Imaging mass spectrometry allows for the direct investigation of tissue samples to identify specific biological compounds and determine their spatial distributions. Desorption electrospray ionization (DESI) mass spectrometry has been used for the imaging and analysis of rat spinal cord cross sections. Glycerophospholipids and sphingolipids, as well as fatty acids, were detected in both the negative and positive ion modes and identified through tandem mass spectrometry (MS/MS) product ion scans using collision-induced dissociation and accurate mass measurements. Differences in the relative abundances of lipids and free fatty acids were present between white and gray matter areas in both the negative and positive ion modes. DESI-MS images of the corresponding ions allow the determination of their spatial distributions within a cross section of the rat spinal cord, by scanning the DESI probe across the entire sample surface. Glycerophospholipids and sphingolipids were mostly detected in the white matter, while the free fatty acids were present in the gray matter. These results show parallels with reported distributions of lipids in studies of rat brain. This suggests that the spatial intensity distribution reflects relative concentration differences of the lipid and fatty acid compounds in the spinal cord tissue. The "butterfly" shape of the gray matter in the spinal cord cross section was resolved in the corresponding ion images, indicating that a lateral resolution of better than 200 μm was achieved. The selected ion images of lipids are directly correlated with anatomic features on the spinal cord corresponding to the white and the gray matter. Increased recognition of the important functions of lipids in biological organisms [1, 2], coupled with the availability of new and more powerful analytical methods of characterizing compounds of this diverse class [3, 4], has propelled the rapid recent growth of the field of lipidomics [5–7]. The diverse functions of lipids include maintaining an electrochemical gradient, subcellular partitioning, cell signaling, energy storage, and membrane anchoring [2]. The most widely recognized role of lipids is to form the lipid bilayer of cellular and organelle membranes [8]. It has been reported that alterations in the glycerophospholipid composition of tissues occur in several diseases, including cancer [9] and Alzheimer's disease [10]. Particular glycerophospholipids and their enzymatic products have been identified in malignant transformations in tissue [11, 12]. In other cases, the expression of phosphatidylserine in the outer leaflet of the membrane has been found to play a role in the recognition of altered cells, such as cancer cells, by macrophages [13, 14]. Lipids also play a role in atherosclerosis [15–17]. Indeed, the propensity of atherosclerotic plaques to rupture may be influenced by their lipid content and the distributions of these lipids within the plaque [18]. Differences in the content of specific lipids including cholesterol in plaque have been detected among the different types of plaque [19].

Lipids are the most common biomolecules found in the spinal cord and make up 50% of its dry weight [20, 21]. The morphology of the spinal cord consists of white matter, the peripheral region containing sensor and myelinated axons, which surrounds the gray matter, composed primarily of neuronal cell bodies [21]. The spinal cord transmits neural signal between the peripheral nervous system and the brain and thus serves for the study of neuronal transmission, including neurological disability [22, 23]. Understanding the nature of such complex biological processes in tissue requires identifying the specific compounds involved and determining where they are located in space and how they change in time. Information on some of these matters is available from studies on neurotransmitters using in situ microelectrodes [24, 25], ultrafiltration followed by chromatography/mass spectrometry [26, 27], and other methods [28–30].

Imaging mass spectrometry (MS) has become an increasingly important tool for the study of complex biological systems, allowing one to record spatial and chemical information simultaneously for multiple ana-

lytes over the sample area. Each pixel on the scanned surface yields a mass spectrum, which can then be compiled to create an image showing the spatial distribution of particular compounds [31, 32]. Such an image can provide chemical correlations with biological function or morphology. The limitations of the approach are that it is highly invasive so time course information is difficult to obtain. Matrix-assisted laser desorption/ ionization (MALDI) and secondary ion mass spectrom-

etry (SIMS) imaging have been used extensively. MALDI imaging is applicable to large molecules such as proteins [33–40] and peptides and can provide a spatial resolution of 100 μm [39]; experiments are typically conducted under high vacuum and after application of an organic matrix to the sample to assist in ionization. Although the method has been primarily applied to proteins, MALDI has seen increasingly wide use in the investigation of distributions of lipids [41–

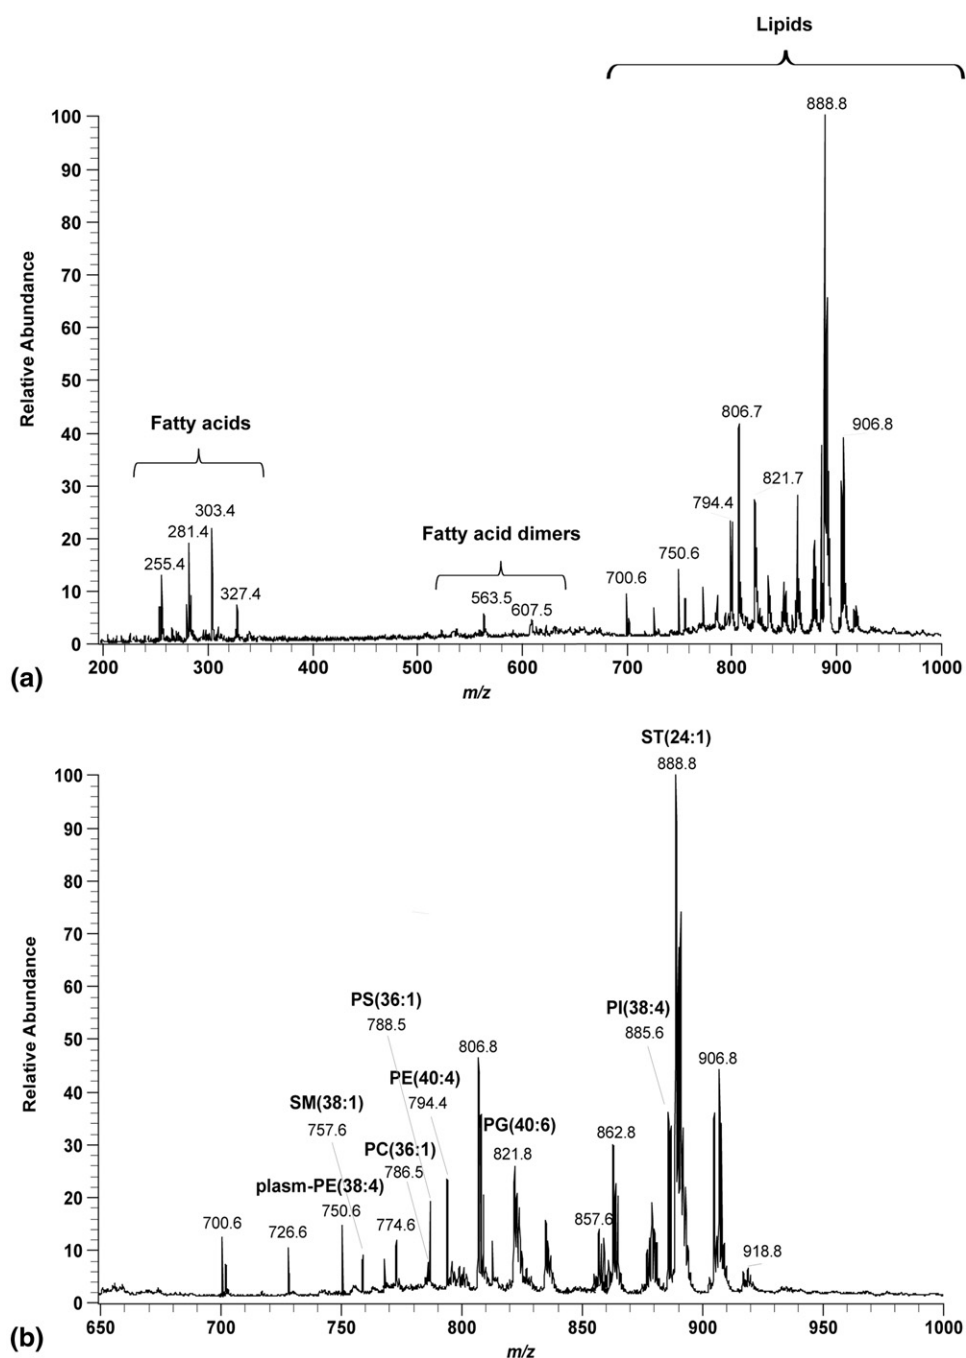

Figure 1. Negative ion DESI mass spectrum recorded on a 15 μm thick rat spinal cord cross-section using MeOH-water 70:30 (% vol/vol) as the solvent spray. (**a**) Full mass spectrum. (**b**) Expanded view of the mass range from m/z 650 to 1000, including the molecular ion, $[M - H]^-$, signals from several lipids. The most intense peaks for each class of lipids are annotated.

48], drug molecules from tissue surfaces [49–54], and in a variety of other applications [55, 56]. Imaging using SIMS potentially provides the advantage of very high spatial resolution of ~100 nm and can be performed without additional sample preparation [51, 57–61]. However, SIMS imaging cannot be conducted under ambient conditions and is a harsher ionization technique that tends to produce more dissociation than MALDI. Desorption electrospray ionization (DESI) mass spectrometry [62] was introduced as a method for the direct analysis of biological samples, including tissue sections. DESI offers the advantage of little or no sample preparation as it does not require the addition of matrix compounds and is conducted at atmospheric pressure under ambient conditions [62]. Its disadvan-

tages include a poorer spatial resolution than MALDI. It is one of a group of ambient ionization methods [63–65] amongst which the laser-based method of laser ablation electrospray ionization (LAESI) [66, 67] has given particularly useful images of biological systems, including in vivo systems. In DESI, a pneumatically-assisted electrospray produces charged droplets, which are directed at the surface of the sample, creating a thin liquid film which dissolves the analytes [68, 69]. The impact of subsequent primary droplets releases secondary microdroplets containing analytes [68, 69]. This so-called 'droplet pick-up' process is followed by the standard electrospray evaporation mechanisms which produce dry ions of the analytes [70, 71]. DESI has been used to construct chemical images of tissue sections [72–86] and

in forensic analysis [87, 88]. The spatial resolution of DESI is typically 200 μm [74] although significantly higher resolution has been reported [75].

This work presents a study of rat spinal cord tissue sections examined by DESI imaging mass spectrometry. Tissues sections were analyzed in both the negative and positive ion modes and tandem mass spectrometry (MS/MS) and exact mass measurements were used to identify the compounds detected. The major challenge to this application of DESI imaging mass spectrometry was the 4 mm size of the rat spinal cord section, which requires a high spatial resolution as reported in previous SIMS [89] and MALDI [90] imaging for spinal cord samples. The present aim was to establish if the distri-

bution of lipids within rat spinal cord tissue sections could be determined and whether DESI lipid imaging mass spectrometry has the potential to serve as a tool for future detection of analyte changes in injured spinal cord samples.

Experimental

Chemicals and Biological Samples

Methanol (MeOH) was purchased from Sigma-Aldrich (St. Louis, MO, USA), and water (18.2 MΩ-cm) was from a PureLab Ultra system by Elga LabWater (High Wycombe, UK). Adult male Long-Evans rats (Hilltop

Lab Animals, Inc., Scottsdale, PA, USA) weighing 300–350 g were used.

Tissue Preparation

All protocols for this experiment were approved by the Purdue Animal Care and Use Committee. All rats were anesthetized deeply with a mixture of 90 mg/kg ketamine and 5 mg/kg xylazine and sacrificed by transcardial perfusion with cold PBS followed by 4% paraformaldehyde. The seventh thoracic (T7) spine was removed by laminectomy. The spinal tissue about 1 cm long was cryostat-sectioned at 15 μm thickness and serially thaw-mounted on glass slides. The slices were dried in the air under room temperature for 2 h, rehydrated in PBS solution for 15 min, and washed once with PBS. Before imaging experiments, samples were dried under vacuum 15 min.

Mass Spectrometry

DESI imaging analysis were performed with a commercial Thermo Scientific LTQ (San Jose, CA, USA) linear ion trap mass spectrometer equipped with a custom-built, automated DESI source operated in both the negative and positive ion modes. The home-built DESI ion source is similar to the OmniSpray source from Prosolia Inc. (Indianapolis, IN, USA), configured as described previously [91]. A sprayer-to-surface distance of 2 mm, a sprayer-to-inlet distance of 2.5 mm, an incident angle to the horizontal of 52° and a collection angle of 10° were used. The spray voltage was set at ±5000 V and the capillary voltage at 5 V. Nitrogen gas was used as the nebulizing gas (140 psi). MeOH-water 70:30 (% vol/vol) was sprayed at a constant flow rate of 1.5 μL/min. For the MS/MS experiments, a series of line scans across the tissue sample was performed during a period of about 1 min. An isolation window of 1.5 mass/charge units, a normalized collision energy of 20%–40% (manufacturer's units) and a Mathieu parameter q_z value of 0.25 during collisional activation were used. Exact mass measurements were performed using a commercial Thermo Scientific LTQ-Orbitrap XL mass spectrometer (Bremen, Germany), with the resolution set to 100,000 to confirm molecular formulae. Mass standards were added into the DESI spray at a concentration of 10 ppm. The $[M - H]^-$ ion of taurocholate and $C_{15}H_{15}O_6N_3P_3F_{20}(C_2F_4)_2$ Ultramark 1621 peak, with theoretical exact masses of 514.2839 and 1005.9727, respectively, were used as standards in the negative ion mode. The $[M + H]^+$ ion of reserpine and the $[M + Na]^+$ ion of cyclosporine A, theoretical exact masses of 609.2812 and 1224.3311, respectively, were used in the positive ion mode [92].

In the imaging experiments, the tissue was scanned using a 2D moving stage (Newport, Richmond, CA, USA) in horizontal rows separated by a 150 μm vertical step until the entire tissue sample was analyzed [81]. The lines were scanned at a constant velocity of 132 μm/s, while collecting one mass spectrum every 1.16 s over the range m/z 150–1000. The ion injection time was set to 500 ms and 5 microscans were averaged. Under these conditions, a lateral spatial resolution of ~200 μm can be achieved in DESI MS imaging [74].

Xcalibur 2.0 software (Thermo Scientific LTQ, San Jose, CA, USA) was used for instrument control, data acquisition and data processing. Lab-written software was used to convert the Xcalibur mass spectra files (.raw) into a format compatible with BioMap. BioMap (freeware, http://www.maldi-msi.org/) was used to process the mass spectral data to generate two-dimensional ion images.

All species are detected as deprotonated forms.
[a](X:Y) represents the different number of carbon atoms and different number of double bonds in the fatty acid chains. The notation (hX:Y) denotes a hydroxylated sulfatide species.
[b]Relative intensities were calculated with respect to the base peak intensity.

Results and Discussion

Identification of Compounds

Before the imaging experiments, the DESI experimental conditions were optimized to maximize the signal intensity obtained from the thin tissue sections in both the negative and positive ion modes. A series of line scans across the tissue sample was performed and the resulting mass spectra were examined.

The negative ion DESI mass spectrum from a rat spinal cord section is shown in Figure 1. In the low mass/charge region (m/z 200–400), ions corresponding to deprotonated free fatty acids are detected. These fatty acids can only be tentatively identified, since the possibility of isomers must be allowed. Based on the mass of the molecular anion, m/z 255 is a palmitic acid (16:0), m/z 281 is an oleic acid (18:1), m/z 283 is a stearic acid (18:0), m/z 303 is an arachidonic acid probably (20:4), and m/z 327 is a docosahexaenoic acid (22:6). The region from m/z 500 to m/z 650 includes dimers of the free fatty acids. In the high m/z region ($m/z > 600$), ions corresponding to the deprotonated forms of various lipids are detected. Figure 1b shows an expanded view of the DESI mass spectrum in the m/z range 650–1000. The lipid species detected from the rat spinal cord section mainly consist of sulfatides (ST), glycerophosphoserines (PS), glycerophosphoinositiols (PI), glycerophosphoethanolamines (PE) and plasmalogens (plasm-PE), glycerophosphoglycerols (PG) and, with a lower intensity, glycerophosphocholines (PC) and sphingomyelin (SM), as denoted in Figure 1b. Only the most intense peaks for each class of lipids have been annotated for better clarity. With a quaternary amine in the head group (Scheme 1), PC and SM ionize poorly in the negative ion mode (and well in the positive mode),

while the polar PS, PG, PI, PE, and ST lipids ionize better in the negative ion mode [93, 94]. Confirmation of the lipid assignments was achieved by tandem mass spectrometry (MS/MS) experiments (Figure 2), spectral comparisons with authentic lipid standards and comparisons to existing electrospray (ESI) mass spectra [94]. The molecular ion detected at m/z 750.6 has been identified as [plasm-PE(18:0/20:4) − H]$^-$ based on its MS/MS behavior (Figure 2a). Loss of the ethanolamine portion of the head group (43 Da) from the precursor ion produces [M − H − C$_2$H$_3$NH$_2$]$^-$, m/z 707.5. The fragment ion detected at m/z 464.2, corresponding to [M − H − C$_{18}$H$_{29}$CHCO]$^-$, would arise from the loss of the fatty acid chain at the sn-2 position as an alkyl ketene [95]. This reaction could also occur after the prior elimination of the ethanolamine portion of the head group (43 Da), yielding the ion detected at m/z 421.1, denoted [M − H − C$_{18}$H$_{29}$CHCO − C$_2$H$_3$NH$_2$]$^-$. The ion denoted [M − H − C$_{19}$H$_{31}$COOH]$^-$, detected at m/z 421.1, could be the result of loss of the fatty acid chain at the sn-2 position while the carboxylate anion [C$_{19}$H$_{31}$COO]$^-$ from the C20:4 fatty acid chain is detected at m/z 303.1 [95]. However, ions due to different compounds may still overlap. To minimize this possibility and separate likely isobaric lipids, high-resolution MS was performed by analyzing the tissues using DESI on the Orbitrap (see Figure S1 in the Supplementary Material). The results show that peak at m/z 750.5411 can be accurately assigned as having the exact mass of [plasm-PE(18:0/20:4) − H]$^-$ with an error of −4.4 ppm. The ion detected at m/z 788.5 in the MS spectrum (Figure 1) has been identified as [PS(18:0/18:1) − H]$^-$ (m/z 788.5463, error: +2.0 ppm on the DESI-Orbitrap). The MS/MS spectrum (Figure 2b) shows a predominant loss of 87 Da from the precursor ion corresponding to

Figure 3. Expanded view of the mass range from m/z 650 to 1000 of the positive DESI mass spectrum recorded on a 15 μm thick rat spinal cord cross-section using MeOH-water 70:30 (% vol/vol) as the solvent spray. The most intense peaks for each class of lipids are annotated.

the serine portion of the head group [93, 94], which would give rise to the $[M - H - C_3H_5NO_2]^-$ fragment ion detected at m/z 701.5. The consecutive elimination as an alkyl ketene from the fatty acid chains at the sn-1 and sn-2 position from the $[M - H - C_3H_5NO_2]^-$ fragment ion are observed, as well as the consecutive elimination of the C18:0 and C18:1 fatty acid chains from the $[M - H - C_3H_5NO_2]^-$ fragment ion [93, 94]. Fatty carboxylic acid anions ($[C_{17}H_{35}COO]^-$ and $[C_{17}H_{33}COO]^-$) are detected at m/z 283.1 and 281.1. Returning to the mass spectrum, the ion detected at m/z 794.4 has been identified as $[PE(18:0/22:4) - H]^-$ on the basis of its accurate mass (m/z 794.5685, error: -2.6 ppm on the DESI-Orbitrap) and its MS/MS behavior (Figure 2c) [96, 97]. As the plasmalogen deprotonated species previously described, the precursor ion is expected to elim-

inate the ethanolamine portion of the head group (43 Da), yielding the ion detected at m/z 751.4, noted $[M - H - C_2H_3NH_2]^-$. Loss of fatty acid chain either at the sn-1 or sn-2 position from the precursor ion are also observed and corresponding fatty carboxylic acid anions are detected at m/z 283.0 and m/z 331.0, respectively. The elimination as an alkyl ketene from one of the fatty acid chains at the sn-1 and sn-2 positions in the precursor ion or from the $[M - H - C_2H_3NH_2]^-$ fragment ion complete this accounting of the observed fragmentation pathways. The MS/MS spectrum of the ion detected at m/z 821.7 (m/z 821.5368, error: $+3.5$ ppm on the DESI-Orbitrap) allows the anion to be identified as $[PG(18:1/20:5) - H]^-$ (Figure 2d) [98–100]. The fragment ion ($[M - H - C_3H_6O_2]^-$) detected at m/z 747.7 would arise from the elimination of the glycerol

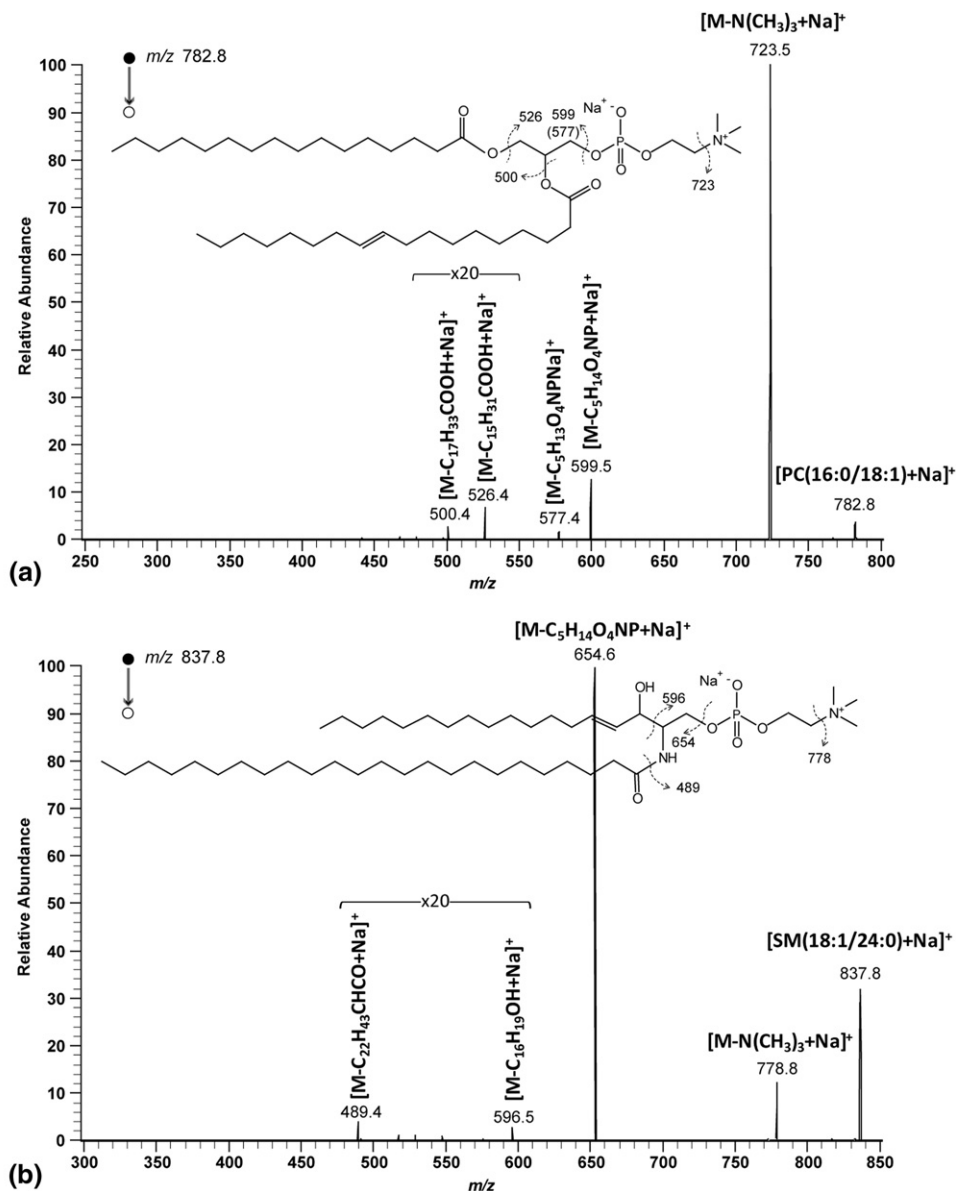

Figure 4. DESI-MS/MS spectra of (**a**) [PC(16:0/18:1) + Na]$^+$, and (**b**) [SM(18:1/24:0) + Na]$^+$ ions (collision energy: 25 eV, laboratory frame).

polar head group (74 Da) from the precursor ion. Thus, the elimination of the fatty acid chain either at the *sn*-1 or *sn*-2 position can occur from both the precursor ion and the $[M - H - C_3H_6O_2]^-$ ion. Fatty carboxylic acid ions ($[C_{17}H_{33}COO]^-$ and $[C_{19}H_{21}COO]^-$) are detected at *m/z* 281.0 and *m/z* 301.1. Loss of the C18:1 or the C20:5 chain as a ketene neutral also occurs from the precursor ion and from the $[M - H - C_3H_6O_2]^-$ fragment ion. The MS/MS spectrum of the ion detected at *m/z* 885.6 (*m/z* 885.5514, error: +1.7 ppm on the DESI-Orbitrap) allows one to identify the anion as $[PI(18:0/20:4) - H]^-$ (Figure 2e). The fragment ion ($[M - H - C_8H_{10}O_5]^-$) detected at *m/z* 723.5 would arise from the elimination of the inositol head group (162 Da) from the precursor ion. Thus, this ion fragments to give three major series of product ions that are formed by neutral loss of free fatty acid, neutral loss of ketene and by formation of fatty carboxylate anions [101]. Sulfatides differ from the lipids discussed thus far in that they do not contain a glycerol-phosphate backbone but instead possess a sphingosine base (Scheme 1). Sulfatide fragmentation described in the literature shows several complex processes [93, 102, 103]. The collision induced dissociation of the $[ST(18:1/24:1) - H]^-$ ion detected at *m/z* 888.8 (*m/z* 888.6255, error: +1.5 ppm on the DESI-Orbitrap), gives rise to a peak at *m/z* 522.5 ($[M - H - C_{22}H_{43}CHCO - H_2O]^-$), which corresponds to the loss of water and the amide linked ketene by cleavage of the amine bond (Figure 2f). Loss of water molecule from the precursor ion is indicated by the product ion at *m/z* 870.8 ($[M - H - H_2O]^-$). The fragment of *m/z* 390.5 ($[C_{26}H_{48}ON]^-$) would arise from the cleavage of the C2–C3 bond of the sphingosine backbone along with loss of the head group via cleavage of the C1–O bond. The fragment ion detected at *m/z* 650.6 ($[M - H - C_{16}H_{29}OH]^-$) appears to arise from loss of the long-chain base after the second carbon. Loss of the chain as a ketene neutral at the *sn*-2 position from the precursor ion would give rise to the $[M - H - C_{22}H_{43}CHCO]^-$ ion, detected at *m/z* 540.5. Finally, the ion detected at *m/z* 259.3 corresponds to the polar head group anion $[C_6H_{11}O_9S]^-$. All of the other peaks in the lipid profile of the spinal cord can likewise be identified based on their CID spectra. A summary of the peak assignments and the relative abundances in the whole spinal cord for negative ion $[M - H]^-$ ions is given in Table 1. These data are consistent with previously reported MS analysis of rat brain sections [45, 80, 89]. Although the sulfatide lipids are not the most abundant in rat spinal cord [21], they correspond to the main detected ions in the negative ion mass spectrum, their more efficient ionization being due to the high acidity of the sulfonic group.

In the positive ion mode, ions are detected in the high *m/z* region with a lower signal/noise ratio than in negative mode, as shown in the expanded view of the DESI mass spectrum in the *m/z* range 650–1000 (Figure 3). The major biomolecules detected are glycerophosphocholines (PC), sphingomyelin (SM), and glycero-

phosphoethanolamines (PE), and plasmalogens (plasm-PE) as protonated $[M + H]^+$ or sodiated $[M + Na]^+$ adducts. Only the most intense peaks for each class of lipids have been annotated for clarity, but the mass spectrum in Figure 3 is dominated by PC species. MS/MS experiments were also performed on the tissue samples and compared to published fragmentation [93, 94, 104] to identify the lipids detected in the full scan mass spectra, as well as accurate mass measurements on the DESI-Orbitrap (see Figure S1 in the Supplementary Material). Indeed, based on its fragmentation behavior, the ion detected at *m/z* 782.8 in the MS spectrum (*m/z* 782.5704, error: +4.5 ppm on the DESI-Orbitrap) has been identified as $[PC(16:0/18:1) + Na]^+$. Predominant loss of 59 Da, representing the $(CH_3)_3N$ group [105–110], from the precursor ion is indicated by a product ion at *m/z* 723.5 ($[M - (CH_3)_3N + Na]^+$) as shown in the MS/MS spectrum (Figure 4a). Loss of the polar head group is also observed and gives rise to the sodiated adduct detected at *m/z* 599.5 ($[M - C_5H_{14}O_4NP + Na]^+$). Additionally, the fragment cation detected at *m/z* 577.4 ($[M - C_5H_{13}O_4NPNa]^+$) would be expected to arise from the loss of the sodiated-complex of the polar head group (205 Da) from the precursor ion [107, 108]. Two ions are detected at *m/z* 500.4 and 526.4 with low abundance and correspond to the loss of one of the two fatty acids (C16:0 and C18:1, respectively) from the precursor ion. Similarly, the peaks at *m/z* 837.8 (*m/z* 837.6767, error: −6.3 ppm using the DESI-Orbitrap) has been identified as $[SM(18:1/24:0) + Na]^+$. The MS/MS spectrum of this ion (Figure 4b) shows a

[e]Species detected as potassiated adducts.

neutral loss of 59 Da, which can be assigned to the loss of the $(CH_3)_3N$ group from the precursor ion [111], yielding the fragment ion detected at m/z 778.8, denoted $[M - (CH_3)_3N + Na]^+$. The most abundant fragment ion detected at m/z 654.6 ($[M - C_5H_{14}O_4NP + Na]^+$) corresponds to the of the polar head group (183 Da) from the precursor ion [111]. In addition, very low abundance peaks at m/z 596.5 and m/z 489.4 are detected, corresponding, respectively, to the elimination of the long-chain base after the second carbon ($[M - C_{16}H_{19}O_4H + Na]^+$) and the fatty acid chain as a ketene neutral ($[M - C_{22}H_{43}CHCO + Na]^+$) from the precur-

sor ion. All of the other peaks in the lipid profile of the spinal cord can likewise be identified based on their CID spectra. A summary of the peak assignments and the relative abundances in the whole spinal cord protonated $[M + H]^+$ and sodiated $[M + Na]^+$ adducts is given in Table 2.

Reported MS studies of rat brain tissues have also yielded strong mass peaks associated with PC in positive ion mode [43, 44, 93, 112]. Although glycerophosphocholines (PC) and glycerophosphoethanolamines (PE) have similar concentrations in rat spinal cords [21], the relative abundances of the PE species are weak

Ion images of (**a**) plasm-PE(38:4), (**b**) PS(36:1), (**c**) PE(40:4), (**d**) PG(40:6), (**e**) PI(38:4), (**f**) ST(24:1), (**g**) (18:1), (**h**) (20:4), and (**i**) (22:6). (**j**) Optical image of the rat spinal cord cross-section.

compared to PC in the positive mass spectra. Indeed, PC are characterized by the presence of a quaternary ammonium group whose positive charge is neutralized by the negative charge of the phosphate group (Scheme 1). Thus, PC readily forms an abundant sodiated species when Na^+ ions are present in the sample because the phosphate anion can be easily sodiated during the DESI process in the positive ion mode. Furthermore, MS studies of standard phospholipid mixtures have shown that in positive ion mode PC and SM (both contain a quaternary ammonium group) suppress the detection of other phospholipid classes [113, 114].

Tissue Imaging

Tissue imaging experiments allow correlation of chemical information with morphological features of the sample. Rat spinal cord cross sections were imaged using DESI-MS in both the negative and the positive ion modes. Each image is a representation of the distribution of ions of one particular *m/z* value and hence a representation of the distribution of the corresponding molecule in the tissue sample. Note that the peak intensity does not exactly represent molecular concentrations in the tissue due to the differences in ionization efficiency, competitive suppression effects or differences in the degree of fragmentation. However, for the same molecule in the same tissue type or closely related compounds in the same tissue, relative peak intensities should approximately reflect differences in intrinsic concentrations. This is a standard assumption in imaging studies and it has been discussed and justified in previous papers [72, 85, 86].

The spatial images of specific lipids and fatty acids in the 3.8 × 3.5 mm area of rat spinal cord cross section in the negative ion mode are shown in Figure 5. For comparison, an optical image is provided in Figure 5j and structural features (white and gray matter) are indicated. Each selected ion image is plotted on the same color scale to allow comparison of ion intensity between images. Ion images show a particular localization in either the white matter (light peripheral region in Figure 5j), which predominantly contains myelinated axons, or gray matter (dark central region in Figure 5j), which predominantly contains the cellular bodies. The image of the ion detected at *m/z* 750.6, identified as the deprotonated form of plasm-PE(38:4), shows an approximately homogeneous distribution in the area of the spinal cord corresponding to the white matter but much lower signals in the area corresponding to the gray matter (Figure 5a). A similar spatial intensity distribution with even more contrast is observed for the deprotonated PE(40:4) detected at *m/z* 794.4 (Figure 5c). PS, PG, PI, and ST lipids (Figure 5b–f) are also mainly located in the area corresponding to the white matter with less abundance in the gray matter. Figure 6 shows the spatial images of PC(36:1) and SM(42:1) lipids in the rat spinal cord cross section in the positive ion mode. Due to the low signal/noise ratio, the quality of the images is not as good as in the negative ion mode. Indeed, the lower signal intensity of the detected lipids (maximum at 80 arbitrary units in positive mode instead of 202 in the negative mode) results in a lower contrast between the spinal cord tissue and the other part of the scanned surface. However, positive ion mode images show the same particular localization in the white matter and support the interpretations made from the negative ion data. Signals at *m/z* 782.5 (Figure 6a) and *m/z* 837.8 (Figure 6b), which correspond to sodiated adducts of PC(34:1) and SM(42:1), are more intense in the white matter. In contrast, the complementary localization of ion images is observed for the fatty

Figure 6. Selected molecular ion $[M + Na]^+$ images of specific lipids from analysis of a 3.8 × 3.5 mm area of rat spinal cord cross-section in the positive ion mode. Ion images of (**a**) PC(34:1) and (**b**) SM(42:1).

acids, Figure 5g–i. Indeed, the intensity of the signal detected at *m/z* 281.4, identified as the deprotonated form of oleic acid (Figure 5g) is higher in the region of the spinal cord corresponding to the gray matter, as is that for arachidonic acid (*m/z* 303.4; Figure 5h) and docosahexaenoic acid (*m/z* 327.4; Figure 5i).

These results agree with the reported studies of rat brains whereby lipids ions were associated with the myelinated axons (white matter) [20, 21], while the fatty acids were present in the region enriched in neuronal cell bodies (gray matter) [80, 115]. This suggests that the spatial intensity distribution reflects relative concentration differences of the lipid and fatty acid compounds in the spinal cord tissue. The "butterfly" shape of the gray matter in the spinal cord cross-section is resolved in the corresponding ion images, indicating that a lateral resolution of less than 200 μm is achieved. The selected ion images of lipids are directly correlated with anatomic features on the spinal cord corresponding to the white and the gray matter.

Conclusion

This study has established that DESI imaging MS is a powerful tool for measuring lipid profiles in rat spinal cord with a spatial resolution less than 200 μm. The resulting ion images reflect the relative concentrations of the species detected from the tissue surface. DESI imaging MS presents advantages in terms of easy implementation and ambient analysis. MS/MS experiments have also been performed to confirm the identities of individual compounds. All these chemical and spatial information may help to a better understanding of lipid biochemistry within the spinal cord. This work presents the fundamental information needed to pursue future studies of spinal cord injury recovery processes. Indeed, DESI imaging technique will be used in future studies to determine the spatial distribution and expression levels of analytes and their changes during the injury recovery process and to evaluate the effects of drug treatment.
