Studying the localized electrocatalytic activity of heterogeneous electro-catalysts is crucial for understanding electrocatalytic reactions and further improving their performance. However, correlating the electrocatalytic activity with the microscopic structure of two-dimensional (2D) electro-catalysts remains a great challenge due to the lack of in situ imaging techniques and methods of tuning structures with atomic precision. Here, we present a general method of probing the layer-dependent electrocatalytic activity of 2D materials in situ using a plasmonic imaging technique. Unlike the existing methods, this approach was used to visualize the surface charge density and electrocatalytic activity of single 2D MoS_2 nanosheets, enabling the correlation of layer-dependent electrocatalytic activity with the surface charge density of single MoS_2 nanosheets. This work provides insights into the electrocatalytic mechanisms of 2D transition metal dichalcogenides, and our approach can serve as a promising platform for investigating electrocatalytic reactions at the heterogeneous interface, thus guiding the rational design of high-performance electrocatalysts.

Heterogeneous electrocatalysis plays pivotal roles in various renew-able energy conversion technologies[1–3]. Quantitative characterization of the localized electrocatalytic activity of heterogeneous electro-catalysts is crucial for understanding electrochemical reactions and further improving their performance. For example, two-dimensional (2D) nanomaterials are promising candidates for electrocatalytic hydrogen evolution reactions due to their high electrochemical performance[4–6]. Correlating the electrocatalytic activity of two-dimensional electrocatalysts with their microscopic structure can guide the design of ideal catalyst materials.

Although substantial work has been accomplished in character-izing the macroscopic catalytic activity of 2D electrocatalysts, these ensemble measurements based on numerous nanosheets limit our understanding of the spatial heterogeneity of catalysis[7–9]. Several

techniques have been used to map the electrocatalytic activity of sin-gle nanosheets of 2D materials at the nanosheet-liquid interface, including scanning electrochemical microscopy (SECM)[10–13], scanning ion conductance microscopy (SICM)[14,15], and single molecule fluores-cence microscopy[16–18]. These approaches offer high spatial resolution. However, the imaging speed is limited, hindering the acquisition of real-time and in situ information during electrochemical reactions. More importantly, a complete electrochemical process includes charge transfer from the electrode to the surface of the electrocatalyst. The electron transport among layers in a single nanosheet also plays a vital role in determining the electrocatalytic performance[19,20]. How-ever, imaging the electrocatalytic activity of 2D electrocatalysts in situ and therefore correlating the electrocatalytic activity with their layer structures remains experimentally challenging.

Here, we report plasmonic imaging of the layer-dependent electrocatalytic activity of 2D transition metal dichalcogenide (TMD) nanosheets, including MoS₂, WS₂, MoSe₂, and graphene (Fig. 1a). The plasmonic-based electrochemical current imaging approach measures the electrochemical reactions of nanoparticles on a gold film with a high temporal resolution[21,22]. Although there has been intensive interests in mapping the electrocatalytic activity of 2D nanomaterials, the large background signal arising from the gold film interferes with the electrochemical reaction signals[23–25], which limits the application of plasmonic imaging in 2D nanomaterials. We therefore propose a strategy to eliminate the interference (Fig. 1b) and distinguish and quantify the surface charge density and electrocatalytic activity of single TMD nanosheets (Fig. 1c); in this strategy, MoS₂ was used as an example. Furthermore, by integrating our developed method of in situ fabrication of the desired layer number of TMDs with surface plasmon etching[26], we precisely visualized the layer-dependent electrocatalytic activity of the same MoS₂ nanosheet in real time, which is a difficult task with other techniques. Thus, the obtained knowledge can provide additional insights into the origin of the underlying mechanisms during electrocatalysis, and this optical imaging technique can be used in measuring the charge transport, defect distribution and electrocatalytic activity of other TMDs.

Results

Mapping the surface charge density of monolayer MoS₂

To excite surface plasmons, we used a home-built inverted microscope (Nikon Ti-E; Japan) with a high numerical aperture (NA = 1.49) oil-immersion objective (Fig. 1a). A beam of *p*-polarized incident light was collimated to illuminate a gold film with a certain incident angle. The reflected light was collected by a high-speed camera to acquire plasmonic images. The MoS₂ monolayers were fabricated in situ by a surface plasmon-driven etching method recently developed by our group[26]. We therefore employed this bifunctional setup to fabricate MoS₂ monolayers and image the electrocatalytic activity of monolayer MoS₂. To block the background charging signal of the gold film, we passivated the gold-coated coverslip with a self-assembled monolayer (SAM) of 1-octadecanethiol molecules. After the mechanically exfoliated MoS₂ multilayers were transferred onto the SAM-coated gold film, we directly converted them into corresponding monolayers while keeping their original lateral size, which was validated by Raman spectroscopy, with the separation between the A₁g and E₂g peaks decreasing from 25.1 to 20.3 cm⁻¹ (Supplementary Fig. 1). We employed a monolayer MoS₂-deposited gold film as the working electrode, a

platinum wire as the counter electrode and Ag/AgCl as the reference electrode in the three-electrode electrochemical cell.

As the plasmonic imaging technique is sensitive to surface charge density[23,27], we examined the plasmonic intensity dependence of monolayer MoS₂ on the surface charge variations before measuring the electrochemical activity. The potential of monolayer MoS₂ on a modified gold film was modulated in the range of 0 V and −0.4 V (vs. Ag/AgCl) in 260 mM phosphate buffer solution (PB). Figure 2a shows an optical image of monolayer MoS₂. We obtained difference plasmonic images of monolayer MoS₂ by subtracting the plasmonic image captured at 0 V from each of the subsequent frames during cycling the potential scanning. Figure 2b exhibits several snapshots of the plasmonic images of monolayer MoS₂ at different potentials, showing a significant increase in the image contrast during the cathodic scan of cyclic voltammetry (CV). The coating of the gold film with 1-octadecanethiol molecules can block background current from the gold substrate, while electrons can tunnel from the gold film to the monolayer MoS₂ through the molecular layer with negligible resistance[28,29]. The electron density of monolayer MoS₂ increased with decreasing potential, causing a shift in its dielectric constant, which was responsible for the observed increase in the plasmonic image contrast (see Supplementary Note 2 and Supplementary Fig. 2 for details). Consequently, we observed that the plasmonic intensity change ($\triangle I/I$) of monolayer MoS₂ decreased rapidly as the potential swept negatively from 0 V to −0.4 V (Fig. 2c). However, the plasmonic intensity of the Au electrode remained constant over the same potential window.

To quantify the charge dependence of the plasmonic intensity, we performed sinusoidal potential modulation on monolayer MoS₂ and captured time-dependent images (see Supplementary Note 3 and Supplementary Fig. 3 for details). The plasmonic intensity versus time presents periodic intensity oscillation (blue line, Fig. 2d) with a synchronous change relative to the applied potential (red dash, Fig. 2d). We conducted a fast Fourier transform (FFT) on the time-domain plasmonic intensity and observed an obvious peak at 20 Hz for monolayer MoS₂, consistent with the frequency of the applied potential (red line, Fig. 2e). There was no response for the gold film (blue line, Fig. 2e), indicating that the observed plasmonic intensity response was derived from monolayer MoS₂. By performing FFT on the plasmonic intensity of each pixel in time sequence images, we extracted the amplitude at the frequency of the modulation potential for each pixel and constructed an FFT image (Fig. 2f, g). The relationship between the surface charge density of monolayer MoS₂ ($\triangle q$) and

the plasmonic intensity $\triangle I/I$ is

$$\triangle q = A \, \triangle I/I \tag{1}$$

where A is a calibration factor, which can be calculated from the slope
of the fitting curve (Fig. 2c). To obtain an accurate calibration factor,
the slope $(\triangle I/I)/\Delta V$ was determined to be 0.12 V^{-1} from the same
potential window (−0.3 V to −0.1 V); $\triangle V$ is the modulation potential.
Since $\Delta q = c\Delta V$, the calibration factor can be expressed as:
$A = c\Delta V/(\triangle I/I)$, where c is the capacitance per unit area, which is
determined to be ~5 μF cm^{-2} for monolayer MoS₂ (see Supplementary
Note 4 and Supplementary Fig. 4 for details)[30]. A was calculated to be
4.17×10^{-5} C cm^{-2}. Consequently, we can image the local surface charge
density of single MoS₂ nanosheets by converting the FFT image with a
calibration factor (Fig. 2h). The surface charge density of MoS₂ is highly
related to its vertical charge transport ability, providing a promising
tool for uncovering the underlying mechanisms of the electrocatalytic
activity of MoS₂ with various thicknesses.

Imaging the electrocatalytic activity of monolayer MoS₂

To image the electrocatalytic activity of monolayer MoS₂, we intro-
duced an outer-sphere redox mediator, [Ru(NH₃)₆]$^{3+/2+}$, which does not
undergo physical interactions with the electrode surface. The elec-
trochemical conversion of chemical species between oxidized and
reduced states causes variations in the refractive index, which can be
detected by our setup. We swept the electrode potential over a
monolayer of MoS₂ between 0 V and −0.4 V (vs. Ag/AgCl) slowly in
0.25 M phosphate buffer containing 10 mM [Ru(NH₃)₆]Cl₃ (Supple-
mentary Fig. 5). The plasmonic images over time and the electro-
chemical current were recorded simultaneously. Both the
conventional cyclic voltammogram and plasmonic intensity of the 1-
octadecanethiol-coated gold electrode showed little response, indi-
cating the successful blocking of the potential charging effect of the
gold film (Supplementary Fig. 6). This plasmonic imaging technique is
sensitive to both surface charging and surface reactions, as discussed
above. To differentiate the two kinds of electrochemical responses of a
single monolayer MoS₂, we subtracted the image sequence acquired in

Fig. 3 | Images of the electrochemical reaction on monolayer MoS₂. a Snapshots of plasmonic images of monolayer MoS₂ at different potentials, showing the spatial distribution of the concentration of $[Ru(NH_3)_6]^{2+}$ ions. The electrolyte was 0.25 M phosphate buffer containing 10 mM $[Ru(NH_3)_6]Cl_3$. The scale bar represents 15 μm. **b** Plasmonic intensity curves of three ROIs adjacent to monolayer MoS₂ vs. potential during the potential sweeping. The cyclic voltammogram measured by the conventional electrochemical method (black line) is shown for comparison.

phosphate buffer without a redox mediator from the image sequence measured in phosphate buffer with a redox mediator (Supplementary Figs. 7–8). After this subtraction, the obtained plasmonic signal of the redox reaction on monolayer MoS₂ only reflected the concentration difference between oxidized and reduced molecules. By following the quantitative relationship between the plasmonic signal and the concentration change of the redox species (Supplementary Fig. 9), the subtracted image intensity was converted numerically to the ion concentration ratio of $[Ru(NH_3)_6]^{2+}/[Ru(NH_3)_6]^{3+}$, which enabled us to map the potential-dependent concentration variations of $[Ru(NH_3)_6]^{2+}$ ions.

Figure 3a presents several snapshots of plasmonic images at different potentials, revealing the spatial distribution of the concentration of $[Ru(NH_3)_6]^{2+}$ ions (also in Supplementary Movie 1). As the electrode potential decreased, the reduction of $[Ru(NH_3)_6]^{3+}$ produced $[Ru(NH_3)_6]^{2+}$ molecules, which diffused outward from monolayer MoS₂ to the surrounding solution. Consequently, the concentration of $[Ru(NH_3)_6]^{2+}$ ions increased, and the image contrast gradually appeared around monolayer MoS₂. We observed the maximum image contrast at −0.4 V, corresponding to the maximum reduction current. As the potential was scanned to 0 V, the image contrast gradually decreased due to the reversible oxidation of $[Ru(NH_3)_6]^{2+}$ to $[Ru(NH_3)_6]^{3+}$ (Fig. 3a) and finally returned to its original value.

We plotted three regions of interest (ROIs) adjacent to the monolayer MoS₂ and observed a potential-dependent variation in the plasmonic intensity (Fig. 3b). As the ROI moved away from monolayer MoS₂, the plasmonic response decreased gradually, indicating the diffusion of $[Ru(NH_3)_6]^{2+}$ ions. To quantify this diffusion process, we applied a constant potential of −0.3 V, and the images were recorded synchronously. According to the two-dimensional semi-infinite diffusion model, the concentration of $[Ru(NH_3)_6]^{2+}$ ions as a function of

diffusion distance (x) and time (t) follows the equation[31,32]:

$$c(x, t) = \frac{M}{\sqrt{4\pi Dt}} \exp\left(-\frac{x^2}{4Dt}\right) \quad (2)$$

where M is the total mass of the diffusing ions and D is the diffusion coefficient. The diffusion coefficient of $[Ru(NH_3)_6]^{2+}$ ions was thus determined to be 4.8×10^{-10} m² s⁻¹ (Supplementary Fig. 10), which is in accord with the values reported in the literature[33,34]. This diffusion coefficient indicated that the reaction current of MoS₂ was dominantly controlled by the mass transport of $[Ru(NH_3)_6]^{3+}$ ions, which allowed us to calculate the reaction current of monolayer MoS₂ using linear diffusion models of planar electrodes. The electrochemical current of monolayer MoS₂ can be determined by performing a Laplace transform according to Fick's law of diffusion (see Supplementary Note 11 for details). As shown in Fig. 3c, the optical CV (orange line) displays the characteristic redox peaks corresponding to the reduction and oxidation of the ruthenium complex, and this result is in good agreement with the conventional CV curve (black line).

Quantifying the layer-dependent electrocatalytic activity of single MoS₂ nanosheets

The imaging capability of electrocatalytic activity for single MoS₂ nanosheets enabled us to study the origin of layer-dependent electrocatalytic activity of single MoS₂ nanosheets, which has been a long-term goal for the community. To unveil the relationship between the layer number and the electrocatalytic activity of MoS₂, we performed subsequent experiments over multilayer MoS₂ and its monolayer counterpart fabricated by our surface plasmon etching method[26]. The lateral size of the MoS₂ nanosheet before and after surface plasmon etching remains unchanged, allowing for the
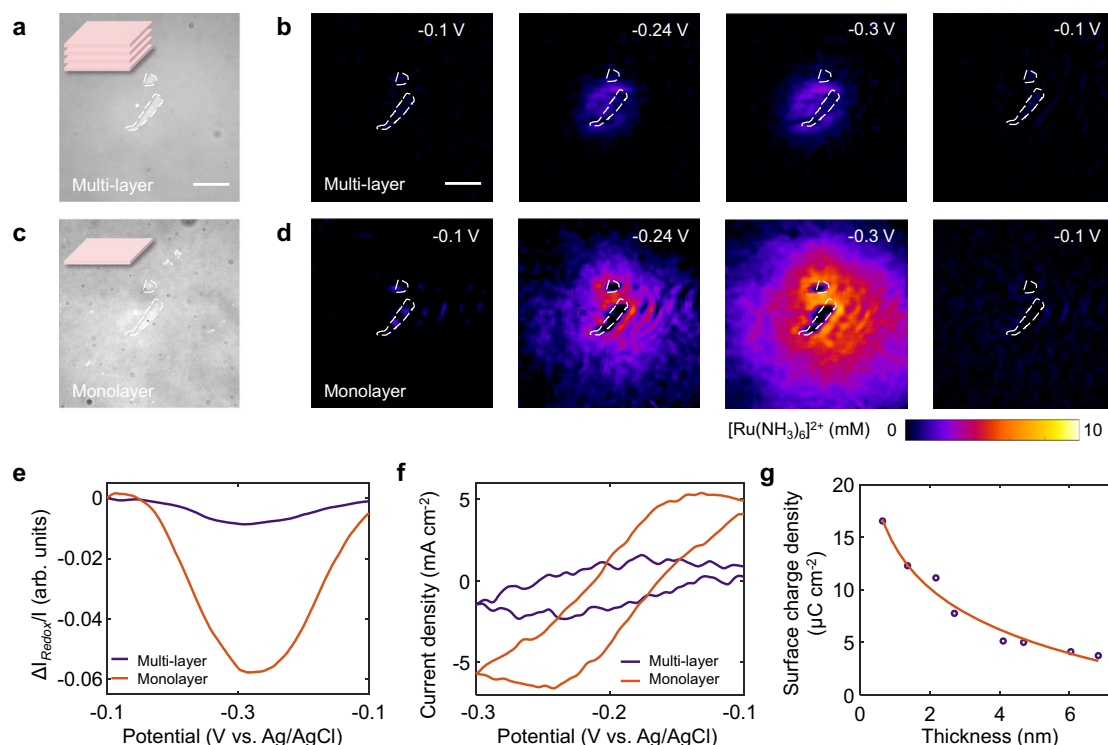

Fig. 4 | Layer-dependent electrocatalytic activity of single MoS$_2$ nanosheets. Optical images and snapshots of plasmonic images of (**a, b**) multilayer MoS$_2$ and (**c, d**) the corresponding surface plasmon-thinned monolayer MoS$_2$ during potential sweeping, illustrating the significant difference in the concentration of [Ru(NH$_3$)$_6$]$^{2+}$ ions. The scale bar represents 20 μm. **e** Plasmonic intensity change ($\Delta I/I$) curves vs. potential of multilayer and monolayer MoS$_2$. **f** Cyclic voltammograms of multilayer and monolayer MoS$_2$ calculated by the electrochemical imaging. **g** The surface charge density of MoS$_2$ dropped quickly as its thickness increased.

quantification of layer-dependent electrocatalytic activity (Fig. 4a and c). The 1.06 nm height of the nanosheet and the Raman peak shifts indicate that MoS$_2$ had been etched into the monolayer (Supplementary Fig. 11). We therefore conducted electrochemical tests using the above MoS$_2$ samples. Two movies of the electrocatalytic reaction of MoS$_2$ are presented in the Supplementary Movie 2. Figure 4b and c show several snapshots from the movies at different potentials. Surprisingly, we observed a higher image contrast for monolayer MoS$_2$, which had a larger diffusion area of [Ru(NH$_3$)$_6$]$^{2+}$, than for multilayer MoS$_2$, implying that monolayer MoS$_2$ was more active in accelerating the local electrocatalytic reactions. The change in the plasmonic intensity of multilayer MoS$_2$ was observably lower than that of the monolayer sample (Fig. 4e). Figure 4f displays the CVs of multilayer and monolayer MoS$_2$ determined from the plasmonic images, and the electrochemical current of monolayer MoS$_2$ was higher than that of multilayer MoS$_2$, indicating that thinner nanosheets possessed better electrocatalytic activity. More importantly, we also observed that the voltammetric half-wave potential ($E_{1/2}$) shifted towards more positive potentials as the thickness of MoS$_2$ decreased (Supplementary Fig. 12), further confirming that charge transfer was accelerated as the number of layers was decreased. When we mapped the surface charge density of these single MoS$_2$ nanosheets with potential modulation (Supplementary Figs. 13–14), the surface charge density of the MoS$_2$ nanosheet decayed rapidly as its thickness increased (Fig. 4g), which further reveals the layer-dependent electrocatalytic activity of MoS$_2$. The thicker MoS$_2$ has lower Schottky barrier height than the thinner one, leading to a better electron transport ability in thicker MoS$_2$ at the Au-MoS$_2$ interface (Supplementary Fig. 15). A contrary trend in Fig. 4g indicates that the charge transfer between MoS$_2$ and Au contact does not affect the layer-dependent surface charge density of MoS$_2$.

Discussion

In electrocatalysis with MoS$_2$, charge transfer from the electrode to the catalytic active sites involves vertical charge transport among layers. Theoretical studies have suggested that the weak van der Waals bonding between the MoS$_2$ layers could generate an energy barrier for the interlayer tunneling of the charges[35,36]. Therefore, the charges in a thicker MoS$_2$ nanosheet must overcome a higher energy barrier during interlayer tunneling, leading to a lower surface charge density and a lower catalytic activity (Fig. 5). The semiconductor-solution interface dominates the performance of semiconductor electrocatalysis[37]. The accumulation of surface charge could make the semiconductor catalyst conductive, facilitating charge transfer across the interface[19,38].

Our results demonstrate that a thinner MoS$_2$ nanosheet can accumulate charge with a higher concentration to achieve a conductivity that is higher than that of a thicker nanosheet. Consequently, both the capability of charge interlayer tunneling and the conductivity modulated by surface charge density contributed to the better catalytic efficiency of the thinner MoS$_2$. Unlike the existing methods for electrochemical measurement of single 2D material nanosheets with nanofabrication[19], our method is easy and facile. Microelectrode-based measurements have provided insights into the electrochemical reaction of 2D MoS$_2$ nanosheets[39], but these methods are limited by low throughput and temporal resolution and cannot acquire real-time electrochemical information, such as can be obtained through diffusion dynamics. Our approach was based on wide-field imaging without the use of a scanning microelectrode, which enabled a fast imaging speed and avoided the possible disturbance of the sample by the microelectrode. More importantly, we can directly visualize the heterogeneous distribution of surface charge, which is associated with the electrocatalytic performance of MoS$_2$.
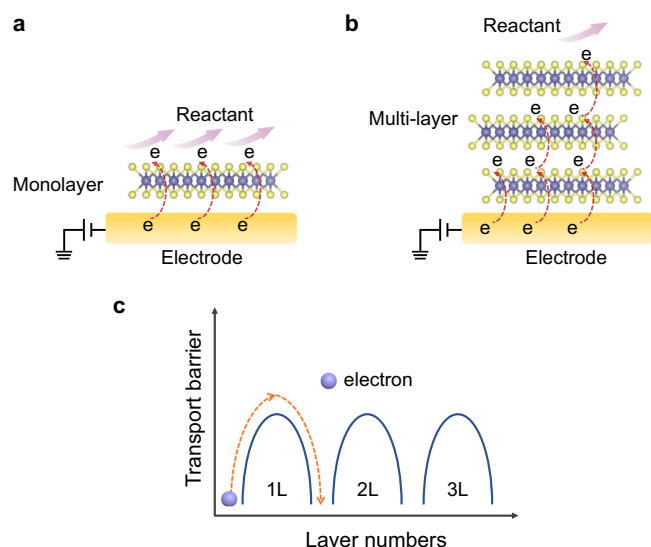

Fig. 5 | Layer-dependent electron transfer mechanism of MoS₂. a, b Schematic illustration depicting electron transfer pathways in the vertical direction of monolayer and multilayer MoS₂ during the electrochemical reaction. **c** Electrons need to cross more transport barriers with increasing numbers of layers.

We also demonstrated the use of this technique in studying the electrocatalytic hydrogen evolution reaction (HER) on single MoS₂ nanosheets (see Supplementary Note 16 and Supplementary Fig. 16 for details). The generated hydrogen molecule leads to the decrease in the local refractive index around MoS₂, which is reflected in the change of plasmonic image contrast. Supplementary Fig. 16b displays snapshots of differential plasmonic images during cathodic potential sweeping, where the image contrast decreases as the potential decreases, and achieves a maximum at the lowest potential. The electrochemical current was converted from the plasmonic signal change, revealing the remarkable hydrogen evolution for MoS₂ around −0.4 V (Supplementary Fig. 16c, d). Moreover, to demonstrate the generality of this imaging method, we probed the electrocatalytic activity of other 2D materials, including graphene, WS₂ and MoSe₂, which exhibited similar layer-dependent electrochemical behaviors (Supplementary Fig. 17). All these results suggest that interlayer charge transfer plays a considerable role in the electrocatalysis of 2D materials. The results obtained could also be used to explain the high electrocatalytic activities of nanostructured semiconductor catalysts[40] and TMDs[5], since these materials can be made conductive by making them thinner.

The spatial resolution of our plasmonic imaging technique is about 250 nm due to the optical diffraction limit, which is lower than that of probe-scanning based imaging techniques for visualizing active site distributions of heterogeneous electrocatalysts[41–43]. Despite of the resolution limit, it is sufficient to probe the surface charge density as a function of the thickness of MoS₂ flakes. Future integration with other high-resolution characterization technologies will allow multifunctional monitoring of a nanostructured electrocatalyst toward establishing structure-activity relationships.

In summary, we have demonstrated a plasmonic imaging method that enables the visualization of the surface charge density and electrocatalytic activity of single 2D electrocatalyst nanosheets in situ. This imaging capability allowed us to study the layer-dependent electrocatalytic activity of MoS₂ and further correlate the layer-dependent electrocatalytic activity with the surface charge density of single MoS₂ nanosheets. Our findings provide additional insights into understanding the electrocatalytic mechanisms of TMDs, and this optical imaging technique can serve as a transformative platform for investigating the microscopic interfacial electrochemical processes of 2D electrocatalysts.

Methods

Instrumentation
The plasmonic imaging setup was built on an inverted total internal reflection microscope (ECLIPSE Ti-E Series, Nikon Instruments Inc.) equipped with a high numerical aperture (NA = 1.49) oil-emersion objective (60×). A beam of p-polarized light from a 680 nm superluminescent diode (SUPERLUM, Ireland) was directed onto the gold film mounted on the objective to excite surface plasmon polaritons, and the reflected light was collected with the same objective and directed to an sCMOS (ORCA-Flash4.0 C11440, Hamamatsu Photonics K.K.), or CCD camera (Pike F-032B, Allied Vision Technologies GmbH) for imaging. The gold chips were prepared by evaporating 2 nm chromium as an adhesion layer followed by a 47 nm gold layer on BK-7 glass coverslips. The gold films were immersed in 10 mM 1-octadecanethiol dissolved in ethanol for 48 h, rinsed with ethanol and water sequentially, and dried with nitrogen gas prior to use.

Sample preparation
Bulk MoS₂ single crystals were purchased from Nanjing MKNANO Tech. Co., Ltd. 1-Octadecanethiol and [Ru(NH₃)₆]Cl₃ were purchased from Sigma Aldrich. The MoS₂ monolayers were fabricated by a surface plasmon polariton-driven etching approach recently developed by our group. A laser diode with a wavelength of 660 nm (OBIS LX, Coherent Inc.) was adopted as the light source to induce layer thinning of the MoS₂ nanosheets. The power density of red light was generally set at 3 mW·mm⁻². The MoS₂ multilayers were mechanically exfoliated from bulk MoS₂ single crystals and transferred onto 1-octadecanethiol-modified gold films. The MoS₂ multilayers were directly converted into corresponding monolayers under surface plasmon-driven etching in deionized water[26].

Electrochemical measurements
The MoS₂ nanosheet-deposited gold film was employed as the working electrode (a platinum wire as the counter electrode and Ag/AgCl as the reference electrode) to construct a three-electrode electrochemical cell. A polydimethylsiloxane (PDMS) electrochemical cell was placed on top of the gold film. For the charging experiment, the electrode potential was applied and controlled using an electrochemical workstation (CorrTest-CS5, Wuhan Corrtest Instrument Corp. Ltd) coupled with an external waveform function generator (33500B Trueform, Keysight Technologies Inc.). A data acquisition card (DAQ USB-6250, National Instruments Corp.) was utilized to synchronize the electrochemical measurements and the CCD camera (100 frames/s). In the charging experiment, cyclic voltammetry was conducted by sweeping the potential between 0 V and −0.4 V (vs. Ag/AgCl) in 260 mM PB solution. A sinusoidal potential modulation amplitude of 100 mV and frequency of 20 Hz were also applied to the sample. In the redox experiment, CV was carried out on an electrochemical workstation (CHI660E, CH Instruments Inc.), and the sequence of plasmonic images was recorded by a sCOMS camera at 200 frames/s. CV was conducted in 260 mM PB (charging) and 250 mM PB solutions containing 10 mM [Ru(NH₃)₆]Cl₃ (redox). In the layer-dependent experiments, we first performed electrochemical tests with the mechanically exfoliated MoS₂ multilayers, then etched this sample into corresponding monolayers in situ with planar surface plasmons[26], and finally, we performed the same electrochemical tests again with the obtained MoS₂ monolayers.

Characterization
Atomic force microscopy (AFM) was performed using a Bruker Dimension Icon system in tapping mode. A Raman spectroscope (LabRAM Nano, HORIBA France SAS) with a laser excitation wavelength of 532 nm was used to obtain the Raman spectra and photoluminescence spectrum of the MoS₂ nanosheets.

Data processing

We employed MATLAB and ImageJ with self-developed codes to process images in this work. In the charging experiment, fast Fourier transform (FFT) was performed on each pixel of the recorded images in the time domain.

Data availability

All data are available within the Article and Supplementary Files. Source data are provided as a Source Data file. Source data are provided with this paper.

Code availability

The code for the image process in this paper is available in Github: https://github.com/XiaonaZhao/Intensity2Current.

Acknowledgements

Author contributions

X.Z., X.-L.Z., and X.-W.L. designed and analysed the experiments. X.Z. performed the experiments and analysed the data. S.-Y.Y., Y.M., and J.-J.C. carried out the theoretical calculations and simulations. X.Z., X.-L.Z., S.-Y.Y., Y.M., J.-J.C., and X.-W.L. discussed the results. X.Z., X.-L.Z., and X.-W.L. wrote the manuscript. All the authors contributed to the manuscript.

Competing interests

The authors declare no competing interests.

Additional information

Supplementary information The online version contains supplementary material available at https://doi.org/10.1038/s41467-022-35633-3.

Correspondence and requests for materials should be addressed to Xiao-Li Zhou or Xian-Wei Liu.

Peer review information *Nature Communications* thanks Xiaonan Shan and the other, anonymous, reviewers for their contribution to the peer review of this work.
