Risk-Return Tradeoff, Income Measurement and Capital Asset Pricing for Life Insurers: An Empirical Investigation

by Sandra G. Gustavson* and Cheng F. Lee**

1. Introduction

Studies analyzing the risk-return tradeoff and its implications for industrial firms have been done by Lintner [1965a], Miller and Scholes [1972], and Lee [1977]. Several researchers, including Beaver, Kettler, and Scholes [1970], and Rosenberg and McKibben [1973], have used accounting information to explain the cross-sectorial fluctuation of systematic risk for industrial firms. Similar analyses are only beginning to be undertaken for the life insurance industry. For example, Harrington [1983] has shown that a significant relationship exists between return and systematic risk, as well as between return and nonsystematic risk, for a sample of life insurance stocks in the 1960s and mid-1970s. The purposes of this study are to further test the risk-return relationship for life insurers and to investigate some of the factors which may influence the systematic and nonsystematic risk measures of these insurers. Additional related matters which are also dealt with include alternative income measures and the cost of capital concept for insurers.

In the next section, the importance of relationships between risk measures and some of the operations of the life insurance industry are discussed. In the third section, the risk-return relationship for life insurers is explored. Possible factors that may influence life insurers' total and systematic risk measures are described in the fourth section, and the results associated with these factors are presented in the fifth section. Finally, a summary and some implications of the empirical findings are provided.

2. Importance of risk and life insurer operations

The risk associated with life insurer stock returns is potentially important for several reasons. Financial theory suggests that returns should be a function of risk; if such a relationship is true for life insurers, as preliminary studies indicate, useful information for managers

* Associate Professor, Department of Insurance, Legal Studies, and Real Estate, The University of Georgia.

** IBE Distinguished Professor of Finance, University of Illinois at Urbana-Champaign.

would include the factors that may tend to influence various risk measures. Armed with such knowledge, managers would be in a better position to make rational decisions regarding the operations of their firms. Launie [1971] discussed the potential calculation and use of capital measures by insurers, and Haugen and Kroncke [1971] studied the relationship between cost of capital and insurance rate regulation. More recently, Lee and Forbes [1980] investigated several alternative methods of deriving estimates for the cost of equity capital for non-life insurers. This idea has not been specifically developed for the life industry, although as noted by Launie [1971, p. 268] a theoretical minimum required rate of return for investments in financial assets is as potentially useful for insurers as is the additional cost of capital idea when applied to investments in fixed assets by industrial firms. Viewed as such, the cost of capital concept may become increasingly useful in the future, as life insurers continue to diversify their operations to meet the challenges from banks and other financial institutions.

As noted above, risk measures have been advocated in the insurance literature as an input for property and liability rate regulation. In addition to the Haugen and Kroncke [1971] work cited previously, Fairley [1979], Hill [1979], Biger and Kahane [1979] have utilized the capital asset pricing model (CAPM) to further explore the application of insurer systematic risk in the regulation of rates. Williams [1983] shows how risk measures (both systematic and total) are also important to regulators in dealing with excess profits. A closely related issue of concern to regulators is insurer and industry capacity to underwrite risks. Doherty [1980] has provided a theoretical basis for using total risk measures to establish the capacity of the non-life industry. Although life insurer rates not currently subject to regulation and capacity issues are not nearly as critical as they are for non-life insurers, it is possible that these same concepts may find application in the life area in the future, especially as concern such as excessive tax sheltering of income and proper regulation of full financial service firms become more prevalent among legislators. Under these scenarios, it will be important to understand not only the existing risk-return relationships for life insurers, but also the factors influencing the relevant risk measures.

A final area which knowledge about risk measures may become increasingly important for life insurers is in regard to solvency. Shaked [1985] recently showed how the variance of returns could be used to help predict the probability of insolvency for life insurers. This topic is sure to be a primary research area in the future, given the upheaval in the financial services industries and the publicity given to such spectacular events as the Baldwin-United failure (see COIL [1985]).

3. Risk-return relationships for life insurers

As noted, the application of financial theory to non-industrial firms in general, and life insurers in particular, is not well developed. Hammond, Melander and Shilling [1976], Hammond and Shilling [1978] and Kahane [1978] have investigated risk-return relationships for non-life insurers. Formisano [1978] and Harrington [1979] have investigated the dividend policy of stock life insurers, but a comprehensive study of the overall applicability of general financial theories to life insurers has not been done. Stowe [1978, p. 431] indicates that a major reason for the difficulty in this regard is the difference between financial and tangible assets. In addition, financial institutions such as life insurers are subject to special

borrowing-lending rate relationships (see Gordon [1974]), their tax obligations are computed in a unique manner, and there are different income measures applicable for reporting earnings to different parties. Therefore, in light of these differences, it is useful to continue the investigation of the degree to which established financial theories are applicable to this type of firm.

The CAPM developed by Sharpe [1964], Lintner [1965], and Mossin [1966] is described by the following relationships:

$$(1) \quad E(R_{i,t}) - E(R_{f,t}) = \beta_i[E(R_{m,t}) - E(R_{f,t})]$$

where

$E(R_{i,t})$ = expected return on asset i during time t .

$E(R_{f,t})$ = expected risk-free return during time t .

$E(R_{m,t})$ = expected market return during time t .

$$\beta_i = \frac{\text{Cov}(R_m, R_i)}{\text{Var}(R_m)}.$$

This model has been discussed extensively in both the finance and insurance literature; in its usual application, it is used to explain the level of common stock returns for an individual security or for a portfolio of securities. The $E(R_{i,t})$ can also be viewed as the firm's cost of equity capital (i.e., the minimum required rate of return from investing in an equity-financed project).

Because of the many differences between life insurers and the industrial firms for which the CAPM was developed, the question arises as to whether the usual risk-return relationships are true for life insurers. As noted, Harrington [1983] found evidence that both systematic and nonsystematic risk are important in explaining returns for stock life insurers. The sample used in this study consists of all stock insurers which primarily operated in the life insurance area and which had continuous price data available for the period 1968 to 1978. Due to considerable merger activity during this period, only 40 companies met these criteria. Table 1 indicates the insurers included in the study, along with three measures of size: admitted assets, insurance in force, and premium volume.

Table 1: Insurers included in study and size data for 1978

Mean	\$ 317,243	\$ 4,040,212	\$ 96,996

Based on prices and dividend data obtained from Standard and Poor's *ISL Daily Stock Price Index*, monthly holding period rates of return, adjusted for stock splits, were calculated for each of the 40 insurers included in the sample. Standard deviations of return were calculated as a measure of each insurer's total risk, and systematic risk as measured by beta was estimated for each company using the following regression technique:

$$(2) \quad R_{i,t} - R_{f,t} = \alpha_i + \beta_i (R_{m,t} - R_{f,t}) + \varepsilon_{i,t}$$

where α_i = intercept term

β_i = beta coefficient for the i^{th} insurer

$\varepsilon_{i,t}$ = error term.

The other variables are as defined for equation (1). The market index used was the Standard and Poor's 500, and the risk-free rate was approximated by monthly Treasury bill rates.

It should be noted that the stocks for most of the 40 sample insurers are traded in the over-the-counter (OTC) market, and several are traded infrequently. Noting that this characteristic causes the β_i coefficients to be biased downwards, Dimson [1979] suggested the following way to compute beta when securities are traded infrequently:

$$(3a) \quad R_{it} - R_{ft} = \alpha_i + \sum_{n=-N}^N \beta_{in} (R_{m,n} - R_{f,n}) + \varepsilon_{it}$$

$$(3b) \quad \text{Dimson } \hat{\beta}_i = \sum_{n=-N}^N \beta_{in}$$

where β_{in} is the slope coefficient of an ordinary least squares multiple regression of the observed return from the market index lagged n time periods. Beta values were computed using the regressions shown in both equations (2), (3a), and (3b), and the resultant values are shown in Table 2.

40	1.280	0.873	0.868	0.443	1.642	3.321

The average monthly rate of return for the 40 insurers during the sample period was 1.01%, with a range from -.23% to 2.63% and a standard deviation of .54%, as indicated in Table 3. The average variance of return was 1.37%, and the average ordinary least squares (OLS) beta was .7543, with a range from .0491 to 1.5438. This OLS beta is somewhat lower than the average OLS betas reported by Lee and Forbes [1980] for 34 non-life insurers and that reported by Harrington [1983] for several samples of life insurers over different time periods. The average Dimson beta estimate for the 40 insurers included in this study is .9276, with a range from -0.1500 to 2.3594.¹

A widely accepted tenet of capital market theory is that higher returns are associated with riskier securities. However, it must be remembered that the theory is stated in terms of expected returns as a function of expected, or ex ante, risk. Most of the empirical tests of the CAPM have, of necessity, utilized ex post risk and return measures. Sharpe [1982] cautions

¹To put these betas in perspective, it is useful to compare them to historical betas found in various nonfinancial industries. Rosenberg and Guy [1976] report the average betas for the period 1966 to 1974 for stocks of firms in several industries. Those with relatively large betas during this time include air transport (1.80), real property (1.70), travel (1.66), and electronics (1.60). Those with relatively low betas include gold (.36), energy and utilities (.60), and telephones (.75). The banking industry had an average beta of .81.

that it is difficult to estimate true ex ante beta values, and that actual ex post rates of return may bear very little relationship to such ex ante betas. With these limitations in mind, preliminary investigation of the risk-return relationships for life insurers was done. In order to investigate the relative importance of systematic vs. nonsystematic risk in explaining returns, regression coefficients were estimated for equation (4):

$$(4) \quad \bar{R}_i = a_0 + a_1 \beta_i + a_2 \sigma_{e_i}^2 + \varepsilon_i$$

where $\sigma_{e_i}^2$ = variance of residuals for insurer i , and other variables are as previously defined,

β_i = estimated beta coefficient from either OLS or Dimson's method.

The estimated equation in terms of OLS beta estimates and Dimson beta estimates are listed in equations (4a) and (4b) respectively.

$$(4a) \quad \bar{R}_i = .120 + .0056 \hat{\beta}_i + .1214 \sigma_{e_i}^2 \quad \bar{R}^2 = .0360$$

(3.6223) (1.2250) (.6650)

$$(4b) \quad \bar{R}_i = .0130 + .0026 \hat{\beta}_i + .3698 \sigma_{e_i}^2 \quad \bar{R}^2 = .1840$$

(6.5160)* (1.9420)* (3.0610)*

[* denotes significance at 5% level]

Equation (4a) indicates that the average rates of return for the 40 life insurers during 1968-1978 are not related statistically to either systematic risk (β_j) or nonsystematic risk ($\sigma_{\epsilon_j}^2$). However, if Dimson's estimates are used, then the average rates of return are significantly related to both systematic risk and nonsystematic risk. This result might be due to the fact that OLS beta estimates are subject to measurement errors as discussed by Dimson. Hence the Dimson's beta estimates are used throughout the rest of this paper.

The results of equation (4b) indicate a strong positive relationship between return and nonsystematic risk, and a relatively weaker, positive relationship between return and systematic risk. This latter result may be somewhat surprising initially, but it must be remembered that both risk and return were measured on an ex post basis for this study. However, it does appear that the nonsystematic component is the more important one in terms of explaining the level of return. One possible explanation for this finding is the unique operations of life insurers relative to other types of firms. Foster [1975] found that the inclusion of an industry factor, in addition to a market factor (as in equation (2)), improved his ability to explain the variation in both non-life and life insurers' rates of return. This finding is in contrast to those for other industries (see Myers [1977]), but is consistent with similar findings reported by Harrington [1983] for life insurers. Such results suggest that singular characteristics of the life insurance industry do indeed exist. These results also indicate that a potentially useful area for future research would be an application of the Arbitrage Pricing Model (developed by Ross [1976, 1977] and tested by Roll and Ross [1980] and others) to the life insurance industry. Because risk has been shown to be important in explaining returns for life insurers, it is important for firm managers to understand 1) the degree of correspondence, if any, between past and future measures of risk, and 2) what controllable factors, if any, particularly impact upon the firm's risk posture.

As already discussed, risk is rarely estimated in an ex ante context. For example, in order to measure an insurer's cost of capital, the usual procedure would be to use the company's historical beta as an input for equation (1). Likewise, measurements of other types of risk are often used with the implicit, and often critical, assumption that the past calculation will remain a valid estimate of the insurer's risk in the future. With respect to beta, Sharpe and Cooper [1972] discuss the issue of stability for stocks listed on the New York Stock Exchange over the period 1926 to 1968. They found that while individual firm betas may change substantially from year to year, the betas for portfolios of securities exhibit a much greater degree of stability over time. Similarly, Harrington [1983] found some evidence of beta instability for life insurers, and Cummins and Harrington [1985] showed that the betas for property-liability insurers, appeared to change considerably during the 1970s. In order to assess the situation with respect to the life insurers included in this study, the period examined is divided into two subperiods of reasonably similar length (1968 to 1973, and 1974 to 1978). A comparison of the first few lines in Table 4 and 5 reveals some interesting factors. The average rate of return and the total risk, as measured by the variance of returns, are not significantly different in the two subperiods. However, there is a considerable difference in the average beta for the 40 life insurers. During the first subperiod, the average Dimson beta is .9433; subsequently, it drops to .6880. The ranges of results around these averages is also quite different. The betas during the second subperiod are more dispersed and are spread over a much wider range than during the first five-year period. These results are important both for investors in life insurance stocks who need to assess the riskiness of insurers and for life company managers who need beta as an input for estimating costs of capital or other types of applications, as discussed in

Section 2 of this paper. While the findings indicate that total risk may remain relatively constant over time, no such assumption about systematic risk appears to be warranted. Thus, it is useful to investigate other methods of explaining and predicting total risk and beta.

4. Factors influencing life insurers' risk measures

Knowledge about the factors which determine a life insurer's risk is important for several reasons. As demonstrated earlier in this paper, an insurer's nonsystematic risk is significantly positively related to the rate of return for the firm's common stock. Also, the insurer's beta, or systematic risk component, is a necessary input for several applications of financial theory. If these risk measures are directly explainable by the levels or changes in certain variables controllable by the insurer, then firm managers are in a position to affect the level of risk through their management activities. Hence, they may be able to partially influence both the stock return and the firm's cost of capital.

Numerous studies have addressed the problem of finding the real determinants of risk for industrial firms. Among the first was the work by Beaver, Kettler and Scholes [1970] (hereafter, BKS), who looked at the relationship between beta and seven accounting variables. BKS were able to explain nearly 45 percent of the variation in beta through regression analysis, with the most useful independent variables being dividend payout, asset growth, and variability of earnings. The same relationship was not able to predict future beta values nearly as well, however. Subsequent inquiries have found other accounting variables which may be useful in explaining beta. Several of these studies are summarized by Myers [1977], who also synthesizes prior work (both theoretical and empirical) in this area to arrive at a list of variables which appear to have a major bearing on industrial firms' betas. These factors are: earnings volatility, financial leverage, growth, and cyclicalities. This latter term is used to describe the degree to which variability in earnings for one firm corresponds with variability of all firms' earnings. The current study focuses on the question of whether these same variables are important determinants of risk for life insurers. In addition, certain dividend-related variables are also examined, due to their importance in explaining stock returns for non-life insurers (see Lee and Forbes [1980]). The explanatory variables utilized in this study are described in the following sections.²

² More detailed definitions and calculation procedures for the variables are available from the authors upon request.

4.1. Leverage

The leverage measure used in this study is defined as:

$$(5) \quad L_i = \frac{\sum_{j=1}^N (PR_{ij}/AA_{ij})}{N}$$

where L_i = leverage measure for insurer i

PR_{ij} = net policy reserves for insurer i in year j

AA_{ij} = total admitted assets for insurer i in year j

N = number of years in period examined.

This leverage measure is the one suggested by Launie [1971], and is similar to the insurance leverage concept adopted by many studies dealing with property-liability insurers (see Haugen and Kroncke [1971] and Quirin and Waters [1975]). In the life insurer case, the policy reserves are viewed as “semi-debt” components in the company’s capital structure, in that they arise out of the sale of insurance, which provides the insurer with funds for investment purposes. Table 3 summarizes the values found for this and the other sample statistics for the study period 1968 to 1978, and Table 4 and 5 present similar information for the two subperiods. All non-price data were obtained from *Best’s Insurance Reports – Life and Health*. The policy reserve figure reported in *Best’s*, which is used to compute L_i in equation (5), is an aggregate figure, which takes into account the policy reserves for life, health, and annuity business, as well as supplementary contracts with and without life contingencies. The average leverage measure for the complete study period is 71.52%, with very little difference between the two subperiods, and a fairly wide range of such measures for the 40 insurers studied.

4.2. Growth

Three measures of insurer growth were identified. Growth measure A is the average annual percentage change in an insurer’s total premium volume. Measure B is the average annual percentage change on insurance in force, and growth measure C is the average annual percentage change in total admitted assets. As indicated in the tables, premium volume grew substantially more during subperiod 2, with the average for the entire period being an annual percentage change of 22.86%. The opposite situation occurred with respect to insurance in force. The average annual increase for the 11-year period was about 15 percent, with the greater growth occurring during subperiod 1. With respect to each measure, the greater variability of results also occurred in the subperiod experiencing the higher average growth. The third measure, relating to growth in admitted assets, was very similar during both subperiods, with the average overall rate being 11.75%. Both the range and standard deviation of results for measure C were also comparable during both periods.

4.3. Dividend yield

A third explanatory variable is dividend yield, which is the average annual stockholder dividend per share divided by the insurer's year-end stock price. The average for the 40 insurers was 2.41%, with the yield during the second subperiod being more than double that of the first. However, the second period results tend to be dominated by the abnormal experience of only one or two insurers.

4.4. Earnings-related variables

The other explanatory variables all are related to the earnings measures used in this study. For industrial firms, the key, but sometimes ambiguous, role played by earnings has been demonstrated in many aspects of traditional financial theory. For instance, in their study showing how the relevant cost of capital measure for investment decisions can be inferred from security market values, Miller and Modigliani [1966] admitted the crucial importance of earnings in the valuation model. But in their empirical application of their theory to the electric utility industry, it was argued that an accounting earnings measure is only a proxy for economic earnings. Several studies involving insurance companies have had similar problems. Foster [1977] investigated the usefulness in company valuation of three different earnings measures for non-life insurers. He found that the inclusion of capital gains and losses (both realized and unrealized) in the earnings measure resulted in the best valuation model, despite the prior claims to the contrary made by many insurance security analysts (see Accounting Principles Board [1971]). Similarly, Lee and Forbes [1980] used four earnings measures in their study on the importance of dividend policy for non-life insurers.

In the limited applications of financial theory to the life insurance industry, problems associated with alternative earnings have also been shown to be important. Fomisano [1978] found earnings to be significant in explaining dividend decisions, but it is unclear as to how earnings were measured in the study. Harrington [1979] used three measures of statutory earnings in his study of dividend policy, and found that the inclusion of capital gains and losses in the definition of earnings tended not to influence life insurer decisions about dividend payments to stockholders. Finally, in preliminary look at the impact of requiring life insurers to report adjusted as well as statutory earnings, Foster [1975] provided some evidence that the aggregate stock market implicitly adjusted earnings measures before 1973, when the reporting requirement went into effect for life insurers. Thus, there is considerable confusion as to how earnings should properly be measured for purposes such as that of the current study. Rather than arbitrarily choose one measure, four different earnings quantities are considered here. Note that all these four measures are statutory in nature.

Earnings measure *A* is the net gain from operations after policyholder dividends and federal income taxes. Revenue reflected in this earnings measure is derived from numerous sources, including premiums for insurance protection, payments for supplementary contracts, and net investment income (exclusive of capital gains). Expenses subtracted included benefit and associated interest payments, increases in some reserves, commissions, insurance taxes, and other general operational expenses. Policyholder dividends are deducted from the net gain, as is done in the convention blank statement of the National Association of Insurance Commissioners (NAIC). As explained in Carter [1977, p. 158], this procedure is usually followed for two reasons, even though policyholder dividends are actually distributions of

surplus. First, the payment of such dividends represents a distribution from the current year's increase in surplus due to operations. And second, policyholder dividends may be partially deducted when calculating federal income taxes. In computing earnings measure A, it should be noted that the federal income tax subtraction does not reflect any tax on capital gains.

Earnings measures B, C, and D modify measure A in order to reflect the effects of capital gains and losses. This component is generally separated from the net gain from operations because of its potentially transitory nature. As explained more fully in Carter [1977, pp. 158-159], annual income would be more variable with the inclusion of capital gains and losses. This aggregation might lead to a misplaced emphasis by management on the realization of capital gains instead of on "an orderly growth in income" (Carter [1977, p. 158]) in the administration of investment activities. In fact, when the Accounting Principles Board originally proposed that all capital gains and losses, both realized and unrealized, be reflected in insurers' income statements, the insurance industry opposed the idea by arguing that such a change would distort investors' opinions and cause stock prices to decline (see APB [1971]). Hence, the net gain from operations (measure A) has been traditionally separated from capital gain and loss components. However, due to the seeming importance of capital gains and losses identified in some prior studies, this study uses several earnings measures which consider not only the net gain from operations, but also the capital gains and losses. Earnings measure B is equal to earnings measure A plus net realized and unrealized capital gains. However, many uncertainties exist in the definition of unrealized gains and losses. For example, realized gains and losses are reported net of associated income tax effects, while unrealized gains and losses are set forth without any accounting for potential tax consequences. Also, fluctuation in security market values are somewhat to be expected (as discussed further in the next paragraph) and do not necessarily imply permanent impairment or improvement of an insurer's portfolio. Therefore, a third earnings measure which considers only realized gains and losses is considered. That is, measure D equals earnings measure A plus net realized capital gains.

In most cases, the addition of only the net capital gains to net gain from operations does not totally reflect the effects of security transactions. Life insurers are required to maintain a liability account entitled the Mandatory Security Valuation Reserve (MSVR) to partially absorb fluctuations in the market value of securities held by the insurers. A brief explanation of the MSVR is provided here; a more complete discussion can be found in Robinson [1977]. The reserve is divided into two components (bond and preferred stocks, and common stocks), and insurers are required annually to add an amount computed by formula to each component, subject to certain maximums. All realized and unrealized capital gains must be added to the MSVR until it has reached its maximum, and all capital losses (both realized and unrealized) must be subtracted from the MSVR until it is reduced to zero. Thus, a capital gain (loss), which increases (decreases) surplus, may be completely offset by an increase (decrease) in the MSVR, which decreases (increases) surplus. The MSVR absorbs gains and losses as long as it has reached neither its maximum nor minimum (zero) levels, and thus partially insulates surplus from potentially large fluctuations due to changing security market values. Therefore, the complete balance sheet effect of capital gains and losses is obtained only in conjunction with changes in the MSVR. Earnings measure C is equal to earnings measure B minus (plus) the increase (decrease) in the MSVR. Measure C represents, therefore, an earnings figure reflecting the change in surplus due to net realized and unrealized capital gains which are not offset by changes in the MSVR.

One set of explanatory variables related to the earnings measures is dividend payout. Four versions (A-D) of this variable correspond to the four similarly labelled measures of earnings. In general, dividend payout is the average annual stockholder dividend per share divided by the earnings per share for the year. A second set of variables is the standard deviation of earnings per share, computed for each of the earnings measures. This variable measures the volatility of earnings and is included in the list by Myers [1977] of those factors which influence industrial firms' betas. Finally, accounting or earnings betas were computed for each measure of earnings. This variable represents the cyclicity factor noted by Myers [1977] and equals the slope coefficient obtained from regressions of the insurer's earnings per share on the average earnings per share for the entire sample. The use of average sample earnings is a common proxy for industry earnings and was used by Foster [1975] in his life insurance study.

Some summary information concerning the earnings-related explanatory variables is found in Tables 3, 4, and 5. In general, there are considerable differences in the four earnings measures. One manifestation of these variations is found by examining the dividend payout numbers. The same dividend figure is used in each case; therefore, the different payout results are strictly a function of differences in earnings. As expected, the series involving measure B are, in most cases, the most volatile. Just looking at the payout results, the averages tend to be higher, for most of the earnings measures, during subperiod 2. However, it should again be noted, when analyzing these results, that a few insurers paid some abnormally high dividends during this period. The standard deviations of earnings exhibit the least amount of differences according to earnings measures, and there is generally a lower amount of dispersion during subperiod 2. In looking at the accounting betas, the results shown in Tables 4 and 5 are, by necessity, based on only a very few observations included in the regression analyses. Thus, more confidence might be placed in the accounting betas reported in Table 3 for the entire sample period, although even in this case, each insurer's beta was estimated using only 11 annual observations. Such a situation is not unusual in estimating accounting betas. Foster [1975] was forced to use only 8 observations in making similar calculations. His accounting betas averaged close to 1.0 for life insurers. In this study, there is a wide range and dispersion of such betas among the 40 insurers, with those based on earnings measures B and C being the least volatile, as expected. The accounting betas are within a more meaningful range than is the case with the other measures. Attention is now turned to the utilization of these variables in an attempt to explain life insurers' total and systematic risk.

5. Analysis of factors influencing risk measures

Regression analysis was done to estimate the coefficients a_i and b_i in the following two equations:

$$(6) \quad \sigma_j^2 = a_0 + a_1X_{1j} + a_2X_{2j} + a_3X_{3j} + a_4X_{4j} + a_5X_{5j} + e_{1j}$$

$$(7) \quad \beta_j = b_0 + b_1X_{1j} + b_2X_{2j} + b_3X_{3j} + b_4X_{4j} + b_5X_{5j} + e_{2j}$$

where σ_j^2 = total risk for insurer j

β_j = systematic risk for insurer j

X_{1j} = leverage factor for insurer j

X_{2j} = dividend payout for insurer j

X_{3j} = growth factor for insurer j

X_{4j} = standard deviation of earnings for insurer j

X_{5j} = accounting beta for insurer j

a 's and b 's = regression coefficients

Several different versions of equations (6) and (7) were estimated, with variations due to time periods and different definitions of earnings and growth.

Table 6 reports the results of the total variance regression of equation (6). The whole period results as indicated in Table 6 show that standard deviation of earnings and accounting beta are two major variables in explaining total variance. In addition, growth rate measure C (asset growth) and dividend payout in terms of earnings measure D are also important in explaining the total variance. The regression results also show that the standard deviation of earnings, growth and payout ratios are important in explaining the variations of total variance for the initial subperiod. However, there are no accounting variables that can be used to explain the cross-sectional fluctuation of total variance in the second subperiod.

Table 7 reports the beta regression of equation (7). For the whole period, only the growth rate measure A in terms of earnings measure B is important in explaining the cross-sectional relation of beta coefficient. In the first subperiod, growth rate measures and accounting beta in terms of earnings measure B are important in explaining the fluctuation of beta cross-sectionally. For the second subperiod, only the accounting betas in terms of earnings measure C are important in explaining the cross-sectional beta fluctuations.

6. Summary and implications

One of the goals of this study has been to further investigate the role of the cost of capital concept for life insurers. Although its derivation through the CAPM is recognized as being desirable from a theoretical standpoint, a major practical problem in computing it has been the difficulty of estimating an insurer's beta as a necessary input. This research had addressed the problem of establishing the real determinants of total risk and beta for insurers, as a way to facilitate their use in various types of applications. If a historical relationship between both total risk and beta and various characteristics of an insurer can be verified, it may be easier to forecast these risk measures in the future. For instance, many of the variables that have been shown to influence the level of beta for industrial firms are controllable, to some extent, by firm managers. Their future values are, therefore, often not difficult to predict. Similarly, since a life insurer's risk is conceptually a function of the company's underwriting and investment risks, its managers may be able to control some of the specific variables influencing the insurer's total and systematic risk measures. A reliable historical link between life insurers' betas and several variables whose values are relatively easy to control and/or predict by management would therefore be useful in risk forecasting. Without some identification of relevant explanatory factors, it is hard for managers to have any impact on an insurer's risk posture. To that end, regression analysis was performed to test the past relationship that existed for 40 life insurers.

Overall, the investigated characteristics were able to explain only a very small amount of the variation in beta. Only growth and accounting betas were found to be significant in explaining beta. The results of the associated examination of factors which may determine an insurer's total risk were similar, in that growth, variation of earnings, accounting betas, and dividend payout were shown to be significant factors, although the overall explanatory power of the model was weak. These findings indicate that the search for relevant variables must continue. For example, items such as a firm's size, its growth in earnings, and its asset beta have been tested in a few previous studies and could be investigated for insurers. However, in light of the relative importance of nonsystematic risk in explaining returns for life insurers, particular emphasis in the search for explanatory factors should be placed on examining features unique to life insurers. For instance, changes in an insurer's liquidity position due to alterations in the demand for policy loans might be a relevant item to be included in future analyses. In addition, if one can be found, an insurer earnings index better than the sample average would be useful in calculating meaningful accounting betas for use as a possible explanatory factors. Along these same lines, this types of research based on the Arbitrage Pricing model may prove useful, as it would encompass factors not adequately considered in the CAPM.

Several supplementary inquiries also were undertaken in this paper. One of these additional investigations involved the nature of the risk-return relationship for stocks of life insurers. The non-systematic component was much more important than the systematic one in explaining the levels of returns. This finding reinforces the already discussed need to identify those insurer-specific and/or industry-specific factors which determine a company's earnings posture.

Another additional finding of this study involved the stability over time of risk measures for insurers. It was shown that total risk, as measured by the variance of returns, is much less volatile than is systematic risk. Therefore, whereas researchers and others should be fairly

cautious in using historical betas as proxies for the future, more confidence may be possible in using past total risk computations as estimates for the future. However, the lack of stability in the systematic risk calculations strengthens the arguments supporting the need to further identify the real determinants of beta.

Finally, in conjunction with the other goals pursued, this study examined four different measures of life earnings. As expected, definition A was the least volatile, while B exhibited the most variability. The use of the different earnings measures did not have a lot of effect in explaining the risk measures. Additional research appears to be necessary before definite conclusions can be drawn about the role of earnings in explaining market behavior. Especially, the Arbitrage Pricing model derived by Ross [1976, 1977] should be used to investigate capital asset pricing for life insurers.
