Editor: Avrim Blum

Abstract. A neural network is said to be nonoverlapping if there is at most one edge outgoing from each node. We investigate the number of examples that a learning algorithm needs when using nonoverlapping neural networks as hypotheses. We derive bounds for this sample complexity in terms of the Vapnik-Chervonenkis dimension. In particular, we consider networks consisting of threshold, sigmoidal and linear gates. We show that the class of nonoverlapping threshold networks and the class of nonoverlapping sigmoidal networks on n inputs both have Vapnik-Chervonenkis dimension $\Omega(n \log n)$. This bound is asymptotically tight for the class of nonoverlapping threshold networks. We also present an upper bound for this class where the constants involved are considerably smaller than in a previous calculation. Finally, we argue that the Vapnik-Chervonenkis dimension of nonoverlapping threshold or sigmoidal networks cannot become larger by allowing the nodes to compute linear functions. This sheds some light on a recent result that exhibited neural networks with quadratic Vapnik-Chervonenkis dimension.

Keywords: neural networks, read-once formulas, threshold gates, sigmoidal gates, PAC learning, Vapnik-Chervonenkis dimension

1. Introduction

The sample complexity, that is, the number of examples required for a learning algorithm to create hypotheses that generalize well, is a central issue in machine learning. How the sample complexity depends on the structure and the parameters that define a hypothesis class is a question that is often amenable to theoretical investigations. In this paper we study the sample complexity for hypothesis classes consisting of nonoverlapping neural networks. These are feedforward networks where each node, except the output node, has exactly one outgoing connection. Since such networks have less degrees of freedom, learning using these hypotheses is expected to be more efficient in terms of sample size and computing time than when using unrestricted neural networks.

The computational complexity of learning using nonoverlapping networks has been extensively studied in the literature. Angluin, Hellerstein, and Karpinski (1993), for instance, investigated the existence of efficient algorithms that use queries to learn networks that are known as Boolean trees or read-once formulas. In particular, they showed that read-once formulas can be exactly identified in polynomial time using both equivalence and membership queries. They also proved a negative result stating that neither equivalence

nor membership queries alone are sufficient to exactly identify all read-once formulas in polynomial time. Research on the learnability of nonoverlapping networks employing neural gates has been initiated by Golea, Marchand, and Hancock (1993). They studied the probably approximately correct (PAC) learnability of so-called μ -Perceptron networks with binary weights: A μ -Perceptron network is a disjunction of threshold gates where each input node is connected to exactly one threshold gate. In particular, they designed algorithms that PAC learn these networks in polynomial time from examples only when these examples are randomly drawn under the uniform distribution. Golea, Marchand, and Hancock (1996) generalized these results to tree structures in the form of μ -Perceptron decision lists. General nonoverlapping architectures that employ threshold gates as network nodes were considered by Hancock, Golea, and Marchand (1994). They gave a polynomial-time algorithm that PAC learns any nonoverlapping threshold network from examples and membership queries under an arbitrary unknown distribution of the examples.

In this article we investigate the sample complexity for nonoverlapping neural networks in terms of their Vapnik-Chervonenkis (VC) dimension. It is well known that the VC dimension of a function class gives asymptotically tight bounds on the number of training examples needed for PAC learning this class. For detailed definitions and results for this model of learnability we refer the reader to Anthony and Biggs (1992), Blumer et al. (1989), and Valiant (1984). Moreover, these estimates of the sample complexity in terms of the VC dimension hold even for agnostic PAC learning, that is, in the case when the training examples are generated by some arbitrary probability distribution (Haussler, 1992). Furthermore, the VC dimension is known to yield bounds for the complexity of learning in various on-line learning models (Littlestone, 1988; Maass & Turán, 1992).

Results on the VC dimension for neural networks abound; see, for instance, the survey by Maass (1995). We briefly mention the most relevant ones for this article. Concerning upper bounds, a feedforward network of threshold gates is known to have VC dimension at most $O(w \log w)$ where w is the number of weights (Baum & Haussler, 1989). Networks using piecewise polynomial functions for their gates have VC dimension $O(w^2)$ (Goldberg & Jerrum, 1995) whereas for sigmoidal networks the bound $O(w^4)$ is known (Karpinski & Macintyre, 1997). With respect to lower bounds threshold networks with VC dimension $\Omega(w \log w)$ have been constructed (Sakurai, 1993; Maass, 1994). Furthermore, Koiran and Sontag (1997) have shown that there are neural networks with VC dimension $\Omega(w^2)$. Among these are networks that consist of both threshold and linear gates, and sigmoidal networks.

Bounds on the VC dimension for neural networks are usually given in terms of the number of programmable parameters, that are, most commonly, the weights, of these networks. In contrast to the majority of the results in the literature, however, we are not looking at the VC dimension of a single network with a fixed underlying graph, but of the entire class of nonoverlapping networks employing a specified activation function. This must be taken into account when comparing our results with other ones.

The first result on the sample complexity for nonoverlapping neural networks is due to Hancock, Golea, and Marchand (1994). They showed that the VC dimension of the class of nonoverlapping networks having threshold gates as nodes—they called these networks nonoverlapping Perceptron networks—is $O(n \log n)$ where n is the number of inputs.¹ We

take this result as a starting line for our work. After introducing the basic definitions in Section 2 we show in Section 3 that the class of nonoverlapping threshold networks has VC dimension $\Omega(n \log n)$, which is—according to the result of Hancock, Golea, and Marchand (1994)—asymptotically tight. Moreover, we show that this bound remains valid even when all networks are required to have depth two and their output gate computes a disjunction. This lower bound is then easily transferred to nonoverlapping networks with sigmoidal gates. In Section 4 we provide a new calculation for an upper bound that considerably improves the constants of Hancock, Golea and Marchand (1994). Section 5 is a short note on how to derive the upper bound $O(n^4)$ for the class of nonoverlapping sigmoidal networks. Finally, in Section 6 we show that adding linear gates to nonoverlapping threshold or sigmoidal networks cannot increase their VC dimension. Interestingly, it was this use of linear gates that lead to a quadratic lower bound for sigmoidal neural networks in the work of Koiran and Sontag (1997). Consequently, if the lower bound $\Omega(n \log n)$ is not tight for nonoverlapping sigmoidal networks one has to look for new techniques in search for asymptotically better bounds.

2. Basic definitions

A *nonoverlapping neural network* is a feedforward neural network where there is at most one edge outgoing from each node (see figure 1). In other words, the connectivity or architecture of the network is a tree.² The notion of “nonoverlapping” can be traced back to the work of Barkai, Hansel, and Kanter (1990) and has been introduced to model a type of biological neural network where the receptive fields of the neurons do not overlap, i.e., are pairwise disjoint. In a nonoverlapping neural network there is exactly one node, the *output node*, that has no edge outgoing. A *nonoverlapping neural network on n inputs* has n leaves, also called *input nodes*. The *depth* of a nonoverlapping neural network is the length of the longest path from an input node to the output node. The nodes that are not

Figure 1. Two examples for nonoverlapping neural networks on seven inputs each. The filled circles are the input nodes, all other ones are computation nodes. Circles with no outgoing connections are output nodes. Network (a) has depth three, network (b) is a depth-two network with a disjunction as output gate such as considered in Section 3. Not shown are the parameters that are associated with each computation node: one weight for each incoming connection and a threshold (except for the output node of network (b) which has no parameters since it is assumed to compute a fixed Boolean disjunction).

leaves are also known as *computation nodes*. Each computation node has associated with itself a set of $k + 1$ real-valued parameters where k is the in-degree of the node: the weights w_1, \dots, w_k and the threshold t .

We use nonoverlapping neural networks for computations over the reals by assigning functions to its computation nodes and values to their parameters. We consider three types of functions that the nodes may use. All types are obtained by applying a so-called activation function to the weighted sum $w_1x_1 + \dots + w_kx_k - t$ where x_1, \dots, x_k are the input values for the node computed by its predecessors. (The values computed by the input nodes are the input values for the network.) A node becomes a *threshold gate* when it uses as activation function the signum function with $\text{sign}(y) = 1$ if $y \geq 0$, and $\text{sign}(y) = 0$ otherwise. A *sigmoidal gate* is a node that uses the sigmoidal function $1/(1 + e^{-y})$. Finally, a *linear gate* applies the identity function, that is, it simply outputs the weighted sum.

A *nonoverlapping threshold network* is a network where all computation nodes are threshold gates. Correspondingly, we speak of *nonoverlapping sigmoidal networks* and *nonoverlapping linear networks*. If we allow more than one type of activation function for a network then we shall assume that each of its computation nodes may use all types specified. Since we restrict our investigations to networks that compute $\{0, 1\}$ -valued functions, we assume the output of a network to be thresholded at $1/2$ if the output node is a linear or sigmoidal gate. Thus we can associate with each network on n inputs a set of functions from \mathbb{R}^n to $\{0, 1\}$ which are obtained by choosing activation functions for its nodes and varying its parameters over the reals. In a *class of nonoverlapping networks* all members have the same number of inputs, denoted by n , and choose gate functions for their nodes from a specified set, which can be of the three types specified above. The set of functions computed by a class of networks is then defined straightforward as the union of the sets computed by its members.

A *dichotomy* of a set $S \subseteq \mathbb{R}^n$ is a partition of S into two disjoint subsets S_0, S_1 such that $S_0 \cup S_1 = S$. Given a set \mathcal{F} of functions from \mathbb{R}^n to $\{0, 1\}$ and a dichotomy S_0, S_1 of S , we say that \mathcal{F} *induces* the dichotomy S_0, S_1 on S if there is a function $f \in \mathcal{F}$ such that $f(S_0) \subseteq \{0\}$ and $f(S_1) \subseteq \{1\}$. We say further that \mathcal{F} *shatters* S if \mathcal{F} induces all dichotomies on S . The *Vapnik-Chervonenkis (VC) dimension* of \mathcal{F} , $\text{VCdim}(\mathcal{F})$, is defined as the largest number m such that there is a set of m elements that is shattered by \mathcal{F} .

3. Lower bounds on the VC dimension for nonoverlapping threshold and sigmoidal networks

In this section we consider nonoverlapping neural networks consisting of threshold and sigmoidal gates. We first establish a lower bound on the VC dimension for a class of nonoverlapping threshold networks with certain restrictions: We assume that each network has only two layers of computation nodes and that the output node computes a disjunction (see figure 1(b) for an example).

Theorem 1. *For each $m, k \geq 1$ there exists a set $S \subseteq \{0, 1\}^{m+2^k}$ of cardinality $|S| = m \cdot k$ that is shattered by the class of nonoverlapping threshold networks of depth two that have a disjunction as output gate.*

Proof: Let the set $S \subseteq \{0, 1\}^{m+2^k}$ be defined as

$$S = \{e_i : i = 1, \dots, m\} \times \{d_j : j = 1, \dots, k\}$$

where $e_i \in \{0, 1\}^m$ is the i -th unit vector, i.e., the vector with a 1 in the i -th component and 0s elsewhere, and $d_j \in \{0, 1\}^{2^k}$ is specified as follows: Let A_1, \dots, A_{2^k} be an enumeration of all subsets of $\{1, \dots, k\}$. We denote the 2^k components of vector d_j by $d_j(1), \dots, d_j(2^k)$. For each $j \in \{1, \dots, k\}$ and $l \in \{1, \dots, 2^k\}$ we define the value of component $d_j(l)$ by

$$d_j(l) = \begin{cases} 1 & \text{if } j \in A_l, \\ 0 & \text{otherwise.} \end{cases}$$

Obviously, S consists of $m \cdot k$ elements. We claim that S is shattered by the class of nonoverlapping threshold networks of depth two having a disjunction as output gate. In order to prove this we show that for each $S' \subseteq S$ there are weights and thresholds for such a network such that this network outputs 1 for elements in S' , and 0 for elements in $S \setminus S'$. Fix some arbitrary $S' \subseteq S$. For $i = 1, \dots, m$ let $\alpha(i)$ be the (unique) element in $\{1, \dots, 2^k\}$ such that

$$A_{\alpha(i)} = \{j : e_i d_j \in S'\}.$$

For convenience we call the input nodes $1, \dots, m$ the e -inputs, and the input nodes $m + 1, \dots, m + 2^k$ the d -inputs. Thus input node $m + l$ becomes d -input l . We employ for each element in the range of α a threshold gate $G_{\alpha(i)}$ that has a connection from d -input $\alpha(i)$ and from none of the other d -inputs. Further, we connect e -input i to gate $G_{\alpha(i)}$ for $i = 1, \dots, m$. (Notice that this may result in gates that have connections from more than one e -input.) The weights of all connections are fixed to 1 and the thresholds of the gates are set to 2. Obviously, there is at most one connection outgoing from each input node, so that the disjunction of these threshold gates is a nonoverlapping network.

Finally, we verify that the network computes the desired function on S . Suppose that $x \in S'$ where $x = e_i d_j$. The definition of α implies that $j \in A_{\alpha(i)}$. Hence component $\alpha(i)$ of d_j has value $d_j(\alpha(i)) = 1$. Since gate $G_{\alpha(i)}$ receives two 1s—one from e -input i and one from d -input $\alpha(i)$ —the output of the network for $e_i d_j$ is 1.

Assume on the other hand that $e_i d_j \in S \setminus S'$. Then $j \notin A_{\alpha(i)}$ and gate $G_{\alpha(i)}$, which is the only gate that receives a 1 from an e -input, receives only 0s from d -input $\alpha(i)$ (which according to the construction is the only d -input $G_{\alpha(i)}$ is connected to). All other gates G_l , where $l \neq \alpha(i)$, receive at most one 1, which is then from d -input l only. Hence, the output of the network for $e_i d_j$ is 0. \square

Choosing $m = n/2$ and $k = \lfloor \log(n/2) \rfloor$ in Theorem 1, we have $m + 2^k \leq n/2 + n/2 = n$. Hence there is a set $S \subseteq \{0, 1\}^n$ of cardinality $m \cdot k = \Omega(n \log n)$ that is shattered by the class of networks considered in the above theorem.

Corollary 1. *The VC dimension of the class of nonoverlapping threshold networks on n inputs is $\Omega(n \log n)$. This even holds if all input values are binary and the class is restricted to nonoverlapping threshold networks of depth two with a disjunction as output gate.*

It is well known that in a network that computes a Boolean function a threshold gate can be replaced by a sigmoidal gate without changing the function of the network. (If necessary, the weights have to be scaled appropriately. See, for instance, Maass, Schnitger, and Sontag (1994) for a treatment in the context of circuit complexity). Thus, the lower bound $\Omega(n \log n)$ also holds for nonoverlapping depth-two networks that may consist of threshold or sigmoidal gates.

Corollary 2. *The class of nonoverlapping depth-two networks on n inputs with threshold or sigmoidal gates has VC dimension $\Omega(n \log n)$. This even holds if the inputs are restricted to binary values.*

We note that depth two is minimal for this lower bound since a threshold gate and a sigmoidal gate both have VC dimension $n + 1$: This follows for the threshold gate from a bound on the number of different regions arising from sets of hyperplanes in \mathbb{R}^n which is due to Schläfli (1901) (see also Cover (1965)). For the sigmoidal gate this follows from the fact that its pseudo dimension is $n + 1$ (Haussler, 1992).

Together with the upper bound $O(n \log n)$ which has been obtained by Hancock, Golea, and Marchand (1994) we get asymptotically tight bounds for the class of nonoverlapping threshold networks.

Corollary 3. *The VC dimension of the class of nonoverlapping threshold networks on n inputs is $\Theta(n \log n)$. This holds also for the class of nonoverlapping threshold networks of depth two. Moreover, this bound remains valid for both classes if the inputs are restricted to binary values.*

4. Improved upper bounds for nonoverlapping threshold networks

In this section we establish upper bounds for the VC dimension of the class of nonoverlapping threshold networks. Regarding the constants these bounds are better than a previous result derived by Hancock, Golea, and Marchand (1994) which is $13n \log(2en) + 4n \log \log(4n)$.

Theorem 2. *The class of nonoverlapping threshold networks on n inputs, where $n \geq 16e$, has VC dimension at most $6n \log(\sqrt{3n})$.*

Proof: We estimate the number of dichotomies that are induced by the class of nonoverlapping threshold networks on an arbitrary set of cardinality m . Using the upper bound $(4n)^{n-1}$ on the number of different nonoverlapping networks (or architectures) on n inputs, which was obtained in Lemma 3 of Hancock, Golea, and Marchand (1994) we first derive an upper bound on the number of dichotomies that a single such network induces when all its weights and thresholds are varied.

Let one such network be given and assume without loss of generality that the computation nodes at the lowest level (i.e., those nodes that have input nodes as predecessors) have in-degree 1 and that all other computation nodes have in-degree at least 2. Each of the

computation nodes at the lowest level induces at most $2m$ dichotomies on a set of cardinality m . The whole level induces therefore at most $(2m)^n$ different dichotomies. The computation nodes with in-degree at least 2 form a nonoverlapping network that consists of at most $n - 1$ nodes and has at most $2n - 2$ edges leading to one of these nodes.

According to a result by Shawe-Taylor (1995)³ the number of dichotomies that a threshold network with N computation nodes, partitioned into ν equivalence classes, and W edges induces on a set of cardinality m is at most

$$2^\nu \left(\frac{emN}{W - \nu} \right)^{W - \nu}.$$

Using $N = n - 1$, $\nu = n - 1$, and $W = 2n - 2$ we get that the number of dichotomies induced by a nonoverlapping threshold network consisting of $n - 1$ computation nodes and $2n - 2$ edges is at most $2^{n-1}(em)^{n-1}$.

Putting the bounds together, the total number of dichotomies induced on a set of cardinality m by the class of nonoverlapping threshold networks on n inputs is at most

$$(4n)^{n-1} \cdot (2m)^n \cdot 2^{n-1}(em)^{n-1}.$$

Assume now that a set of cardinality m is shattered. Then

$$\begin{aligned} 2^m &\leq (4n)^{n-1} \cdot (2m)^n \cdot 2^{n-1}(em)^{n-1} \\ &= 2(16en)^{n-1} \cdot m^{2n-1} \\ &\leq 2(mn)^{2n-1}. \end{aligned}$$

For the last inequality we have used the assumption $n \geq 16e$. Taking logarithms on both sides we obtain

$$m \leq (2n - 1) \log(mn) + 1.$$

We weaken this to

$$m \leq 2n \log(mn). \tag{1}$$

Assume without loss of generality that $m \geq \log n$. Then it is easy to see that for each such m there is a real number $r \geq 1$ such that m can be written as $m = r \log(rn)$. Substituting this in (1) yields

$$\begin{aligned} r \log(rn) &\leq 2n(\log(rn \log(rn))) \\ &= 2n(\log(rn) + \log \log(rn)) \end{aligned} \tag{2}$$

$$\leq 3n \log(rn). \tag{3}$$

The last inequality follows from $\log(rn) \leq \sqrt{rn}$ which holds since $rn \geq 16e$. We divide both sides by $\log(rn)$ and get

$$r \leq 3n. \quad (4)$$

This implies

$$r \log(rn) \leq 3n \log(3n^2).$$

Resubstituting $m = r \log(rn)$ for the left hand side and rearranging the right hand side yields

$$m \leq 6n \log(\sqrt{3n})$$

as claimed. \square

In the statement of Theorem 2 the number of inputs is required to satisfy $n \geq 16e$. We shall show now that we can get the upper bound as close to $4n \log(\sqrt{2n})$ as we want provided that n is large enough.

Theorem 3. *For each $\varepsilon > 0$, the class of nonoverlapping threshold networks on n inputs has VC dimension at most $4(1 + \varepsilon)n \log(\sqrt{2(1 + \varepsilon)n})$ for all sufficiently large n .*

Proof: (Sketch) Fix $\varepsilon > 0$ and $r \geq 1$. For n sufficiently large we have $\log(rn) \leq (rn)^\varepsilon$. Using this in the inequality from (2) to (3) we can infer $r \leq 2(1 + \varepsilon)n$ in place of (4). Proceeding similarly as in the last steps of the proof this leads then to the claimed result. \square

5. A note on the upper bound for nonoverlapping sigmoidal networks

Using known results on the VC dimension it is straightforward to derive the upper bound $O(n^4)$ for nonoverlapping sigmoidal networks. We give a brief account.

Proposition 1. *The class of nonoverlapping sigmoidal networks on n inputs has VC dimension $O(n^4)$.*

Proof: The VC dimension of a sigmoidal neural network with w weights is $O(w^4)$. This has been shown by Karpinski and Macintyre (1997). By Sauer's Lemma (see, e.g., Anthony and Biggs (1992)) the number of dichotomies induced by a class of functions with VC dimension $d \geq 2$ on a set of cardinality $m \geq 2$ can be bounded from above by m^d . Thus a nonoverlapping sigmoidal network on n inputs induces at most $m^{O(n^4)}$ dichotomies on such a set. Combining this with the bound $(4n)^{n-1}$ employed in the proof of Theorem 2 and using similar arguments we obtain the bound as claimed. \square

6. Nonoverlapping neural networks containing linear gates

From the work of Goldberg and Jerrum (1995) it has been known that neural networks employing piecewise polynomial activation functions have VC dimension $O(w^2)$, where w is the number of weights. The question whether this bound is tight for such networks has been settled by Koiran and Sontag (1997). They have shown that networks consisting of threshold and linear gates can have VC dimension $\Omega(w^2)$. This result was somewhat unexpected since networks consisting of linear gates only compute linear functions and therefore have VC dimension $O(w)$. On the other hand, networks consisting of threshold gates only have VC dimension $O(w \log w)$. This follows from work of Cover (1968) and has also been shown by Baum and Haussler (1989). Results that this bound is tight for threshold networks are due to Sakurai (1993) and Maass (1994).

Therefore, the question arises whether a similar increase of the VC dimension is possible for nonoverlapping threshold or sigmoidal networks by allowing some of the nodes to compute linear functions. We show now that this cannot happen.

Theorem 4. *Let \mathcal{N} be a class of nonoverlapping neural networks consisting of threshold or sigmoidal gates and let \mathcal{N}^{lin} be a class of neural networks obtained from \mathcal{N} by replacing some of the gates by linear gates. Then $\text{VCdim}(\mathcal{N}) \geq \text{VCdim}(\mathcal{N}^{\text{lin}})$.*

Proof: We show that in a nonoverlapping network of threshold or sigmoidal gates nodes computing linear functions can be replaced or eliminated without changing the function of the network. Assume N is a nonoverlapping network and y is a node in N computing a linear function. If y is the output node then y can be replaced by a threshold gate or a sigmoidal gate, where weights and threshold are modified if necessary. (Note that the output of the nonoverlapping neural network is thresholded at $1/2$ for linear and sigmoidal output gates.)

If y is a hidden node (i.e., a computation node that is not the output node) then there is a unique edge e outgoing from y to its successor z . Denote the weight of e by w . Assume that y computes the function $u_1x_1 + \dots + u_kx_k - t$ where x_1, \dots, x_k are the predecessors of y , and u_1, \dots, u_k, t are its weights and threshold. We delete node y and edge e , and introduce k edges from x_1, \dots, x_k respectively to z . We assign weight wu_i to the edge from x_i for $i = 1, \dots, k$ and decrease the threshold of z by wt . It can readily be seen that the resulting network is still nonoverlapping and computes the same function as N . \square

Combining Theorems 2 and 3 with Theorem 4 we obtain an upper bound for the class of nonoverlapping neural networks with threshold or linear gates.

Corollary 4. *The class of nonoverlapping neural networks on n inputs with threshold or linear gates has VC dimension at most $6n \log(\sqrt{3}n)$ for $n \geq 16e$. Furthermore, for each $\varepsilon > 0$, the VC dimension of this class is at most $4(1 + \varepsilon)n \log(\sqrt{2(1 + \varepsilon)}n)$ for all sufficiently large n .*

The technique used in the proof can also be applied to nonoverlapping neural networks that employ a much wider class of gates. If the function computed by a gate can be

decomposed into a linear and a non-linear part then the method of deleting a hidden linear node works the same way. Only if the node to be treated is the output node there have to be made some further demands on its function: A sufficient condition is, for instance, monotonicity. If the non-linear part of the gate function is monotonous then a linear output node can be replaced by such a gate without decreasing the VC dimension of the network.

7. Conclusions

Finding methods that incorporate prior knowledge into learning algorithms is an active research area in theoretical and applied machine learning. In the case of neural learning algorithms such knowledge might be reflected in a restricted connectivity of the network generated by the algorithm. We have studied neural networks where each node has at most one outgoing connection and have analyzed the impact that this restriction has on the sample complexity for classes of these networks. The results we derived are given in terms of bounds for their VC dimension.

In this article we have established the asymptotically tight bound $\Omega(n \log n)$ for the class of nonoverlapping threshold networks. We have also derived an improved upper bound for this class. Further, we have considered the implications of having linear gates in nonoverlapping networks: Due to our result demonstrating that the use of linear gates in nonoverlapping threshold networks cannot increase their VC dimension, a known technique to construct networks with quadratic VC dimension does not work for nonoverlapping networks. As a consequence of this, the gap between the currently best known lower and upper bounds for the class of nonoverlapping sigmoidal networks, which are $\Omega(n \log n)$ and $O(n^4)$, is larger than it is for general, i.e. possibly overlapping, sigmoidal networks. To reduce the gap and to extend these investigations to other frequently used types of gates are challenging open problems for future research.

Acknowledgments

I would like to thank two anonymous referees for helpful comments. Part of this work was done while the author was with the Institute for Theoretical Computer Science at Technische Universität Graz, A-8010 Graz, Austria. This work is supported in part by the ESPRIT Working Group in Neural and Computational Learning II, NeuroCOLT2, No. 27150.

Notes

1. Since a nonoverlapping neural network on n inputs has $O(n)$ weights, it is convenient to formulate the bounds in terms of the number of inputs. We follow this convention throughout the paper.
2. Adopting this notion from graph theory, such a network might most appropriately be called a neural tree. However, this term is avoided here since it is already in use for a completely different classification method based on neural computations along the branches of a decision tree (see, e.g., Golea and Marchand (1990) and Sirat and Nadal (1990)). I thank the anonymous referee who pointed this out.
3. We do not make use of the equivalence relations involved in this result but of the improvement that it achieves compared to Baum and Haussler (1989).
