Abstract

Background: Domestic violence is one of the most common forms of violence against women. Domestic violence during pregnancy is associated with adverse perinatal and maternal outcomes. We aimed to assess whether domestic violence was associated with mode of delivery, low birthweight and preterm birth in two sites in Nepal.

Methods: In this prospective cohort study we consecutively recruited 2004 pregnant women during antenatal care at two hospitals between June 2015 and September 2016. The Abuse Assessment Screen (modified) was used to assess fear and violence. Having ever experienced either fear or violence was defined as any domestic violence. Obstetric outcomes were obtained from hospital records for 1381 (69%) women, selecting singleton pregnancies only. Mode of delivery was assessed as birth by cesarean section or not. A birthweight of less than 2500 g was defined as low birthweight and preterm birth as birth before completion of 37 weeks gestation. Descriptive and multiple logistic regression analyses were performed to assess associations.

Results: Twenty percent of the women reported any domestic violence. Among all 1381 women, 37.6% gave birth by cesarean section. Of those women who delivered by cesarean section, 84.7% had an emergency cesarean section. Less than 10% of the babies were born prematurely and 13.5% were born with low birthweight. We found no significant association between exposure to any domestic violence during pregnancy and risk of a low birthweight baby or birth by cesarean section. However, having experienced both violence and fear was significantly associated with giving birth to a preterm infant [aOR 2.33 (95% CI;1.10–4.73)].

Conclusions: Domestic violence is common in Nepal. This is a potential risk factor for severe morbidity and mortality in newborns. We found that the risk of having a preterm baby was higher for pregnant women who experienced both fear and violence. This should be recognized by the health sector. In this study, no significant differences were found in the rate of cesarean section nor low birthweight for women who had experienced any domestic violence compared to those who did not.

Keywords: Domestic violence, Perinatal outcomes, Low birthweight, Preterm birth, Cesarean section

Background

Domestic violence (DV) is one of the most common forms of violence against women [1]. It is defined in Nepal by the Ministry of Law, Justice and Parliamentary Affairs as any form of physical, mental, sexual, or economic harm, including acts of reprimand or emotional harm,

perpetrated by one person on another with whom he or she has a family relationship [2]. The term DV is applied in Nepal instead of intimate partner violence (IPV) because women often live in extended families and other family members may be the perpetrators of violence.

In Nepal, women typically relocate to their husband's homes after marriage and may become vulnerable to various forms of DV in the new household setting [3]. A woman's submissive role in her new home may generate fear irrespective of violence, mainly due to inequalities and power imbalances between men and women [4].

Women's fear is considered as emotional violence perpetrated by her husband or other family members [5].

The five-item Abuse Assessment Screen (AAS) has been widely used internationally to identify DV during pregnancy [6], including in low-income populations and with uninsured women in Brazil and Sri Lanka [7]. One of the questions in the AAS assesses 'fear'. Women are asked 'are you afraid of someone in the family?' The other questions assess if they have ever been emotionally, physically or sexually abused. A positive answer to any of the AAS questions defines a woman as having experienced any form of DV [5].

Since 2002, DV has been on the health agenda in Nepal and recognized as a risk factor for adverse pregnancy and childbirth outcomes [8]. Direct and/or indirect pathways lead from DV to adverse health outcomes [9]. Direct violence can result in physical injury and/or death [9]. Examples of indirect effects of DV are delayed or no health consultations and stress [9]. Stress during pregnancy raises cortisol levels which can lead to constriction of the blood vessels, limiting blood flow to the uterus and resulting in reduced blood supply to the unborn child [10, 11]. This in turn may cause low birth-weight (LBW) [11]. A further consequence of stress during pregnancy may be preterm contractions and preterm birth (PTB) [10].

LBW (< 2500 g at birth) is an important determinant of infant survival and development [12]. In 2010, the highest regional proportion of LBW babies (26%) was recorded in South Asia [13]. In Nepal, the proportion of infants born with LBW was 12.4% in 2011 [14]. LBW may be the result of intrauterine growth restriction or preterm birth. Preterm birth (PTB) is defined as being born before 37 weeks of gestational age. It may be spontaneous and the result of infections and/or premature rupture of membranes, or provider-initiated through induction or cesarean section (CS) [15]. Worldwide estimates of PTB range from 9% in high income countries to 11.8% in low income countries [16].

Increased operative interventions have also been associated with DV. Women exposed to DV are at increased risk of giving birth by Cesarean Section (CS) according to European studies [17, 18]. Women reporting current suffering from adult sexual abuse had the highest risk of an elective CS [17]. There are large variations in CS rates within countries, depending on the type of health facility and sector (public or private). In Nepal, CS estimates range from 1.6 to 49.5% [19].

DV has been increasingly acknowledged as a concern within the scope of antenatal care, and a range of studies have assessed its potential detrimental health effects on pregnant women and their newborns [20, 21]. Only a few studies have been conducted in low and middle income countries (LMICs) on DV and perinatal outcomes

and the results are inconclusive [22–25]. In Nepal, no prior studies have explored this topic. The aim of our study was to assess whether DV was associated to mode of delivery and explore the relationships between DV and LBW and PTB, in a prospective cohort of non-selected pregnant women.

Methods

We performed a prospective cohort study in which we followed singleton pregnant women recruited from two hospitals in Nepal – Dhulikhel Hospital (DH) and Kathmandu Medical College and Teaching Hospital (KMC). DH is a community-based non-profit tertiary care institution situated 30 km east of Kathmandu and KMC is a public-private referral hospital in Kathmandu city.

Pregnant women between 12 to 28 weeks of gestational age were consecutively recruited to the study in both sites during antenatal care [26]. Women with disabilities in vision and hearing, severe illness, in need of emergency assistance, or who did not understand Nepali, were excluded. A Color-Coded Audio Computer-Assisted Self-Interview (C-ACASI) was used wherein women answered a questionnaire in private on a tablet computer [26]. This allowed us to obtain information directly and confidentially from women about DV, sociodemographic and obstetric characteristics, and anxiety and depression. Information on birth outcomes was retrieved from the women's delivery records at DH and KMC. The extracted data was entered manually into a form developed in Open Data Kit (ODK) by trained research assistants and the first and second authors, between June 2015 and September 2016.

Of the 2004 women included at baseline, corresponding delivery records were identified for a total of 1382 (69%) of the women (DH 681, KMC 701). One woman from KMC was excluded due to twin delivery. Thus among 2003 women, 1381 had given birth at the two hospitals. Details of the recruitment process into the baseline study are published elsewhere [26].

Variables

The information on background characteristics and DV was collected at baseline using a modified version of the five-item Abuse Assessment Screen (AAS). A detailed description of the AAS, including our modifications to it, is presented elsewhere [26]. The women were asked to indicate whether they were ever afraid of anyone in their family, had experienced emotional and physical violence in their lifetime, physical and sexual violence before pregnancy and physical violence in their current pregnancy. Women with an affirmative response to any of the five AAS screening questions for DV were classified as having experience of 'any form of DV' and those with a negative responses were classified as having 'no exposure'. Sub-categories were created within the group

of women having experience of any DV. Women who reported they feared someone in the family but gave negative responses to any other experience of DV were classified as having experienced 'fear only'. In Nepal, 'fear' for women might either be related to power imbalances in her new home after marriage or due to DV [26]. Women who responded affirmatively to any physical, emotional or sexual violence, but not to fear, were classified as being exposed to 'violence only'. Women with affirmative responses to the questions on fear and violence were classified as having experience of 'both fear and violence'.

The sociodemographic characteristics included age, education and income of the woman and her husband and, for women only, their caste, ethnicity, family structure, geographical setting, knowledge of a financial incentive to give birth in health institutions, and permission to use their own income.

Symptoms of anxiety and depression were assessed with the Hopkins Symptom Checklist-5 (HSCL-5) which includes feeling fearful, nervousness or shakiness, feeling hopeless about the future, feeling blue, and worrying too much about things. Women were asked to indicate the severity of their feelings on a scale from one ('not at all') to four ('extremely'). Total mean score was calculated following guidance for use of this short version of the scale, and women who scored above two were defined as suffering from mental distress [27].

The outcome data collected from the medical records included mode of delivery and the status of the newborn: live birth or not, gestational age and weight, Apgar score at five minutes after birth, and whether the newborn was transferred to the neonatal intensive care unit (NICU). Infants weighing less than 2500 g were defined as being born with LBW. PTB was defined as a delivery before 37 completed weeks of gestation.

Women whose mode of delivery was by CS were compared to women who gave birth vaginally; either spontaneous or instrumental. Indications of CS were classified as prolonged labour, breech presentation, cephalo-pelvic disproportion, other fetal causes including fetal distress and intrauterine growth restriction or maternal causes such as maternal distress, antepartum hemorrhage, etc., and previous CS. For some women, information was missing on the indication for CS and they were classified as unknown.

Statistical analysis

Descriptive analyses were performed using SPSS software version 24 to assess and compare the socio-economic and obstetric characteristics of the women between exposed and unexposed. We also assessed if there were significant differences between the women with and without delivery records. The women's obstetric characteristics were compared between the two hospitals. To estimate associations

between DV reported in pregnancy and risks of having LBW, PTB and birth by CS, crude and multiple logistic regression analyses were performed in two models. Based on prior studies, we adjusted for study site, age, education and parity in the first model. Additional adjustments for geographical setting and family type were performed in the second model. Finally, we performed stratified regression analyses by parity adjusting for the same co-variables in both models except for parity. Confidence intervals (CI) were calculated at the 95% level.

Results

Birth outcomes were obtained for 69% ($n = 1381$) of the women recruited to the study at baseline. The women for whom no delivery records were found did not differ significantly from the women who gave birth at the hospitals in terms of their DV status, sociodemographic characteristics, baseline symptoms of anxiety and depression, or parity (Additional file 1). A total of 283 women (20.5%) reported having experience of any form of DV. A total of 235 (17%), reported being afraid of someone in the family at the time of completing the questionnaire, while 5.2% reported having experienced emotional or physical abuse combined, 2.5% physical abuse only, 1.5% physical abuse during the current pregnancy, and 0.9% had experienced sexual abuse (Additional file 3). The women reporting any DV were significantly younger, less educated and had less autonomy over their income. They were also more often from rural areas, of Dalit (the most oppressed social class) and Janajatis, and reported more symptoms of anxiety and depression at baseline (Table 1).

Among all 1381 women, the majority of women visited antenatal care (ANC) at least four times. However, a higher proportion (38.2%) of women at KMC had less than four ANC visits compared to DH (4.9%) (Table 2).

Among all women, 37.6% gave birth by CS. Of those women who delivered by CS, 84.7% had an emergency CS. Previous CS (27.6%) was the most common indication for CS. Less than 10% of the newborns were born preterm and 13.5% were born with low birthweight (Table 2).

Women giving birth at DH were significantly less likely to be delivered by CS (28.3%) compared to KMC (46.6%), and more newborns born at DH had a lower birthweight (15.9%) compared to KMC (11.0%) (Additional file 2). There was no significant difference between the two hospitals as to gestational age at birth (Additional file 2).

We found no statistically significant association between DV and mode of delivery, nor between DV and LBW (Table 3). Having reported both violence and fear was significantly associated to PTB after adjustments, aOR 2.27 (1.16–4.79) in model one and aOR 2.33 (1.10–4.73) in model 2, for all women (Table 3). In the stratified analyses

^eHSCL-5 score: Hopkins Symptom Checklist score-5

this significant relationship was only present for primiparous women (Table 3).

Discussion

Women reporting both violence and fear were significantly more likely to give birth before term compared to women who did not report any experience of DV. This relationship remained significant only for primiparous

women in the stratified adjusted analysis. We did not find a significant association between any form of DV reported in pregnancy and having a LBW baby or giving birth by CS.

Nine percent of newborns in our study were born pre-term, based on the assessment of gestational age by women's reported last menstrual period, This is in line with 8.1% PTB found in a tertiary hospital of Nepal [28].

^aamong women with complete case information (N = 1330)

Compared to other LMICs, our estimated rate of PTB was slightly higher than in Tanzanian (7.9%) and Vietnamese (2.7%) cohorts [22, 23]. These other studies both used obstetric ultrasound scanning before 24 weeks of gestation to determine gestational age at birth. Our reliance on women's reported last menstrual period may have yielded a falsely high prevalence rate of PTB due to recall bias as in Brazilian and Canadian studies [24, 29]. At the two sites in our study anomaly scanning is performed but not routine dating scanning. Prior studies have shown particular forms of violence, especially severe forms of physical or sexual violence, to be associated with LBW and PTB [22–24]. In line with the Vietnamese [23] and Tanzanian [22] studies, we found that experiencing both fear and violence was associated to PTB. In our study, having experienced both fear and violence, very likely included the women experiencing more severe violence compared to those reporting fear only or violence only. However, more detailed patient histories may have helped us to identify other subgroups of women.

The prevalence of LBW in our study is 13.5%, aligning with the reported national rate [14] and similar to a Brazilian study where LBW was reported as 13.8% [15]. The proportion of LBW in our study is higher than in other cohort studies in LMICs [22, 23, 30]. This may be due to the low socio-economic status of women in our study, as this factor is one of the strongest predictors of LBW in low-income countries [31]. As in Brazil [30] and Pakistan [25], we also found no association between DV and LBW.

Based on information from 150 countries, 18.6% of all births occur by CS, with the lowest proportion (6%) in low-income countries [32]. In our study, among all births, 37.6% occurred by CS, with CS rates at KMC being significantly higher than at DH. These CS rates are far higher than the national Nepali average of 12.0% (public sector 1.6% and private sector 49.5%) [19]. This may be due to the fact that both hospitals are tertiary level referral hospitals and they neither are government hospitals. Contradictory to two European studies [17, 18], however, women exposed to DV in our study were not at a higher risk of having a CS. The lack of association in our study may be the result of selection biases. It is possible that women who were exposed to DV and had poor perinatal outcomes, delivered elsewhere. We can also hypothesize that controlling behaviors by abusers may have hindered women from returning to the hospitals to receive treatment for pregnancy complications or to give birth. By contrast, it may have been more likely for women with no exposure to DV to be encouraged by their families to seek hospital care when experiencing pregnancy complications. These potential selection biases could have led to an underestimation of the association between DV and poor outcomes.

We might also have misclassified exposed women as non-exposed to any DV. The questions we asked about abuse may have excluded context-specific DV; for example, DV perpetrated by mothers-in-law by depriving daughters-in-law of food, impeding access to pregnancy care or accepting DV as the husbands right to discipline his family [3]. Also, women may have underreported DV on account of its sensitivity and taboo status in Nepal, because women are taught to silently endure DV, or reporting it may have felt like a hindrance to familial reconciliation [3]. Additionally, women may have encountered DV at a later stage in their pregnancies than when our estimates were made between 12 to 28 weeks of gestational age. Any women who experienced DV after this time period would have been classified as non-exposed in our study; hence the lack of associations we found could be due to diluting of effects.

The etiologies of PTB and LBW are multifactorial and we have not taken all factors into account, such as women's short stature, low body mass index (BMI), smoking (or second-hand smoking by use of low quality household fuel), and alcohol consumption [33]. Likewise, physical work during pregnancy, hemoglobin levels below 11 g/dl, and poor nutritional status during pregnancy were significantly associated with LBW in another study in a tertiary hospital of Nepal [34]. These findings were supported in the recent Nepal Demographic and Health Survey (NDHS) 2016 where 17% of women in reproductive age groups were classified as undernourished with BMIs of < 17 kg/m² [35]. These confounders may dilute any effect of DV in our study.

Despite the limitations, our study is notable for its inclusion of a large non selective population of pregnant women at two sites. Although we could not identify birth records for all women, we found no significant selection biases in the background variables between the women with and without delivery records. In Nepal, 57% of births take place at a health facility [35]. Many women in Nepal give birth at home. This offers some explanation for why we only found records for 69% of the women attending ANC. The study information was obtained with standardized instruments, and the delivery outcomes were recorded independent of the baseline information. To our knowledge, this is the first prospective cohort study conducted with pregnant women in routine care in Nepal.

Conclusions

DV is potentially lethal, and ANC provides a window of opportunity to identify exposed women, improve their safety, and provide relevant care. Our study indicates that DV is among the risk factors for preterm delivery, which may lead to severe morbidity and mortality in newborns.

To improve the response of health care systems to DV in LMICs, it is important to continue to increase evidence-based knowledge about the effects of DV on pregnant women, as well as the capacity of staff working in ANC to respond to DV, and explore the implementation of interventions.

Acknowledgements

We are thankful to the funders of this study, the departments of obstetrics and gynecology at DH and KMC, our research assistants Buna Bhandari, Nabina Shrestha, and the C-ACASI team of Prabin Shakya and Pramita Shrestha. We would like to acknowledge Johan Håkon Bjørngaard at NTNU for his constant guidance in the statistical analyses, as well as the other members of the ADVANCE study team: Ragnhild Lund from NTNU (Norway); Rajendra Koju at DH and Sunil Kumar Joshi at KMC, both affiliates of Kathmandu University (Nepal); Kumudu Wijewardene, Dinusha Chamanie Perera and Munas M. Muzrif at the University of Sri Jayawardenepura (Sri Lanka); Katarina Swahnberg at Linneaus University Kalmar (Sweden) and Jacquelyn C. Campbell at Johns Hopkins University (USA). Addressing Domestic Violence in Antenatal Care Environments (ADVANCE).

Funding

The ADVANCE study is funded by the Research Council of Norway, grant number 220893, and supported by the Liaison Committee for Education, Research and Innovation in Central Norway (Samarbeidsorganet), grant number 16/29034.

Availability of data and materials

Data associated with this study are not publicly available due to their sensitive nature, and given that release of the information could compromise the safety of the research participants. However, after deleting identifiable data such as age, date of birth, and surname, the data could be made available from the corresponding author on reasonable request.

Authors' contributions

KDP designed and developed the study, collected and analyzed the data, and drafted the manuscript. PR also participated in data collection and analysis. ED and JJI participated in development of the research protocol, study design, drafting and editing of the manuscript. SS participated in data collection. ML and BS participated in conception of this study, the development of the research protocol, study design, data analysis and drafting of the manuscript. All authors made revisions to the drafts of the manuscript, read and approved the final draft, and agreed to be accountable for all aspects of the work.

Ethics approval and consent to participate

Ethical approval for the study was obtained from two Regional Committees for Medical and Health Research Ethics in Norway (REK Central Norway 2014/613 and REK Sør-Øst C 2014/146), the Nepal Health Research Council (NHRC Reg. no. 81/2014 and Reg. no. 08/2014), and the Institutional Review

Committee of Kathmandu University (KUIRC 55/44). Verbal consent was chosen over written consent given women's low literacy rates in Nepal [35], and the ethic committees approved the verbal consent process. Participants completed the C-ACASI questionnaire in a private room. The study was publicly referred to as one on 'women's reproductive health' rather than a study on DV. All participating women were provided with a brochure on 'safe motherhood', and an anonymous looking business card with the telephone number for a female psychosocial counsellor at the One Stop Crisis Management Centre (OCMC) at DH and the safehouse run by the Women's Rehabilitation Centre (WOREC) for participants at KMC.

Consent for publication
