Genome-wide meta-analysis of cognitive empathy: heritability, and correlates with sex, neuropsychiatric conditions and cognition

V Warri¹, KL Grasby², F Uzevsky^{1,3}, R Toro^{4,5,6}, P Smith¹, B Chakrabarti⁷, J Khadake⁸, E Mawbey-Adamson⁸, N Litterman⁹, J-J Hottenga^{10,11,12}, G Lubke¹³, DI Boomsma¹⁰, NG Martin², PK Hatemi¹⁴, SE Medland², DA Hinds⁹, T Bourgeron^{4,5,6,16} and S Baron-Cohen^{1,15,16}

We conducted a genome-wide meta-analysis of cognitive empathy using the ‘Reading the Mind in the Eyes’ Test (Eyes Test) in 88,056 research volunteers of European Ancestry (44,574 females and 43,482 males) from 23andMe Inc., and an additional 1497 research volunteers of European Ancestry (891 females and 606 males) from the Brisbane Longitudinal Twin Study. We confirmed a female advantage on the Eyes Test (Cohen’s $d = 0.21$, $P < 2.2 \times 10^{-16}$), and identified a locus in 3p26.1 that is associated with scores on the Eyes Test in females ($rs7641347$, $P_{meta} = 1.58 \times 10^{-8}$). Common single nucleotide polymorphisms explained 5.8% (95% CI: 4.5%–7.2%; $P = 1.00 \times 10^{-17}$) of the total trait variance in both sexes, and we identified a twin heritability of 28% (95% CI: 13%–42%). Finally, we identified significant genetic correlation between the Eyes Test and anorexia nervosa, openness (NEO-Five Factor Inventory), and different measures of educational attainment and cognitive aptitude.

Molecular Psychiatry (2018) **23**, 1402–1409; doi:10.1038/mp.2017.122; published online 6 June 2017

INTRODUCTION

Cognitive empathy, defined as the ability to recognize what another person is thinking or feeling, and to predict their behaviour based on their mental states, is vital for interpersonal relationships, which in turn is a key contributor of wellbeing. Cognitive empathy is distinct from affective empathy, the latter of which is defined as the drive to respond to another’s mental states with an appropriate emotion.^{1,2} Difficulties in cognitive empathy have been found in different psychiatric conditions, particularly autism.³ The dissociation between cognitive and affective empathy (the latter is often intact in autism, for example, whilst it is invariably impaired in antisocial personality disorder) suggests these have independent biological mechanisms.

Differences in cognitive empathy have been identified in individuals with psychiatric conditions such as autism,⁴ schizophrenia^{5,6} and anorexia nervosa.⁷ This includes either elevated or reduced cognitive empathy in comparison to neurotypical controls, either of which can contribute to difficulties in social interactions and wellbeing.⁸ However, although such alterations in cognitive empathy in psychiatric conditions are well established, little is known about the genetic correlates of cognitive empathy. For example, it is unclear to what extent, differences in cognitive empathy are a genetic risk factor for

developing various psychiatric conditions. Furthermore, as previous studies have often used self-report or performance tests, results from these studies may be influenced by the characteristics of the test and/or factors associated with the psychiatric conditions themselves. In sum, from previous studies, it is difficult to tease apart the genetic and non-genetic contributions to performance in cognitive empathy, and how these relate to various psychiatric conditions.

Here we investigate the genetic architecture of this aspect of social cognition using a well-validated test, the ‘Reading the Mind in the Eyes’ Test (Eyes Test). The Eyes Test is a brief online test where participants are shown photographs of the eye regions and have to identify the appropriate emotion or mental state they express.² It has been widely used to investigate differences in cognitive empathy in a range of neuropsychiatric conditions including autism,⁴ schizophrenia,⁹ bipolar disorder,¹⁰ anorexia nervosa¹¹ and major depressive disorder.¹² The NIMH Research Domain Criteria (RDoC) lists the Eyes Test as one of several important tests for characterizing variation in social processes, under the category of Perception and Understanding of Others (<http://1.usa.gov/1Qs6Mdl>).¹³ We conducted a genome-wide association meta-analysis of cognitive empathy in more than 89,000 individuals of European ancestry, and investigated both

single nucleotide polymorphism (SNP)-based and twin-based heritabilities. We further conducted bivariate genetic correlation analyses for psychiatric conditions, psychological traits and brain volumes. We finally conducted gene-based enrichment analysis and investigate potential genetic sources of sex differences.

MATERIALS AND METHODS

Participants

23andMe. Research participants were customers of 23andMe, and have been described in detail elsewhere.^{14,15} All participants completed an online version of the 'Reading the Mind in the Eyes' test (Eyes Test)² online on the 23andMe research participant website (36 items). In total, 88,056 participants (44,574 females and 43,482 males) of European ancestry completed the Eyes Test and were genotyped. All participants provided informed consent and answered questions online according to 23andMe's human subjects protocol, which was reviewed and approved by Ethical & Independent Review Services, an AAHRPP-accredited private institutional review board (<http://www.eandireview.com>). Only participants who were primarily of European ancestry (97% European Ancestry) were selected for the analysis using existing methods.¹⁶ Unrelated individuals were selected using a segmental identity-by-descent algorithm.¹⁷

Brisbane Longitudinal Twin Study. In addition, 1497 participants (891 females and 606 males) of Caucasian ancestry with genotype data from the Brisbane Longitudinal Twin Study (BLTS) completed the short version (14 questions) of the Eyes Test online as part of a study on genetic and environmental foundations of political and economic behaviors.¹⁸ Participant ages ranged from 18 to 73 ($M=37$, $s.d.=14$). Twin heritability was estimated from 749 twin individuals (including 122 complete monozygotic pairs and 176 complete dizygotic pairs). All participants provided online consent and the study was approved by the QIMR Berghofer Human Research Ethics Committee.

Measures

The 'Reading the Mind in the Eyes' Test (Eyes Test) is a brief questionnaire of cognitive empathy. Participants are shown scaled, black and white photographs of eye regions of actors and they have to choose the cognitive state portrayed from the four options provided. The Eyes Test has good test-retest reliability (for example, reliability of 0.833 in the Italian version,¹⁹ and 0.63 in the Spanish version²⁰),⁴ and scores are unimodally and near-normally distributed in the general population. In the BLTS data set, there was a modest test-retest correlation of 0.47 in 259 participants who retook the test after a gap of nearly 2 years (Supplementary Note section 1). For each correct answer on the Eyes Test, participants score 1 point, so the scores ranged from 0 to 36 on the full version of the Eyes Test and 0–14 on the short version of the Eyes Test. Further details are provided in Supplementary Note section 1.

Genotyping, imputation and quality control

23andMe cohort. DNA extraction, genotyping, imputation and initial quality control were completed by 23andMe. Participants provided saliva samples, and DNA extraction and genotyping were performed by the National Genetic Institute. All participants were genotyped using one of four different platforms (V1, V2, V3 and V4). Briefly, the V1 and V2 chips were based on the Illumina Human Hap550+ BeadChip (560,000 SNPs), the V3 on the Illumina OmniExpress+ Beadchip (950,000 SNPs). The V4 had a fully customized array of approximately 570,000 SNPs. Across all platforms, a total of 1,030,430 SNPs were genotyped. For this analysis, we included only participants with a genotype call rate greater than 98.5%, and SNPs that passed the Hardy–Weinberg Equilibrium Test at $P < 10^{-20}$ and had a genotype rate $>90\%$. In addition, SNPs present only on platform V1, Chromosome Y and mitochondrial SNPs were excluded due to small sample sizes and unreliable genotype calling respectively. Using trio-data, where available, SNPs that failed the parent–offspring transmission test were also excluded. Imputation was performed using Minimac2²¹ using the March 2012 (v3) release of the 1000 Genomes Phase 1 reference haplotypes phased using Beagle²² (V3.3.1). Our analyses were restricted to SNPs that had a minor allele frequency of at least 1%, which left 9,955,952 SNPs after quality control. Genotyping, imputation and preliminary quality control were performed by 23andMe.

BLTS cohort. The BLTS participants were genotyped on Illumina HumanCoreExome-12 v1.0 or Human610-Quad v1.0 chips. These samples were genotyped in the context of a larger genome-wide association project. Genotype data were screened for genotyping quality (GenCall < 0.7 from the Human610-Quad v1.0), individual and SNP call rates (< 0.95 and < 0.99 for exome markers on the HumanCoreExome-12 v1.0 chip), Hardy–Weinberg Equilibrium ($P < 10^{-6}$) and MAF (< 0.01). The data were checked for non-European ancestry, pedigree, sex and Mendelian errors. Data from the two different chips were separately phased using SHAPEIT2 and imputed to the 1000 Genomes reference panel (Phase 1 v3) using Minimac3. After imputation SNPs with a MAF $< 0.05\%$ were excluded, leaving 11,133,794 SNPs for analyses. We further excluded SNPs with imputation $r^2 < 0.6$ for meta-analysis.

Statistical analyses

Association analyses. Linear regression for the 23andMe cohort was performed for the Eyes Test scores using age, sex and the first four ancestry principal components as covariates. For the sex-stratified analyses, sex was excluded as a covariate. The same regression model was used for the BLTS after accounting for relatedness using RAREMETALWORKER. Inverse variance weighted meta-analysis was performed using Metal.²³ Post meta-analysis, we excluded SNPs that were only genotyped in the BLTS cohort due to the small sample size, but included SNPs that were only genotyped in the 23andMe cohort. LD pruning was performed using Plink²⁴ with an r^2 of 0.1. We calculated the variance explained by each individual SNP²⁵ using the following formula:

$$R_{\text{gic}}^2 / (1 - R_c^2) = (t^2 / ((n - k - 1) + t^2)) \times 100$$

where $R_{\text{gic}}^2 / (1 - R_c^2)$ is the proportion of variance explained by the SNP after accounting for the effects of the covariates, t is the t -statistic of the regression co-efficient, k is the number of covariates and n is the sample size. We corrected for winner's curse using an FDR-based approach.²⁶

Heritability and genetic correlation. We used the intercept from Linkage Disequilibrium Score Regression (LDSR) to calculate genomic inflation in the meta-analysis due to population stratification²⁷ (<https://github.com/bulik/ldsc>). The intercept for the non-stratified genome-wide association study (GWAS) was 1.01 (0.006), for the males-only GWAS was 1.006 (0.006), and for the females-only GWAS was 1.005 (0.006). SNP heritability and genetic correlation were calculated using LDSR. Difference in heritability between males and females was tested using:

$$Z_{\text{diff}} = (h_{\text{males}}^2 - h_{\text{females}}^2) / \text{sqrt}(SE_{\text{males}}^2 + SE_{\text{females}}^2)$$

where Z_{diff} is the Z score for the difference in heritability for a trait, $(h_{\text{males}}^2 - h_{\text{females}}^2)$ is the difference SNP heritability estimate in males and females, and SE is the standard errors for the heritabilities. We calculated two-tailed P -values in R. We performed genetic correlation using summary GWAS data using LDSR. For all genetic correlation analyses, we used LD data from the north west European population as implemented in LDSR. Intercepts were not constrained in the analyses. We used Bonferroni correction to correct for multiple testing in the genetic correlation. We also provide the Benjamini–Hochberg adjusted q -values in Supplementary Table 5. We note that Bonferroni correction is likely to be conservative due to the reasonably high degree of phenotypic and genetic correlations between the traits tested. Further details about the samples used are provided in Supplementary Note section 2.

Twin heritability. Twin heritability was estimated from 749 twin individuals (including 122 complete monozygotic pairs and 176 complete dizygotic pairs) in the BLTS using full information maximum likelihood in OpenMx²⁸ in R, which makes use of all available data. All twins completed the short version of the Eyes Test, and for those who completed the test twice only their first attempt was included in analyses. ADE, ACE, AE, CE and E models were fit to the data and fit indices compared to determine the best-fitting model. Standardized variance components are reported from the best-fitting model, the AE model and, for completeness, from the ADE and ACE models. Further details are given in Supplementary Note section 4.

Gene-based analyses and sex difference analyses. We used MetaXcan²⁹ using tissue weights from the GTEx to perform gene-based analysis (<https://github.com/hakyimlab/MetaXcan>). MetaXcan uses summary statistics to perform gene-based association analyses. It incorporates eQTL data from the GTEx consortium to infer gene level expression based on the

summary GWAS statistics provided. This can be used to identify tissue-specific gene expression for the trait of interest. Here, we performed gene-based analysis for the non-stratified GWAS meta-analysis for nine neural tissues: anterior cingulate cortex (BA24), caudate basal ganglia, cerebellar hemisphere, cerebellum, cortex, frontal cortex (BA9), hippocampus, hypothalamus, nucleus accumbens basal ganglia and putamen basal ganglia, using gene-expression regression coefficients for these tissues from the GTEx project. This is based on tissues from 73 to 103 individuals. We chose neural tissues as cognitive empathy can be assumed to be a neural phenotype. As MetaXcan predicts expression level from SNP information, we filtered out genes whose correlation with predicted models of expression was < 0.01 , as incorporated in MetaXcan. This step helps guard against false positives, by removing genes whose expressions are poorly predicted by the model. We used an FDR-based correction to correct for all the tests run across all the tissues. Details of sex-difference analyses are provided in Supplementary Note section 3.

Data availability

Summary level data may be requested from 23andMe and received subject to 23andMe's standard data transfer agreement. We have also provided summary statistics for the first 10,000 LD-pruned SNPs for the three GWAS analyses (males-only, females-only and non-stratified) as Supplementary Data.

RESULTS

Heritability

In collaboration with 23andMe and the BLTS cohort, we conducted three separate genome-wide association study meta-analyses (GWAMAs) of the Eyes Test: a males-only GWAMA ($n=44,088$), a females-only GWAMA ($n=45,465$) and a non-stratified GWAMA ($n=89,553$). The study protocol is provided in Figure 1. All participants from the 23andMe cohort completed the full version of the Eyes Test online, comprising 36 questions (mean score = 27.47 ± 3.67), while participants from the BLTS cohort completed the short version of the Eyes Test (14 questions,

mean = 8.85 ± 2.34) (Supplementary Note Section 1). Scores on the Eyes Test were significantly associated with age and sex in the 23andMe cohort (age: -0.026 ± 0.0007 ; $P < 2.2 \times 10^{-16}$, sex (females): 0.77 ± 0.02 ; $P < 2.2 \times 10^{-16}$). We used LDSR to calculate the heritability explained by all the SNPs in HapMap3 with minor allele frequency $> 5\%$. We identified a significant narrow sense heritability of 5.8% (95% CI: 4.5%–7.2%; $P = 1.00 \times 10^{-17}$) in the non-stratified GWAMA. We calculated the twin heritability from 749 twin individuals (including 122 complete monozygotic pairs and 176 complete dizygotic pairs) in the BLTS. Heritability, from the best-fitting additive genes/unique environment (AE) model, was 28% (95% CI: 13%–42%) (Supplementary Note Section 4).

Genetic correlation

We next investigated how the non-stratified Eyes Test is genetically correlated to psychiatric conditions and specific psychological and cognitive traits for which summary GWAS data were available (Supplementary Table 5). After correcting for multiple testing (Bonferroni correction $\alpha = 2.08 \times 10^{-3}$), we identified significant positive genetic correlations between Eyes Test scores and the NEO-Five Factor Inventory measure of openness ($r_g = 0.54 \pm 0.14$; $P = 1.17 \times 10^{-4}$),³⁰ We also identified significant positive correlations with different measures of cognition and education: college years ($r_g = 0.40 \pm 0.06$; $P = 2.48 \times 10^{-11}$),³¹ educational attainment (0.34 ± 0.04 ; $P = 1.49 \times 10^{-17}$),³² and childhood cognitive aptitude (calculated as Spearman's g and is, hence, independent of word knowledge)³³ ($r_g = 0.34 \pm 0.10$; $P = 1.2 \times 10^{-3}$). In addition, we identified a significant positive genetic correlation between the Eyes Test scores and anorexia nervosa ($r_g = 0.25 \pm 0.08$; $P = 1.9 \times 10^{-3}$) (Figure 2). We did not identify a significant genetic correlation between autism and scores on the Eyes Test.

We also investigated if subcortical brain volumes are correlated with performance on the Eyes Test. We used data from the

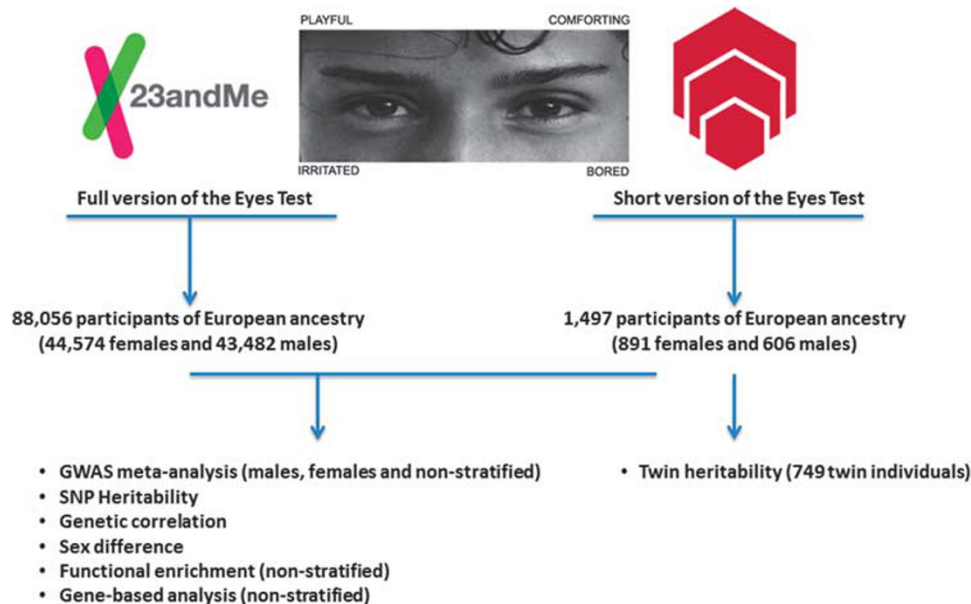

Figure 1. Schematic diagram of the study protocol. 88,056 research participants of European ancestry from 23andMe completed the full version of the Eyes Test and were genotyped. An additional 1,497 participants of European ancestry from the Brisbane Longitudinal Twin Study completed the short version (14 questions) of the Eyes Test and genotyped. Genome-wide association meta-analysis was performed on the combined cohort of 89,553 participants. Three separate meta-analyses were performed: males-only, females-only and non-stratified. Subsequently, functional enrichment and gene-based analysis was performed for the non-stratified GWAMA. SNP heritability and genetic correlation using LDSR was performed for the GWAMA. Sex differences were also investigated using the same data set. In parallel, twin heritability was calculated from 749 twin individuals from the Brisbane Longitudinal Twin Study who had completed the short version of the Eyes Test. GWAMA, genome-wide association study; GWAS, genome-wide association study; LDSR, Linkage Disequilibrium Score regression; SNP, single nucleotide polymorphism.

Figure 2. Genetic correlations between the Eyes Test and psychiatric conditions, psychological traits and subcortical brain volumes. Genetic correlations and standard errors for the Eyes Test (GWAMA). Figures above the bars represent *P*-values. All *P*-values with $P < 0.05$ provided. * represents significant genetic correlations after Bonferroni correction. Point estimate represents the genetic correlation, and the error bars represent the standard errors. BPD features is borderline personality disorder features, ICV is intracranial volume. We have removed the genetic correlation for agreeableness from this figure due to the high standard errors. The genetic correlations, standard errors and *P*-values for all traits including agreeableness are provided in Supplementary Table 5.

ENIGMA consortium for six subcortical regions and intracranial volume.²⁵ We excluded the amygdala, even though it is relevant for social cognition, as the low heritability of the amygdala could not be accurately quantified using LDSR.²³ None of the correlations were significant after Bonferroni correction. However, we identified nominally significant positive correlation between the Eyes Test scores and the volumes of the caudate nucleus²⁵ ($r_g = 0.24 \pm 0.09$; $P = 9.25 \times 10^{-3}$) and volume of the putamen ($r_g = 0.21 \pm 0.08$; $P = 1.33 \times 10^{-2}$), which together form the dorsal striatum. All genetic correlations are provided in Supplementary Table 5.

We also investigated sex-stratified genetic correlations between the Eyes Test and educational attainment, the only relevant phenotype where we had access to sex-stratified data. We

identified a modest, significant genetic correlation between educational attainment and the Eyes Test in the males-only data set: $r_g = 0.23 \pm 0.05$; $P = 2.6 \times 10^{-3}$. We identified a higher, significant genetic correlation between educational attainment and Eyes Test in the females-only data set: $r_g = 0.39 \pm 0.06$; $P = 5.88 \times 10^{-11}$. These results suggest that females share greater pleiotropy between general cognition and cognitive empathy than males, indicating different genetic mechanisms for the development of cognitive empathy.

Genome-wide association meta-analyses

GWAMA of the non-stratified and the males-only data sets did not identify any significant loci. In the females-only analysis, we identified one locus at 3p26.2 that was significant at a threshold of

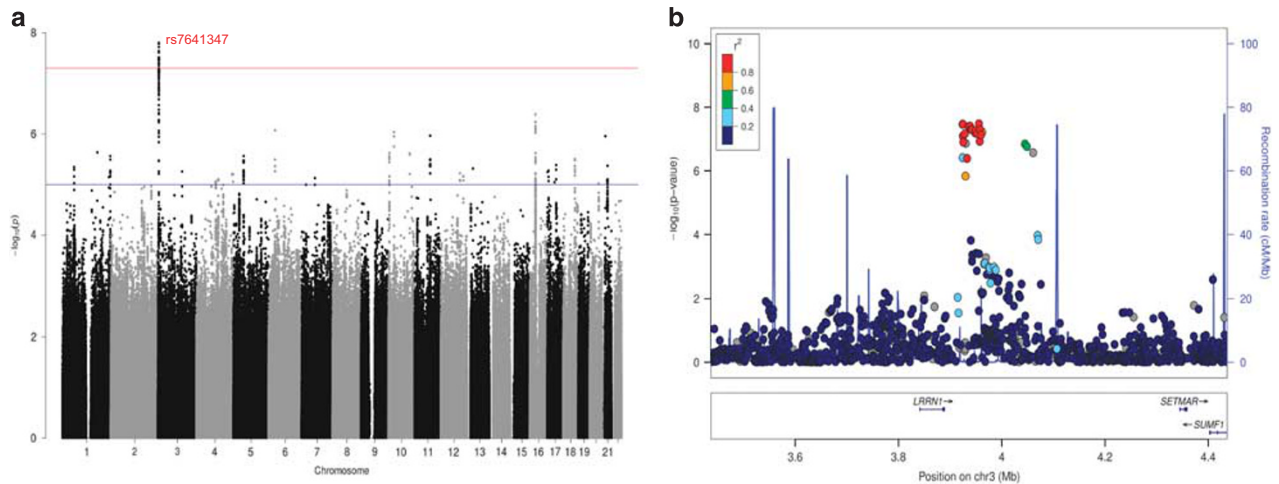

Figure 3. Manhattan plot and regional association plot for the Eyes Test (females) meta-analysis GWAS. **(a)** Manhattan plot of the Eyes Test meta-analysis (female). x axis is the chromosomal position of the SNP, and y axis is the negative logarithm of the P -value. The red line indicates genome-wide significant threshold of 5×10^{-8} . Lead SNP for all loci with $P < 1 \times 10^{-6}$ is provided. $n = 44,574$, and $\lambda_{GC} = 1.05$. LDSR intercept = 1.01. **(b)** Regional association plot of the significant locus for the Eyes Test (females) meta-analysis. GWAS, genome-wide association study; LDSR, Linkage Disequilibrium Score regression; SNP, single nucleotide polymorphism.

$P < 5 \times 10^{-8}$. This locus contains 21 significant SNPs in high LD (Figure 2), with concordant effect direction for 19 SNPs in the 23andMe and BLTS data sets. The leading SNP rs7641347 ($P_{meta} = 1.58 \times 10^{-8}$) explained 0.067% of the total variance, which reduced to 0.013% of the total variance after correcting for winner's curse.²⁶ Of the two SNPs with discordant effects in the two data sets, rs114076548 was the most-significant SNP in the 23andMe data set and had $P = 6.49 \times 10^{-9}$. We did not identify any inflation in the P -values of the GWAMA due to population stratification using LDSR (intercept = 1.01 ± 0.007) (Figure 3).

The leading SNP (rs7641347) is located in an intron of *SUMF1* and was nominally significant in the non-stratified analysis ($P_{meta} = 1.1 \times 10^{-5}$), but non-significant in the males-only analysis ($P_{meta} = 0.49$). In addition, SNPs in high LD ($r^2 > 0.8$) were also not nominally significant in the males-only analysis. Together, all 21 SNPs span a region of approximately 77 kb 3p26.2 (Supplementary Table 1). At this locus, in addition to *SUMF1*, two other genes are present: Leucine Rich Neuronal 1 (*LRRN1*) and SET Domain And Mariner Transposase Fusion Gene (*SETMAR*). *LRRN1* is highly expressed in brain tissues,³⁴ with highest median expression in the putamen, nucleus accumbens and the caudate nucleus, all three of which are part of the striatum. Deletion of 3p26.1 and 3p26.2 can cause developmental delay, hypotonia and epileptic seizures and has been implicated in autism.³⁵

The most significant SNP in the males-only GWAS meta-analysis (rs4300633 in 16p12.3, $P = 9.11 \times 10^{-8}$) explained 0.062% of the variance, and the most significant SNP in the non-stratified GWAS meta-analysis (rs149662397 in 17q21.32 $P = 1.58 \times 10^{-7}$) explained only 0.029% of the variance. All LD-pruned SNPs in the three GWAMA analyses with $P < 1 \times 10^{-6}$ are provided in Supplementary Table 2. The QQ-plot and locus-zoom plot for the females-only meta-analysis, and the Manhattan and QQ-plots for the males-only and non-stratified analyses are provided in Supplementary Note section 5. Gene-based analyses using MetaXcan²⁹ for 10 neural tissues (Materials and methods) and functional enrichment analyses for the non-stratified GWAMA did not identify any significant results (Supplementary Tables 3 and 4).

Sex differences

We also investigated sex-differences in the Eyes Test. There was a significant female advantage on the scores of the full Eyes Test

(males = 27.08 ± 3.75 ; females = 27.85 ± 3.55 ; Cohen's $d = 0.21$, $P < 2 \times 10^{-16}$), replicating previous results³⁶ (Figure 4). There was no significant difference in males-only or females-only SNP heritability estimates (males = $7.1\% \pm 1.1\%$, females = $6.7\% \pm 1.1\%$; $P = 0.79$). There was a reasonably high but incomplete genetic correlation between males and females ($r_g = 0.68 \pm 0.12$; $P = 2.70 \times 10^{-8}$). Binomial sign test of LD-pruned nominally significant SNPs in the sex-stratified analyses identified that 61% (95% CI: 59–62%) of the SNPs had a concordant effect direction ($P < 2.2 \times 10^{-16}$). We further investigated the effect direction and statistical significance of all independent SNPs with $P < 1 \times 10^{-6}$. SNPs that were of suggestive significance in one sex were not nominally significant in the other (Supplementary Table 2 and Supplementary Note section 5), which was supported by Cochran's Q-value. However, the effect sizes of these SNPs are likely to be inflated by winner's curse, and after correcting for winner's curse, we did not identify significant Cochran's Q-value (Supplementary Table 2). We do note that the correction is conservative. Using MetaXcan²⁹ we identified the top cortically expressed genes ($P < 0.05$) for both sexes and calculated the overlap in the genes. We did not find any enrichment in gene overlap (Fold difference = 1.2, $P = 0.264$). We also investigated if there was an enrichment of female-overexpressed or male-overexpressed cortical genes for the Eyes Test (Materials and methods) and did not find any significant enrichment (Supplementary Note section 3 and Supplementary Tables 6 and 7).

DISCUSSION

To the best of our knowledge, this is the first large-scale genetic study investigating the genetic architecture of cognitive empathy. We investigated heritability estimates of the Eyes Test in two samples. In our sample of 749 twin individuals (which included 122 complete monozygotic pairs and 176 complete dizygotic pairs), heritability was approximately 28% (95% CI: 13%–42%). This is in keeping with previous studies that have investigated heritability of other facets of empathy in twins. A meta-analysis of empathy in twins identified that approximately a third of the variance is heritable.³⁷ In our sample of 88,056 unrelated research volunteers from 23andMe, SNP-based heritability was estimated using LDSR, and approximately 5% of the trait was additively heritable. It is likely that heritability of cognitive empathy changes

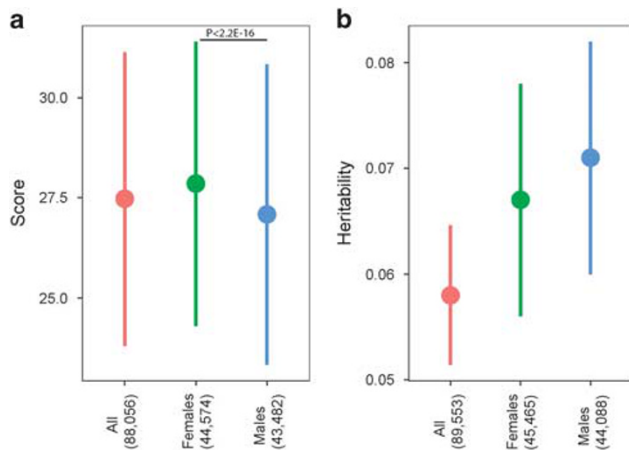

Figure 4. Mean scores and SNP heritability. **(a)** Mean phenotypic scores and standard deviations for the Eyes Test in the 23andMe cohort. Point estimate provides the mean score, and the error bars represent standard deviations. Difference in mean scores between males and females was highly significant ($P < 2.2 \times 10^{-6}$; Cohen's $d = 0.21$). Numbers in brackets indicate the number of participants in each GWAS. All: non-stratified GWAS; Females: Females-only GWAS; Males: Males-only GWAS. **(b)** Mean SNP heritability estimates and standard errors for the Eyes Test in the GWAMA. Point estimate provides mean SNP heritability, and error bar represents standard errors. There was no significant difference in SNP heritability estimates between males and females ($P = 0.79$). Numbers in brackets indicate the number of participants in each GWAMA. All: non-stratified GWAMA; Females: Females-only GWAMA; Males: Males-only GWAMA. GWAMA, genome-wide association study meta-analyses; GWAS, genome-wide association study; SNP, single nucleotide polymorphism.

with age (which was significantly correlated with scores on the Eyes Test in this data set), as is observed in prosocial behavior.³⁷ In our analyses, age was included as a covariate, and thus our SNP heritability estimate is likely to represent the lower bound of the SNP heritability.

We identified significant positive genetic correlations with different measures of cognitive ability including educational attainment. This reflects the phenotypic correlation between measures of cognitive empathy and cognitive ability. A meta-analysis has identified a significant positive correlation between scores on the Eyes Test and IQ ($n = 3583$; $r = 0.24$; 95% CI: 0.16–0.32),³⁸ perhaps reflecting that the Eyes Test has a verbal component that includes a varied mental state lexicon (matching a mental state word to an emotional expression). Other tests of theory of mind are also positively correlated with cognitive aptitude and measures of intelligence.^{39–41} This may reflect that theory of mind and in particular joint attention in infancy may facilitate language development and learning from others.⁴² Theory of mind may also be related to cognitive aptitude and IQ because we often infer another person's mental state through their speech – speech is the 'print-out' of a person's mind – so verbal IQ and language skills may facilitate theory of mind and vice versa. We also found a significant positive genetic correlation with the NEO-Openness to experience which likely reflects a previous correlation at a phenotypic level between measures of empathy and personality.⁴³ With psychiatric conditions, there was a significant positive correlation with anorexia. One study identified that individuals with anorexia report higher personal distress,⁴⁴ a subscale on a widely used measure of empathy, while other studies have reported that deficits in social cognition in anorexia may be attributable to comorbid alexithymia.⁴⁵ Our research suggests that a genetic contribution to higher cognitive

empathy increases one's genetic risk for anorexia. This warrants further research.

We did not identify a significant genetic correlation between the Eyes Test and autism. This may be due to heterogeneity in performance in the Eyes Test, since only a subset of individuals with autism show impaired performance on the Eyes Test.^{4,13} In addition, the cognitive phenotype of autism involves non-social aspects (such as excellent attention to detail), not just social deficits. A meta-analysis reported global or selective deficits in performance on the Eyes Test in individuals with schizophrenia, anorexia, bipolar disorder and clinical depression, but preserved or even enhanced performance for individuals with non-clinical depression and borderline personality disorder.⁴⁶ However, these studies are typically conducted in small sample sizes. Performance on the Eyes Test may be influenced by multiple factors related to psychiatric conditions, and may not measure a direct causal relationship between psychiatric conditions and cognitive empathy.

We also note the nominally significant genetic correlation between volume of the caudate nucleus, putamen and scores on the Eyes Test. Although the correlations were not significant after Bonferroni correction, this is of potential interest as neuroimaging studies have reported activation in both the putamen⁴⁷ and caudate nucleus⁴⁸ during tasks of social cognition. In humans, the ventral striatum is composed of the nucleus accumbens and olfactory tubercle, whereas the dorsal striatum is composed of the caudate nucleus and putamen. There is some evidence to support the role of the striatum in theory of mind,⁴⁹ and further research is needed to confirm that cognitive and affective empathy utilize different neural circuits. Using larger GWAS samples of subcortical brain volumes will help better understand if common genetic variants contribute to both volumes of the dorsal striatum and cognitive empathy.

We also identified one locus that is significantly associated with empathy in females. The top SNP (rs7641347) had a P -value = 1.58×10^{-8} . One of the closest genes to this locus, *LRRN1*, is highly expressed in striatum according to the GTEx database. However, we were unable to identify any eQTL that specifically linked this locus to the gene. *LRRN1* is a gene that is not well characterized. In chicks, *Lrrn1* is necessary for the formation of the mid-brain hind-brain boundary.⁵⁰ The locus was significant in females, nominally significant in the non-stratified analyses, and non-significant in the males-only analyses, suggesting a sex-specific involvement of this locus in cognitive empathy measured using the Eyes Test. We note that even with approximately 90,000 individuals this GWAMA was underpowered to detect loci of significant effect, owing to the relatively low variance explained per SNP. Future research needs to investigate the functional significance of *LRRN1* in human brain development and its role in neurodevelopmental conditions.

It is also interesting to note that while twin and SNP-based heritability did not vary between the sexes in our study, we replicated the female-advantage on the Eyes Test in the largest sample to date. Sex-stratified analyses also allowed us to investigate the genetic correlation between males and females, and subsequently, sex-specific imputed gene expression in cortical tissues. Male-female genetic correlation was only modest, which was supported by a binomial sign test. In comparison, other traits for which we had sex-stratified data, genetic correlation was considerably higher (for example, self-reported empathy:⁵¹ $r_g = 0.82 \pm 0.16$, systemizing⁵¹: $r_g = 1.0 \pm 0.16$; educational attainment³²: $r_g = 0.91 \pm 0.02$). We also did not identify a significant overlap between the genes identified for the sex-stratified GWAS. All of this suggests that there is some sex specificity in the genetic architecture of cognitive empathy. Investigating how this sex-specific architecture is expressed and interacts with prenatal steroid hormones⁵² will help shed further light on the biological contributions to the female superiority on the Eyes Test.

In conclusion, we identify a genetic locus that is associated with scores on the Eyes Test in females. We identify significant positive genetic correlations between scores on the Eyes Test and three phenotypes: anorexia nervosa, cognitive aptitude and educational attainment, and openness to experience. Phenotypic sex-differences for the Eyes Test may be partly due to different genetic architectures in males and females, interacting with postnatal social experience.

CONFLICT OF INTEREST

David A Hinds and Nadia Litterman are employees of 23andMe, Inc. The remaining authors declare no conflicts of interest.

ACKNOWLEDGMENTS

This study was funded by grants from the Templeton World Charity Foundation, Inc., the Medical Research Council, the Wellcome Trust, the Autism Research Trust, the Institut Pasteur, the CNRS and the University Paris Diderot. V.W. is funded by St John's College, Cambridge, and Cambridge Commonwealth Trust. The research was carried out in association with the National Institute for Health Research (NIHR) Collaboration for Leadership in Applied Health Research and Care East of England at Cambridgeshire and Peterborough NHS Foundation Trust. The views expressed are those of the author(s) and not necessarily those of the NHS, the NIHR or the Department of Health. The research was supported by the National Human Genome Research Institute of the National Institutes of Health (grant number R44HG006981). The National Science Foundation (grant numbers 0729493 and 0721707) supported the research on the Brisbane Longitudinal Twin Study. F.U. was supported by the British Friends of Haifa University, the Israel Science Foundation (grant no. 449/14), the British Friends of Hebrew University and the Joseph Levy Charitable Foundation. T.B. was supported by the Institut Pasteur, the University Paris Diderot, CNRS, and the Bettencourt-Schueller Foundation. We acknowledge with gratitude the generous support of Drs Dennis and Mireille Gillings in strengthening the collaboration between SBC and TB, and between Cambridge University and the Institut Pasteur. This publication was made possible through the support of a grant from the Templeton World Charity Foundation, Inc.
