas species were taken from the FactPS database, and the FSstel database were adopted to calculate the liquid metal (LIQU) solution. Closed system calculations were performed with temperature and pressure fixed at 1600 °C and 1.0 atm, respectively.

Pre-treatment and Smelting

SiMn sludge collected from the scrubbers at Eramet in Norway contained approximately 55% moisture and was dried at 110 °C for 16 h prior to pelletizing (Fig. 1a). Carbon black was used as the source of carbon and lime as fluxing material. Iron was added in the form of either pure iron powder (Sigma-Aldrich 12,310-1 KG-R) or iron scrap. The chemical composition of the various raw materials and the

experimental material mixtures are summarized in Tables 1 and 2, respectively.

Prior to smelting, 360 g of dried and pelletized SiMn sludge was mixed with approximately 20 g of Fe powder or Fe scrap, 55 g of carbon black and a varying amount of lime in graphite crucibles. The crucibles were placed in an open 75 kW induction furnace (Fig. 1b), heated to a temperature of 1600 °C and held for 2 h in a reductive CO/CO₂ atmosphere established by the carbon source and the graphite crucible. In the case of using Fe scrap, the scrap was pre-smelted at 1200 °C before adding the rest of the raw materials. The crucible was covered in a layer of insulation to reduce heat loss, and a type-C thermocouple was used to measure the temperature in the crucible.

Characterization

Phase analysis of the SiMn sludge raw material was carried out by a Bruker D8 A25 X-ray diffractometer (XRD), with Cu-K α radiation. Additional elemental analysis of the sludge and final slags was done by a Philips PW 2404 X-ray fluorescence spectrometers (XRF). The slags were separated from the metal fractions and pulverized in a ceramic mortar before analysis. Compositional analysis of the produced

metal fractions was carried out by a JEOL JXA-8500F electron probe micro-analyzer (EPMA), fitted with five wavelength dispersive X-ray spectrometers (WDS) and an energy dispersive X-ray spectrometer (EDS). The levels of phosphorus and sulfur in all raw materials were also measured by inductively coupled plasma sector field mass spectrometry (ICP-SFMS).

Results

Characteristics of Raw Materials

The primary components of the SiMn sludge were by XRD analysis found to comprise of tephroite, leucite, and quartz, seen in Fig. 2. The elemental analysis in Table 1 complements the XRD analysis in that the sludge consists of manganese oxide (MnO), silicon dioxide (SiO₂), and carbon (C) as major components. Minor components include alumina (Al₂O₃), magnesia (MgO), lime (CaO), ferric oxide (Fe₂O₃), alkalis, i.e., sodium oxide (Na₂O) and potassium oxide (K₂O), and heavy metals, i.e., zinc oxide (ZnO) and lead monoxide (PbO). The compositional analysis of carbon black, lime, and Fe powder is taken from the specifications of the respective raw materials, except for the content of P and S. Fe scrap was measured to contain small concentrations of C, silicon (Si), and manganese (Mn).

Thermochemical Calculations

The distribution of phases resulting from equilibrium calculations at the smelting temperature is plotted as a function of added lime in Fig. 3a. Vertical lines representing the respective lime additions of the current experiment are also

The concentrations of phosphorus and sulfur are given in ppmw, as measured by ICP-SFMS

marked. The chemical compositions of the liquid slag and liquid metal are also plotted in (b) and (c)/(d), respectively. Addition of CaO is important for slag formation and the kinetics of slag-metal reactions. The incorporation of added CaO in the liquid slag is apparent in (b), and the lower activity of SiO₂ in the slag drives Si from the liquid metal into the liquid slag, while Al₂O₃, MgO, and K₂O show a slight decrease in the liquid slag upon addition of CaO. Solid calcium silicates start to precipitate at high enough CaO levels. Addition of CaO has a noticeable effect on reducing the amount of dissolved S in the liquid metal and is also found to drive off alkalis, i.e., Na₂O and K₂O, to the gas phase.

Metal and Slag Characteristics

Smelting produced metal alloys with fairly complex microstructures (Fig. 4). All metals consist of a mixture of two primary phases, which are visible as bright and dark areas in the backscatter micrographs. The different contrasts arise from varying phase compositions, also known as Z-contrast, which is summarized for all samples in Table 3. The phosphorus level of all samples remains relatively constant around 490–568 ppmw. Sample A displays a considerable higher level of sulfur, 1040 ppmw, compared to samples B and C, 309–335 ppmw.

Table 4 Summary of slag phase composition in wt.%, as measured by XRF

#	Sample A	Sample B	Sample C
C	1.74	0.34	0.55
Na ₂ O	1.57	<0.01	0.00

PbO	0.00	0.00	0.00

A more accurate measure on the levels of phosphorus (P) and sulfur (S) is also summarized for all raw materials in the bottom part of Table 1. With concentrations of 136 ppmw P and 0.017 wt.% S, the SiMn sludge is by far, although still low, the largest source of P and S in these experiments.

The chemical compositions of the various slags are summarized in Table 4. Without any added CaO, i.e., in sample

A, the slag is found to consist primarily of SiO_2 , Al_2O_3 , MgO , MnO and lesser concentrations of CaO and K_2O . On the other hand, in samples with added CaO , i.e., in samples B and C, the slags are found to consist primarily of CaO and SiO_2 , with lesser concentrations of Al_2O_3 , MnO , and MgO . All slags contain considerable levels of SO_3 , which can be found primarily as MnS in sample A, and CaS in samples B and C (Fig. 5). Heavy metals, i.e., ZnO and PbO , are no longer present.

Discussion

Conventional FeMn alloys contain 75–95 wt.% Mn with less than 6 wt.% Si, and FeSiMn alloys typically contain over 60 wt.% Mn with 10–35 wt.% Si [4]. The measured concentrations of Si (Table 3) deviate from the expected reduction in Si calculated for samples B and C in Fig. 3, which may be a result of kinetic limitations in the smelting process and/or inhomogeneities in the final metal products. Microscopic methods are limited in determining bulk material compositions, and alternative methods should be considered. All metals produced in the current experiments fall into the FeSiMn category. Si units are sought after, and such specialized alloys also find their uses in industrial applications. Commercial FeSiMn alloys are typically found to contain up to a maximum of 0.25 wt.% P, while the current level of P is comparable to that of premium-grade low-P alloys with concentrations close to 0.05 wt.% P. Fe(Si)Mn alloys also have strict requirements on the presence of S, with concentrations typically ranging from 0.01 to 0.05 wt.% [4]. In the current experiments, the distribution of S is found to depend upon the addition of CaO . While the metal of sample A is measured to contain approx. 0.1 wt.% S, which is far too high for most alloys, the concentration is reduced to acceptable levels of 0.03 wt.% in samples B and C.

Calcium is commonly added in iron- and steel-making processes for refining, desulfurization, and modifying the remaining sulfide inclusions into CaS , which is less detrimental to the mechanical properties of the final product. Precipitated sulfides are primarily found as MnS in sample A or as CaS in samples B and C (Fig. 5). CaO increases the basicity of the slag and extracts S from the metal, binding it to CaS . The melting point of CaS is greater than that of MnS , i.e., 2000 °C versus 1610 °C, improving the high-temperature properties of the metal even further. It is, however, important to note that calcium treatment cannot be applied to all kinds of steels, e.g., requiring high formability, as such treatments may generate very hard calcium aluminate inclusions. The chemical compositions of the slags in Table 4 correlate well with that predicted by the thermochemical calculations in Fig. 3b, suggesting close to equilibrium conditions. The calculations also suggest that there is an increased driving force for the alkalis to leave the system through the gas phase when adding CaO and is also supported experimentally. While alkalis, i.e., Na_2O and K_2O , remain present in the slag of sample A, their presence is mitigated by the addition of CaO in samples B and C. The presence of Zn and Pb has also become negligible in all samples, due to their high volatility. Alkalis and other volatiles are known to cycle and accumulate and may lead to operational challenges, e.g., for submerged arc furnaces. Small concentrations of residual MnO remain in the slags and, according to equilibrium calculations, and additional CaO is needed in order to extract the remaining amounts. However, the compositions of current slags are comparable to those of conventional steel-making slags, which opens up the possibility of recycling them in construction and agricultural industries [6].

Conclusions

Current experiments present an opportunity for recycling of SiMn sludge collected from scrubbers at an industrial plant in Norway. Mixed with secondary Fe sources, the sludge has proved useful to produce FeSiMn alloys with P-levels comparable to that of premium-grade low-P alloys. Small amounts of Zn and Pb that accompany the sludge were readily removed in the off-gas at 1600 °C. The presence of alkalis and S could be managed by adding CaO to the raw material mix, resulting in increased evaporation of alkalis and capture of sulfides as CaS in the slags. The final composition of the final slags proved to correspond to conventional steel-making slags.
