

Stress-related mucosal disease in the critically ill patient

Marc Bardou, Jean-Pierre Quenot and Alan Barkun

Abstract | Bleeding from stress-related mucosal disease in critically ill patients remains an important clinical management issue. Although only a small proportion (1–6%) of patients admitted to an intensive care unit (ICU) will bleed, a substantial proportion exhibit clinical risk factors (mechanical ventilation for >48 h and a coagulopathy) that predict an increased risk of bleeding. Furthermore, upper gastrointestinal mucosal lesions can be found in 75–100% of patients in ICUs. Although uncommon, stress-ulcer bleeding is a severe complication with an estimated mortality of 40–50%, mostly from decompensating an underlying condition or multiorgan failure. Although the vast majority of patients in ICUs receive stress-ulcer prophylaxis, largely with PPIs, some controversy surrounds their efficacy and safety. Indeed, no single trial has shown that stress-ulcer prophylaxis reduces mortality. Some reports suggest that the use of PPIs increases the risk of nosocomial infections. However, several meta-analyses and cost-effectiveness studies suggest PPIs to be more clinically effective and cost-effective than histamine-2 receptor antagonists, without considerable increases in nosocomial pneumonia. To help clinicians use the most appropriate strategy for treatment of patients in the ICU, this Review presents the latest information on all aspects of stress-related mucosal disease.

Bardou, M. *et al.* *Nat. Rev. Gastroenterol. Hepatol.* **12**, 98–107 (2015); published online 6 January 2015; doi:10.1038/nrgastro.2014.235

Introduction

Critically ill patients are at risk of bleeding from stress-related mucosal disease (SRMD),¹ which is an important clinical problem.^{2,3} Patients who experience SRMD have a prolonged stay in intensive care and an increased risk of mortality.^{4–6} Even though the true incidence is debated, only a small proportion of critically ill patients will actually bleed.^{7,8} For example, a cohort study conducted in Germany and published in 2014 found a bleeding rate of 0.9%.⁶ Nevertheless, the clinical factors that predict a higher risk of bleeding are increasingly found among patients admitted to an intensive care unit (ICU).^{3,7,8} Stress-ulcer prophylaxis (SUP) has been found to be efficacious and is thus considered as a standard of care in the ICU, included in the mnemonic FASTHUG (Feeding, Analgesia, Sedation, Thromboembolic prophylaxis, Head of bed elevation, stress Ulcer prophylaxis, Glucose control) that was developed by ICU physicians to ensure that key aspects of care are addressed during each patient encounter.⁹ Histamine-2 receptor antagonists (H2RAs) have been found to be efficacious in preventing SRMD bleeding in the ICU setting, as have PPIs.^{3,7,8,10} Their comparative efficacies, the possible development of nosocomial pneumonia and cost-effectiveness remain subjects of controversy, with disparate data in the literature.^{10–12} Therefore, uncertainty over whether routine SUP is indicated in critically ill patients still exists among clinicians in 2014. In this Review, the latest information on all aspects of SRMD are provided as an overview.

Epidemiology of stress-ulcer bleeding

Endoscopies performed within 72 h of the onset of illness have shown that 75–100% of critically ill patients exhibit gross gastric lesions.¹³ Lesions are most often diffuse subepithelial haemorrhages and erosions; however, if massive bleeding occurs it suggests that an ulcer has developed.²

Many definitions of stress-ulcer bleeding have been put forward since it was first described in 1969.¹⁴ Although occult bleeding, as defined by guaiac stool positivity in samples from nasogastric tube or emesis, has been proposed as a working definition of stress-ulcer bleeding, the more relevant clinical presentation is that of overt bleeding manifesting as haematemesis, coffee ground emesis, melena, or bloody nasogastric aspirate. Pooled results from 10 randomized trials of prophylactic therapy (versus placebo or no therapy) performed from 1980 to 1998 suggested an incidence of 17% for stress-ulcer bleeding.² However, in reports from the past 10 years, the incidence of SRMD-associated clinically significant bleeding or stress-ulcer bleeding (variably defined to include overt bleeding combined with transfusion, haemodynamic instability and/or the need for intervention) has markedly decreased. Indeed, from a pooled estimate of 8% in older randomized trials,² with the advent of improved care of critically ill patients, appropriate prophylactic therapy and increasing use of enteral feedings,^{1,7,15,16} the reported pooled incidence in what are principally trials, published between 1993 and 2010, or retrospective analyses spanning over the same time frame, is now <1%.^{6,17,18} Nonetheless, SRMD and clinically significant bleeding remain important clinical problems as the associated mortality is high, related primarily to the patients' underlying illness.

Key points

- Prevalence of clinically important stress-ulcer bleeding is low (~1%), but because of its severity it remains an important issue
- Prophylaxis for stress-ulcer bleeding should be restricted to patients with acknowledged risk factors because of the risk of nosocomial infection
- Despite controversies, PPIs seem to be the most clinically effective and cost-effective strategy
- Randomized clinical trials and observational studies are needed to assess new preventive strategies and to adapt therapeutic management approaches of upper gastrointestinal bleeding to the intensive care unit setting
- Stress-ulcer prophylaxis is being overused; two-thirds of patients without risk-factors receive treatment, two-thirds continue treatment upon transfer from the intensive care unit and one-third are discharged home on treatment without a new indication

Risk factors for SRMD

Critically ill patients are at increased risk of developing SRMD and subsequent stress-ulcer bleeding as a result of both underlying disease and therapeutic intervention. In a multicentre study of 2,252 patients, Cook *et al.*⁴ identified respiratory failure (defined as the need for mechanical ventilation for at least 48 h) and coagulopathy (defined as a platelet count of <50,000 platelets per ml³, an international normalized ratio [INR] >1.5, or a partial-thromboplastin time of more than two times the control value) as strong independent risk factors for SRMD, with an odds ratio (OR) of 15.6 and 4.3, respectively. Another analysis from the same group published in 1999 identified renal failure, as assessed by maximum serum creatinine level, as an independent predictor of upper gastrointestinal bleeding (UGIB) in patients requiring mechanical ventilation; enteral nutrition and stress-ulcer prophylaxis with ranitidine were shown to confer significant protective effects (RR = 0.30; 95% CI 0.13–0.67, $P = 0.04$ and 0.39; 0.17–0.83, $P = 0.24$, for enteral nutrition and ranitidine, respectively).¹⁹ However, these risk factors were defined more than 20 years ago.⁴ Other factors have since been reported to be associated with increased risk of SRMD, such as age >50 years, maximum serum creatinine levels, acute and chronic hepatic injury, sepsis, shock, or male gender. Indeed, numerous reviews of the literature have been published on this topic over the past 20 years.^{8,16,19–26} According to the American Society for Health-System Pharmacists guidelines, major risk factors—such as mechanical ventilation and coagulopathy—are only found in a minority of patients admitted to the ICU.²⁷ The main risk factors for SRMD are summarized in Table 1.

Pathophysiology of SRMD

SRMD is a multifactorial disease of which the underlying mechanisms are not fully understood. Briefly, an intricate system of interactions ultimately causes a breakdown of the mucosal protective defences, leading to injury of the gastrointestinal wall and ulceration from aggressive physiological factors (Figure 1).^{17,26} Generally, SRMD lesions are located in the acid-producing areas of the stomach (that is, the upper body and fundus).

The structural integrity of the gastric mucosa is maintained by defence mechanisms,²⁸ including the

production of prostaglandins, mucin glycoproteins, water, bicarbonates, trefoil factor family peptides, phospholipids and heat-shock proteins (HSPs), particularly HSP70.^{28–31} Prostaglandins stimulate mucosal blood flow, and mucus and bicarbonate production, thereby enhancing epithelial cell growth and repair.³² The mucous bicarbonate barrier forms a physical barrier against the influx of luminal acid and pepsin, and is also important in trapping bicarbonate anions that have diffused from the gastric epithelial cells.²² Bicarbonate is powerful enough to neutralize the pH within the mucus gel on the epithelial cell surface despite a luminal pH of 1.5–2.0.^{33,34} Gastric epithelial cell restitution (or re-epithelization) is a defensive mechanism whereby rapid, energy-dependent migration of epithelial cells occurs towards areas of superficial damage, leading to the restoration of epithelial integrity.²² Oxygen free-radical formation³⁵ and physiological stress³⁶ have been implicated in reducing the rate of cellular proliferation and gastric epithelial restitution.

Among the aggressive physiological factors that might act to break down the mucosal protective defences, splanchnic hypoperfusion (or gastric mucosal ischaemia) is thought to be the major underlying cause of SRMD in critically ill patients.³⁷ The shunt of blood away from the viscera and skin is an adaptation to stress that aims to preserve perfusion to the vital organs during an insult. Temporary shunting of visceral blood flow is well tolerated; however, it becomes maladaptive, as it results in lesions, when prolonged. MacLaren and colleagues³⁸ showed that shock or hypotension is associated with a small but significant increased risk of gastrointestinal haemorrhage (OR, 1.17; 95% CI 1.04–1.33) whereas hypertension seems to be protective (OR, 0.77; 95% CI 0.67–0.87). Gastric mucosal perfusion decreases early during critical illness^{39,40} owing to a number of factors: activation of the sympathetic nervous system; increased catecholamine release and vasoconstriction, notably within the gastrointestinal tract; hypovolaemia; decreased cardiac output; release of proinflammatory cytokines;^{41–44} and impaired production of nitric oxide.^{35,45} Decreased microcirculation in the gastrointestinal tract is even more likely to be observed in patients with sepsis,³⁹ even if sepsis is not unanimously described as an independent risk factor for SRMD.^{4,38} As a consequence of splanchnic hypoperfusion gastrointestinal motility is decreased,⁴⁶ delaying the removal of acidic material and other irritants from the stomach, prolonging exposure to gastric acid and resulting in a corresponding increase in the risk of ulceration.^{37,43,44}

The factors favouring gastroduodenal mucosal damage in patients in the ICU are a decrease in the washout effect⁴⁷ leading to local intramural acidosis, increased free-radical formation,^{48,49} decreased acid-buffering capacity,⁵⁰ a decrease in mucus and bicarbonate secretion,^{49,51–53} and possibly a defect in epithelial cell restitution.⁵⁴ The end result of these effects is an increase in H⁺ ion back-diffusion and disruption of the epithelial barrier,^{37,47,50,55,56} ultimately allowing injury to the gastric mucosa. Pepsin might cause direct injury to the gastric mucosa, but

Table 1 | Risk factors for stress-ulcer bleeding from multiple regression analysis

Reference	Risk factor for stress related mucosal damage*	OR (95% CI or P value)

MacLaren <i>et al.</i> (2014) ²⁷	Sex: male versus female	1.17 (1.03–1.33) [‡]

*Other risk factors that were identified by simple regression analysis, but lost statistical significance after multiple regression include: hypotension; sepsis; hepatic failure; glucocorticoid administration; and anticoagulation therapy. [‡]Propensity score odds ratio. Abbreviation: INR, international normalized ratio.

becomes inactive if the pH is >4.5.³⁷ In addition, pepsin facilitates the lysis of clots, which could enhance bleeding from SRMD.^{57,58}

Pharmacological prophylaxis of SRMD

Initiation of SUP using acid-suppressants in the ICU setting is now established practice. Two landmark studies published in 1994 and 1999 by the Canadian Critical Care Trials Group serve as the benchmark for SUP in this context,^{4,20} and 1999–2010 estimates indicate that ~90% of patients in ICU receive some type of SUP.⁶ The different approaches to prevent SRMD-related bleeding are based on the understanding of the pathophysiology and recognized risk factors described earlier.

Effect on mortality

Results from randomized clinical trials

No single study or meta-analysis has reported a decreased overall mortality related to SUP approaches. To our knowledge, Krag and colleagues⁵⁹ have published the most recent meta-analysis of randomized clinical trials comparing SUP versus placebo or no prophylaxis in 2014. In this analysis, 20 trials totalling 1,971 patients were included; all studies were judged as being at high risk of bias as advised by the Cochrane Collaboration. Among these 20 randomized controlled trials (RCTs), 16 were single-centre trials, 18 assessed H2RAs and two assessed PPIs. Using overall mortality as a primary end point, no statistically significant difference was reported between patients receiving SUP and those receiving no prophylaxis or placebo (fixed effect relative risk [RR] 1.00; 95% CI 0.84–1.20; *P* = 0.87; *I*² = 0%).⁵⁹ Similarly, no difference was observed between treatment versus placebo across all subgroup analyses; for example when assessing H2RAs or PPIs, or patients fed enterally or

not. Of note, after the inclusion of old studies (16 of 20 were published before 1994), the meta-analysis mostly assessed H2RAs and was unable to accurately compare PPIs to H2RAs. Furthermore, in two meta-analyses published in 2012 and 2013—which included 13 RCTs totalling 1,587 patients¹⁰ and 14 RCTs totalling 1,720 patients,¹² respectively—PPIs were not found to be more effective than H2RAs in reducing overall mortality (ICU mortality OR = 1.19; 95% CI 0.84–1.68 and RR = 1.01; 95% CI 0.83–1.24, respectively). A study by Kotlyanskaya *et al.*⁶⁰ (published in abstract form) was not included in the meta-analysis by Barkun *et al.*¹⁰ and is the only difference between the two meta-analyses.

Data from observational cohorts

Few reports are available on the effect of SUP on overall or ICU mortality rates. A retrospective cohort study, published in 2014, used information from the Colorado Multiple Institutional Review Board and analysed data from 35,312 patients requiring mechanical ventilation for >24 h.³⁸ Propensity-score-adjusted and propensity-score-matched multivariate regression models suggested that PPIs were associated with an increased risk of death in the ICU compared with H2RAs (15.3% versus 12.3%, respectively; *P*<0.001).³⁸ Unfortunately, this study cannot conclude on causation because of its design and the inability to completely remove confounding factors; moreover, the authors did not assess patients in the ICU who did not receive SUP and thus the net effect of PPIs or H2RA cannot be estimated.

Prevention of bleeding

Results from randomized clinical trials

Results are more consistent in supporting a role for SUP in reducing the risk of gastrointestinal bleeding. In the Krag *et al.*⁵⁹ meta-analysis, the risk of bleeding in the ICU was reduced by 59% (fixed effect RR 0.41; 95% CI 0.31–0.53) in patients treated with SUP compared with those treated with placebo or no prophylaxis. Interestingly, the meta-analysis by Barkun *et al.*¹⁰ suggested the same magnitude of reduced risk of bleeding in patients treated with PPIs compared with those treated with H2RAs (OR = 0.30; 95% CI 0.17–0.54), as did the meta-analysis by Alhazzani *et al.*,¹² showing that both clinically important RR = 0.36; 95% CI 0.19–0.68) and overt bleeding (RR 0.35; 95% CI 0.21–0.59) were reduced in patients treated with PPIs compared with those treated with H2RAs. On the contrary, another meta-analysis published in 2010 did not find strong arguments in favour of PPIs over H2RAs for stress-related UGIB or for mortality.¹³

Data from observational cohorts

SUP has become the standard of care in the ICU, sometimes irrespective of the presence of risk factors; the benefit of SUP using real-world data is therefore not easy to estimate because of the absence of a control group. A retrospective single-centre German study published in 2014, in which 91.3% of the patients received SUP (mostly PPIs), did not suggest any difference in terms of bleeding between no treatment and any of the SUP

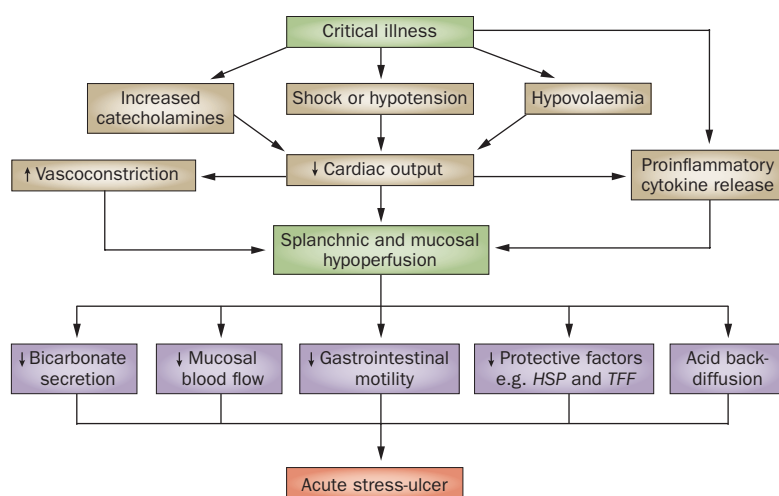

Figure 1 | Pathophysiology of stress-ulcer bleeding. Abbreviations: HSP, heat shock proteins; TFF, trefoil factor family peptides. Adapted with permission from Elsevier © Stollman, N. & Metz, D, *J. Crit. Care* 20, 35–45 (2005).

agents that were used (including combinations of PPIs and H2RAs, PPIs and sucralfate or any other combination).⁶ The retrospective cohort study by MacLaren *et al.*,³⁸ described earlier, suggested that PPIs were associated with a greater risk of gastrointestinal haemorrhage than H2RAs (34% versus 30.7%, respectively; $P < 0.001$). As this finding contradicts the hypothesis that stronger acid suppression reduces gastrointestinal bleeding, the study authors suggest that whereas both drug classes inhibit acid production, H2RAs might also limit reperfusion injury, possibly reducing oxidative stress after mucosal injury.³⁸ To conclude, in patients with recognized risk factors, good evidence supports the use of PPIs to prevent stress-ulcer bleeding.

Evidence for adverse events caused by SUP

The acidity of gastric contents represents the major control factor for bacterial survival in the stomach. Gastric and duodenal bacterial overgrowth frequently occurs in conditions characterized by diminished gastric acid secretion.⁶¹ Thorens *et al.*⁶² conducted an RCT in which 47 outpatients were randomly allocated to receive 4 weeks of 20 mg omeprazole or 800 mg cimetidine, daily. Bacterial overgrowth, assessed by culture of gastroduodenal contents, was present in 53% of the patients receiving omeprazole and 17% of those receiving cimetidine. A subsequent study also showed that both PPIs and H2RAs induced bacterial overgrowth, with a substantially more-pronounced effect with PPIs than H2RAs.⁶³ Furthermore, leucocyte function might be impaired in patients taking PPIs because of an inhibition of reactive oxygen intermediate production with consequential reduction of neutrophil bactericidal activity.⁶⁴ The two types of infections most frequently discussed with the use of acid-suppressive agents are nosocomial (or ventilator-associated) pneumonia and diarrhoea associated with *Clostridium difficile* infection. The association between the use of acid-suppressive agents and community-acquired or hospital-acquired

infections,^{10,65–67} and *C. difficile* infection and recurrence,^{68–73} are sources of ongoing controversy because of methodological limitations in study design.

Results from randomized clinical trials

Two meta-analyses published in 2012 and 2013 of RCTs comparing SUP agents did not provide evidence of an increased risk of nosocomial pneumonia attributable to PPIs. Indeed, the ORs were 1.05 (95% CI 0.69–1.62)¹⁰ and 1.06 (95% CI 0.73–1.52).¹² Interpretation of these results must be performed with caution as only seven studies reported on nosocomial pneumonia. Interestingly, the meta-analysis that compared prophylaxis to placebo or no prophylaxis did not suggest any increased risk of nosocomial pneumonia in the prophylaxis group (RR 1.16; 95% CI 0.84–1.58).⁵⁹ One RCT conducted from 2010 to 2011 in Iran, in which 137 patients on mechanical ventilation were randomly assigned treatment with sucralfate or pantoprazole, found a significant increase in the incidence of pneumonia in the pantoprazole group (36.4% versus 14.1%, respectively; $P < 0.001$).⁷⁴ Again, results from this study must be interpreted with caution because of methodological issues. No evidence exists regarding the risk of *C. difficile* infection related to SUP as this association was not a reported outcome in any of the RCTs.

Data from observational cohorts

A 1 day prevalence study conducted in 17 European countries in which 1,417 ICUs provided reports from 10,038 patients showed that 4,501 (44.8%) patients had infections, 2,064 (20.6%) of which were ICU-acquired infections, with Enterobacteriaceae (34.4%), *Staphylococcus aureus* (30.1%) and *Pseudomonas aeruginosa* (28.7%) being the three most frequent.⁷⁵ Pneumonia was the most frequent site of infection, accounting for 47% of the patients. SUP was an independent risk factor for infection (OR 1.38; 95% CI 1.20–1.60).⁷⁵ Buendgens *et al.*⁶ found that PPIs were associated with the occurrence of pneumonia in univariate analysis (OR 1.79; 95% CI 1.47–2.02) but not in multivariate analysis (OR 1.28; 95% CI 0.95–1.73). Sucralfate was confirmed to have a protective effect against infection (OR 0.68; 95% CI 0.50–0.73).⁶ MacLaren *et al.*³⁸ only compared PPIs to H2RAs, finding that PPIs were associated with a significant increase in ICU-acquired pneumonia incidence (34% versus 30.7%, respectively; $P < 0.001$). A case–control study of 110 patients with ventilator-associated pneumonia and 110 ventilated controls without pneumonia did not find SUP to be a significant risk factor for pneumonia (OR 1.01; 95% CI 1.00–1.02; $P = 0.08$).⁷⁶

Cohort or case–control studies published within the past 10 years almost unanimously suggest an increased risk of acquiring *C. difficile* infection in patients receiving SUP in the ICU, even if the absolute risk is small compared with that for nosocomial pneumonia. A case–control study including 67 patients and 134 controls (20 controls and 40 patients with *C. difficile* infection were ICU patients) reported duration of PPI use to be positively associated with the risk of developing *C. difficile*

infection (OR 1.14; 95% CI 1.02–1.27).⁷⁷ Buendgens *et al.*⁶ reported an OR of 3.11 (95% CI 1.11–8.44) for patients receiving PPIs versus no SUP, which is much stronger than the risk associated with the use of third-generation cephalosporins (OR 1.8; 95% CI 1.0–3.23) or fluoroquinolone (OR 1.87; 95% CI 1.1–3.14); no such risk was described for H2RAs. MacLaren *et al.*³⁸ also suggested the risk of *C. difficile* infection to be higher in patients on PPIs than H2RAs (3.4% versus 2.6%, respectively; $P=0.002$). Interestingly, an online survey conducted among Australian and New Zealand intensive care physicians suggests that *C. difficile* is perceived as less of a threat (14% of the physicians perceived *C. difficile* as a threat) than ventilator-associated pneumonia (21% of the physicians).⁷⁸

Risk:benefit ratio of SUP

Defining the risk:benefit ratio of SUP in patients who are critically ill or on mechanical ventilation is not easy, as both bleeding and ICU-acquired infections carry a risk of increased death in ICU (OR 1.59; 95% CI 1.06–2.41 *C. difficile*-associated diarrhoea; OR 1.82; 95% CI 1.52–2.18 nosocomial infection; OR 2.5; 95% CI 1.19–5.25 UGIB).⁶ Overall, mortality might be the best reflection of a risk:benefit analysis. Meta-analyses from RCTs report no effect on mortality, whereas data from observational studies suggest—although not unanimously—that PPIs might increase mortality compared with H2RAs.³⁸ Nevertheless, as there are strong arguments in favour of a protective effect of PPIs in the prophylaxis of stress-ulcer bleeding, with no clearly proven increased risk of adverse events, the risk:benefit ratio of SUP in high-risk patients can be considered positive.

Actual trends in SRMD prophylaxis

Despite the vast number of publications on the topic that have defined the most relevant risk factors for SRMD and discussed the use of sucralfate, PPIs or H2RAs, epidemiological studies published in 2014 highlight that the proportion of patients in ICU receiving SUP is >90% and although most of them receive PPIs, a substantial proportion (up to 20%) receive a combination of different medications, including PPIs and H2RAs.^{6,38,79} Additionally, it has been shown that, although most of the patients receiving SUP in ICU present with at least one recognized risk factor, continuation of acid-suppressive therapy during hospitalization outside the ICU occurs in >86% of patients and that 24.2% are being discharged from the hospital still receiving acid-suppressive therapy.⁸⁰ The cost implications of this issue are discussed later.

Among patients with no risk factors it is indeed of concern that up to 68.1% are being placed on prophylaxis at ICU admission; 60.4% continue treatment upon transfer from the ICU and about 30% are being discharged home on an agent without a new indication.^{79,81}

In conclusion, it seems reasonable to recommend SUP (preferably with PPIs) in high-risk patients, that is, those with well-defined risk factors such as mechanical ventilation for at least 48 h and coagulation disorders.

For patients receiving enteral nutrition or medication of any type there is no reason to prescribe intravenous PPIs, enteral route is the most appropriate. SUP should not be given to low-risk patients because of the potential increased risk of nosocomial infection.

Enteral nutrition for prophylaxis of SRMD

The use of acid blockers or antiseptory agents in patients in the ICU has been questioned because of uncertain efficacy and safety concerns. Furthermore, the rationale for PPI or H2RA use might be considered weak as decreased mucosal blood flow with subsequent tissue ischaemia is thought to be the mechanism responsible for stress-induced gastropathy, with an amplification loop driven by subsequent activation of inflammatory and vasoconstrictive mediators, a mechanism that PPIs and/or H2RA are unlikely to have an effect on. Enteral nutrition has been suggested to improve mucosal blood flow and reverse the generation of these inflammatory mediators.⁸² However, clinical studies evaluating the effectiveness of enteral nutrition versus acid-suppressive medications have shown variable results.⁸³ No RCTs to date have assessed enteral nutrition as SRMD-related bleeding prophylaxis in critically ill patients. One RCT published in the early 1990s only described that additional prophylaxis in the form of sucralfate or ranitidine added no protective effect to total parenteral nutrition alone.⁸⁴

Marik *et al.*¹ performed a systematic review of the literature to investigate the benefits and risks of SUP in the ICU setting and the possible influence of enteral nutrition. A total of 1,836 patients across 17 studies were included in the analysis and they found that the reduced risk of gastrointestinal bleeding with H2RAs (OR 0.47; 95% CI 0.29–0.76) was only observed in patients not receiving enteral nutrition. Furthermore, whereas H2RAs apparently did not carry an increased risk of nosocomial pneumonia in fasting patients, a significant increase in risk was observed among enterally fed patients (OR 2.81; 95% CI 1.2–6.56; $P=0.02$).¹ Similarly, hospital mortality was also found to be increased in patients receiving enteral nutrition and H2RA therapy (OR 1.89; 95% CI 1.04–3.44; $P=0.04$), suggesting that SUP might be unnecessary and possibly deleterious in this patient population.¹ Interestingly, studies originating from the same team have suggested that enteral feeding can either have no effect on clinically important bleeding (multiple regression OR 1.0; $P=0.99$),⁴ or may decrease the risk by 70% (OR: 0.30; 95% CI 0.13–0.67; $P=ns$).²⁰ Unfortunately, shortcomings in the identification of who had received enteral nutrition and the lack of per-patient analyses limit any conclusions that can be made.

Management of UGIB in the ICU

Critical care physician perspective

Most of the guidelines that have been published on managing gastrointestinal bleeding in the ICU are based on the non-ICU literature as there is not enough supporting evidence to specifically develop treatment paths.^{85,86} An urgent need exists to produce evidence as some of the

guidelines published outside the ICU setting⁸⁷ might not be adaptable to patients bleeding in ICU. We describe the management of UGIB in the ICU on the basis of expert opinion.

The management of patients with SRMD is similar to that of other patients in the ICU presenting with non-variceal UGIB, keeping in mind the commonly more severe disease acuity and multiple comorbidities often present in this ICU patient population. Detailed reviews and contemporary consensus recommendations have been published on the management of patients with nonvariceal UGIB.^{85,87–89} The approach might, of course, be altered if the critically ill patient is suspected to have variceal bleeding.⁹⁰ Although airway, breathing and circulation remain the most crucial steps in the initial assessment of patients presenting with acute UGIB, these factors have usually already been optimized in an ICU setting. A minimum blood work-up in all patients should include bloodtyping and crossmatching for an appropriate number of units of packed red blood cells along with determinations of haemoglobin, haematocrit, platelets and electrolyte levels, and coagulation time. Depending on the severity of the acute bleed and if it is indicated (mainly when prothrombin time and factor V are <50% of the normal range), prompt and appropriate resuscitation with either crystalloids or colloids, packed red blood cells and fresh frozen plasma, is required.^{87,88}

Vitamin K, vitamin-K-dependent factors or fibrinogen are usually administered in case of anticoagulant supratherapeutic dosing. Saline or Ringer acetate are preferred to hydroxyethyl starch, as hydroxyethyl starch has been shown to increase the need for renal-replacement therapy in patients in the ICU and might even increase the risk of severe bleeding (RR 1.52; 95% CI 0.94–2.48; $P=0.09$).^{91,92} A systematic review of 10 RCTs comparing restrictive versus liberal red blood cell transfusion strategies in 1,780 patients with suspected UGIB from a variety of clinical settings, including the ICU and patients with SRMD, concluded that a restrictive approach led to a 42% reduction in the probability of receiving transfusions with no effect on mortality, rates of cardiac events, morbidity, or length of hospital stay.⁹³ These data support a restrictive strategy with a haemoglobin transfusional threshold value of <70 g/l for transfusion, which is further strengthened by the results of a recent large RCT in patients with variceal and nonvariceal UGIB published in 2013.⁹⁴ Nevertheless, in critically ill patients a haemoglobin transfusional level ~90 g/l has been proposed, mostly in case of coronary artery disease,⁹⁵ although red blood cell transfusion increases oxygen delivery but not oxygen consumption.⁹⁶ The objective is to maintain mean arterial pressure >65 mmHg and urinary excretion >0.5 ml/kg/h.

Placement of a nasogastric tube might be appropriate in the ICU, mostly to assess for rebleeding as altered gastrointestinal motility and the use of vasopressive drugs might delay exteriorization of bleeding or haemodynamic changes. However, as the negative predictive value of a nasogastric tube aspirate is low, around 60%, its usefulness is questioned.⁹⁷

Enteral nutrition must be stopped and gastric content removed with soft aspiration to enable gastroscopy, or prokinetic agents considered, as discussed later. For the same reason, sedation and analgesia should be reinforced in patients receiving mechanical ventilation. In patients on anticoagulants, coagulopathy is usually reversed, using vitamin K, vitamin-K-dependent factors or fibrinogen; however, this process should not delay early endoscopy, defined as within 24 h of acute UGIB, keeping in mind that endoscopic haemostasis can be safely performed in patients with an elevated INR as long as it is not supra-therapeutic (that is, up to around 2.5).^{87,88} A platelet transfusion threshold of $50 \times 10^9/l$ has been proposed for most patients, with a target of $100 \times 10^9/l$ for patients in whom platelet dysfunction is suspected.⁹⁸

Well-validated risk stratification scoring systems in the setting of UGIB can help identify the ideal time to perform endoscopy.⁹⁹ The Rockall score can be calculated using data for seven pre-endoscopic factors (clinical Rockall) and 11 postendoscopic factors.¹⁰⁰ The use of prokinetics before endoscopy might be considered in selected patients. Indeed, meta-analyses show that erythromycin is associated with a decreased need for repeat endoscopy in patients with evidence of ongoing active bleeding and blood in the stomach (haematemesis, coffee ground vomiting, or bloody nasogastric aspirate).¹⁰¹ However, use of erythromycin has failed to change outcomes in terms of length of stay, transfusion requirements and need for surgery in patients with nonvariceal UGIB.

Although many patients might already be on a PPI in the ICU, it is nonetheless pertinent that a Cochrane systematic meta-analysis found no evidence that pre-endoscopic administration of PPIs led to a reduction in the most important clinical outcomes, but this practice does result in a downstaging of high-risk endoscopic ulcers into low-risk lesions.¹⁰² Therefore, this approach might be cost-effective when early endoscopy is not feasible or local expertise is limited. The use of pre-endoscopic PPIs, however, should not replace appropriate initial resuscitation or delay the performance of early endoscopy.¹⁰³ The optimal dose remains unknown but many clinicians choose to use the high-dose intravenous PPI infusion of an 80 mg bolus followed by 8 mg/h infusion,¹⁰⁴ as the highest quality evidence comes from trials using this regimen.

The gastroenterologist perspective

On the basis of RCT data, current management recommendations for UGIB suggest the performance of early endoscopy within 24 h of presentation.^{87,88} In the ICU a more urgent endoscopy might be considered as it has been suggested that in patients with a Glasgow-Blatchford score >12, mortality is reduced when endoscopy is performed within the first 13 h.¹⁰⁵ In patients with massive haematochezia and/or in case of haemodynamic instability guidelines published in 2006 recommend performing upper endoscopy as soon as possible in the presence of this symptom as it will be a presenting feature in ~10% of patients ultimately found to have an upper gastrointestinal source of bleeding.¹⁰⁶ The treatment of ulcers (if noted at endoscopy) is well defined

and outlined later. The treatment of other lesions, such as Dieulafoy ulcers or mucosal vascular abnormalities has been less well studied, but in the presence of one or multiple lesions that are thought to be the source of bleeding, an assessment of the presence of high-risk stigmata of the lesion(s) is performed. Whether gastroduodenal ulcers, erosions or oesophagitis are noted, if only low-risk stigmata are present, single intravenous PPI therapy is indicated without endoscopic haemostasis. Endoscopic therapy is recommended only for high-risk endoscopic lesions and is the cornerstone of management with modalities that include injection, mechanical and thermal treatments.^{87,88} Haemostatic powders have now been adapted for use in the gastrointestinal tract,¹⁰⁷ resulting in substantial reductions in rebleeding in select patients, but reported benefits on mortality and rates of surgical intervention are variable, although the data are purely observational and patient numbers are limited.^{87,88} Following successful endoscopic haemostasis, PPI therapy has further improved outcomes. A high-dose intravenous PPI approach has been favoured by guidelines (80 mg bolus if the patient has not been on a PPI, followed by 8 mg/h for 72 h); however, the optimal dose and route of administration remain unclear.^{87,88}

The acute management of patients on antiplatelet agents is based on weighing risks and benefits, but RCT data support the early reintroduction of acetylsalicylic acid within 3–5 days of the acute haemorrhage in patients with bleeding ulcers who are taking acetylsalicylic acid for secondary cardiovascular disease prevention.¹⁰⁸ The theoretical interaction between clopidogrel and PPI seems unlikely to be of clinical importance and should not deter physicians from administering PPIs, if clinically indicated.¹⁰⁹ The long-term secondary prophylaxis of patients with SRMD-related bleeding has not been studied, but it is reasonable to at least consider applying the same recommendations as for bleeding ulcers occurring outside the ICU. However, discussion of this idea is beyond the scope of this Review.^{87,88}

Cost considerations and guidelines

In 1995, a Canadian matched cohort study identified clinically important bleeding to be associated with per patient costs of ~CND\$12,215.¹¹⁰ Schupp *et al.*¹¹¹ subsequently performed an economic analysis, but unfortunately limited the costs solely to drug acquisition. More important cost-drivers are known to include possible complications of SRMD and its prophylaxis,¹¹² daily costs and duration of hospital stay, especially in the ICU.

Two decision models have assessed the cost-effectiveness of SRMD prophylaxis using either H2RA or PPI therapies during hospitalization. One study concluded that H2RA therapy seems to reduce costs with comparable survival benefit compared with PPIs for SUP.¹¹³ However, this study adopted mortality as a primary effectiveness measure, an outcome that has not been shown to be affected by SRMD prophylaxis, as discussed earlier.^{10,12} Also, this analysis included the possible complication of *C. difficile* infection, even though this association with PPI use remains highly debated in

the hospital setting.¹¹⁴ The second decision model concluded that PPI prophylaxis was the most cost-effective, in fact economically dominant, prophylactic strategy.¹¹⁵ However, in both cost-effectiveness analyses, the probability of ventilator-associated pneumonia occurrence affected the aforementioned conclusions even though it remains controversial as to whether or not acid suppression increases the risk of this iatrogenic complication. The discrepancy in these conclusions highlights the poor quality, small sample sizes and limited generalizability of contemporary care trials, emphasizing the need for prospective controlled assessments of both bleeding and possible infectious complications.

A number of society guidelines have been published over the past 15 years in an attempt to optimally guide acid-suppression use for SRMD prophylaxis, with most published before the flurry of meta-analytical studies discussed above. These society guidelines include an authoritative set of recommendations by the American Society for Health-System Pharmacists that were developed for the most part before the PPI era.¹¹⁶ In 2008, the Eastern Association for the Surgery of Trauma guidelines suggested no differences in efficacy between H2RAs and PPIs.¹¹⁷ In 2013, although no specific trials have investigated the benefit of SUP in patients with sepsis, the Surviving Sepsis Campaign guidelines favoured the use of PPIs over H2RAs for SRMD prophylaxis.⁹⁶

Although uncertainty exists about the optimal strategy for effective SRMD prophylaxis in high-risk patients, it is well established that antisecretory therapy is not warranted in patients at low risk, as discussed earlier. Although the definitions of inappropriate use have varied among studies and with the publication of the latest meta-analytical data, inappropriate in-hospital use is common. Outside the ICU, in-hospital PPI use has been shown to vary between 50% and 60% of patients, with 18–34% of patients erroneously discharged on a PPI into the community with attendant inpatient and outpatient costs.⁷⁷ A retrospective chart review of 1,769 patients admitted to family medicine and general internal medicine teaching services demonstrated an inappropriate in-hospital acid-suppressive agent use of 22.1% (presumably in large part because of unjustified concerns of SRMD).¹¹⁸ In total, 54% of these patients were discharged on antisecretory medication that were deemed unnecessary upon audit review, with an estimated annual inpatient and outpatient cost of US\$67,000. A 2010 analysis of a US national administrative database demonstrated a ~69% rate of inappropriate prescribing for SRMD prophylaxis in ICU or Coronary Care Unit.¹¹⁹ Resulting overall hospital and discharge medication costs might reach US\$753,267 per year nationally over the 30 days after leaving the hospital.¹¹⁸

Although early interventional studies suggested that the implementation of guidelines might impact favourably on practice and resource utilization in the ICU,^{120,121} a 2013 national cluster RCT demonstrated no differences in hospital use of PPIs for nonvariceal UGIB following a structured multidisciplinary multifaceted educational intervention.¹²²

New approaches

New therapeutic approaches might be assessed based on an improved understanding of the underlying mechanisms. For example, increasing gastrointestinal microvascular blood flow might be beneficial. As discussed previously, improved management of cardiac output in the ICU can explain the decrease in SRMD over time, although the link between recognized risk factors, such as sepsis, and SRMD might not involve decreased microcirculation.¹²³ As reported in a 2014 review, several studies have attempted to increase microcirculatory flow parameters but with limited efficacy.¹²⁴ Other pharmacological options to prevent SRMD can be hypothesized based on its pathophysiology. For example, gastric bicarbonate secretion is stimulated by nitric oxide in a process that involves cyclic GMP, under the control of phosphodiesterase 1 and 5; phosphodiesterase 5 inhibitors, such as sildenafil, might increase bicarbonate secretion. Additionally, phosphodiesterase 5 inhibitors might increase mucosal blood flow, as it has been shown that vardenafil protects the digestive tract after ischaemia-reperfusion injury.¹²⁵ As HSPs (mostly HSP70) protect the gastric mucosa through inhibition of apoptosis, pro-inflammatory cytokines and cell adhesion molecules, regulators that enhance HSP70 expression could represent interesting agents for the prevention of SRMD. Unfortunately, most of the HSP70-targeted compounds that are being developed are inhibitors.¹²⁶ Moreover, it is highly challenging to design and power clinical trials aimed to compare new therapeutic options to PPIs or H2RAs. Indeed, with an actual prevalence of SMRD of ~1%, more than 10,000 patients would have to be included to prove a 50% relative risk reduction.

Conclusions

Stress-ulcer bleeding is an increasingly less frequent condition in the contemporary era of markedly improved overall care for critically ill patients. However, SRMD is

still associated with substantial mortality and costs, and prospective trials comparing modern-day prophylactic approaches, including enteral nutrition, are needed. The almost universal (>90%) prescription of SUP in critically ill patients must be questioned and the risk:benefit ratio reassessed because of the decrease in incidence of SMRD. In addition to randomized trials, there is a need for prospective cohort studies to better quantify and understand outcomes in the real-world setting.

Treatment strategies need to be evaluated on a case-by-case basis, taking into account the expected benefits of therapy balanced against the patient's risk factors for bleeding and the risk of nosocomial pneumonia or *C. difficile* infection in the local epidemiological context. Generally speaking, SUP is not warranted in non-ICU patients, except where confirmed clinical indications exist. Educational programmes are needed to decrease unjustified overuse of SUP in patients in ICUs¹²⁷ and promote appropriate treatment discontinuation after ICU and upon hospital discharge.

Review criteria

We conducted a literature search using the OVID, MEDLINE, EMBASE, PubMed, and ISI Web of Knowledge 4.0 databases to identify articles published in English or French from January 1994 to 15th October 2014. A highly sensitive search strategy was used to identify randomized controlled trials, cohort and case-control studies conducted in adults, using combinations of search terms, including: "stress ulcer bleeding", "stress related mucosal lesion", "stress related mucosal disease", "stress ulcer", "gastroduodenal damages", "intensive care unit", "critically ill", "epidemiology", "prevention", "prophylaxis", "guidelines", "histamine-2 receptor antagonists", "sucralfate" and "proton pump inhibitors". In addition, recursive searches and cross-referencing were performed and manual searches of the reference lists of articles identified in the initial search were completed.
