The ion chemistry of the title compounds, a nonafluorobutyl methyl ether and a hydrofluoropropane, is elucidated by a combination of studies using atmospheric pressure ionization mass spectrometry and triple quadrupole mass spectrometry. In the positive ion mode, the hydrofluoroether readily forms an $[M - F]^+$ ion, attributable to hydronium ion induced dehydrofluorination, the product of which can be further hydrated to give a protonated hydrofluoroester. By contrast, the hydrofluoropropane does not react with the hydronium ion but rather gives hydrofluoroalkenylium cations via H atom and F atom abstraction by the dioxygen radical cation. In the negative ion mode, the fluorobutyl methyl ether undergoes dissociative electron capture with O_2^- , $O_2^-(H_2O)$, O_3^- , and NO_2^- to generate the fluorobutoxy anion, which can dissociate by $CF_2=O$ loss to give the perfluorocarbocation when the precursor ions are internally excited. The hydrofluoropropane reacts readily with common atmospheric anions to form molecular complexes with F^- , O_2^- , and O_3^- and the strongly H-bonded species, $O_2^-(HF)$ and $F^-(HF)$. Interestingly, isomeric pentafluoropropanes form in the reaction with O_2^- , either $O_2^-(HF)$ or $F^-(HF)$, depending on the specific pattern of the fluoro substitution. Following the 1987 Montreal Protocol, participating countries proceeded to phase out chlorine containing fluids, widely used in many industrial and consumer applications (refrigeration, foaming, aerosol propulsion), for their effect on the depletion of the Earth's ozone layer [1]. The search for nonchlorinated substitutes for hydrochlorocarbons (HCCs), hydrochlorofluorocarbons (HCFCs), and chlorofluorocarbons (CFCs), has focused primarily on fluorine containing chemicals, including hydrofluorocarbons (HFCs) and hydrofluoroethers (HFEs). In contrast to CFCs, HFCs and HFEs are considered ozone-safe substances for their lack of chlorine and bromine substituents, which, released as free atoms, are known to strongly interfere with the ozone cycle. Moreover, thanks to their hydrogen content, HFCs and HFEs are

expected to undergo reactions with free radicals in the well-mixed lower layer of the Earth's atmosphere, the troposphere, which will prevent them from reaching the stratosphere.

When introducing new compounds of synthesis for use in applications, it is mandatory to know in detail their behavior and reactivity under different experimental conditions to which they might become exposed while in use or when released into the environment. The lifetime in the atmosphere of hydrogen-containing fluorinated compounds is governed essentially by their reaction with the hydroxyl radical in the troposphere and lower stratosphere [1]. Therefore, ion/molecule reactions occurring in the mesosphere and lower thermosphere should not have an effect on the atmospheric lifetimes of these compounds. Nevertheless, the gas phase ion chemistry and specific ion/molecule reactions of such volatile organic compounds is of interest, both for fundamental knowledge and for application-oriented research and development related to analytical chemistry (e.g., electron capture detectors for gas chromatographs, CIMS instruments for fast-response chem-

ical sensors) and plasma technologies (e.g., plasma processing of materials). Specifically, novel nonthermal plasma-based technologies are currently being developed for the removal of VOCs (volatile organic compounds) from contaminated air [2]. A major focus of our research in this field deals with the ionic reactions occurring in such air plasmas, which can be conveniently produced by corona discharges at atmospheric pressure, and investigated by means of APCI-MS analysis [3–7]. Finally, it is worth mentioning that the interest in such novel plasma-based treatment processes is also attributable to the possibility of abatement of ozone-safe compounds which are, however, implicated as greenhouse gases.

The present account reports the results of an investigation of positive and negative ions formed from fluoroether HFE-7100 (nonafluorobutyl methyl ether composed of two inseparable isomers, $(\text{CF}_3)_2\text{CFCF}_2\text{OCH}_3$ and $\text{CF}_3(\text{CF}_2)_3\text{OCH}_3$), and fluoropropane HFC-245fa (1,1,1,3,3-pentafluoropropane) in air plasmas at atmospheric pressure. Both HFE-7100 and HFC-245fa were recently recommended by EPA as new viable substitutes for CFCs [8]. Their gas phase ion chemistry is so far unreported.

Two experimental approaches were used in this investigation to study the ionic reactions of the title compounds in air. First, experiments were conducted with a single analyzer APCI-MS apparatus to gain essential information on the ions which are produced from the investigated compounds within the air plasma. Such experiments usually allow for the inference of major ionization and fragmentation routes and other important ion/molecule reactions. An obvious limitation of this experimental set-up is the lack of MS/MS capabilities: the recorded APCI spectra are due to all the products of the reactions of the organic compounds with all the background ions. To gain a better insight into the ion chemistry of the title compounds in air, their reactivity towards specific atmospheric ions (H_3O^+ , O_2^- , O_3^- , NO_2^- , and their hydrates) was then extensively investigated using an APCI source coupled to a triple quadrupole mass spectrometer. The APCI source was fed with air to produce the reactant ions, which were mass-selected and allowed to react with the fluorocompound in the collision cell of the triple quadrupole. The results from the two experimental approaches provide an integrated picture of the atmospheric ion chemistry of the title compounds. Additional results obtained with a third compound, the fluoropropane HFC-245ca (1,1,2,2,3-pentafluoropropane), isomeric with HFC-245fa, are also reported for comparison.

Experimental

Materials

HFE-7100 [nonafluorobutyl methyl ether composed of two inseparable isomers, $(\text{CF}_3)_2\text{CFCF}_2\text{OCH}_3$ and

$\text{CF}_3(\text{CF}_2)_3\text{OCH}_3$, purity 99%] and HFC-245ca (1,1,2,2,3-pentafluoropropane, purity 99%) were commercial R.P. products of Aldrich (St. Louis, MO), HFC-245fa (1,1,1,3,3-pentafluoropropane, purity 98%) was from SynQuest Laboratories (Alachua, FL); they were used as received. High purity synthetic air, with a specified H_2O impurity of less than 5 ppm, was used as background gas.

Instrumentation and Procedures

APCI spectra of HFE-7100 and HFC-245fa in air plasma were performed by a TRIO 1000 II instrument (Fisons Instruments, Manchester, U.K.), equipped with a Fisons APCI source. A schematic of this source and of the experimental set up used for the introduction of vaporized samples was given previously [3]. The ion source is kept at near atmospheric pressure by flowing a stream of buffer gas (synthetic air in the present investigation) at $4000\text{--}5000\text{ mL}\cdot\text{min}^{-1}$ introduced through the nebulizer line, a capillary of ca. 2 mm i.d. The final length (ca. 1 cm) of the nebulizer line is wrapped externally with a heating wire, which controls the temperature of the APCI source. Liquid analytes are introduced as vapors which are stripped from a small reservoir by an auxiliary flow of buffer gas. This flow is adjusted to a value (typically $5\text{--}50\text{ mL}\cdot\text{min}^{-1}$) such as to obtain a concentration of the analyte in the APCI source within the range $100\text{--}1000\text{ ppm}_v$. Two such lines are available on this instrument and merge into a capillary (i.d. = 0.3 mm) which enters the APCI source running coaxially inside the nebulizer line. Gaseous samples are allowed into the source through one of the two lines after dilution with auxiliary buffer gas flowing through the second line. The two merging flows are independently adjusted by means of two flowmeters, so as to achieve a good intensity of sample signals over the background (typically $5\text{--}30\text{ mL}\cdot\text{min}^{-1}$). The concentration of the fluorocarbon samples in air achieved within the APCI source was not quantified.

The needle electrode for corona discharge was kept at 3000 V. Ions leave the source through an orifice, ca. 50 μm in diameter, in the counter electrode (the "sampling cone", held at 0–150 V relative to ground), cross a region pumped down to ca. 10^{-2} Torr (1 Torr = 133.3 Pa) and, through the orifice in a second conical electrode (the "skimmer cone", kept at ground potential), reach the low pressure region hosting the focusing lenses and the quadrupole analyzer. It was shown earlier that collision induced decomposition (CID) experiments can be usefully conducted in the intermediate pressure region between sampling and skimmer cones by the proper adjustment of V_{cone} , the difference between their potentials [3]. In our experiments, spectra are recorded at several different values of V_{cone} ranging from the lowest possible value (1–5 V) necessary to achieve an acceptable signal to noise ratio up to 150 V. Each experiment also includes, prior to the introduction of the analyte, a preliminary analysis of the "back-

ground" spectra with only air introduced into the APCI source, again at several different values of V_{cone} [3]. Before conducting an experiment at 300 °C, the nebulizer was kept at 300–400 °C for a few of hours and the inlet lines were heated with the help of a heating gun.

Ion/molecule reactions of $\text{H}_3\text{O}^+(\text{H}_2\text{O})_n$ ($n = 0-2$), O_2^- , $\text{O}_2^-(\text{H}_2\text{O})$, NO_2^- , O_3^- , N_2O_2^- , NO_3^- with HFE-7100, HFC-245fa and HFC-245ca were performed by a Finnigan TSQ 700 triple quadrupole mass spectrometer (Finnigan MAT, San Jose, CA) equipped with an APCI source. A stream of air was introduced through the sheath gas line with a head pressure of 20 psi. The reagent positive or negative ion, generated by APCI of air, was selected using the first mass analyzer (Q1); the source parameters were optimized to obtain the highest signal to noise ratio for each selected ion. Specifically, for $\text{H}_3\text{O}^+(\text{H}_2\text{O})$ and $\text{H}_3\text{O}^+(\text{H}_2\text{O})_2$, the following experimental conditions were used: source and capillary temperature 50 °C, corona current at 3.7 μA , capillary voltage at 5 V, and turbo lenses voltage at 15 V for $\text{H}_3\text{O}^+(\text{H}_2\text{O})_2$ and at 30 V for $\text{H}_3\text{O}^+(\text{H}_2\text{O})$. Linear increase of the turbo lenses voltage is not sufficient to induce complete declustering of H_3O^+ ion, requiring for this task a deep change of the operative conditions of the source. The highest yield of H_3O^+ was obtained by increasing the source and the capillary temperature to 150 °C and 80 °C, respectively, and the corona current to 6 μA . The capillary and turbo lenses voltages were then adjusted to maximize the reagent ion signal. In the negative ion mode, the temperature of the source and of the capillary were maintained at 50 °C, while the corona current was the parameter giving the biggest change in the yield of the different ions: a value of 1.5 μA was chosen to maximize the intensity of O_2^- and $\text{O}_2^-(\text{H}_2\text{O})$ ions, while 3.7 μA corona current were applied in the case of all the other selected ions (NO_2^- , O_3^- , N_2O_2^- , NO_3^-).

The temperature of the manifold was maintained at 70 °C and neutral reagents were introduced into the collision cell, Q2, via a leak valve (Granville Phillips Co., Boulder, CO). The collision cell pressure was varied between $3.0 \cdot 10^{-4}$ and $2.5 \cdot 10^{-3}$ Torr (uncorrected values) and the optimized collision energy was found to be nominally 0 eV. Mass spectra of ion/molecule reaction products were recorded by scanning the second analyzer, Q3.

Ion/molecule reaction of O_2^+ with HFC-245fa was performed by a Finnigan TSQ 70 triple quadrupole mass spectrometer (Finnigan MAT, San Jose, CA) equipped with an EI source. The manifold and ion source temperatures were maintained at 150 and 70 °C, respectively. O_2^+ was generated by 70 eV electronic ionization (EI) of residual air in the source, and isolated by Q1. HFC-245fa was introduced into Q2 via a leak valve at a pressure of $5.0 \cdot 10^{-4}$, $1.0 \cdot 10^{-3}$, and $1.5 \cdot 10^{-3}$ Torr (uncorrected values) in three independent experiments. Mass spectra of ion/

molecule reaction products were recorded by scanning Q3.

All experiments were replicated at least twice, yielding in all cases reproducible results.

Results and Discussion

Ionization of organic compounds within the APCI source is due to ion/molecule reactions with ions of the air plasma generated by corona discharge. These reagent ions are readily observed when pure air is introduced into the source and produce what we call the 'background' spectra. 'Background' spectra are routinely acquired and analyzed prior to each experiment under the specific experimental conditions of temperature and humidity that will be used in the experiment. The "background" spectra obtained in the present study under various different experimental conditions are consistent with earlier ones, which were described in detail in previous publications [3,6]. Briefly, major "background" positive ions are $\text{H}_3\text{O}^+(\text{H}_2\text{O})_n$, with $\text{NO}^+(\text{H}_2\text{O})_n$ being also observed although in lower abundance. Depending on the APCI source temperature and on the amount of residual humidity in the apparatus, more- or less-heavily solvated ions prevail at low values of V_{cone} : typically, in dry air at 30 °C, complexes with $n = 1-4$ are observed, the most abundant usually being $\text{H}_3\text{O}^+(\text{H}_2\text{O})_3$, while at high temperatures (300 °C) smaller clusters prevail. In addition, minor amounts of $\text{O}_2^+(\text{H}_2\text{O})$ and $\text{O}_2^+(\text{H}_2\text{O})_2$ are also detected at 300 °C. As V_{cone} is gradually increased, collision induced dissociation produces smaller clusters and eventually the bare H_3O^+ and NO^+ ions. Finally, at yet higher values of V_{cone} ($\geq 90-100$ V) only three signals are detected, at m/z 29, 32, and 33, which are attributed to N_2H^+ , O_2^+ , and O_2H^+ , respectively, formed in endothermic ion/molecule reactions [6].

Hydrates $\text{O}_2^-(\text{H}_2\text{O})_n$ and $\text{O}_3^-(\text{H}_2\text{O})_n$ are the major "background" negative ions, with n ranging typically between 0 and 3 depending, as for the positive cluster ions, on the temperature and on the amount of residual humidity within the APCI source. In addition, the

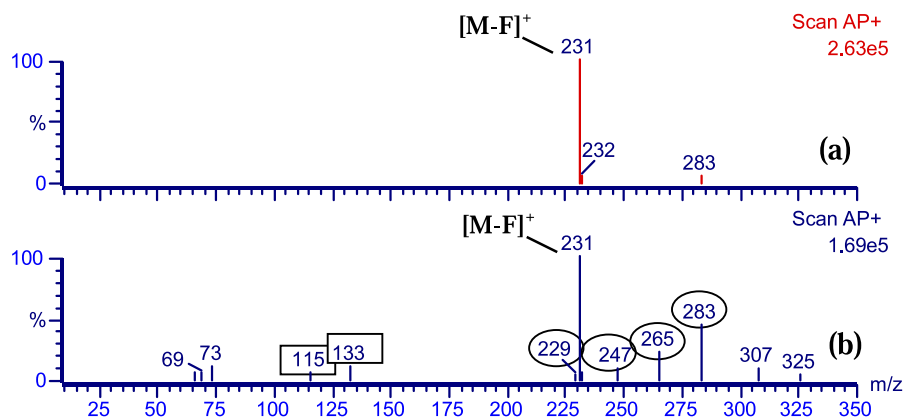

Figure 1. Positive APCI spectra of HFE-7100 in synthetic air recorded at $V_{\text{cone}} = 1$ V and (a) 300 °C (b) 30 °C. Enclosed in rectangles: ion/molecule complexes of $\text{C}_2\text{FH}_4\text{O}_2^+$ (m/z 79) with water molecules. Enclosed in circles: ion/molecule complexes of $\text{C}_5\text{F}_7\text{H}_4\text{O}_2^+$ (m/z 229) with water molecules.

O_2^- (O_2) species is also detected, more prominently at 300 °C. As V_{cone} is gradually increased, the clusters decrease in size by releasing water molecules, and eventually the bare anions are collected. At yet higher values ($V_{\text{cone}} \geq 70$ –80 V), a signal at m/z 16 is observed which is attributed to O^- . Depending on the source conditions, minor signals are also seen in the background spectra at m/z 46, 60, and 62, which are attributed to NO_2^- , N_2O_2^- , and NO_3^- , respectively. Such anions are reasonably related to corona-induced reactions in air which are known to produce NO_x . Specifically, the attribution of the signal observed at m/z 60 in APCI experiments to N_2O_2^- rather than CO_3^- was briefly discussed in an earlier publication [3].

The results are organized in two major sections, one for positive and the other for negative ions. Within each section, the behavior in air plasma of the two VOCs is described and discussed with reference to the results of specific ion/molecule reactions performed with the APCI-TSQ instrumentation. For convenience, at the beginning of each section a table is included which summarizes the main results obtained in the APCI-TSQ selected ion/molecule reaction studies with the compounds investigated.

Positive Ions

The ionic products observed in the reactions performed with APCI-triple quadrupole are summarized in Table 1.

Scheme 1. Proposed route for formation of m/z 229 and 79 in APCI-MS of HFE-7100 in humid air.

HFE-7100 (Nonafluorobutyl Methyl Ether)

The positive APCI spectrum of HFE-7100 (M) at low values of V_{cone} both at 300 °C and 30 °C is dominated by a signal at m/z 231 attributable to $[\text{M} - \text{F}]^+$ species (Figure 1). It is evident from Figure 1b that several additional ions are present at 30 °C: as discussed in detail later, these are water clusters of two product ions at m/z 229 and 79, which are attributed to the species $\text{C}_5\text{F}_7\text{H}_4\text{O}_2^+$ and $\text{C}_2\text{FH}_4\text{O}_2^+$, respectively.

The proton affinity and the ionization energy of HFE-7100 are not available to support any hypothesis on the ionization of this isomeric pair of compounds under APCI conditions: important clues came, however, from the study of the reaction with H_3O^+ in the collision cell of the triple quadrupole. Regardless of the pressure inside the cell, the only observed product was invariably the $[\text{M} - \text{F}]^+$ species, likely formed via proton transfer and elimination of a molecule of hydrogen fluoride, as exemplified in eq 1.

It is reasonable to assume that the same process is taking place in the air plasma at atmospheric pressure within the APCI source, where H_3O^+ and its hydrates are the major “background” ions.

Scheme 4. Proposed route for formation of the ions at m/z 95, 113, 115, and 133 in APCI-MS of HFC-245fa.

(30 °C), the signals due to HFC-245fa remained of low intensity with respect to those of the background also when the hydrofluorocarbon was present in high concentration inside the source (Figure 2c). Interestingly, under these conditions the products of fluoride transfer ($\text{C}_3\text{F}_4\text{H}_3^+$, m/z 115) and hydride transfer ($\text{C}_3\text{F}_5\text{H}_2^+$, m/z 133), which are not detected at 300 °C, could be readily observed as free ions and/or as ion/molecule complexes. Thus, $\text{C}_3\text{F}_5\text{H}_2^+$ is mainly detected as the ion/molecule complexes ($\text{C}_3\text{F}_5\text{H}_2^+$)M at m/z 267 and ($\text{C}_3\text{F}_5\text{H}_2^+$)(M)(H₂O) at m/z 285. The observation of the products of fluoride transfer ($\text{C}_3\text{F}_4\text{H}_3^+$, m/z 115) and hydride transfer ($\text{C}_3\text{F}_5\text{H}_2^+$, m/z 133) provides strong support for the proposal of their intermediacy in the ionization/dissociation routes sketched in Scheme 4. The different degrees to which the processes described in Scheme 4 are observed at 30 °C and 300 °C are ascribed to the higher internal energy of the ions at 300 °C.

Other significant signals in the APCI spectrum of HFC-245fa at 300 °C are detected at m/z 93, 111, and 129 (Figure 2a). A first hypothesis that they could be due to species $\text{C}_3\text{F}_3^+(\text{H}_2\text{O})_n$ ($n = 0-2$) had to be rejected, based on experiments performed with D₂O at different values of V_{cone} . These experiments, not shown, indicated that the ion at m/z 129 contains only two exchangeable protons and can be viewed as a monohydrated species, i.e., the hydrate complex of the ion at m/z 111. The latter, however, has no exchangeable protons and therefore cannot be a water cluster of the ion at m/z 93.

Further experiments were performed by varying the amount of water in the APCI source. Figure 4 reports a few examples of spectra obtained with increasing amounts of water while maintaining constant both V_{cone} and the amount of HFC-245fa admitted into the APCI source. It is easily seen that as the amount of water is increased, the abundance of ${}^+\text{CF}_2\text{-CH}=\text{CHF}$ at

m/z 95 and $\text{CF}_2\text{-CH}=\text{CF}_2^+$ at m/z 113 decreases suggesting that both ions are quenched by water. Such decay is matched by complex changes in the observed ion population which are due to the combination of different reactions involving water as the neutral reagent: C—O covalent bond formation via water addition and HF eliminations and clustering of the products of such reactions. A rationale for the processes occurring within the plasma in humid air is offered in Scheme 6 which is based on and consistent with all experimental results obtained in experiments conducted with D₂O and in CID experiments performed by increasing V_{cone} .

As the amount of water inside the source is increased, the abundance of the ions ${}^+\text{CF}_2\text{-CH}=\text{CHF}$ and $\text{CF}_2\text{-CH}=\text{CF}_2^+$ (m/z 95 and 113) decreases, while that of their products of H₂O addition and HF elimination increases (m/z 93 and 111, labeled **a** and **b**, respectively). Note that these products are detected mainly as hydrates, **a**(H₂O)_{*n*} and **b**(H₂O)_{*m*} ($n, m = 0-3$) (Figure 4). Note also the complication that the hydrates **a**(H₂O)_{*n*} ($n = 1-3$) and **b**(H₂O)_{*m*} ($m = 0-2$) are isobaric (m/z 111, 129, 147) since **a** and **b** differ by 18 mass units because of the substitution of a hydrogen by a fluorine.

A second HF elimination step is then observed from ions **a** and **b** forming, respectively, product ions **a'** (m/z 73) and **b'** (m/z 91). These ions are also detected mainly as water complexes, **a'**(H₂O)_{*n*} and **b'**(H₂O)_{*m*} (Figure 4). Moreover the complexes **a'**(H₂O)_{*n*} ($n = 1-3$) are isobaric with **b'**(H₂O)_{*m*} ($m = 0-2$) (m/z 91, 109, 127). Reciprocal interferences are however eliminated when water is lost by increasing V_{cone} and the dissociation behavior of the bare ions, at m/z 73 and 91, can be observed. Both species undergo characteristic CO loss which provides further support for their assignments. Another interference is due to the superposition of the signal attributable to **a'** with that attributable to the background ion

Scheme 5. Proposed mechanism for formation of m/z 64 in the reaction of HFC-245fa with O_2^+ .

^aObserved only at high pressure.

V_{cone} is due to C₄F₉O⁻ ions (m/z 235) (Figure 5a). Upon increasing of V_{cone} , this species dissociates to the following product ions: C₃F₇⁻ (m/z 169), CF₃⁻ (m/z 69), and F⁻ (m/z 19) (Figure 5b). In addition, the product CH₃OCF₂CF₂⁻ (m/z 131) is also seen.

The reactivity towards HFE-7100 of each of the major background negative ions produced by APCI of air was studied by means of selected ion/molecule reaction experiments performed with the APCI-triple quadrupole instrument. In these experiments C₄F₉O⁻ ions are observed as products of the reaction of HFE-7100 with O₂⁻, O₂⁻(H₂O), O₃⁻, and NO₂⁻ ions. In Figure 6 the spectrum of the reaction products of O₃⁻ with HFE-7100 is reported as an example. In contrast, no products were observed when NO₃⁻ and N₂O₂⁻ were used as reactant ions. In the reaction of O₂⁻ with HFE-7100, C₃F₇⁻ ions are also formed. In order to establish whether such C₃F₇⁻ ions are primary products formed in a parallel reaction of O₂⁻ with M or are rather due to fragmentation of C₄F₉O⁻ ions, the following experiment was performed. HFE-7100 was ionized in the APCI source and the C₄F₉O⁻ ions thus produced were mass-selected

with Q1 and subjected to collision induced dissociation in the collision cell of the triple quadrupole. C₃F₇⁻ was the only fragmentation product observed in several experiments covering a large energy range (80–160 eV). Based on these results, the C₃F₇⁻ ions observed in the reaction of O₂⁻ with M can be reasonably considered to be the products of fragmentation of the C₄F₉O⁻ primary product ions.

The electron affinity of HFE-7100 is not known, but dissociative electron transfer seems to be the most probable way for the formation of C₄F₉O⁻ ions in the reactions with background anions B⁻ (eq 2). The observation of C₃F₇⁻ product ions only in the reaction of M with O₂⁻ is consistent with the fact that the electron affinity of O₂⁻ is the lowest one among the reactive background ions (O₂⁻: 0.45 eV; NO₂⁻: 2.27 eV; O₃⁻: 2.10 eV [12]). Thus, when B⁻ is O₂⁻, reaction (2) is the most exothermic and forms C₄F₉O⁻ ions with an energy content sufficient to dissociate to C₃F₇⁻ via CF₂=O loss. Furthermore the electron affinity of the background ions which do not react with HFE-7100, i.e., NO₃⁻ and

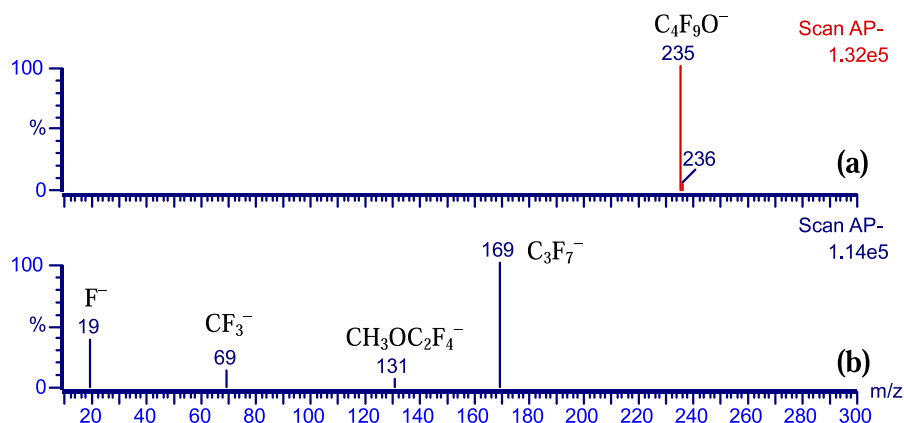

Figure 5. Negative APCI spectra of HFE-7100 in synthetic air recorded at 30 °C and (a) $V_{\text{cone}} = 1$ V, (b) $V_{\text{cone}} = 70$ V.

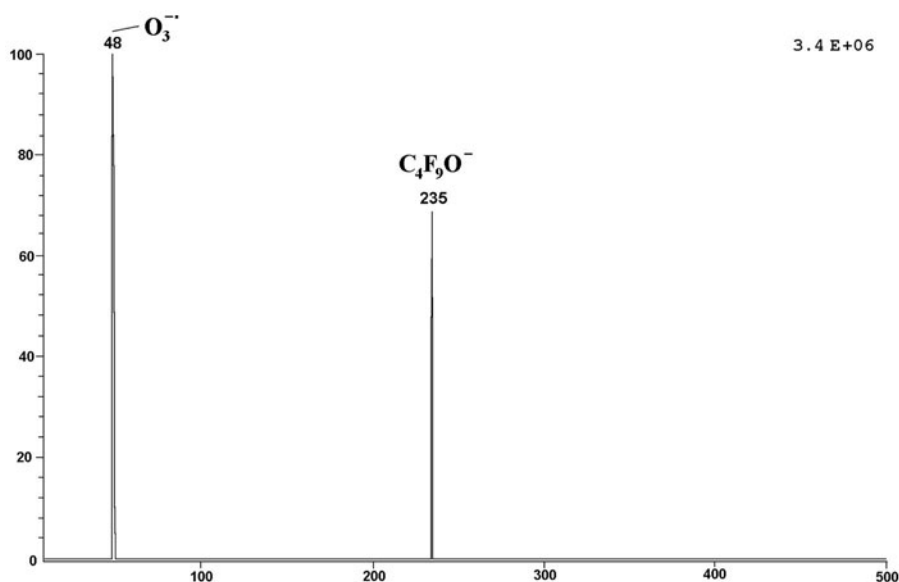

Figure 6. APCI-TSQ mass spectrum of the products of the reaction of $\text{O}_3^{\bullet-}$ with HFE-7100 at a nominal pressure of about $3 \cdot 10^{-4}$ Torr.

$\text{N}_2\text{O}_2^{\bullet-}$, is the highest among the anions submitted to reaction (NO_3^- : 3.94 eV; $\text{N}_2\text{O}_2^{\bullet-}$: 2.93 eV [12]).

The results of these ion/molecule reaction experiments conducted with the triple quadrupole allow us to infer the origin of $\text{C}_4\text{F}_9\text{O}^-$ ions observed in the air plasma of the APCI source. The fact that under these conditions C_3F_7^- ions are not observed at low values of V_{cone} (Figure 5a), when $\text{O}_2^{\bullet-}$ is the most abundant species of the background, is reasonably due to the higher efficiency of ion cooling via thermalizing collisions in the APCI ionization chamber with respect to the triple quadrupole collision cell, because of the considerably higher pressure.

HFC-245fa (1,1,1,3,3-Pentafluoropropane)

The negative APCI spectra of HFC-245fa (M) at 30 ° and 300 °C are dominated by ion-neutral complexes with the anions of the background (Figure 7). Ion-neutral complexes of M with F^- and $\text{F}^-(\text{HF})$ are also observed, sometimes including water molecules, $\text{F}^-(\text{HF})(\text{H}_2\text{O})_m(\text{M})_n$. Upon increasing V_{cone} consecutive losses of M and H_2O take place, leading to $\text{F}^-(\text{HF})$ (at V_{cone} ca. 30 V) and eventually to the bare anion F^- (at V_{cone} ca. 70 V). The formation of $\text{F}^-(\text{HF})_n$ is common in wet atmospheres and has been attributed to cluster-mediated reactions [13]. Another interesting species, detected in the spectrum at $V_{\text{cone}} = 20$ V, is an ion at m/z 52 of composition $[\text{H}, \text{F}, 2\text{O}]$, the structure and origin of which are described below.

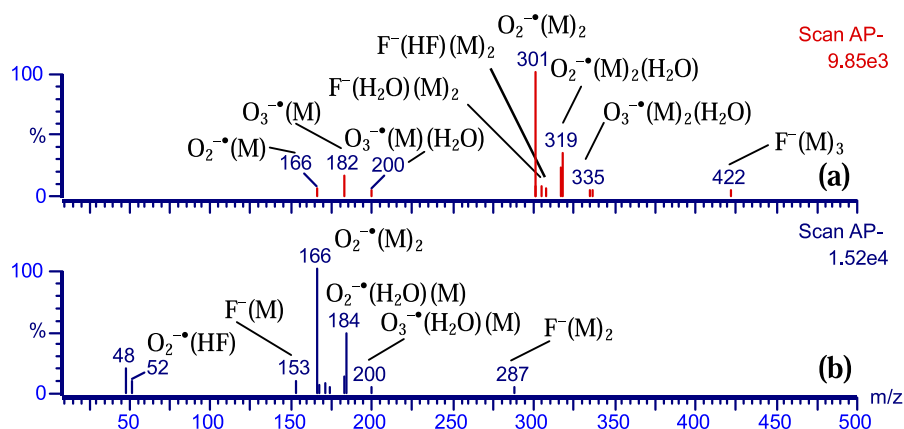

Figure 7. Negative APCI spectra of HFC-245fa in synthetic air recorded at $V_{\text{cone}} = 1$ V and 300 °C.

Scheme 7. Proposed mechanism for formation of m/z 52 in the reaction of HFC-245fa with O_2^- .

When allowed to selectively react in the triple quadrupole with each of the major anions formed in the air plasma, HFC-245fa confirmed its high association ability, already observed in the APCI source. Thus, reaction of HFC-245fa (M) with B^- ($B^- = O_2^-, O_2^-(H_2O), O_3^-, NO_2^-, NO_3^-, N_2O_2^-$) inside the collision cell of the triple quadrupole produced the complexes $B^-(M)_n$ ($n = 1, 2$) (Table 2).

As mentioned above and shown in Table 2, the reaction of O_2^- with HFC-245fa forms an additional product with m/z 52, which we believe is best viewed as the ion/molecule complex $O_2^-(HF)$. Scheme 7 shows a possible mechanism for the formation of such a product, which involves base induced HF 1,2-elimination. The structure $O_2^-(HF)$ has been attributed to the product anion, based on the known proton affinities of O_2^- ($1476 \text{ kJ} \cdot \text{mol}^{-1}$ [12]) and F^- ($1554 \text{ kJ} \cdot \text{mol}^{-1}$ [12]) and on its dissociation behavior. Thus, when formed in the APCI source of the triple quadrupole set-up and activated by collisions inside the collision cell, this ion dissociates to O_2^- via HF elimination, in agreement with the greater thermochemical stability of $O_2^- + HF$ ($-316.8 \text{ kJ} \cdot \text{mol}^{-1}$ [12]) with respect to $F^- + \cdot O_2H$ ($-247.2 \text{ kJ} \cdot \text{mol}^{-1}$ [12]) (Figure 8).

In contrast to $O_2^-(HF)$, which was observed both under APCI conditions and in the triple quadrupole,

the species $F^-(HF)$ (m/z 39) was never detected among the products of the reactions of HFC-245fa studied in the triple quadrupole. Interestingly, the isomeric pentafluoropropane HFC-245ca (1,1,2,2,3-pentafluoropropane) under the same experimental conditions produces $F^-(HF)$ in the reaction with O_2^- . The product $F^-(HF)$ is indicated in the literature as the species with the strongest known hydrogen bond so far reported, recently determined to be $191.7 \text{ kJ} \cdot \text{mol}^{-1}$ [14]. Also, Morris et al. [15] reported the formation of $F^-(HF)$ in the reaction of O_2^- with a fluoropropane (CF_3CFHCF_3) studied by the SIFT technique. CO_2 and the ethyl radical CF_2-CFH_2 were indicated as the neutral products of this reaction.

Conclusions

The gas phase ion chemistry in air of HFE-7100 and HFC-245fa has been investigated by APCI-MS and by studying their reactions with selected atmospheric ions (H_3O^+ , O_2^+ , O_2^- , O_3^- , NO_2^- , NO_3^- , $N_2O_2^-$ and their hydrates) in a triple quadrupole mass spectrometer. The results of the two different approaches are complementary and produce an interesting map of the main ionic processes occurring in air plasmas by the fluorinated CFC-substitutes studied here. Interestingly, the reaction

Figure 8. MS/MS spectrum of the ion $O_2^-(HF)$ generated by APCI of HFC-245fa in the APCI-TSQ instrument.

between HFC-245fa and H_3O^+ does not lead to oxygenation of the fluorocarbon via C—O bond formation, in contrast with what was found with other HFCs [6] and with HFE-7100. A common process is, instead, the condensation of fluorinated unsaturated cations with water followed by HF loss. This reaction leads to the oxidation of the compounds, so it can constitute an ionic pathway for the decomposition of these compounds by corona discharges.

Both HFE-7100 and HFC-245fa react with O_2^- , the former by a dissociative electron transfer process, the latter by association and a base-induced elimination process, leading to the formation of the ion/molecule complex $\text{O}_2^-(\text{HF})$. The fluoropropane HFC-245ca, isomeric with HFC-245fa and studied for comparison, shows the same behavior of HFC-245fa in the reaction with H_3O^+ while it reacts differently with O_2^- , giving rise to the formation of the complex $\text{F}^-(\text{HF})$. The position of the fluoro substitution is, therefore, a determinant in the interaction of O_2^- with the pentafluoropropanes.

Knowledge of the ion chemistry in air and of the oxidation processes initiated by the ions examined is of importance in the development of plasma-based technologies for the removal of these compounds from contaminated air as well as in the evaluation of their impact in the atmosphere.
