Introduction: The Chelsea Critical Care Physical Assessment tool (CPAx) is a performance-based measurement instrument to evaluate respiratory function, functional mobility and grip strength in critically ill adults [1]. The CPax has established construct validity and high interrater reliability in a general ICU population [2], but little is known about its validity to measure change over time (cross-sectional-validity).

Objectives: The current study investigated cross-sectional validity at three relevant, pre-specified timepoints across the ICU and hospital stay in critically ill adults on prolonged mechanical ventilation.

Methods: This prospective, longitudinal, clinimetric study was conducted in a mixed ICU of a Swiss academic hospital. Participants were assessed by certified physiotherapists at three predefined timepoints: ICU baseline (between 72-144 h after the onset of mechanical ventilation), ICU discharge and hospital discharge. We hypothesized that the relationship of the CPax with other measurement tools would differ between these timepoints due to temporal changes in the measured characteristics. Based on this theoretical model we determined 22 a-priori defined hypotheses about the relationship of the CPax-GE with other instruments such as the Medical Research Council sum score (MRC-SS), ICU Mobility Scale (IMS) or Sequential Organ Failure Assessment (SOFA)

Results: CPax data of 58 participants (70.7% male) with a median age of 68 years (IQR 56-73), APACHE II score of 32 (28-36) and ICU stay of 7.97 days (6.69-12.85) were analysed. Cross-sectional validity was excellent with 86% (6 out of 7), 89% (8 out of 9) and 83% (5 out of 6) of the a-priori hypotheses accepted at ICU baseline, ICU discharge and hospital discharge, respectively. Floor (10%) and ceiling effects (6%) were likewise highly acceptable.

Table 1 Selection of a-priori hypothesis and test-results

Hypothesis	n	Spearman's rank correlation coefficient (r)	confirmed
ICU Baseline			
CPAx with MRC-SS (r=0.5 to 0.8)	58	0.639	yes
CPAx with IMS (r=0.6 to 0.9)	58	0.711	yes
CPAx with SOFA (r= -0.4 to -0.7)	58	-0.341	no
ICU Discharge			
CPAx with MRC-SS (r=0.6 to 0.9)	50	0.809	yes
CPAx with IMS (r>0.7)	50	0.883	yes
CPAx with SOFA (r= -0.4 to -0.7)	50	-0.482	yes
Hospital Discharge			
CPAx with MRC-SS (r=0.5 to 0.8)	31	0.674	yes
CPAx with IMS (r>0.7)	32	0.856	yes

Conclusion: The CPax demonstrated cross-sectional validity as an indicator of change over time. Floor and ceiling effects were low enabling therapists to detect change across the ICU and hospital stay. The CPax can therefore be recommended to assess physical function and activity in critically ill adults from ICU baseline to ICU and hospital discharge.

Intensive Care Medicine Experimental 2020, 8(2): 000074

Introduction: Imipenem/cilastatin/relebactam (IMI/REL) is a fixed-dose combination of imipenem, a carbapenem antibacterial agent, cilastatin, a renal dehydropeptidase inhibitor, and relebactam, a novel β -lactamase inhibitor.

Objectives: To analyze the efficacy and safety of IMI/REL and piperacillin/tazobactam (PIP/TAZ) in patients with hospital-acquired bacterial pneumonia (HABP) and ventilator-associated bacterial pneumonia (VABP) from the phase 3 RESTORE-IMI 2 trial (NCT02493764) grouped by geographic region.

Methods: Randomized patients received IMI/REL (500 mg/500 mg/250 mg) or PIP/TAZ (4000 mg/500 mg) intravenously every 6 hours for 7–14 days; dosing was adjusted for renal impairment. Efficacy endpoints included all-cause mortality (ACM) through day 28, clinical response at early follow-up (EFU) in the modified intention-to-treat population (MITT), and microbiological response at end of treatment (EOT) in the microbiological MITT population (mMITT). The MITT included patients who received ≥ 1 dose of study treatment and did not have only gram-positive cocci on the baseline respiratory specimen Gram stain; the mMITT comprised patients from the MITT with ≥ 1 baseline pathogen, excluding monomicrobial infection with organisms known to be intrinsically resistant to IMI/REL (methicillin-resistant *Staphylococcus aureus*, *Enterococcus faecium*, *Legionella* spp., *Stenotrophomonas* spp., or *Burkholderia* spp.). Differences in efficacy endpoints and 95% CIs were adjusted by the Miettinen & Nurminen method. The safety population included patients who received ≥ 1 dose of study treatment. Adverse events (AEs) were collected for 14 days posttreatment. Efficacy and safety were analyzed by geographic region; patients were not randomized based on geographic blocks.

Results: Of 531 MITT patients, 264 received IMI/REL and 267 received PIP/TAZ. Most patients were from Eastern Europe (52%), followed by Asia (14%), South America (13%), North/Central America (11%), and Western Europe (9%). Mean age ranged from 47–71 years, and 57–80% were male. At baseline, 39–72% had APACHE II scores ≥ 15 , 44–80% had Clinical Pulmonary Infection Scores ≥ 6 , and 13–47% had moderate to severe renal impairment (creatinine clearance < 60 to ≥ 15 mL/min). Across all regions, day 28 ACM was lower with IMI/REL vs PIP/TAZ and clinical response at EFU and microbiological response at EOT was higher with IMI/REL vs PIP/TAZ (Table). IMI/REL and PIP/TAZ had a comparable safety profile; $\geq 85\%$ of patients reported ≥ 1 AE, and serious AEs ranged from 20–59%. No regional differences in AE incidence were noted.

Table. Proportion of Patients With ACM Through Day 28, Favorable Clinical Response at EFU, and Favorable Overall Microbiological Response at EOT by Region

	IMI/REL		PIP/TAZ		Difference*	
	n/m	%	n/m	%	%	95% CI
28-day ACM (MITT)	264		267			
Overall	42/264	15.9	57/267	21.3	-5.3	-11.9 to 1.2
Asia	5/39	12.8	8/36	22.2	-9.4	-27.5 to 8.2
North/Central America	1/21	4.8	5/39	12.8	-8.1	-23.2 to 11.4
South America	10/38	26.3	11/32	34.4	-8.1	-29.6 to 13.5
Eastern Europe	24/142	16.9	26/135	19.3	-2.4	-11.6 to 6.8
Western Europe	2/24	8.3	7/25	28.0	-19.7	-41.2 to 25.5
Clinical response at EFU (MITT)	264		267			
Overall	161/264	61.0	149/267	55.8	5.0	-3.2 to 13.2
Asia	25/39	64.1	19/36	52.8	11.3	-11.0 to 32.7
North/Central America	17/21	81.0	24/39	61.5	19.4	-5.9 to 40.1
South America	24/38	63.2	17/32	53.1	10.0	-13.0 to 32.3
Eastern Europe	82/142	57.7	77/135	57.0	0.7	-10.9 to 12.3
Western Europe	13/24	54.2	12/25	48.0	6.2	-21.5 to 32.9
Microbiological response at EOT (mMITT)	215		218			
Overall	166/215	77.2	148/218	67.9	9.7	1.6 to 17.9
Asia	23/31	74.2	19/29	65.5	8.7	-14.7 to 31.5
North/Central America	17/18	94.4	18/32	56.3	38.2	13.5 to 56.9
South America	22/28	78.6	12/20	60.0	18.6	-7.6 to 44.1
Eastern Europe	95/121	78.5	88/115	76.5	2.0	-8.7 to 13.8
Western Europe	9/17	52.9	11/22	50.0	2.9	-27.8 to 33.1

*Differences and 95% CIs were based on the Miettinen & Nurminen method.

^an/m = number of patients with a survival status of death or unknown/number of patients in the MITT population.

^bn/m = number of patients with a favorable clinical response/number of patients in the MITT population.

^cn/m = number of patients with a favorable microbiological response/number of patients in the mMITT population.

ACM, all-cause mortality; EFU, early follow-up; EOT, end of treatment; IMI/REL, imipenem/cilastatin/relebactam; MITT, modified intention-to-treat population; mMITT, microbiological modified intention-to-treat population; PIP/TAZ, piperacillin/tazobactam.

Conclusion: In clinically complex patients, the efficacy and safety of IMI/REL were comparable across treatment groups and regions, supporting the use of IMI/REL as an effective treatment for HABP/VABP in all regions. The incidence of AEs was typical of patients with HABP/VABP who receive antibacterials.

Intensive Care Medicine Experimental 2020, **8(2)**: 000114

Introduction: Septic shock (SS) is usually responsible of a dysautonomic syndrome including an impairment of cardiovascular variability, the onset of inappropriate tachycardia, an immunosuppression and an increased mortality. In experimental SS, β_1 -adrenergic blockade is associated with cardiovascular benefits and possibly immune modulations.

Objectives: The main goal of this study was to investigate the effect of β_1 -adrenergic modulation on lymphocyte subpopulations in a rodent experimental model of SS.

Methods: SS was induced by cecal ligation and puncture (CLP) in wild type (WT) mice with or without esmolol (ultra-selective β_1 -blocker) and in β_1 -AR knock out mice (β_1 KO). Assessment 18 hours after surgery included *in vivo* cardiac function assessed by echocardiography. Blood was collected for cytokine measurements. Splenocytes were isolated to assess lymphocyte subpopulations by flow cytometry and cultured 72h with a cell trace to measure cell proliferation capacities.

Results: SS was characterized in WT CLP compared to WT sham animals by a decrease in heart rate (HR) (318 ± 31 in CLP vs. 360 ± 48 bpm in sham animals, $p = 0.01$) and in mean arterial pressure (MAP) (mean \pm SD) (62.2 ± 11.8 vs. 84.8 ± 6.9 mmHg, $p < 0.0001$). Compared to WT sham, WT CLP animals showed an increase in both pro- and anti-inflammatory cytokines (IL6: 10.58 ± 15.01 vs. 0.05 ± 0.03 ng/ml, $p = 0.004$, IL10: 2.28 ± 1.22 vs. 0.04 ± 0.01 ng/ml, $p = 0.004$), a decrease in Th4 lymphocytes (10.7 ± 3.1 vs. 16.1 ± 1.8 % of T lymphocytes, $p = 0.0001$) and an increase in regulatory T cell percentage (12.49 ± 2.74 vs. 7.55 ± 1.75 % of T helper, $p < 0.0001$). Compared to WT sham, WT CLP animals showed a decrease of lymphocytes proliferation (66.7 ± 9.5 vs. 78.6 ± 7.1 % of proliferative lymphocytes, $p = 0.025$).

Compared to WT CLP, HR in WT CLP + esmolol, was decreased (273 ± 45 in WT CLP + esmolol vs. 318 ± 31 bpm in WT CLP animals, $p = 0.005$). There was no difference in MAP between WT CLP + esmolol and WT CLP (67.4 ± 17.3 vs. 62.2 ± 11.8 mmHg, $p = 0.20$). In WT CLP + esmolol, pro- and anti-inflammatory cytokines decreased compared to WT CLP (IL6: 0.64 ± 0.52 vs. 10.58 ± 15.01 ng/ml, $p = 0.004$, IL10: 0.41 ± 0.28 vs. 2.28 ± 1.22 ng/ml, $p = 0.002$). The T helper lymphocytes percentage in the spleen increase in WT CLP + esmolol compared to WT CLP (14.7 ± 2.9 vs. 10.7 ± 3.1 % of T helper, $p = 0.007$). The regulatory T lymphocytes percentage was decreased in WT CLP + esmolol compared to WT CLP (10.09 ± 3.03 vs. 12.49 ± 2.74 % of T helper, $p = 0.03$). There is a trend increase in splenocyte proliferation percentage for WT CLP + esmolol animals (72.0 ± 4.2 vs. 66.7 ± 9.5 % of proliferative lymphocytes, $p = 0.72$). Hemodynamic and immune pattern results were similar in β_1 KO septic animals compared to β_1 KO sham animals.

Conclusion: β_1 -adrenergic modulation by esmolol reduce septic shock-related immunosuppression by decreasing regulatory T lymphocyte percentage, increasing lymphocyte counts and trend to increase proliferation.

Intensive Care Medicine Experimental 2020, **8(2)**: 000170

Introduction: Restrictive use of antibiotics is required to prevent the rapid emergence and spread of multidrug-resistant pathogens but practice is challenging for critically ill patients. Gram staining should provide immediate information for predicting pathogenic bacteria, however, the effectiveness of Gram staining for initial antibiotic choice on clinical outcomes is not investigated in intensive care units (ICUs).

Objectives: To compare the clinical response between initial antibiotics selection based on Gram staining information and guidelines recommendation in patients with ventilator-associated pneumonia (VAP), which is one of the most common hospital-acquired infection in ICUs.

Methods: The GRam stain-guided Antibiotics ChoicE for Ventilator-Associated Pneumonia (GRACE-VAP) trial was a multicenter, randomized, open-label non-inferiority clinical trial conducted in 12 ICUs in Japan from April 2018 to April 2020. Eligibility criteria was aged ≥ 15 years, with mechanical ventilation for at least 48 hours and diagnosed as VAP with a modified clinical pulmonary infection score ≥ 5 . Patients were randomly assigned to receive Gram stain-guided initial antibiotic treatment (Gram-stain group) or guidelines-based treatment (standard group). The primary endpoint was clinical response rate which was defined as that fulfilling all four of the following components: completion of antibiotic therapy within 14 days, improvement or lack of progression of baseline radiographic findings at the end of therapy, resolution of signs and symptoms of pneumonia 7 days after the end of therapy, lack of antibiotic agent re-administration due to pneumonia within 7 days. We set non-inferiority margin at 20% for primary endpoint with one-sided alpha level of 0.025. Secondary endpoints included the coverage rates of initial antibiotic therapies, the selected rates of anti-pseudomonal agents and anti-MRSA agents as initial antibiotic therapies, 28-day all-cause mortality, ICU-free days, ventilator-free days, and adverse events.

Results: A total of 206 patients underwent randomization (103 patients to the Gram-stain group and 103 patients to the standard group). The median age was 69 (range: 16-93) years, and men accounted for 68.4%. The median hospital stay from ICU admission to enrollment was 4 (range: 3-34) days. The backgrounds were similar between groups. In a per-protocol analysis, the clinical response was observed in 79/103 patients (76.2%) with the Gram-stain group and 74/103 (71.7%) with the standard group (risk difference, 0.049 95% confidence interval, -0.07 to 0.17; $p < 0.001$ for non-inferiority). Both anti-pseudomonal agents and anti-MRSA agents were significantly less administered in Gram-stain group than standard group (72 cases vs. 103 cases, $p < 0.001$; 63 cases vs. 103 cases, $p < 0.001$, respectively). The coverage rates of initial antibiotic therapies and 28-day all-cause mortality were similar (86.4% vs. 92.2%; $p = 0.18$, 13.6% vs. 17.5%, $p = 0.39$, respectively), and all other secondary outcomes were also similar between groups.

Conclusion: The GRACE-VAP trial showed Gram stain-guided treatment significantly restricted the use of broad-spectrum antibiotics than guidelines-based treatment with similar clinical responses in patients with VAP in ICU. This reinforced the utility of Gram staining in the setting of critical care to ameliorate the spread of multidrug-resistant pathogens. (Trial Registration; Clinicaltrials.gov NCT03506113)

Intensive Care Medicine Experimental 2020, **8(2)**: 000186

Introduction: Sepsis is a life-threatening pathological host response to an infection often leading to significant vascular leakage. The elementary molecular mechanisms remain incompletely understood and specially the role of the micro RNAs (MIR) has not been investigated further in detail. We hypothesized that specific MIRs might be up-regulated in the septic endothelium thereby contributing to vascular barrier breakdown.

Objectives: To identify MIRs, regulated in the septic endothelium and to elucidate their role in endothelial permeability.

Methods: Possible regulated MIRs were screened by an unbiased MIR array approach from murine lung endothelial cells (CD146 + magnetic isolation). *In vivo*, the effect of specific MIRs on permeability was assessed in a transgenic zebrafish larvae (flk:mCherry) and a murine knockout (KO B6.Cg-Mir155tm1.1Rsky/J) model. Both Lipopolysaccharides (LPS) and cecal ligation and puncture (CLP) were used for the induction of systemic inflammation. Readouts were pulmonary permeability (Evans Blue, Wet-to-Dry), activity scoring and survival. Mechanistic studies were done in human umbilical vein endothelial cells (HUVECs) using standard molecular biology tools (RT-PCR, Immunoblots) and functional real-time permeability measurements (ECIS-TER). Furthermore, immediate post mortem kidney biopsies ($n = 16$) were performed to evaluate the expression of MIRs in a septic human organism.

Results: MIR155 was significantly upregulated in the array (25 \times). Transgenic overexpression of MIR155 in zebrafish - as a screening tool - led to a extensive induction of vascular permeability (eye assay, $p < 0.01$). The same was observed when MIR155 was experimentally overexpressed in human ECs *in vitro* and permeability was measured ($p < 0.04$). Moreover, MIR155 inhibition protects against classical permeability mediators (i.e. thrombin, $p < 0,03$). We identified Claudin-1 (a tight junction protein) both on protein and mRNA level as putative MIR155 target both by overexpression and inhibition. Interestingly, *in vivo* the heterozygote MIR155 knockout mouse showed a protected phenotype with regard to capillary leakage and survival (40% benefit, $p < 0.01$). MIR155 was also increased in septic human renal tissue compared to kidney biopsies from non-septic patients ($p = 0.01$).

Conclusion: Using an unbiased MIR-array approach, we found that MIR155 is upregulated in septic endothelium in mouse and men. It

might contribute to the pathophysiology of vascular leakage in a Claudin-1 dependent manner. Future studies have to clarify if MIR155 could be a potential therapeutic target.

Intensive Care Medicine Experimental 2020, **8(2)**: 000237

Introduction: Between 2012-2015, the PEPaNIC randomized controlled trial, which included 1440 critically ill infants and children, showed that withholding parenteral nutrition during the first week in the paediatric intensive care unit (PICU) (late-PN), as compared with initiating supplemental PN early (early-PN), improved PICU outcomes (1) and improved neurocognitive development assessed 2 years later (2). The latter was explained by avoiding early-PN induced adversely altered DNA-methylation of 37 CpG sites (3). As a large number of patients were younger than 1 year of age at randomization and given that assessment of most neurocognitive domains is only possible from 4 years of age onwards, we performed a 4-year follow-up to determine the impact of late-PN versus early-PN on physical, neurocognitive, and emotional/behavioural development. This pre-planned, 4-year follow-up study of the 1440 PEPaNIC patients and of 369 matched healthy children was blinded for treatment allocation (ClinicalTrials.gov-NCT01536275).

Methods: Studied clinical outcomes included anthropometrics, health status, parent/caregiver-reported executive functions, and emotional/behavioural problems, and clinical tests for intelligence, visual-motor integration, alertness, motor coordination and memory. Univariable and multivariable linear and logistic regression analyses adjusted for risk factors assessed the impact of late-PN versus early-PN on the outcomes and investigated a potential mediation role of the adversely altered DNA-methylation of 37 CpG sites previously shown to be evoked by late-PN as compared with early-PN (3).

Results: Overall, at 4 years follow-up, patients (356 late-PN patients, 328 early-PN patients) could be tested neurocognitively. They revealed worse anthropometric, health status, neurocognitive and emotional/behavioural developmental outcomes than the healthy control children. Outcomes of late-PN patients were never worse than those of early-PN patients. In contrast, late-PN patients had fewer internalizing ($P = 0.042$) and externalizing problems ($P = 0.046$), and fewer total emotional/behavioural problems ($P = 0.007$) than early-PN patients, which were normalized by late-PN. Avoiding the early-PN induced adversely altered DNA-methylation status of the 37 CpG sites statistically explained its impact on the behavioural outcomes.

Conclusion: Four years after randomization to late-PN or early-PN in the PICU, late-PN did not show harm, and was found to protect against emotional/behavioural problems, with altered DNA-methylation as a potential biological mediator hereof. These data further support de-implementation of PN-use early during critical illness in infants and children.

Intensive Care Medicine Experimental 2020, **8(2)**: 000277

Introduction: The mortality rate of ARDS is high (35–46% from mild to severe) [1]. The acute phase is usually accompanied with moderate to severe hypoxemia. Positive end-expiratory pressure (PEEP) may improve oxygenation but at the same time may induce barotraumas. The best PEEP selection method is still under debate.

Objectives: The aim of the study was to compare PEEP titration with electrical impedance tomography (EIT) and with ventilator-embedded pressure-volume (PV) loop in moderate to severe ARDS.

Methods: This randomized control trials study was conducted from April 2017 to February 2019 in the ICU of FEMH. Patients with moderate to severe ARDS according to Berlin criteria were included. Total eighty-seven ARDS patients were randomized to either EIT group ($n = 42$) or PV group ($n = 45$). The exclusion criteria were clinical contraindications applying EIT or high PEEP level.

All patients were total sedated to prevent any spontaneous breathing and ventilated under volume-control mode (IBW/6ml/kg) and FiO_2 100%. The PV group used Hamilton G5 to measure the PV loop. The lungs were inflated with an increase pressure of 3 $\text{cmH}_2\text{O}/\text{sec}$ from 5 cmH_2O to 40 cmH_2O . The pressure was kept constant at 40 cmH_2O for 1 second. Subsequently, the lungs were passively deflated down to 5 cmH_2O . PEEP with maximal hysteresis (volume difference in the PV loop) was defined as optimal. In the EIT group, optimal PEEP was defined according to the regional compliance method published elsewhere [2]. The methods are illustrated in Fig. 1.

Parameters including optimal PEEP, airway pressures, compliance (Cr_s) and APACHE II, $\text{PaO}_2/\text{FiO}_2$, ICU day, resistance of the respiratory system (R) were measured and recorded.

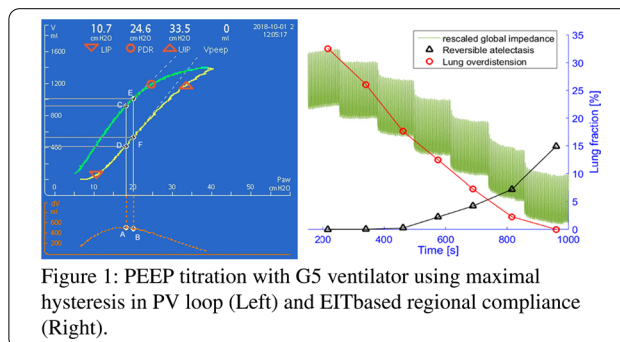

Figure 1: PEEP titration with G5 ventilator using maximal hysteresis in PV loop (Left) and EIT-based regional compliance (Right).

Results: After optimization, PEEP was significantly higher in the PV group (17.4 ± 1.7 vs. 16.2 ± 2.6 cmH_2O , PV vs. EIT groups, $p = 0.02$). After 48 hours, driving pressure was significantly higher in the PV group (12.4 ± 3.6 vs. 10.9 ± 2.5 cmH_2O , $p = 0.04$). Lung mechanics and oxygenation did not differ between the groups. The survival rate was

lower in the PV group (44.4% vs. 69.0%, $p = 0.02$; hazard ratio 2.1, confidence interval 1.1 to 3.9).

Conclusion: In moderate to severe ARDS, PEEP titration guided with EIT, compared with PV curve, was associated with improved driving pressure and survival rate. These findings support the use of EIT-based PEEP titration in ARDS.

Intensive Care Medicine Experimental 2020, **8(2)**: 000462

Introduction: Trauma remains a leading cause of mortality. The leading cause of preventable deaths in trauma patients is uncontrollable hemorrhage. During recent years' Damage Control Resuscitation (DCR) and Damage Control Surgery (DCS) has been the main strategy in the management of major hemorrhage in trauma patients. One aspect of DCR is permissive hypotension. However, the duration of hypotension that can be tolerated without affecting the brain is unknown. The authors have in a previously published experimental study shown that prolonged (90 minutes) and severe hypotension (mean arterial pressure (MAP) of 40 mmHg) results in irreversible metabolic perturbation evaluated by a marked and lasting increase in the lactate to pyruvate ratio (LP ratio) measured by intracerebral microdialysis (MD). Furthermore, the same study showed that the cerebral biochemical changes in response to severe hypotension was reflected in the cerebral venous outflow.

Objectives: In the present study we investigate the effect of 60 min severe hypotension (MAP equal 40 mmHg) on the brain's energy metabolism and seek to verify earlier findings that venous cerebral blood can be used as a marker of global cerebral energy state. The hypothesis is that hemorrhagic shock for 60 min results in less severe metabolic changes evaluated as a temporarily increase in the hemisphere LP ratio.

Methods: The study was approved by the Danish Animal Experiments Inspectorate. 10 pigs were anaesthetized, and vital parameters recorded. Probes for monitoring brain tissue oxygenation (PbtO₂) and intracranial pressure was placed in the right and left hemisphere respectively. Microdialysis catheters were placed in the left parietal lobe, femoral artery and superior sagittal sinus for analysis of lactate, pyruvate, glucose, glycerol and glutamate. The superior sagittal sinus was chosen for analysis of cerebral venous blood due to the anatomic characteristics of the pig. In the pig, most of the cerebral blood is drained via paraspinal venous plexa and only a minor part passes into the internal jugular vein. Hemorrhagic shock was induced by bleeding the animal until MAP of 40 mmHg was achieved. The MAP was kept around 40 mmHg by further withdrawing or infusing shed blood. After 60 min the pigs was resuscitated with autologous blood and observed for 3 hours.

Results: The volume of shed blood was (median (interquartile range)) 1469 mL (1378.4-1583.44 mL) and median blood loss per kilogram was 35 mL/Kg (31.9-36.8 mL/Kg).

During the period of hemorrhagic shock, MAP decreased to a median value of 39mmHg (35-42). Accordingly, CPP decreased to low levels of 33 mmHg (28-39). Similarly, PbtO₂ decreased to near critical levels of 19 mmHg (8-23). After resuscitation with shed blood MAP increased to near baseline levels ($p < 0.05$). The CPP showed a similar response, normalizing, but not reaching baseline levels ($p < 0.05$). In contrast, PbtO₂ increased to levels exceeding baseline values and stayed at that level during the rest of the observation period ($p < 0.05$)

At baseline the lactate to pyruvate ratio (LP ratio) in the hemisphere, artery and sagittal sinus were 13 (8-16), 21 (18-24) and 9 (6-22), respectively. After induction of hemorrhagic shock, the LP ratio from the left hemisphere in 9 pigs increased to levels indicating a reversible perturbation of cerebral energy metabolism 19 (12-30). The same pattern was seen in LP measurements from the femoral artery 28 (20-35) and sagittal sinus 22 (19-26). At the end of the experiment hemisphere, artery and sinus LP ratios were 16 (10-23), 17 (15-25), and 17 (10-27), respectively. Although hemisphere and sinus LP ratios decreased, they did not reach baseline levels ($p < 0.05$). In one pig hemisphere LP ratio increased to a level indicating irreversible metabolic perturbation (LP ratio > 200)

Conclusion: During 60 min of severe hemorrhagic shock intracerebral microdialysis shows signs of perturbations of cerebral energy metabolism, and these changes trends towards baseline values after resuscitation. Since time apparently is an important factor in the prevention of irreversible brain damage future studies should focus on methods (e.g. vasoactive drugs) to prolong the period in which permissive hypotension is safe for the brain. Sagittal sinus microdialysis values followed hemisphere values but were not distinguishable from systemic arterial values. Venous (jugular bulb) microdialysis might have a place in monitoring conditions where global cerebral ischemia is a risk, but further studies are required.

Intensive Care Medicine Experimental 2020, **8(2)**: 000463

Introduction: Oral chlorhexidine is used widely for mechanically ventilated patients to prevent ventilator-associated pneumonia but recent studies show an association with excess mortality [1,2].

Objectives: The primary objective of this study was to determine whether de-adoption of oral chlorhexidine and parallel implementation of a standardized oral care bundle reduces mortality in mechanically ventilated patients. Secondary outcomes were infection-related ventilator-associated complications (IVACs), oral health dysfunction and oral procedural pain.

Methods: A stepped wedge cluster randomized controlled trial with-integrated process evaluation conducted December 2017 to January 2019 in 6 academic intensive care units (ICUs) in Toronto, Canada [3]. Clusters were randomized to de-adopt oral chlorhexidine and implement a standardized 5-part oral care bundle comprising oral assessment, tooth brushing, mouth moisturization, lip moisturization and secretion removal every two months. We used an integrated knowledge translation strategy including point-of-care education, audit and feedback, and reminders to facilitate change in oral care [4]. Analyses were adjusted for patient characteristics, clustering within sites and secular trends. Trained observers conducted random evaluation of fidelity to the oral care bundle.

Results: A total of 3260 patients were enrolled; 1560 baseline (control), 1700 intervention phase. We found no difference in crude ICU mortality, 332 (21.2%) (control) and 400 (23.5%) (intervention) (adjusted odds ratio [aOR], 1.13; 95% confidence interval [CI], 0.82-1.54; $P = 0.46$) or the time to IVACs (adjusted hazard ratio, 1.06; 95% CI, 0.44-2.57; $P = 0.90$). Oral procedural pain was not significantly different (aOR, 0.62; 95% CI, 0.34-1.10; $P = 0.10$), however, oral health dysfunction scores significantly improved in the intervention phase (-0.96; 95% CI, - 1.75 to - 0.17; $P = 0.02$). Among 348 randomly observed oral care encounters, we identified 100% compliance with oral chlorhexidine de-adoption between control and intervention periods ($P < 0.0001$) and delivery of 4 out of 5 elements of the oral care bundle increased ($P < 0.0001$) in the intervention phase.

Conclusion: Among patients receiving mechanical ventilation, de-adoption of oral chlorhexidine and implementation of a standardized oral care bundle was not associated with lower mortality, IVACs or oral procedural pain, but did improve oral care. Our results indicate active de-adoption of oral chlorhexidine for IVAC prevention from clinical practice is needed due to lack of benefit and a standardized oral care bundle results in clinically important improvements in oral health and should be adopted into practice.

Intensive Care Medicine Experimental 2020, **8(2)**: 000512

Introduction: High Flow Nasal Cannula (HFNC) provides heated and humidified high gas flow (30 to 60 L/min) that reduces the inspiratory effort in hypoxemic patients [1]. No study showed the effects of HFNC in patients with increased respiratory drive from systemic inflammation and acidosis.

Objectives: HFNC might decrease effort measured by esophageal pressure swing (ΔP_{es}) in non-intubated patients with diagnosis of extra-pulmonary sepsis and septic shock.

Methods: We performed a prospective, multicentric physiological study in non-intubated sepsis and septic shock patients admitted to the Intensive Care Units of Maggiore Policlinico Hospital in Milan and of Sant'Anna Hospital in Ferrara. Exclusion criteria were: diagnosis of pneumonia, GCS < 12 and contraindication to the positioning of the esophageal catheter. Study protocol consisted of 3 consecutive phases of 20 minutes: first low flow oxygen (LFO), then HFNC and lastly LFO. FiO_2 was titrated to maintain SpO_2 of 92-96%. During all phases, esophageal pressure and electrical impedance tomography waveforms were continuously recorded.

Results: We present preliminary results on 22 patients (68 ± 14 yo), 11 (50%) with diagnosis of septic shock, with median serum lactate level of 2.30 [1.20-3.37] mmol/L and SOFA score 5 [4-9]. During HFNC, spontaneous effort measured as ΔP_{es} (see Figure 1) and as esophageal Pressure-Time Product (PTP) decreased, together with respiratory rate (RR), in comparison to LFO. Positive airway pressure generated by HFNC is showed by increased End Expiratory Lung Impedance ($\Delta EELI$) (see Table). Interestingly these effects were maintained, in part, also when patients were switched back to LFO.

	LFO	HFNC	LFO	ANOVA P VALUE
FiO ₂ (%)	32[28-36]	24[21-29]*	24[22-37]	0.01
SpO ₂ (%)	96[94-96]	96[95-96]	96[95-96]	0.526
PaO ₂ /FIO ₂	256[204-355]	312[250-360]	278[229-327]	0.232
Rox Index	13[9-21]	19[15-28]*	17[11-25]	<0.001
RR (bpm)	22[17-24]	19[14-23]**	20[15-24]	<0.001
$\Delta EELI$ (au)	baseline	728[22 - 1496]*	348[23- 1338]*	<0.01
ΔP_{es} (cmH ₂ O)	8[6-9]	5[4-7]*	7[5-12]	<0.01
PTP (cmH ₂ O*s/min)	185[143-256]	130[82-180]*	165[90-237]	0.01

*Post-Hoc Tukey $p < 0.05$ vs phase 1 **Post-Hoc Tukey $p < 0.05$ vs phase 1 and phase 3

Conclusion: HFNC reduces the inspiratory effort and provides positive airway pressure in patients with sepsis and septic shock.

Intensive Care Medicine Experimental 2020, **8(2)**: 000544

Introduction: Septic shock associated with cardiovascular failure is one of the most important reasons of death in Intensive Care Units. The mechanisms of the heart failure associated to sepsis remain unclear. Some ex-vivo data suggested a hypothetical mitochondrial failure induced by the pro-inflammatory mediators released during septic shock. However, those anomalies were not confirmed in vivo.

Objectives: This experiment aims at exploring the cardiac oxidative metabolism and its relation with perfusion and work through positron emission tomography (PET) imaging with [11C] acetate tracer, during an endotoxic shock in a pig model.

Methods: Forty anesthetized and mechanically ventilated pigs (mean weight = 25kg) were randomized into two groups: controls and those challenged with intravenous lipopolysaccharid (LPS-150 µg/kg/min during 30 min) to achieve a status of profound hypodynamic shock. No vasopressors were used. Animals were exclusively crystalloid fluid resuscitated as needed, following standard hemodynamic parameters. Heart rate (HR) and arterial blood pressure were continuously monitored throughout the study period. As a direct myocardial work reflection, the rate pressure product (RPP, in mmHg*bpm) was calculated as the product between HR and systolic blood pressure (SBP).

Subjects were submitted to PET-scan at three different time frames: before LPS infusion, during the early stage of the endotoxic shock (T = 60 minutes after infusion) and at a late time (T = 450 min from the beginning of the experiment). After the second PET-scan, animals in both groups were randomized to receive an infusion of ESMO-LOL (dosed enough to lower the HR of 20%) in order to evaluate the impact of beta-blockers in the endotoxic shock. For each PET-scan, [11C] acetate was used as tracer for the combined assessment of myocardial mean blood flow (F, in mL/min/g) and oxidative metabolism (k₂, acetate clearance rate, a measure of MVO₂ rate, in mL/min). Definition of myocardial regions of interests (ROIs) and kinetic modeling were performed using PMOD software (Pmod 3.4).

Results: In the LPS group (n = 20), the RPP increased respectively from 11708 to 14473 mmHg*bpm (p = 0,03) between the baseline (T = 0 min) and the LPS early stage (T = 60 min after infusion). In the same time, quantification of PET images performed before and after the endotoxic shock does not reveal significant changes in values of microcirculation or oxidative metabolism. These results show a dissociation during LPS challenge between the myocardial work that increased and the cardiac oxidative metabolism and the cardiac microcirculation which remained stable.

As expected, the adjunction of beta-blockers reduced the RPP (18097 vs 13613 mmHg*bpm; p = 0,02) and increased the microcirculation (1,408 vs 2,101 mL/min/g; p = 0,02) between the second and the last PET. No impact on the oxidative metabolism has been identified.

Conclusion: (1) These results suggest that despite the increased myocardial work caused by the LPS challenge, no significant changes in myocardial flow nor oxidative metabolism were found. These suggest a decoupling between work and PET results. The dysregulation of these adaptive phenomena may participate in the onset of myocardial involvement in sepsis. (2) The beta-blockers increased the microcirculation but had no effects on the oxidative metabolism.

Intensive Care Medicine Experimental 2020, **8(2)**: 000555

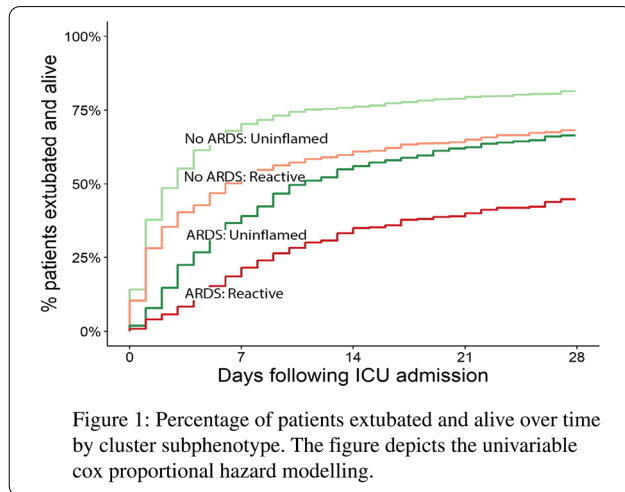

Introduction: Biological subphenotypes have been identified in acute respiratory distress syndrome (ARDS) [1, 2], which have shown to provide prognostic- and possibly predictive enrichment [2–4]. Differentiation of biological subphenotypes in ARDS is mainly driven by inflammatory parameters measured in plasma. Considering that this inflammatory response can also be observed in other types of acute respiratory failure and patients admitted to the ICU for other reasons [5], the question arises whether these subphenotypes are limited to ARDS.

Objectives: To determine whether these biological subphenotypes and their prognostic- and predictive enrichment could be extended to a general ICU population, irrespective of fulfilling the definition of ARDS.

Methods: This was a secondary analysis of the Molecular Diagnosis and Risk Stratification of Sepsis (MARS) study (ClinicalTrials.gov identifier NCT01905033), a prospective observational study of adult patients admitted to the ICU. Two previously proven parsimonious models

were used to determine the biological subphenotype of each patient. First, a cluster based model distinguishing an uninflamed and reactive subphenotype based on plasma levels of interleukin-6, interferon gamma, angiopoietin 1/2, and plasminogen activator inhibitor-1 [2]. Second, a latent class analysis (LCA) model revealing a hypo-inflammatory and hyper-inflammatory subphenotype using plasma levels of interleukin-8, protein C, and bicarbonate [4]. The prognostic enrichment was assessed with logistic regression analysis (30-day mortality) while correcting for the mediating effect of ARDS and with Cox regression analysis (ICU-mortality and ventilator-free days), for both biological phenotyping models. As part of predictive enrichment, blood leukocyte gene expression profiles in biological subphenotypes were analyzed by principal component analysis.

Results: We analyzed the data of 2500 patients (674 with ARDS and 1826 without ARDS). Here, we only report the results of patients without ARDS. The cluster-derived reactive subphenotype was, independently of ARDS, associated with (1) a higher 30-day mortality (OR 1.48, CI 1.16-1.89), (2) a higher probability of ICU mortality (HR 2.43, CI 1.90-3.11), and (3) a lower probability of successful extubation while alive (HR 0.66, CI 0.59-0.74; Figure 1) compared to the uninflamed subphenotype. The blood leukocyte gene expression profiles of each individual subphenotype were similar for patients with and without ARDS (all $p > 0.05$; Figure 2). LCA-derived subphenotypes showed similar profiles (data not shown).

Conclusion: The prognostic- and predictive enrichment of biological ARDS subphenotypes can be extended to a general ICU population. Using the concept of biological subphenotypes for splitting cohorts of critically ill patients could add to improving future precision-based trial strategies and lead to identifying treatable traits for all critically ill.

Introduction: Biomarkers can be of help in understanding critical illness and to identifying and stratifying sepsis. Adrenomedullin is a peptide hormone with vasoactive properties, with reported prognostic and potentially therapeutic value in sepsis.

Objectives: The aim of this study was to investigate how levels of circulating bioactive adrenomedullin (bio-ADM) at admission to the

intensive care unit (ICU) correspond to morbidity and mortality in sepsis patients as well as in a general ICU population.

Methods: Admission blood samples from all patients admitted to four ICUs during 2016 were batch-analysed. Patients fulfilling the sepsis-3 criteria were identified. Primary outcomes were the predictive capacity of bio-ADM to identify sepsis patients and the association of bio-ADM with 30-day mortality in the ICU. Secondary outcomes were the need for circulatory and renal support. A commonly used bio-ADM cutoff of 70 pg/mL was validated.

RESULTS. Bio-ADM in 1867 consecutive adult patients were analysed, and 632 patients fulfilled the sepsis criteria of whom 267 had septic shock. The median bio-ADM in the entire ICU population was 40 pg/mL, compared to 74 pg/mL in sepsis patients, 107 pg/mL in septic shock and 29 pg/mL in the non-septic patients. Sepsis was identified with an odds ratio (OR) of 1.64 for log2-transformed bio-ADM, after adjusting for severity of the disease. The association of elevated bio-ADM and 30-day mortality was equally strong in sepsis patients and the ICU population with an adjusted OR of 1.23 and 1.22, respectively. Higher levels of bio-ADM were associated with an increased need of renal replacement therapy with adjusted ORs of 2.28 and 1.97 for the ICU-population and the sepsis patients respectively, and with an increased need of vasopressors with adjusted OR of 1.33 for both populations. In the sepsis cohort, bio-ADM provided additional information to lactate on 30-day mortality. The cutoff of 70 pg/mL of bio-ADM was able to differentiate between survivors and non-survivors, but a threshold of 108 pg/mL performed better in the sepsis cohort.

Conclusion: Admission bio-ADM is an independent sepsis biomarker. In addition, bio-ADM levels are associated with 30-day mortality and organ failure in sepsis patients as well as in a general ICU-population.

Intensive Care Medicine Experimental 2020, **8(2)**: 000703

Introduction: Critically ill patients have an increased risk of dysphagia after prolonged oro-tracheal intubation (OTI) [1, 2]. COVID-19 is a multisystem disease caused by SARS-COV-2, characterized by acute respiratory failure; severe forms usually need mechanical ventilation (MV) support and required OTI; for prolonged courses tracheostomy is mandatory [3, 4].

Objectives: The purpose of this study was to evaluate dysphagia in critically ill COVID-19 patients, analyzing relations with clinical and biological data concerning MV during the ICU stay. Moreover, an analysis about recovery rate from dysphagia and its characteristics were reported.

Methods: This was a retrospective study on COVID-19 cohort patients admitted to intensive care unit (ICU); patients died before the first evaluation were excluded from the analysis. Dysphagia score has been reported in agreement with *Gugging Swallowing Screen* (GUSS) [5]. GUSS stratified the severity of dysphagia into severe (0–9), moderate (10–14), mild (15–19) or no dysphagia (20 points), according to clinical evaluation made by speech and language therapist (SLT). Data related

to MV days, ICU length of stay (LOS) and other clinically relevant variables were analyzed.

Results: Forty-two consecutive patients were admitted to ICU, with an average age of 61 years (SD 12); according to exclusion criteria, 31 (74%) were evaluated by the nurse and the SLT. Twenty-five of them were mechanically ventilated; 19 (76%) patients were treated with OTI, and 6 (24%) of them were tracheostomized; median MV days were 11 (7.5 - 16). At first SLT evaluation, 14 (45.2%) patients showed no dysphagia, 5 (16.1%) a mild degree of dysphagia, 6 (19.4%) a moderate level of dysphagia and 6 (19.4%) patients had a severe dysphagia. Mean first GUSS evaluation was 15.1 (SD 6.5), with a median of 19 (IQR = 12-20).

A correlation was found between distribution of GUSS score at first evaluation and ICU LOS ($p < 0.001$), MV days ($p < 0.001$), age ($p = 0.03$) and tracheostomy ($p = 0.04$). No correlation was found with BMI, SAPS, SOFA, NEMS at admission, sex, comorbidities (COPD, OSA, diabetes, Hypertension and IHD), pronation maneuvers and initial PEEP setting. After 7 days from the first SLT evaluation, GUSS stratification showed 2 (6.5%) patients with severe form of dysphagia, 2 (6.5%) with moderate dysphagia, 4 (12.9%) with mild dysphagia and finally 23 (74.2%) without dysphagia. This 7-days evolution resulted significantly different from baseline ($p < 0.001$). Severe, moderate, mild and none dysphagia significantly evolved on day 14 ($p = 0.01$) with a prevalence of 0%, 3.2%, 9.7%, 87.1% respectively. Intriguingly, severe forms of dysphagia were no longer found at 12 days.

Conclusion: In COVID-19 patients, dysphagia disorders were related to the length of the MV, to ICU LOS and to tracheostomy placement. The GUSS temporal evolution could suggest that a multidisciplinary synergic approach to dysphagia management, which consist of a nurse and a SLT, would seem to improve the outcome of this symptom in critically ill COVID-19 patients. Futures analysis are necessary to confirm the hypothesis that the SLT treatment could have a positive predictive role in dysphagia recovery.

Intensive Care Medicine Experimental 2020, **8(2)**: 000750

Introduction: Over the past two decades, high-flow nasal cannula oxygenation (HFNCO) devices that deliver heated and humidified oxygen at flows up to 60 L/min, were developed as an alternative to low/intermediate-flow devices. HFNCO has emerged as a safe and useful supportive therapy in many clinical situations and is considered a valuable tool in enhancing patients' comfort and oxygenation¹.

The simplicity and potential benefit of HFNCO has led to its widespread use in and out of the Intensive Care Unit (ICU), even in situations where the evidence is sparse. Patients with established ceilings of treatment that prohibit intubation, who develop worsening respiratory failure is such an example. These patients are often treated with some form of non-invasive ventilation (NIV). However, discomfort and complications associated with NIV may outweigh potential benefits, and its use may extend the dying process without providing an acceptable quality of life in survivors or an acceptable quality of death in non survivors 2,3. The use of HFNCO is seen as a potential alternative to NIV, however the impact of HFNCO around end of life (EoL) has not been extensively investigated.

Objectives: The aim of this study was to assess the number of patients receiving HFNCO initiated by an outreach team near the EoL, the indications for its use, as well as any beneficial and/or unintended effects.

Methods: We conducted a retrospective observational study of all ward patients that were initiated on HFNCO within 10 days of death, over 2 years (January 2017 to January 2019), in a 950 bedded, tertiary London hospital, with a dedicated outreach service. All HFNCO initiation decisions and implementation are made by the outreach service. We reviewed electronic patient records and collected patient demographics, reasons for HFNCO initiation, initial HFNCO flow and oxygen settings, patients' response and adverse events, as well as EoL decision-making.

Results: During the study period, 736 patients received HFNCO with 95 (12.9%) receiving it within 10 days prior to death. Sixty-five of them (68.4%) were more than 70 years old and 44.2% were female. The commonest reason for hospital admission was respiratory failure (51.6%) and the commonest reason for HFNCO initiation was hypoxia (67.4%). Twenty-six patients (27.4%) were recognised as EoL before initiation of HFNCO, and 6 (6.3%) after the HFNCO failed to improve their condition. Details on EoL decision-making are shown in table 1. Palliative care referral was made in 82.1% of EoL patients. When HFNCO continued, 27/32 (87.1%) died within 7 days; of those in whom HFNCO was discontinued, 32/61 (52.4%) died within 7 days. In the majority of the cases (61.1%), there were no adverse events associated with HFNCO. In the remaining patients, the most frequently documented adverse event was general discomfort, mainly due to nasal administration of high flow gas.

HFNCO practices around EoL	n (%)
Discussion of EoL preferences on HFNCO initiation	
Discussed with patient	39 (41.1)
Discussed with family	32 (33.7)
Not discussed	20 (21.1)
Not documented	4 (4.2)
Existing documentation of EoL preferences	
Documented	73 (76.8)
Not documented	22 (23.2)
HFNCO use around EoL	
Discontinued	53 (55.8)
Continued	32 (33.7)
Already discontinued prior to EoL determination	
	8 (8.4)
Not documented	2 (2.1)

Conclusion: Approximately 13% of HFNCO use initiated by the outreach service in our hospital is for ward patients that are approaching EoL. This rescue therapy is primarily used in hypoxic respiratory failure, aiming to improve comfort. However, treatment related discomfort in almost 40% of patients highlights the importance of palliative care involvement and optimisation of traditional EoL comfort measures. Whether HFNCO actually extends the dying period in such patients requires further investigation.

Correspondence: F. Bloos

Intensive Care Medicine Experimental 2020, **8(2)**: 000790

Introduction: Invasive candida infection in sepsis patients is associated with a high mortality. Long time to positivity in culture-based pathogen detection further increases the risk of death by delaying antifungal therapy (1). Serum (1,3)- β -D-glucan (BDG) has a high diagnostic accuracy for detecting ICI (2) and is available within few hours. However, the clinical significance of BDG is unclear and current guidelines hesitate in recommending this diagnostic tool.

Objectives: To investigate whether guidance by serum-BDG concentrations results in an earlier antifungal therapy in sepsis patients with high risk of ICI and therefore reduces mortality.

Methods: CandiSep was a prospective multicenter randomized trial conducted in 18 ICUs in Germany (4). Patients within 24 hrs after onset of severe sepsis or septic shock and high risk for ICI were included. Risk factors for ICI were total-parenteral nutrition, recent abdominal surgery, preexisting antimicrobial therapy, or renal replacement therapy. Exclusion criteria included a diagnosed ICI or anticipated antifungal therapy. Patients were randomized into a control or a BDG-group. Patients of the control group received targeted antifungal therapy according to current guidelines (3). In the BDG group, treating physicians received BDG-results taken at and 24 hours after enrollment. Antifungals were started when at least one BDG serum concentration was ≥ 80 pg/ml. Primary endpoint was 28 day all-cause mortality.

Results: Of 2324 eligible patients, 339 patients were included in an intention-to-treat analysis comparing the BDG-group (n = 172) with standard of care (n = 167). Of those, 99 patients received antifungals in the BGD group and 46 patients in the control group. Time from

randomization to antifungal therapy was 1.1 (IQR 1.0-2.2) days in the BDG group and 4.4 (IQR 2.0-9.1 days, $P < 0.01$) in the control group. The 28-day mortality rate was 33.7% in the BDG group and 30.5% in the control group ($P = 0.53$; relative risk of death: 1.1, 95% CI 0.8-1.5, see figure for Kaplan-Meier-curve).

Conclusion: BDG guidance was associated with early initiation of antifungal therapy but did not reduce mortality. These results do not support BDG-guided preemptive antifungal therapy in sepsis patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 000932

Introduction: Patients with obesity are at higher risk for community-acquired and ICU-acquired infections. However, no study has evaluated the relationship between obesity and ventilator-associated pneumonia (VAP).

Objectives: The aim of our study was to determine the impact of obesity on the incidence of VAP.

Methods: Planned ancillary study of the NUTRIREA-2 open-label RCT, performed in 44 French ICUs. Adults (18 years or older) receiving invasive mechanical ventilation and vasopressor support for shock were randomly assigned (1:1) to either parenteral nutrition or enteral nutrition, both targeting normocaloric goals (20-25 kcal/kg per day), within 24 h after intubation.

Obesity was defined as body mass index (BMI) ≥ 30 kg/m² at ICU admission. VAP diagnosis was adjudicated by an independent blinded committee, based on all available clinical, radiological, and bacteriological data. Only first VAP episodes were taken into account.

Incidence of VAP was analyzed using a competing risk approach, with extubation, death and ICU discharge alive as competing risks. An adjusted analysis was performed including variables collected at ICU admission with $p < 0.2$ in the univariate analysis. The choice of adjustment variables was based on scientific knowledge, and potential collinearity.

In a subgroup of patients ($n = 151$), we also evaluated the impact of obesity on abundant microaspiration of gastric contents and

oropharyngeal secretions (defined as the presence of significant levels of pepsin (> 200 ng/ml) and salivary amylase (> 1685 UI/ml) in $> 30\%$ of tracheal aspirates, collected during the 48h following intubation).

Results: Among the 2410 patients included in the NUTRIREA-2 trial, 85 (4%) were excluded because of missing data on BMI. 699 of the 2325 (30%) included patients had obesity. Female gender (36% vs 32%), age (67 ± 11 vs 65 ± 15 years), Sofa score at ICU admission (med (IQR) 11 (8, 13) vs 10 (8, 13), and comorbidities significantly ($p < 0.05$) differed between obese and non-obese patients. No significant difference was found in percentage of patients who received enteral nutrition between obese and non-obese patients (51% vs 50%).

224 VAP were diagnosed (60 in the obese group and, 164 in the non-obese group). The incidence of VAP at day 28 was 8.6% vs 10.1% in obese and non-obese patients, respectively; HR: 0.845, 95% CI: [0.63; 1.14], $p = 0.26$. After adjustment on gender, age and Knaus score, no significant difference was found in VAP incidence between obese and non-obese patients (adjusted HR: 0.914, 95% CI: [0.675; 1.238], $p = 0.56$). Vomiting at day 7 was more frequent in obese than in non obese patients (24% vs 19%, $p = 0.008$).

No significant difference was found in percentage of patients with abundant microaspiration of gastric contents (31% vs 19%, $p = 0.13$), or oropharyngeal secretions (63% vs 65%, $p = 0.86$) between obese and non-obese patients.

Conclusion: Our results suggest that obesity has no significant impact on the incidence of VAP.

Intensive Care Medicine Experimental 2020, **8(2)**: 000958

Introduction: Previous studies reported a various incidence of deep vein thrombosis (DVT) after decannulation from Extracorporeal membrane oxygenation (ECMO), ranging from 18 to 85% depending on screening method. The actual incidence of ECMO associated DVT is

therefore unclear and the role of anticoagulation and potential risk factors is undetermined. Furthermore, it is unclear if cannula-associated DVT is more common in ECMO patients compared to critically ill patients without ECMO.

Objectives: To determine incidence and risk factors of DVT following decannulation from ECMO, to assess the relationship with level of anticoagulation and to compare the cannula-associated DVT rate in patients with and without ECMO.

Methods: We conducted a prospective cohort study in a 30-bed, closed format mixed medical-surgical ICU from a Dutch tertiary referral hospital. All consecutive adult patients who were successfully weaned from ECMO and underwent a routine venous duplex ultrasound of the large vessels following decannulation to assess the presence of DVT between January 2018 and March 2020 were included. We performed three multivariable logistic regression analysis to determine the association between anticoagulation with heparin and the occurrence of DVT after ECMO treatment: 1), mean aPTT per 10 seconds increase; 2), time weighted average aPTT under 50 seconds; and 3), time weighted average aPTT under 60 seconds, adjusted for sex, age, ECMO-mode and duration of ECMO treatment. Multivariable stepwise backward logistic regression was performed to assess risk factors for DVT. We compared cannula-associated DVT rate in ECMO patients with a prospective composed cohort of 53 critically ill adult patients without ECMO support receiving a central venous catheter (CVC) for at least 48 hours in which the inserted vein was screened for DVT after CVC removal with duplex ultrasound.

Results: During the study period 95 patients received ECMO of which 38 were successfully weaned from ECMO. Eight patients had no ultrasound of the large vessels after decannulation leaving 30 patients eligible for analyses. Of these 30 patients 14 (47%) received veno-arterial ECMO. DVT was found in 15 patients (50%) of which 10 patients (33%) had a DVT in a cannulated vein (cannula-associated DVT). Overall, patients with DVT had a longer duration of ECMO treatment (4.7 days \pm 2.4 vs 6.9 days \pm 3.4, $p = 0.047$) and were more often on veno-venous (VV) ECMO (33% vs 73%, $p = 0.07$). Multivariable logistic regression analysis showed no correlation between level of anticoagulation and the occurrence of DVT. With the stepwise backward logistic regression analysis, we found VV-ECMO mode to be the only independent risk factor for DVT after ECMO (OR 5.5; 95%CI 1.16-26.41). We found no difference between the ECMO and CVC cohort regarding cannula-associated DVT rate (33% vs 32.1%).

Conclusion: DVT following ECMO is frequent with half the patients showed DVT after decannulation, although pure cannula-associated DVT was not higher compared to CVC-associated DVT in a non-ECMO cohort of critically ill patients. We identified VV-ECMO as an independent risk-factor for DVT after ECMO. The level of anticoagulation based on aPTT values is not associated with the occurrence of DVT following ECMO. Administration of a higher dose of heparin seems therefore not justified to prevent DVT during ECMO treatment.

Intensive Care Medicine Experimental 2020, **8(2)**: 001146

Introduction: Continuous administration of vasoactive drugs represents cornerstone of hemodynamic management in septic shock. Standard care of patients with vasodilatory shock includes infusions of catecholamines, vasopressin agonists and, newly, angiotensin II. Single dose of intravenous vanilloids – capsaicin and its analogue nonivamide – substances responsible for pungent taste of some eggplants, caused increase of blood pressure in anesthetized mice. We designed proof-of-concept study in a large porcine model of progressive peritoneal sepsis to analyze the hemodynamic effects of capsaicin and nonivamide.

Methods: 28 anesthetized, mechanically ventilated and instrumented pigs were assigned into six groups: control groups receiving either capsaicin (CC, $n = 3$) or nonivamide (CN, $n = 3$); sepsis groups treated either with (SNa, $n = 3$) or without norepinephrine (S, $n = 3$), and sepsis groups treated with capsaicin (SC, $n = 6$) or nonivamide (SN, $n = 6$). Sepsis was induced by autologous feces (2 g/kg) inoculation into peritoneal cavity. Continuous infusion of vasopressors was administered if the mean arterial pressure (MAP) dropped below 65 mmHg and no further positive hemodynamic response was elicited via fluid resuscitation. Vasopressors were titrated to maintain MAP between 65 and 70 mmHg. Before, 6, 12, 18 and 24 h after the induction of peritonitis (fixed timepoints) we measured, in addition to systemic, regional (renal, portal and femoral) and microvascular (gut mucosal) hemodynamics, oxygen kinetics (DO₂/VO₂), organ function (lung, kidney, liver, heart), and energy metabolism (lactate kinetics, acid base balance).

Results: Administration of both vanilloids to non-septic animals did not induce significant changes in measured variables, although MAP and systemic vascular resistance tended to increase. Septic animals developed classical hemodynamic alterations with increased cardiac output and reduced systemic vascular resistance. Systemic hemodynamic effect of capsaicin and nonivamide administration was comparable to that observed in norepinephrine group. Nonivamide significantly increased blood flow through the portal vein at 6 and 9 hour after infusion initiation when compared to norepinephrine. Neither of tested vasopressors affected progressive sepsis-induced disturbances in energy metabolism and multiorgan functions.

Conclusion: To the best of our knowledge, this is the first report of intravenous administration of the vanilloids in the established porcine model of progressive peritoneal sepsis. We demonstrated their therapeutic potential in reversal of sepsis-induced vasodilatory shock. While promising, further investigation into the mechanisms of action is necessary.

Introduction: The functionally respiratory monitoring is essential in the clinical management of patients under mechanical ventilation. Clinical monitoring is a field in constant evolution aiming at developing less-invasive, continuous, safer and inexpensive methods that provide accurate, and relevant data to aid in better clinical decision making.

Objectives: Validation of a novel, non-invasive and continuous method to monitor end expiratory lung volume based on expired CO₂ kinetics (EELVCO₂) by comparison with computer tomography measured volume in mechanically ventilated patients. Being a functional lung volume we specifically compared EELVCO₂ with normally aerated end-expiratory lung volume measured by computed tomography (EELVCT-NA).

Methods: We included patients under passive mechanical ventilation. EELVCO₂ was measured by the capnodynamic method, which combines the Fick principle for CO₂, measured CO₂ elimination obtained from volumetric capnography and the mole balance equation for CO₂ across the lungs. Expired CO₂ was synchronized with flow and volume measured by the ventilator's spirometer (Servo-I, Maquet Critical Care) to reconstruct a breath-by-breath volumetric capnogram. A modified repetitive breathing pattern adding brief expiratory holds in 3 consecutive breaths of the measuring cycle of 9 breaths, changed alveolar CO₂ concentration to solve the capnodynamic equation. The resulting EELVCO₂ values were continuously displayed on the computer screen. EELVCT-NA was measured during a 8-10 seconds expiratory hold. Lung EELVCT-NA was afterwards determined by manually segmenting all lung CT slices using OsiriX™ (Pixmeo, Geneva, Switzerland) summing all CT compartments with a density between -900 to -500 Hounsfield Units. Pearson's correlation coefficient was used to assess correlation between methods and the Bland-Altman method was used to assess accuracy and precision.

Results: Presented data correspond to 19 patients. Median(min-max) PaO₂/FiO₂ was 201(95-430). In 3 patients PaO₂/FiO₂ was < 100 and in 7 patients between 100-200. Median (min-max) lung volumes were 1445 ml (564-2544 ml) for EELVCO₂ and 1305 ml (252-2361ml) for EELVCT-NA. Correlation between EELVCO₂ and EELVCT-NA was r₂ = 0.78(p < 0.001). Bias(limits of agreement) of EELVCO₂ were - 139 ml(- 771 ml to 493 ml).

Conclusion: The new non-invasive and continuous EELVCO₂ method presented a high correlation and good agreement with normally aerated CT lung volume performing with clinically relevant accuracy and precision.

Where did all the women go? The underrepresentation of women in educational resources during COVID-19

T. Hall¹; C. Dangoisse²; V. Metaxa³

Intensive Care Medicine Experimental 2020, **8(2)**:001215

Introduction: Intensive care medicine (ICM) is a growing specialty. The Centre for workforce intelligence has predicted an expansion which would require anywhere between a 25 to 125% increase in the medical ICU workforce by 2033 [1]. This will require a substantial increase in recruitment to the specialty.

We know that women are currently underrepresented in ICM at consultant level and in leadership positions. According to General Medical Council (GMC) and Faculty of Intensive Care Medicine (FICM) data, 55% of UK medical graduates are women but only 20% of ICU consultants are women. These trends are similar in Europe and the rest of the world [2] and form part of a wider picture – less than 25% of the most influential healthcare leadership positions worldwide are held by women [3].

This gender gap within ICM means that the specialty is excluding half of Medicine's talent pool and therefore not producing a workforce that is diverse and representative of the population it serves. The world economic forum showed in its' 2014 report that there is a correlation between a country's global competitiveness index and its' gender gap index [4]. If we extrapolate this to the field of Medicine, it suggests that a gender balanced ICU medical workforce could lead to improvements in the field of ICM and subsequently patient outcomes [5].

An important factor in career choice within medicine is the availability of role models and mentorship. Both male and female doctors are more likely to choose a specialty when they identify a positive role model [6]. For female trainees, having a female role seems to be particularly important [7].

Objectives: Covid-19 brought ICM into the spotlight. Whereas previously many trainees may not have had exposure to ICM, the pandemic changed this situation. Critical care societies from around the world produced excellent free online resources to educate and inform doctors who were now treating the surge of ICU patients in various settings.

We wanted to ascertain the percentage of female speakers at webinars, to see if intensive care societies are fostering female trainees' and consultants' careers by providing female role models. Most societies have issued statements regarding gender parity; we wanted to see whether they demonstrate inclusive leadership and are true advocates of gender equity [8].

Methods: We reviewed webinars produced in response to Covid-19 during a 3 month period (March, April and May 2020) by a few of the most prominent Intensive Care Medicine and Anaesthesia societies to which we were personally exposed. The choice was subjective but felt to represent webinars which were widely available and to which a significant proportion of doctors would have been exposed in Europe. The speakers were not approached individually and asked as to how they identify their gender. We therefore ascertained the gender of the speakers subjectively.

Results:

Society	M	F	Percentage Female
European Society of Intensive Care Medicine	57	14	19.7
Intensive Care Society	31	13	29.5
European Extracorporeal Life Support Organization	41	11	21.2
Association of Anaesthetists	38	21	35.6

These preliminary results show that women are grossly underrepresented in these webinars.

Conclusion: This lack of representation at a higher level within ICM will do little to encourage women into an already male dominated specialty. The ESICM equality goal which states "ESICM should aim for gender representation according to the gender proportion in the critical care medicine workforce" [9] does not go far enough to address this problem. To tackle the issue of gender inequality within ICM and build a diverse and sustainable workforce, we must provide role models and mentors to help attract female doctors to this specialty. It is time we start putting our theoretical aspiration for equal gender representation into practice.

001224**Temporary transvenous diaphragm neurostimulation in mechanically ventilated patients – preliminary results from a randomized controlled trial**M. Dres¹; M. Gama De Abreu²; T. Similowski¹¹Respiratory and critical care, APHP. Sorbonne University, Paris, France;²Klinik für Anästhesie und Intensivtherapie, Universitätsklinikum Carl Gustav Carus, Dresden, Germany**Correspondence:** N. Mehta*Intensive Care Medicine Experimental* 2020, **8(2)**:001224

Introduction: Mechanical ventilation (MV), while lifesaving, can lead to ventilator-induced diaphragm dysfunction (VIDD) and be associated with difficulty in weaning and prolongation of MV. Mitigating VIDD may thus improve respiratory function and reduce duration of MV.

Objectives: We assessed the effects of temporary transvenous diaphragm neurostimulation (TTDN) using bilateral phrenic stimulation with a multi-electrode central venous catheter (Lungpacer Diaphragm Pacing Therapy System) on clinical outcomes and respiratory function in a multicenter, open label, randomized controlled trial. In contrast to inspiratory muscle strength training, this therapy does not depend on patients' cooperation.

Methods: Patients on invasive MV for > 96 hours who failed at least two spontaneous breathing trials and satisfied readiness to wean criteria were randomized (1:1) to TTDN, consisting of up to 120 stimulations per day for up to 30 days, or standard of care (SoC). Clinical outcome measures included the proportion of successfully weaned subjects, mean days on MV and 30-day survival. The maximal inspiratory pressure (MIP) and rapid shallow breathing index (RSBI) were also determined. The diaphragm thickening fraction was assessed with M-mode ultrasound in a subset of patients and assessed by an ultrasound corelab blinded to group assignment.

Results: A total of 112 patients were randomly assigned to groups (57 TTDN and 55 SoC). The stimulation catheter was successfully placed in 43 (75%) subjects and at least 50% of the protocol-required stimulations were successfully delivered in 34 (60%) subjects. In this per-protocol subset, the incidence of successful weaning was 84% and 74% ($p = 0.436$), duration of MV to successful weaning/study completion was 12.4 ± 9.1 and 14.1 ± 10.8 days ($p = 0.438$); survival through

Day 30 was 91% and 85% ($p = 0.414$) for the TTDN and SoC groups, respectively. Change in MIP from baseline was significantly different: 20 ± 3 (TTDN) and 5 ± 2 cmH₂O (SoC) [difference 15 ± 4 cmH₂O, $p = 0.0002$]; change in RSBI from baseline was also significantly different: -48 ± 13 (TTDN) and -18 ± 9 (SoC) [difference -30 ± 15 , $p = 0.049$], with both variables showing a stimulation dose-response relationship in TTDN subjects. Compared to baseline, diaphragm thickening fraction changed by 60% (TTDN) vs -39.5% (SoC) ($p = 0.03$) and 34.8% (TTDN) vs. -34.2% (SoC) ($p = 0.334$) for the right and left hemidiaphragms, respectively. There were no unanticipated adverse device effects noted in the study.

Conclusion: TTDN increased the diaphragm thickening fraction and improved MIP and RSBI. While this study was not powered to show clinical efficacy, the results will contribute to defining the patient population and effect size to appropriately power future studies for clinical outcomes.

Introduction: Community-acquired pneumonia (CAP) is the most common cause of sepsis in the developed world. Identifying factors associated with mortality is one of the main research issues with the aim to describe high-risk subsets (1). Different combinations of clinical data and host-response features may naturally cluster into previously undescribed subsets or subphenotypes (2) that may have different risks for a poor outcome and may respond to different etiologies. Similar studies have been made in sepsis (3) and ARDS (4) patients, but information in CAP is lacking.

Objectives: To derive CAP subphenotypes from clinical data and relationship with host-response inflammation, organ damage, etiology and clinical outcomes

Methods: Retrospective analysis of data sets using statistical, machine learning methods. Phenotypes were derived among 6963 patients (16 552 unique patients) who were evaluated in the emergency department (ED) from Spain and were diagnosed with pneumonia. Candidate variables were selected on clinical relevance and based on their association of CAP onset, availability during the first clinical examination, outcomes, missingness and correlations. The TRIPOD statement were followed (5). Missing data above 35% were excluded from analysis and the Little's test was used to assess the distribution and pattern of those included. Highly correlated variables were excluded ($r > 0.85$). Multiple imputation with chained equations (MICE) was used to account for missing data. Ordering points to identify the clustering structure (OPTICS) plots were used to determine the optimal clustering strategy, and K-means clustering was the most appropriate method and therefore used. Robustness and internal validation were assessed through Dunn's test and cluster silhouettes. We studied the frequency and clinical characteristics of the predicted phenotype groups. All analysis were performed with R version 3.6.1.

Results: Twenty-three variables were selected. These clusters were identified with different size, laboratory and clinical characteristics. Members of Cluster 1 (33.5%) were the youngest [age: 45 (SD = 13.8)], less comorbid [Charlson Index: 0.7 (1)] 62.6% were male, 54.4% were current smoker and 4.9% used inhaled steroids. Individuals from

Cluster 2 (39.5%) were the eldest [age: 79.8 (8.6)], the most comorbid [Charlson Index: 4.6 (1.6)], gender was equally distributed (male 49.8%), the lesser smokers (9.7%), with a 15.4% of inhaled steroids usage. Patients from Cluster 3 (27%) were old [age: 71.6 (13.1)], predominantly male (78.5%), with comorbidities [Charlson Index: 3.8 (1.8)] and smokers (58.9%), and were those ones who used inhaled steroids the most (33.2%). Signs and symptoms in cluster 1, 2 and 3 respectively were: respiratory rate: 22.8 (5.6), 24.8 (5.9) and 31.7 (7.8); heart rate: 98 (14.4), 92 (17) and 106 (21); SpO₂: 96% (IQR = 94-97), 94% (92-96) and 90% (85-93); systolic blood pressure: 121 (20), 139 (25), and 126 (29). Fever was more common in Cluster 1 (90.4%). Inflammatory biomarkers as: C-reactive protein and white blood cells in Cluster 1, 2 and 3 respectively were: 16.8 (8.3-26.7), 14 (6.4-23.1) and 20.4 (10.4-29); and: 11.405 (7.600-16.200), 11.520 (8.200-15.900) and 14.500 (10.200-19.800). Organ damage were more common in Cluster 3 with higher respiratory, hemodynamic and renal SOFA score system. Hospital admission occurred in 74.2% of Cluster 1, 94.7% of Cluster 2 and 99% of Cluster 3's patients. Critical care admission was more common in Cluster 3 (36.5%) than Cluster 2 (8.8%) and Cluster 1 (14.6) respectively. Thirty-day and 1-yr mortality was higher in Cluster 3 (4.4% and 18.2%, respectively) compared to Cluster 1 (0.2% and 1.9%) and Cluster 2 (0.3 and 10.1%) respectively. Pneumococcal pneumonia was the most frequent etiology [Cluster 1 (21.7%), Cluster 2 (15.7%) and Cluster 3 (25.4%)]. Atypical pneumonia (Legionella, Mycoplasma and Chlamydia) was more frequent in Cluster 1 (3.6%, 2.6% and 1.2% respectively).

Conclusion: In this retrospective analysis of data sets from patients evaluated in the ED with CAP, 3 clinical subphenotypes were identified that were related with host-response patterns, etiology and clinical outcomes. External validation and further research are needed to determine the utility of these subphenotypes in clinical care.

Intensive Care Medicine Experimental 2020, **8(2)**: 001247

Introduction: During the COVID-19 pandemic, restrictions on hospital visitations created an unprecedented emotional stress on isolated patients and grieving families, leading to significant communication challenges [1-4]. Junior Doctors (JDs) have had to broach sensitive topics of life and death over the phone. Although there is a paucity of data on interventions to support effective communication, written

and structured conversation guides are amongst the most validated [5-8].

Methods: We developed a framework in collaboration with our palliative care team to guide JDs through telephone communication with relatives of ICU patients; this outlined common events such as admission, daily updates, deterioration and bereavement.

We supported the roll out of a nurse-led video-calling service to facilitate sensitive communication, by creating a standard operating procedure (SOP) to outline instructions and define clinical governance limits [3, 6, 7].

We distributed a questionnaire to JDs working in ICU during the pandemic, to evaluate whether our tools improved their confidence in effectively communicating with relatives (using a Likert scale 1 to 5 = not at all confident to very confident) and their perception of whether the video-calling service improved communication with families.

Results: We received 21 responses from JDs, 57% of whom had been redeployed from other departments. Pre COVID-19, only 10% of JDs had experienced difficult conversations with relatives about critically unwell patients once a week or more. During the pandemic, this increased to 100% of them having difficult conversations at least three times a week.

75% of JDs scored their initial confidence in telephone communication with relatives as neutral/not confident/not at all confident; following the introduction of our framework, 76% felt confident/very confident. 71% of JDs found example conversations for different scenarios outlined in the framework helpful. Many commented that the framework was useful as point of reference and in providing phrases.

81% of JDs were able to arrange a video-call post introduction of the SOP and felt that a nurse led video-calling service was helpful. All JDs felt that video-calls improved communication with patients' families. The main challenges identified with video-calling were concerns about confidentiality, time-burden and technical issues.

The difficulties faced by JDs in telephone discussions were the lack of non-verbal cues, technology issues, interruptions, and difficulty aligning perception of illness severity with reality. JDs commented on the emotional toll these conversations had taken on their mental health particularly when breaking bad news, describing these as "very sad", "stressful", and "traumatic".

Conclusion: The introduction of our framework for telephone communication has improved the confidence of JDs in their ability to interact with patient's relatives over the phone during the COVID-19 pandemic. The roll out of a nurse led video-calling service was felt to improve communication and was successfully facilitated by the introduction of a SOP.

Our work helps recognise the need to develop structured tools to support communication. It has been an opportunity to appreciate the emotional burden placed on JDs which is reflected in the experience of many filling this role throughout the country [9-10].

Future quality improvement interventions include assessing the families' experience of communication, providing relatives with written information about ICU and organising debriefing for JDs.

Epidemiology and risk factors of ventilator-associated pneumonia in COVID-19 patients: a propensity-score matched analysis

M. Martínez Martínez¹; F.J. Ramos Gomez¹; FX. Nuvials Casals¹; O. Roca¹; R. Ferrer Roca¹

¹Intensive care department, Vall d'Hebron University Hospital, Barcelona, Spain

Correspondence: M. Martínez Martínez

Intensive Care Medicine Experimental 2020, **8(2)**: 001314

Introduction: Coronavirus disease 2019 (COVID-19) causes a respiratory failure that may require Intensive Care Unit (ICU) admission and mechanical ventilation (MV). Ventilator associated pneumonia (VAP) is a frequent complication in mechanically ventilated patients. However, there is no data about prevalence and risk factors for VAP in patients with COVID-19.

Objectives: To analyse the prevalence and risk factors for VAP in COVID-19 patients.

Methods: Retrospective observational study including all invasive mechanically ventilated COVID-19 patients admitted in the ICU in Vall d'Hebron University Hospital between March and April 2020. VAP was defined according to ATS/IDSA guidelines (1). Results were described using mean (standard deviation), median (interquartile range) or frequency (percentage). Differences between continuous variables were analysed using Student T-test or Mann-Whitney U-test, as appropriate. Differences between categorical variables were assessed using Chi2 test or Fisher exact test.

To account for imbalances of baseline characteristics between both groups a propensity score matching was performed using the R[®] package "matchit" with a nearest neighbour algorithm and a 1:1 matching ratio (2). Differences in variables in the matched cohort were assessed as previously described. To determine which variables were independently associated with VAP development, a logistic regression analysis was also performed in both non-matched and matched cohort using variables with $p < 0.1$ in the univariate analysis. P -value < 0.05 was considered statistically significant.

Results: A total of 353 patients were admitted on the study period and 250 required invasive MV. Median age was 59 (51-67), 69.2% (173) were male. Median APACHE was 11 (8-13) and SOFA 4 (3-5). 100 patients (40%) developed VAP. Patients who developed VAP were more frequently male, had a higher APACHE and SOFA score, were more frequently admitted to a newly open unit, and received more frequently treatment with corticosteroids and tocilizumab. These variables were included in the propensity score matching. The results of the multivariate logistic regression analysis for the risk of VAP are shown in table 1. Treatment with corticosteroids was independently associated with a higher risk of VAP in both non-matched (OR 3.364; 95% CI 1.829-6.185; $p < 0.001$) and matched cohort (OR 2.071; 95% CI 1.141-3.758; $p = 0.017$).

Table 1. Multivariate analysis in the unmatched and matched cohorts.

Variable	Unmatched cohort			Matched cohort			
	OR	95% CI	p-value	OR	95% CI	p-value	
APACHE	0.930	0.849-1.019	0.121	APACHE	0.960	0.872-1.056	0.400
SOFA	1.539	1.197-1.979	0.001	SOFA	1.234	0.960-1.588	0.100
Corticosteroids	3.364	1.829-6.185	<0.001	Corticosteroids	2.071	1.141-3.758	0.017
Tocilizumab	1.918	1.047-3.512	0.035	Age	1.019	0.993-1.047	0.157
Gender (male)	1.769	0.944-3.314	0.075				
Newly Open ICU	1.800	1.002-3.235	0.049				

OR: Odds ratio; CI: Confidence interval; APACHE: Acute Physiologic Assessment and Chronic Health Evaluation Score; SOFA: Sequential Organ Failure Assessment Score

Conclusion: VAP is a prevalent complication among COVID-19 patients. Those mechanically ventilated COVID-19 patients who received treatment with corticosteroids may present a higher risk of developing VAP.

H and L-subphenotype prevalence in ARDS patients with and without SARS-CoV-2

M. Chotalia¹; JE. Alderman¹; D. Parekh¹; M. Bangash¹; J. Patel¹

¹Birmingham acute care research group, University of Birmingham, Birmingham, United Kingdom

Correspondence: M. Chotalia

Intensive Care Medicine Experimental 2020, **8(2)**: 001350

Introduction: It is unclear whether patients with Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) ARDS present with an atypical form of pulmonary illness, characterised by preserved lung compliance and low lung weight - termed L-subphenotype, or whether they reflect 'traditional' ARDS characterised by low lung compliance and high lung weight - H-subphenotype [1].

Objectives: To calculate the prevalence of H and L-subphenotypes in ARDS patients with and without SARS-CoV-2 admitted to a single centre ICU.

Methods: This is a single-centre, retrospective study from the Queen Elizabeth Hospital Birmingham, UK. Two cohorts of ICU patients that assumed to be 65% of static compliance in severe lung disease [3]. Patients with average semi-quantitative radiography scores ≤ 8 and a Cdyn > 26 ml/cmH₂O were classified as the L-subphenotype whilst patients with average semi-quantitative radiography scores ≥ 8 and a Cdyn ≤ 26 ml/cmH₂O were classified as the H-subphenotype. Patients who did not meet these criteria were placed in discordant 1 and 2 (D1, D2) groups. Statistical analysis was performed using GraphPad Prism v.8.0. Continuous data is presented as median (IQR) and analysed

using a Mann-Whitney-U test. Categorical data is presented as number (%) and analysed using a chi-squared test.

Results: 112 patients with SARS-CoV-2 ARDS and 121 patients with CAP ARDS met the inclusion criteria. The prevalence of H and L-subphenotypes were similar between SARS-CoV-2 and CAP ARDS cohorts. ICU mortality was lower in patients classified as L-subphenotype and higher in patients classified as H-subphenotype (Figure 1).

Table 1: Clinical characteristics of SARS-CoV-2 and CAP ARDS cohorts

	SARS-CoV-2	CAP	p value
Age (years)	56 (46 - 63)	64 (49 - 74)	0.0006
Gender (%Male)	85 (76%)	71 (59%)	0.0080
P/F ratio	15 (12 - 17)	15 (11 - 25)	0.188
Dynamic compliance (mls/cmH2O)	28 (23 - 34)	27 (22 - 32)	0.156
CXR opacification score	9 (7 - 10)	8 (6 - 10)	0.422
ICU mortality (%)	45 (40%)	42 (35%)	0.438

Conclusion: The prevalence of H and L-subphenotypes was similar in ARDS cohorts with and without SARS-CoV-2, indicating that SARS-CoV-2 respiratory failure is not an atypical form of ARDS requiring an alternative ventilation strategy. Given the lower mortality of patients classified as L-subphenotype, the heterogeneity in compliance and lung weight and the presence of these subphenotypes may simply reflect different patterns of disease severity.

Intensive Care Medicine Experimental 2020, 8(2): 001362

Introduction: Acute kidney injury (AKI) is commonly observed in intensive care unit (ICU) and affects more than 50% of these patients. The consequences of AKI are well described (increased mortality, length of hospital stay, risk of chronic kidney disease (CKD)). Acute kidney disease (AKD) has been recently proposed to define the disease process after AKI and before CKD among patients in which renal pathophysiologic processes are in progress. We know that patients who suffered from AKI may have different clinical trajectories and outcomes (early, late or absence of recovery, early or late relapse, AKD or CKD), but to date, no cohort study has been able to accurately describe them.

Objectives: The main objective of this study was to assess the different clinical trajectories and evaluate risk and timing of AKD and CKD after AKI in ICU. Secondary objectives were to evaluate the long-term incidence of CKD after AKI in critically ill patients and to propose the ideal timing for post-intensive care clinics.

Methods: We conducted a prospective 5-years follow-up cohort study in a medical ICU in Bordeaux University Hospital (France). Our center participated in the Artificial Kidney Initiation in Kidney Injury (AKIKI) study, during which all patients with AKI from stage 1 of the KDIGO classification were prospectively screened from September 2013 to May 2015. Patients were included if they were ≥ 18 years of age, received invasive mechanical ventilation, catecholamine infusion, or both, and developed AKI. We excluded patients with estimated glomerular filtration rate (eGFR) < 90 mL/min/1.73 m² (CKD-EPI) prior to ICU admission. AKI was classified according to the KDIGO classification. AKD was defined as a condition wherein criteria for AKI stage 1 or greater persists ≥ 7 days after an exposure. CKD was defined by eGFR < 60 mL/min/1.73 m² (CKD-EPI) at least 90 days after AKI. Renal recovery was defined by the absence of KDIGO criteria. Early recovery was kidney recovery within 7 days and late recovery was renal recovery from 7 to 90 days after AKI.

Results: 304 patients suffered from AKI. Among them, 72/304 (24%) had prior CKD and were excluded and 232 patients were enrolled: AKI stage 1, 62/232 (27%), AKI stage 2, 50/232 (21%) and AKI stage 3, 120/232 (52%). Age was 62 ± 16 years, 142/232 (63%) were men. Basal serum creatinine (SCr) was 78 ± 18 μ mol/l and no patients had missing baseline creatinine value. Mechanical ventilation was required for 192/232 (83%) and 191/232 (82%) required catecholamine use. Length of mechanical ventilation and catecholamine use were respectively 4 [2-8] days and 2.5 [1-5] days. SOFA score was 11.2 ± 3.4 and SAPS II was 62 ± 19 . Among patients with AKI, 61/232 (26%) died, 65/232 (28%) recovered early and among them 3/65 (5%) recovered early but secondary suffered from AKD resulting in 109/232 (47%) who had been progressing to AKD (figure). Among AKD patients, 41/109 (38%) died, 21/109 (19%) had late recovery and 47/109 (43%) developed CKD. CKD also developed in patients who recovered early and late, in respectively, 11/65 (17%) and 5/21 (24%) for a total of 63 out of 232 (27%) patients included in the study. At the end of 5 years follow-up, CKD prevalence was 31%. Among CKD patients, 16/65 (17%) patients had already recovered and had developed a secondary relapse. A post-intensive care clinic from 30 to 90 days after ICU discharge could have failed to detect CKD in 16/63 (25%) patients.

Conclusion: Because of many different clinical trajectories, a simple SCr dosage, within 3 months of ICU discharge in patients who had suffered from AKI was not sufficient to detect and prevent CKD. Assessment of progressive markers (hypertension, proteinuria) appears to be essential.

001370**Impact of sex and ICU treatment duration on creatinine and potassium excretion in critically ill patients**M. Van Bakelen-Knip¹; L. Hessels²; C. Cordeiro³; S. Berger⁴; M. Nijsten²¹Critical care department, University Medical Center Groningen, Groningen, Netherlands; ²Critical care department, University Medical Center Groningen, Groningen, Netherlands; ³Research and development, Paramedir Bv, Groningen, Netherlands; ⁴Dt of nephrology, University Medical Center Groningen, Groningen, Netherlands**Correspondence:** M. Nijsten*Intensive Care Medicine Experimental* 2020, **8(2)**: 001370

Introduction: Critically ill patients may have considerable and sustained loss of muscle mass. This loss may amount to more than 1% per day in ICU patients. It has been shown that urinary creatinine excretion (UCE) is a useful marker of muscle mass in non-ICU and ICU patients [1]. Recently we found that ICU patients display a negative potassium balance immediately after ICU admission, compatible with loss of intracellular volume, such as muscle mass.

Objectives: In the current study we compared UCE with urinary potassium excretion (UPE), where UCE served as marker of absolute muscle mass and UPE was hypothesized to indicate loss of muscle mass. We analyzed the time course of UCE with UPE in patients admitted for up to 30 days to our ICU and analyzed if there was a difference in UPE between males and females.

Methods: Patients for whom 24 h UCE and UPE were available between ICU day 1 and 30 were analyzed. Our computerized potassium regulation system regulated potassium administration in all patients. This system does not distinguish between males and females in their recommended potassium dose.

Results: 17,000 patients, aged 60 ± 16 year, 62% male, with a hospital mortality of 18% and 61,000 UCE and 45,000 UPE measurements were analyzed. UCE on ICU admission was 49% higher in males compared to females ($P < 0.001$) and decreased by 1.2%/d ($P < 0.001$). Mean UPE showed a bimodal time course with a near stable excretion between ICU day 7 to 30 (88 ± 59 and 79 ± 54 mmol/d in males and females respectively; $P < 0.001$). This difference between males and females in UPE of 9 mmol/d corresponds to the expected difference on the basis of muscle intracellular potassium concentration and observed muscle loss as reflected by UCE.

Conclusion: During prolonged ICU stay, there is a sustained difference in potassium excretion between males and females that is consistent with the muscle mass loss derived from creatinine excretion. Future balance studies could establish if creatinine and potassium excretion are suitable markers for direct monitoring of muscle mass loss.

001429**Effects of prone positioning on venous return in patients with acute respiratory distress syndrome**C. Lai¹; I. Adda¹; J.L. Teboul¹; R. Persichini¹; F. Gavelli¹; L. Guerin¹; X. Monnet¹¹Médecine intensive réanimation, Bicetre Hospital AP-HP, Le Kremlin-Bicêtre, France**Correspondence:** C. Lai*Intensive Care Medicine Experimental* 2020, **8(2)**: 001429

Introduction: Prone positioning in patients with acute respiratory distress syndrome (ARDS) has variable effects on cardiac index. It has been reported that prone positioning increases cardiac preload and cardiac index in patients with preload responsiveness. We made the hypothesis that the increase in cardiac preload was related to an increased mean systemic filling pressure (Pms), the forward pressure of venous return.

Objectives: To examine the effects of prone positioning on venous return and its determinants such as Pms and venous return resistance (Rvr) in patients with ARDS.

Methods: We included 22 patients with moderate to severe ARDS in whom prone positioning was decided. Preload responsiveness was assessed at baseline using an end-expiratory occlusion test. Hemodynamic measurements, including cardiac index, central venous pressure (CVP), Pms and Rvr (the latter two estimated through the

heart-lung interactions method) were measured in semi-recumbent, supine horizontal (in 15 patients) and after prone positioning.

Results: Prone positioning significantly increased Pms (from 24 (19-34) to 35 (32-46) mmHg). This was partly due to the trunk lowering performed before prone positioning. In seven patients, prone positioning increased cardiac index $\geq 15\%$. All were preload responsive. In these patients, prone positioning increased Pms by 82 (76-95)%, CVP by 33 (21-59)%, (Pms – CVP) by 144 (83-215)%, while it increased Rvr by 71 (60-154)%. In 15 patients, prone positioning did not increase cardiac index $\geq 15\%$. In these patients, prone positioning increased Pms by 28 (18-56)% ($p < 0.05$ vs. patients with significant increase in cardiac index), CVP by 21 (7-54)%, (Pms – CVP) by 28 (23-86)%, and Rvr by 37 (17-77)%. Eleven of these 15 patients were preload unresponsive.

Conclusion: Prone positioning increased Pms, CVP and Rvr. The resulting change in cardiac index depended on the extent of increase in (Pms-CVP), of preload responsiveness and of the increase in Rvr. Cardiac index increased only in preload responsive patients if the increase in Rvr was lower than the increase in the (Pms – CVP) difference.

001619**The association between the Sequential Organ Failure Assessment scores in particular systems and intensive care unit mortality in patients ≥ 80 years old – a prospective cohort study**J. Fronczek¹; H. Flaatten²; B. Guidet³; K. Polok¹; D. De Lange⁴; J. Fjølner⁵;J. Górka¹; C. Jung⁶; S. Leaver⁷; RP. Moreno⁸; A. Rhodes⁹; W. Szczeklik¹¹Intensive care and perioperative medicine, Jagiellonian University Medical College, Kraków, Poland; ²Department of anaesthesia and intensive care, Haukeland University Hospital, Bergen, Norway; ³Réanimation Médicale, Hôpital Saint-Antoine, Paris, France; ⁴Department of intensive care medicine, Utrecht University, Utrecht, Netherlands; ⁵Department of intensive care, Aarhus University Hospital, Aarhus, Denmark; ⁶Dep. of cardiology, pulmonology and angiology, University Hospital of Düsseldorf, Düsseldorf, Germany; ⁷Research lead critical care directorate, St George's Hospital, London, United Kingdom; ⁸Unidade de cuidados intensivos neurocríticos, Hospital de São José, Centro Hospitalar de Lisboa Central, Nova Médical School, Lisbon, Portugal; ⁹Anaesthesia and intensive care medicine, St George's University Hospitals NHS Foundation Trust, Londres, United Kingdom**Correspondence:** J. Fronczek,*Intensive Care Medicine Experimental* 2020, **8(2)**: 001619

Introduction: The Sequential Organ Failure Assessment (SOFA) score is being used to predict mortality in patients admitted to intensive care units (ICUs). The extent of organ failure in the SOFA is quantified using a point score with equal weights of abnormalities in different systems.

Objectives: To determine the relative contribution of alterations in different systems to the risk of ICU mortality in a population of very old intensive care unit patients (VIPs).

Methods: We used data from the Prognostic Score in the Very Old ICU Patients (VIP2) prospective, multicentre study (NCT03370692) which recruited consecutive patients ≥ 80 years old between May 2018 and May 2019. Worst SOFA scores within 24 hours from admission to the ICU was reported overall and in categories (i.e. respiratory, cardiovascular, hepatic, coagulation, renal and neurological systems). Logistic regression was used to study the association between the SOFA score and mortality.

Results: We included 3898/3919 (99.5%) patients who had complete data on all components of the SOFA score in the analysis. The median age in the sample was equal to 84 years (IQR: 81-87), 2078 (53.3%) patients were male. The median SOFA score was equal to 6 points (IQR: 4-9) and 1022/3898 (26.2%) patients died in the ICU. Odds ratios for ICU mortality associated with the number of points in a given system (1, 2, 3, or 4 points respectively) with 0 points set as the reference category were as follows (95% confidence intervals shown in brackets):

- respiratory: 1.21 (0.91-1.61), 1.67 (1.29-2.15), 1.63 (1.24-2.14), 3.51 (2.53-4.86),

- cardiovascular: 1.15 (0.90-1.45), 0.62 (0.36-1.07), 0.98 (0.77-1.25), 1.83 (1.48-2.26),
- neurologic: 1.49 (1.20-1.85), 2.33 (1.76-3.09), 2.57 (1.95-3.39), 5.12 (4.11-6.37),
- renal: 1.57 (1.29-1.91), 1.78 (1.42-2.23), 2.59 (1.90-3.53), 2.21 (1.56-3.12),
- coagulation: 1.13 (0.91-1.39), 1.33 (0.99-1.79), 2.71 (1.54-4.76), 0.78 (0.18-3.36),
- hepatic: 1.23 (0.98-1.55), 1.54 (1.14-2.06), 1.80 (0.85-3.81), 1.91 (0.68-5.30).

Conclusion: Our results suggest that the current SOFA score may be too simplistic to capture the relative contribution of individual organs' dysfunction to the risk of ICU mortality in a population of patients ≥ 80 years old.

Erythromycin as a prokinetic: what dose and duration are optimal?

N. Shaikh¹; M. Rahman²; C. Arshad²; M. Ranjan²

¹Hamad Medical Corporation, Doha, Qatar; ²Sicu, HMC, Doha, Qatar

Correspondence: N. Shaikh

Intensive Care Medicine Experimental 2020, **8(2)**: 000011

Introduction: Erythromycin is a potent prokinetic agent and has a shorter onset of action time. The combination of prokinetic medications is increasingly used as they accelerate the prokinetic action and at the same time decrease the adverse effects.

Objectives: Aim of our study was to know the effective prokinetic dose, duration of usage, response and safety of erythromycin in patients already on metoclopramide.

Methods: All patients in surgical and trauma intensive care unit having enteral feed intolerance and already on metoclopramide for 24 hours were enrolled in the study prospectively. Patient's demographic data, diagnosis, surgical intervention, disease severity scores, erythromycin dose, duration, any adverse effects, factors affecting erythromycin response and outcome were recorded. All these patients received 125 mg syrup erythromycin twice daily through nasogastric tube and nasogastric tube was clamped for 2 hours and half amount of previous enteral feeds were resumed. If patient did not tolerate the feeds, the erythromycin dose was increased every 24 hours in the increment of 250, 500 and 1000 mgs.

Results: Total of 313 patients were included in the study. Males were higher in number (77.6%) and majority (48.2%) of patients with feed intolerance were post laparotomy. Ninety percent patients responded to prokinetic erythromycin therapy, 54% received lower dose (125 mg twice daily) and 14% had diarrhoea. Mean duration of erythromycin therapy was 4.98 days. The most effective dose of erythromycin was 125mg twice daily ($P = 0.001$). It was significantly effective in patients with multiple organ dysfunction and shock ($P = 0.001$ and 0.003 respectively). Patients not responding to erythromycin therapy had a significant higher mortality ($p = 0.001$).

Conclusion: Post-laparotomy patients had higher enteral feed intolerance. Erythromycin was effective in 125 mgs dose and minimal duration. Patients who did not tolerate feeds despite increasing dose of erythromycin had higher mortality.

Methotrexate carried in lipid core nanoparticles prevents cardiac dysfunction by increasing angiogenesis and availability of intracellular adenosine in the left ventricle of sepsis-induced rats

N.M. Lopes¹; MC. Guido¹; Cl. Albuquerque¹; L. Jensen²; RC. Maranhão¹

¹Lipids and Metabolism Laboratory, Heart Institute of the State of Sao Paulo (InCor), Sao Paulo, Brazil; ²Experimental biology laboratory, Heart Institute of the State of Sao Paulo (InCor), Sao Paulo, Brazil

Correspondence: N.M. Lopes

Intensive Care Medicine Experimental 2020, **8(2)**: 000015

Introduction: In sepsis, besides the dysregulation of the immune system and disturbances of several vital organs, life-threatening cardiac dysfunction often occurs. We showed in previous studies that LDE, a non-protein lipid core nanoparticle, is able to concentrate in inflammatory sites. When carried in LDE, the cellular uptake of methotrexate (MTX) increased several-fold compared to the uptake of the commercial version. LDE-MTX formulation was shown to modulate the immune response in rats with myocardial infarction, reduce the inflammation and improve the post-infarction cardiac function by increasing angiogenesis, thereby improving hypoxia.

Objectives: To test whether LDE-MTX can improve the cardiac status in septic rats.

Methods: Sepsis was induced in Wistar rats by two I.P. injections of lipopolysaccharide (LPS, 10 mg/kg) administered with a 24 h interval. Rats were allocated in a Control group (CT, without sepsis) and 3 groups with sepsis: LDE, treated with LDE only; MTX, with commercial MTX (1 mg/kg); and LDE-MTX, with LDE-MTX (1 mg/kg). Echocardiography was performed 72 h after sepsis induction. Animals were euthanized for morphometric analysis of the LV and protein expression analysis of inflammatory, apoptotic, angiogenesis, hypoxia and adenosine bioavailability markers in the LV.

Results: Septic rats treated with LDE developed diastolic dysfunction and presented decreased diastolic volume and diameter of the LV. LDE-MTX group had the appearance of diastolic dysfunction and alterations in LV dilation totally prevented. Also, LDE-MTX treatment elicited cardiac hypertrophy through the increase of the thickness of septum and of the LV posterior wall. LDE-MTX increased LV mass and relative heart weight, as compared to the other groups. Morphometric analysis showed increased myocyte diameter in LDE-MTX when compared to other groups. All groups showed no differences in the protein expression of inflammatory (lymphocytes, tumor necrosis factor, interleukins) and apoptotic (caspases and B-cell lymphoma family) markers, although LDE-MTX showed higher expression of CD68 (macrophage marker). In LDE, hypoxia was remarkably higher while LDE-MTX showed higher angiogenesis and lower cellular hypoxia, respectively represented by vascular endothelial growth factor (VEGF) and hypoxia-inducible factor 1 alpha. MTX showed no effects in angiogenesis or hypoxia. The intracellular adenosine bioavailability was increased in LDE-MTX-treated animals, promoted by higher expression of the A1 receptor, as compared to CT. Myocyte diameter was positively correlated with VEGF ($r^2 = 0.52$; $p < 0.0001$).

Conclusion: The appearance of cardiac dysfunction associated to sepsis, was successfully avoided by the treatment with LDE-MTX. This outcome is conceivably associated to different effects observed in this group, such as the development of an adaptive hypertrophy as result of the modulation of different pathways, such as the activation of angiogenesis mechanisms, increase of adenosine bioavailability and immune recruitment to the LV.

Stress ulcer prophylaxis plus enteral nutrition versus enteral nutrition alone in critically ill patients at risk for gastrointestinal bleeding: a propensity-matched analysis

H. Ohbe¹; Y. Hideo¹

¹Department of clinical epidemiology and health economics, The University of Tokyo, Bunkyo City, Japan

Correspondence: H. Ohbe

Intensive Care Medicine Experimental 2020, **8(2)**: 000019

Introduction: As an alternative to stress ulcer prophylaxis (SUP), enteral nutrition (EN) alone may provide prophylaxis against stress-related gastrointestinal bleeding. In animal studies, EN increased gastrointestinal blood flow and luminal pH, contributing to the protection of the gastric mucosa [1]. Similarly, a previous prospective study of Intensive care unit (ICU) patients showed that both continuous EN and SUP independently increased gastric pH and gastric colonization [2]. However, the effects and safety of SUP in ICU patients receiving EN are poorly understood.

Objectives: To evaluate whether EN alone provides prophylaxis against stress-related gastrointestinal bleeding and reduces drug complications compared with concomitant pharmacological SUP and EN.

Methods: Using data for July 2010 to March 2018 from the Japanese Diagnosis Procedure Combination inpatient database, we identified adults with at least one risk factor for gastrointestinal bleeding and who had received EN within 2 days of intensive care unit admission. We allocated patients who had received intravenous or enteral SUP (proton-pump inhibitor and/or histamine-2 receptor antagonists) within 2 days of receiving EN as the SUP group, and patients who had received EN alone as the control group.

Results: We identified 50,663 eligible patients, and 4615 patients (9%) constituted the SUP group. After propensity score matching, there was no significant difference in in-hospital mortality and endoscopic hemostasis for gastrointestinal bleeding between the two groups. The SUP group was more likely to have hospital-acquired pneumonia (odds ratio, 1.25; 95% confidence interval, 1.06–1.46) than the control group. Patients who had received proton-pump inhibitors were more likely to receive percutaneous coronary intervention for acute myocardial infarction (odds ratio, 1.51; 95% confidence interval, 1.04–2.18) than patients without SUP.

Conclusion: Our results suggest that among patients at risk for gastrointestinal bleeding who had received EN, SUP may not reduce in-hospital mortality or gastrointestinal bleeding but may increase complications of hospital-acquired pneumonia or acute myocardial infarction. Future randomized control trials are warranted to confirm our findings.

Intensive Care Medicine Experimental 2020, **8(2)**: 000066

Introduction: Hypoxic ischemic brain injury (HIBI) is the leading cause of morbidity and mortality in patients who survive cardiac arrest. The goal of HIBI management is to augment cerebral oxygen delivery by optimizing mean arterial pressure in these patients. Real-time cerebral autoregulation monitoring provides a method of identifying the patient specific optimal mean arterial pressure (MAPOPT) but while this method has been well established in traumatic brain injury patients, similar studies are lacking in HIBI patients.

Objectives: Our systematic review aims to determine (a) the average MAPOPT in post-cardiac arrest HIBI patients, (b) the feasibility of identifying MAPOPT, (c) the brain tissue oxygenation levels when within proximity to the MAPOPT, and (d) the relationship between neurological outcome and MAPOPT.

Methods: We carried out this review in accordance with the PRISMA guidelines. We searched MEDLINE (Ovid), Embase (Ovid), EBM Reviews (Ovid), CINAHL (EBSCO), the Cochrane Database of Systematic Reviews and the WHO Global Health Library from inception to October 31 2019. We also searched the Cochrane Central Register of Controlled Trials (CENTRAL), BioMed Central, ClinicalTrials.gov, WHO International Clinical Trials Registry Platform (ICTRP) and Thomson Center Watch for unpublished works and ongoing clinical trials.

We included all studies that used cerebral autoregulation to determine MAPOPT in adult patients (> 16 years old) who achieved return of spontaneous circulation (ROSC) post-cardiac arrest. Patients had to be intubated and ventilated while undergoing invasive cardiovascular and neurovascular monitoring in an Intensive Care Unit. We excluded studies where patients had any history of traumatic brain injury, ischemic stroke or intracranial hemorrhage.

Results: We identified six studies with 181 patients. There was wide variability in cerebral autoregulation monitoring methods, length of monitoring, calculation and reporting of MAPOPT. Amongst all studies, the median or mean MAPOPT was consistently above 65 mmHg (range: 70-114 mmHg). Definitions of feasibility varied amongst studies and was difficult to summarize. Some studies defined feasibility as the ability to calculate one MAPOPT value during the monitoring period while others defined it as the duration of monitoring time for which MAPOPT could be calculated. Only one study noted that brain tissue oxygenation increased as patients' MAP approached MAPOPT. However, this effect disappeared when the MAP exceeded MAPOPT. Finally, there was no consistent association between MAPOPT and neurological outcome.

Conclusion: There is considerable heterogeneity in determining MAPOPT due to differences in autoregulation monitoring. Further standardized randomized controlled trials and prospective studies are needed to assess the clinical utility of MAPOPT guided strategies on improving neurological outcomes after ROSC.

Accuracy of Mortality Prediction by Machine Learning Models Compared to Clinician's Intuition in Critically Ill PatientsS. Patel¹; Y. Wolfe¹; N. Puri¹¹Critical care, Cooper University Health Care, Camden, United States of America**Correspondence:** Y. Wolfe*Intensive Care Medicine Experimental* 2020, **8(2)**: 000096

Introduction: Intensive Care Units (ICUs) treat patients with high mortality risk. Early and accurate mortality estimation is crucial for guiding care and resource allocation. Identification of patients with poor trajectories is difficult and often wrought with biases. Machine Learning (ML) with quality data is a means of accurate mortality prediction. Several studies compared machine learning models to severity illness scores in predicting mortality. To our knowledge, no study has compared ML and clinician feature importances.

Objectives: We compared important features for mortality chosen by ML models and clinicians.

Methods: We extracted data from the eICU Collaborative Research Database. The dataset included 27 variables (26 independent and 1 dependent) and 147,233 values. Mortality was the dependent variable for our prediction models. Exploratory data analysis performed in Python. Missing data imputed with Sklearn Iterative Imputer. Feature selection performed using Pearson correlation and Sklearn Select From Model library. Top ten features for the ML group chosen by the frequency in the top ten for Pearson Correlation and four ML model feature selection methods. ICU clinicians filled out a survey to choose the top ten features that predict mortality. Fifty-one surveys filled out, and the most common features compiled to create a top ten list. The mortality outcome of death was rare (136,451 alive versus 8,184 died). Given the imbalanced dataset, we employed an oversampling technique (SMOTE). The top features in both groups were passed through Logistic Regression (LR) and Naive Bayes (NB) algorithms. Area Under Receiver Operator Characteristic (AUROC) was chosen as our metric.

Results: White blood count (WBC), Prothrombin Time (PT), Lactate, Hypoglycemia, and PaO₂/FiO₂ ratio were the top features for the ML group. Clinicians chose hepatic failure, advanced age, immunosuppressed status, and history of metastatic cancer. The AUROC for the ML group in predicting mortality was 0.865 (LR); 0.840 (NB), as compared to 0.737 (LR); 0.744 (NB) for clinicians. As a benchmark, we compared our feature inputs to SAPS II and APACHE IV scores input into LR and NB. SAPS II and APACHE IV performance were 0.842 (LR); 0.844 (NB) and 0.855 (LR); 0.855 (NB) respectively.

Conclusion: ML models can identify important features for accurate ICU mortality prediction. ML predictive models can be important adjuncts to augment clinical decision making.

Lung-protective mechanical ventilation for 50 hours is associated with hippocampal apoptosis and shifts the behavior of hippocampal microglia from anti-inflammatory to pro-inflammatoryT. Bassi¹; E. Rohrs²; K. Fernandez²; M. Ornowska²; M. Nicholas²; S. Reynolds¹¹Physiology, Simon Fraser University, Burnaby, Canada; ²Critical care, Fraser Health Authority, New Westminster, Canada**Correspondence:** T. Bassi*Intensive Care Medicine Experimental* 2020, **8(2)**: 000128

Introduction: The hippocampus is part of the limbic system known as an emotional neuro-circuit, and its activity is coupled with the breathing cycle. 1 Ventilation-Induced Brain Injury (VIBI) was recently identified preclinically, 2 where VIBI was characterized by hippocampal neuroinflammation and apoptosis. However, these studies used high-tidal-volume mechanical ventilation for short durations (for up to 3½ hours), and the effect on the hippocampus of long-term lung-protective (i.e. gold standard) mechanical ventilation (MV) is not known. We hypothesize that lung-protective MV for 50 hours in a non-injured preclinical model shifts the behavior of hippocampal microglia towards inflammation, contributing to local apoptosis. The interaction between the apoptotic process and microglia cells has been described in other conditions, such as epilepsy and traumatic brain injury. 3–5 Characterizing changes in the behavior of hippocampal microglia might assist in a better understanding of the neuro-inflammatory process happening during VIBI. This data might also contribute to the design of future studies into cognitive dysfunction after MV.

Objectives: To investigate whether lung-protective mechanical ventilation in a porcine model for 50 hours modifies microglia behavior, and to analyze the level of hippocampal apoptosis after 50 hours of lung-protective mechanical ventilation.

Methods: We ventilated eight human-size pigs (MV group) using lung-protective MV for 50 hours in a mock ICU, and compared them with six never-ventilated pigs (NV group). Ventilation settings were

adjusted to achieve and maintain a tidal volume of 6-8 ml/kg, with a PEEP of 5 cm H₂O. The pigs' hippocampi were harvested, and machine-learning software was used to count and classify cells. Percentages of cells stained by the TUNEL and IBA1 markers were then determined. Microglia behavior was determined, and quantified following biometric cellular characteristics based on pre-established criteria in the literature.

Results: The hippocampal apoptotic percentage was 38% (44,797/117,886) in the MV group and 1% (338/33,805) in the NV group ($p < 0.01$). Total microglia population as a percentage of total cell population, including those displaying pro- and anti-inflammatory characteristics, was 36% (74,212/205,006) in the MV group and 10% (58,398/589,888) in the NV group ($p < 0.01$). Analysis of MV group microglia identified 81% (60,111/74,212) with anti-inflammatory characteristics and 19% (14,101/74,212) with pro-inflammatory characteristics ($p < 0.01$). Analysis of the NV group microglia identified 84% (49,288/58,398) with anti-inflammatory characteristics and 16% (9,110/58,398) with pro-inflammatory characteristics ($p < 0.01$). The percentage of microglia with pro-inflammatory characteristics was slightly, but significantly higher in the MV group (19%) than in the NV group (16%, $p < 0.05$). The percentage of microglia with anti-inflammatory characteristics was also significantly different; 81% in the MV group, compared to 84% in the NV group ($p < 0.05$).

Conclusion: Lung-protective MV for 50 hours in a non-injured preclinical model is associated with VIBI, characterized by high hippocampal apoptotic percentage and also a shift in the behavior and number of hippocampal microglia from anti-inflammatory to pro-inflammatory.

Intensive Care Medicine Experimental 2020, **8(2)**: 000131

Introduction: The approach to limit therapy in very old intensive care unit patients (VIPs) significantly differs between regions. The focus of this multicenter analysis is to illuminate, whether the Clinical Frailty Scale (CFS) is a suitable tool for risk stratification in VIPs admitted to intensive care units (ICUs) in Germany. Furthermore, this investigation elucidates the impact of therapeutic limitation on the length of stay and mortality in this setting.

Methods: German cohorts' data from two multinational studies (VIP-1, VIP-2) were combined. Univariate and multivariate logistic regression were used to evaluate associations with mortality.

Results: 415 acute VIPs were included. Frail VIPs (CFS > 4) were older (85 [IQR 82-88] vs. 83 [IQR 81-86] years; $p < 0.001$) and suffered from an increased 30-day-mortality (43.4% versus 23.9%, $p < 0.0001$). CFS was an independent predictor of 30-day-mortality in a multivariate logistic regression model (aOR 1.23 95%CI 1.04-1.46; $p = 0.02$). Patients with any limitation of life-sustaining therapy had a significantly increased 30-day mortality (86% versus 16%, $p < 0.001$) and length of stay (144 [IQR 72-293] versus 96 [IQR 47.25-231.5] hours, $p = 0.026$).

Conclusion: In German ICUs, any limitation of life-sustaining therapy in VIPs is associated with a significantly increased ICU length of stay and mortality. CFS reliably predicts outcome.

Intensive Care Medicine Experimental 2020, **8(2)**: 000144

Introduction: The growing proportion of nonagenarian ICU patients challenges intensive care medicine. Due to the unclear benefit to patients and a high consumption of health care resources, these oldest-old patients represent both an ethical and political problem. This study compared outcome differences between nonagenarian and octogenarian ICU patients.

Methods: 7900 acutely admitted older critically ill patients from two large, multinational registers were included. The primary endpoint was ICU-, the secondary endpoint 30-day-mortality. Baseline characteristics including frailty assessed by the Clinical Frailty Scale (CFS), management and outcomes were compared between octogenarian (80-89.9 years) and nonagenarian (≥ 90 years) patients. Logistic regression was used to calculate a propensity score on being nonagenarian and to evaluate univariable and multivariable associations with the endpoints.

Results: The nonagenarians accounted for 10% of the entire cohort. They evidenced higher rates of frailty (58% vs 42%; $p < 0.001$), but lower SOFA scores at admission (6 ± 5 vs. 7 ± 6 ; $p < 0.001$). Management strategies differed with octogenarians receiving higher rates of organ support while nonagenarians had higher rates of life-sustaining treatment limitation (40% vs. 33%; $p < 0.001$). ICU mortality was similar (27% vs. 27%; $p = 0.973$) in octogenarians and nonagenarians. However, being a nonagenarian was independently associated with increased 30-day-mortality after adjustment of the propensity score (OR 1.18 95%CI 1.02-1.38; $p = 0.03$).

Conclusion: Nonagenarians had higher 30-day mortality compared to octogenarian patients. Being a nonagenarian should be considered an independent risk factor for mortality and – together with disease severity and pre-existing functional capacity – to effectively guide triage decisions.

Intensive Care Medicine Experimental 2020, **8(2)**: 000155

Introduction: Most critically ill patients experience the disruption of circadian body temperature (BT) rhythm after intensive care unit (ICU) admission. However, there is limited evidence on the relationship between circadian BT variation and outcomes in patients during ICU stay.

Objectives: To assess the impact of circadian BT variation on prognosis in ICUs patients.

Methods: A multicenter retrospective cohort study was performed with eICU Collaborative Research Database, which comprises 139367 patients at 335 distinct ICUs across the United States from 2014 to 2015. Adult patients with complete records of continuous bedside core BT monitoring during the first 24 hours of ICU stay were included. According to circadian BT variation (mean night-time BT/mean daytime BT), participants were divided into two groups: ratio ≤ 1 and ratio > 1 . Logistic and linear regression were performed to investigate the relationship between circadian BT variation and prognosis (ICU mortality, length of ICU stay [ICU-LOS], and length of hospital stay [hospital-LOS]). Sensitivity analysis was conducted according to Acute Physiology and Chronic Health Evaluation IV (APACHE IV) ≤ 64 or > 64 . Furthermore, an external cohort was performed with Multiparameter Intelligent Monitoring in Intensive Care II database.

Results: A total of 6093 patients were analyzed. Patients with circadian BT variation ≤ 1 ($n = 2473$) had higher ICU mortality, longer ICU-LOS and hospital-LOS than those with circadian BT variation > 1 ($n = 3620$). After multivariable adjustments, circadian BT variation ≤ 1 increased ICU mortality (odds ratio [OR], 1.231, 95% confidence intervals [CI], 1.009 – 1.502), prolonged ICU-LOS (β , -0.420 , 95%CI, -0.657 to -0.182), and hospital-LOS (β , -0.836 , 95%CI, -1.247 to -0.426) in ICU patients. The association remained significant in sensitivity analysis and external cohort.

Conclusion: Circadian BT variation may be associated with higher ICU mortality, longer ICU-LOS, and hospital-LOS in critically ill patients. Our findings will further develop our knowledge on the vital role of circadian rhythm in ICU and indicated that circadian BT variation may assist with early risk stratification.

Temporary transvenous diaphragm neurostimulation plus lung-protective mechanical ventilation is associated with greater heart rate variability after 50 hours compared to ventilation alone

T. Bassi¹; M. Nicholas²; K. Fernandez²; M. Ornowska²; E. Rohrs²; S. Reynolds¹

Intensive Care Medicine Experimental 2020, **8(2)**: 000162

Introduction: Heart rate variability (HRV) is an accepted method for measuring sympathetic/parasympathetic balance and it is influenced by vagal afferent signals coming from the lungs.1,2 The effect of lung-protective mechanical ventilation (MV) on sympathetic/parasympathetic nervous system balance has not been demonstrated. Greater R-R interval variance reflects a normal physiological state with parasympathetic predominance; lower R-R interval variance indicates sympathetic predominance, which correlates with high mortality and inflammation.3 Studying HRV during MV is important to better understand the inflammatory insult associated with MV. Temporary transvenous diaphragm neurostimulation (TTDN) is a novel technology that assists MV by creating negative pressure targeting the reduction of the pressure-time-product (PTP), and may influence the HRV.

We hypothesize lung-protective MV progressively downregulates parasympathetic activity over the course of 50 hours and that MV + TTDN will upregulate parasympathetic activity due to more physiological alveolar stretch resulting in greater HRV after 50 hours of the experiment.

Objectives: To compare the sympathetic/parasympathetic nervous system balance after 50 hours of lung-protective MV alone and with TTDN assistance.

Methods: We used sixteen pigs between 51-64 kg, eight under lung-protective MV (MV-Only) and eight under lung-protective MV plus TTDN (MV + TTDN) for 50 hours. Ventilation parameters were set to achieve and maintain tidal volume 6-8 ml/kg, and PEEP of 5 cm H₂O. TTDN targeted between 15-20% reduction in PTP during MV. The MV + TTDN group received phrenic nerve stimulation every other breath in synchrony with MV. ECG data were analyzed over two periods after MV initiation; hours 0 to 6 (start) and hours 44 to hour 50 (end). Root mean square of the standard deviation of the R-R intervals (RMSSD) was chosen as the HRV time-domain method of analysis.

Results: In total, 815,658 R-R intervals were analyzed across the sixteen subjects; 407,762 in the MV-Only group and 407,896 in the MV + TTDN group ($p > 0.05$). In the MV-Only group the RMSSD was 0.90 ms at the start and 0.81 ms at the end of the study; and in the MV + TTDN group it was 0.81 ms at the start and 0.91 ms at the end ($p = 0.007$, between groups).

Conclusion: MV resulted in a reduction of the HRV in the MV-Only group after 50 hours which might indicate a downregulation in parasympathetic activity. The MV + TTDN group showed higher HRV after 50 hours of MV which might point towards upregulation in parasympathetic activity.

Introduction: Respiratory support plays an important role in patient's recovery after cardiovascular surgery. Intellivent-ASV® is a closed-loop ventilation mode that adjusts automatically ventilation and oxygenation settings according to patient weight, lung function (as assessed by the ventilator) and continuous input of end-tidal carbon dioxide and oxygen saturation in both passive and spontaneous breathing patients. There is an ability to improve patient's safety and reduce physician's workload with using intellectual modes of ventilation.

Objectives: To compare the effect(s) of Intellivent-ASV and conventional ventilation modes.

Methods: In this randomized controlled trial 40 adult patients were ventilated with conventional ventilation modes and 40 with Intellivent-ASV after uncomplicated cardiac surgery. Hamilton G5 ventilators were used and 8 physicians were involved into the study. All actions of physician's, ventilator settings and changes were monitored

and recorded during respiratory support in ICU. Care of both groups was standardized, except modes of postoperative ventilation. We compared:

the physician's workload, through accounting number of manual ventilator settings and time they spent near the ventilator in every group;
duration of tracheal intubation in ICU;
evaluation of ventilation safety by considering driving pressure, mechanical power, positive end expiratory pressure and tidal volume level.

Results: There were significant differences in the duration of respiratory support in ICU: 226 ± 31 min (Intellivent group) vs 271 ± 78 min (control) ($p = 0,001267$).

In Intellivent group the number of manual ventilator settings and physicians time spent near the ventilator before tracheal extubation were lower: 0 vs 4 (2-6), and 35 (25-53) sec vs 164 ± 69 sec respectively ($p < 0,001$ in both cases).

Intellivent-ASV provided a significant more protective ventilation through reduction in the driving pressure, tidal volume, FiO₂ and PEEP levels, but without differences between PaO₂/FiO₂ ratio.

- ΔP and Vt were significantly lower in Intellivent group - ΔP on mechanical ventilation was 6 (5-7) cm H₂O vs 7,25 (6,5-9,5) cm H₂O ($p < 0,001$) and pressure support level - 5 (5-5) cm H₂O vs 8 (7-10) cm H₂O; Vt on mechanical ventilation was 6 (5,2-7) vs 7 (6-9,5) ml/kg/PBW ($p = 0,000003$).
- PEEP and FiO₂ level were also significantly lower in Intellivent group during all phases of respiratory support in ICU. PEEP on mechanical ventilation was 5 (5-7,5) cm H₂O vs 7 (5-11,5) cm H₂O and FiO₂ level was 26 (22-30) % vs 34 (30-40) %. During spontaneous ventilation phase in Intellivent group PEEP was 5 (5-5,5) cm H₂O vs 7 (5-10) cm H₂O and FiO₂ 26 ± 4 % vs 30 (29-40) %.
- Mechanical power (simplified equation) was lower in Intellivent group 8,17 (5,99-10) vs 8,58 (6,34-13,7) J/min ($p = 0,0467$).

There were no significant differences between the groups in Vt values during spontaneous ventilation: 8 (7-9) vs 8 (7-10) ml/kg/PBW in control group, as well as in undesirable events and duration of ICU and hospital stay.

Conclusion: Application of Intellivent-ASV mode after uncomplicated cardiac surgery provides more protective mechanical ventilation and reduces the physician's workload without compromising the quality of respiratory support and safety of patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 000180

Introduction: Sepsis is a life-threatening organ dysfunction due to a pathological host response to an infection. Vascular barrier breakdown represents a key component of this maladaptive host response and the release of pre-stored Angiopoietin-2 (Angpt-2) from the endothelium is a direct driver of this phenomenon via deactivation of its target receptor "Tie2". Currently, an Angpt-2 modulating therapy does not exist. Screening an FDA-drug library, we identified the antifungal Bifonazole (BIFO) as a potential reducer of Angpt-2 *in vitro*. We hypothesize that BIFO might decrease circulating Angpt-2 and therefore, diminish capillary leakage.

Methods: Endothelial cells were isolated from human umbilical veins (HUVECs) and used for *in vitro* studies after stimulation with BIFO (RT-PCR, immunoblot, ELISA, immunocytochemistry, transendothelial electrical resistance (TER)). *In vivo* studies were performed on endotoxemic C57Bl6 mice treated with BIFO (lung RT-PCR, immunoblot, ELISA).

Results: We found that BIFO can reduce spontaneous Angpt-2 release in a time- and dose-dependent manner in HUVECs after 8 ($p < 0.05$), 12 and 24 h (veh: 15.58 ± 0.7 vs BIFO: 8.56 ± 0.8 ng/ml, $p < 0.001$). In addition, after TNF- α challenge, BIFO was still able to reduce this stimulated Angpt-2 release (veh: 30.3 ± 3.8 vs BIFO: 22.2 ± 2.5 ng/ml, $p < 0.01$). Measuring the TER to quantify endothelial permeability, BIFO was sufficient to increase TER in two models of hyperpermeability (Thrombin and PMA) (veh: 0.82 ± 0.10 vs BIFO: 1.01 ± 0.02 , $p < 0.05$). As BIFO reduced not only Angpt-2 release but also cellular content by 27% ($p < 0.05$), an exocytosis-independent mechanism directly affecting Angpt-2 biosynthesis seems involved. Consistently, Angpt-2 transcription (mRNA) was reduced in lungs of BIFO-stimulated mice (veh: 1.00 ± 0.38 vs BIFO: 0.55 ± 0.43 , $p < 0.05$).

Conclusion: The antifungal BIFO can reduce release and synthesis of the endothelial-destabilizing factor Angpt-2 *in vitro*. Henceforth, our results suggest that BIFO might counterpart the pathophysiology of endothelial permeability in inflammation via a reduction of Angpt-2 transcription (mRNA). More *in vitro* studies are needed to further investigate mechanisms of the pharmacological effect of BIFO on the regulation of Angpt-2. *In vivo* studies that are currently ongoing are supposed to confirm the results in a murine sepsis-model.

Intensive Care Medicine Experimental 2020, **8(2)**: 000188

Introduction: Subclavian vein catheterization has many advantages compared to other sites for central venous access. Unfortunately, central venous catheter (CVC) misplacement is common (up to 9.3% after a right-sided catheterization). To avoid CVC misplacements, the right supraclavicular fossa ultrasound view can be used to confirm correct guidewire J-tip position in the lower part of the superior vena cava prior to CVC insertion.

Objectives: To demonstrate the usefulness of a real-time ultrasound method for guidewire positioning during infraclavicular CVC placement in the right subclavian vein, and to determine the number of CVC misplacements occurring when using this method. The hypothesis was that the incidence of misplaced CVCs could be reduced to 1%.

Methods: The study was approved by the Swedish Ethical Review Authority and registered as a clinical trial at clinicaltrials.gov (NCT03812757). Sample size calculation showed that 93 patients should be included. All vein punctures were performed prospectively, under real-time ultrasound guidance with a micro-convex probe. The right supraclavicular fossa ultrasound view was used to confirm correct guidewire position (Figure 1) and misplaced guidewires were adjusted prior to CVC insertion. A post-procedural chest X-ray was obtained to determine definitive CVC tip position.

Results: One hundred patients were included. Successful catheterization of the right subclavian vein was achieved in all patients. In 14 cases the guidewire J-tip was initially misplaced in either the ipsilateral internal jugular vein ($n = 8$) or in the left brachiocephalic vein ($n = 6$). In 12 of these cases it was possible to adjust the guidewire J-tip to a correct position in the superior vena cava. In 2 cases it was impossible to adjust the guidewire J-tip from a position in the left brachiocephalic vein, and the suboptimal positions were finally accepted. Both CVC tips were confirmed with chest X-rays in the left subclavian vein, as expected. The remaining 98 CVCs all had a tip position in the lower part of the superior vena cava, determined by chest X-ray.

Conclusion: Although the hypothesis could not be confirmed, this study demonstrates that the use of the right supraclavicular fossa ultrasound view to guide guidewire positioning reduced the incidence of CVC misplacements to 2% and thus is useful to avoid CVC misplacements in right infraclavicular subclavian vein catheterization.

Intensive Care Medicine Experimental 2020, **8(2)**:000193

Introduction: The glomerular filtration rate (GFR) is an index of the renal filtration function, and is estimated clinically by the creatinine clearance (CrCl). Since the kidney is the primary excretory organ for most hydrophilic drugs such as beta-lactam antimicrobials, drug dosage is determined based on the CrCl. It is well known that kidney function changes rapidly in critically ill patients. Predictions of CrCl could be useful to avoid subtherapeutic drug plasma levels in hyper-clearance patients and drug toxicity in hypo-clearance patients.

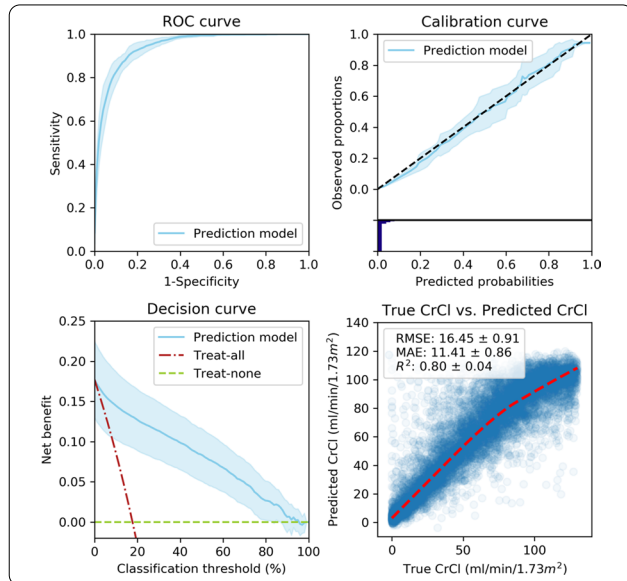

Objectives: The purpose of this study was to generate a daily prediction of kidney function on the next day in the ICU. For this purpose, we developed and internally validated prediction models for CrCl on the next day of ICU stay in adult patients.

Methods: This study was a retrospective preplanned secondary analysis of the EPaNIC multicenter randomized controlled trial database [1]. CrCl was calculated by daily urine output (UO), urine creatine (UCr), and serum creatinine (SCr). The development cohort ($n = 1458$ patients, equivalent to 11726 patient-days) consisted of all ICU adult patients with available CrCl for the previous day. Clinical data were retrieved from the EPaNIC research database and from the clinical patient data management system database. The models were developed with gradient boosting method (GBM) machine-learning algorithm for both classification and regression. We first classified whether CrCl would be above $130 \text{ ml/min/1.73 m}^2$ and then regressed all the CrCl classified as below $130 \text{ ml/min/1.73 m}^2$. Model performance (Mean \pm SD) was internally validated with 10-fold cross validation for discrimination, calibration, net benefit analysis, coefficient of determination (R^2), mean absolute error (MAE), and root mean square error (RMSE).

RESULTS. A total of 479 patients (32.8%), equivalent to 2077 patient-days (17.7%), had CrCl above $130 \text{ ml/min/1.73 m}^2$ on the next day. The five most important variables for both the classification and regression models were mean CrCl, CrCl of the previous day, age, SCr of the previous day, and UO of the previous day. As shown in Fig. 1, the classification model had an area under the receiver operating characteristic

curve (AUROC) of 0.94 ± 0.01 , calibration slope of 0.90 ± 0.09 , and calibration in the large of 0.00 ± 0.04 . At the classification threshold maximizing sensitivity and specificity, net benefit with respect to treat-none was 0.14 ± 0.04 , and net benefit with respect to treat-all was 0.09 ± 0.07 . For the remaining 979 patients having CrCl below $130 \text{ ml/min/1.73 m}^2$ on the next day, the regression model had RMSE of 16.45 ± 0.91 , MAE of 11.41 ± 0.86 , and R^2 of 0.80 ± 0.04 .

Conclusion: Prediction models based on routinely collected clinical data were able to accurately predict CrCl of the next day in the ICU. These predictions could be used to more accurately determine hydrophilic drug doses in critically ill patients. These findings should be externally validated.

Intensive Care Medicine Experimental 2020, **8(2)**:000194

Introduction: Introduction/Background: Ischemia/reperfusion (I/R) is frequently associated with microcirculatory deterioration (1). Microcirculatory disturbances are associated with reduced outcome (2). Both colloidal as well as crystalloid fluids are used for macrohemodynamic optimization in I/R. However, impact of colloids or crystalloids on microcirculation is unclear. Aim of this study was to compare the effects of colloids vs. crystalloids on microcirculation of vital organs in I/R injury.

Methods: Methods: This study was performed in 32 anesthetized and mechanically ventilated pigs. Animals were randomized in two equal groups receiving either colloids (Voluven[®] 6%, Fresenius Kabi[®], Bad Homburg, Germany) or crystalloids (Sterofundin[®] ISO 1/1 E, B. Braun[®], Melsungen, Germany) for hemodynamic optimization. Volume optimization was performed before and after I/R using consecutive

volume loading steps of 7 ml/kg of either colloids or crystalloids until increases of cardiac output $\geq 15\%$ were absent. I/R was induced by 48 minutes of aortic cross clamping. Microcirculatory blood flow of kidney, liver and small intestine was assessed using Laser-Speckle-Contrast-Imaging providing mean microcirculatory blood flow (mFlux). Cardiac output was measured using pulmonary artery thermodilution and arterial pressure was assessed using invasive micro-tip catheter. Primary outcome measures were hepatic, renal and ileal microcirculatory blood flow 4,5 h after I/R. Secondary outcome measures were macrohemodynamic parameters and laboratory findings. Statistical analysis was performed using mixed-model analysis for comparison between groups. Values are given as mean (95% confidence interval), two-tailed p-values of < 0.05 were considered significant.

Results: Results: Colloids significantly improved ileal mean microcirculatory blood flow (mFlux) compared to crystalloids 4,5 h after I/R (767.52 (676.47 - 858.57) vs. 594.24 (494.28 - 694.20), $p = 0.007$). This was accompanied by a significant increase in cardiac output (l/min) (3.01 (2.71 - 3.30) vs. 2.94 (2.09 - 2.70), $p = 0.008$). There were no significant differences of renal or hepatic microcirculatory blood flow between colloid and crystalloid group (mFlux kidney: 509.20 (426.87 - 591.52) vs. 443.41 (361.54 - 525.28), $p = 0.304$; mFlux liver: 606.06 (509.44 - 702.67) vs. 546.70 (442.10 - 651.30), $p = 0.353$, respectively). Comparison of colloids vs. crystalloids revealed no significant difference in regard to arterial pressure. While there was no significant difference in regard to urine output (ml) between groups (1144.82 (852.35 - 1537.63) vs. 780.55 (579.98 - 1049.43), $p = 0.071$), animals receiving colloids had significant lower values of serum creatinine (mg/dl) compared to crystalloids (2.43 (2.33 - 2.53) vs. 2.63 (2.52 - 2.74), $p = 0.021$).

Conclusion: Conclusions: Advantageous effects on intestinal microcirculation could be found for colloids. This was accompanied by improvements of macrocirculation. In conclusion, use of colloids may improve outcome in I/R injury.

Role of Transcranial Doppler Ultrasound as a predictor of outcome in severe traumatic brain injury and its correlation with Glasgow Coma Scale and Full Outline Of Unresponsiveness Score

T. Elsefi¹; AM. Fayed²; T. Zaytoun²

¹Intensive Care, Health Education England, London, United Kingdom;

²Intensive care, Alexandria Faculty of Medicine, Alexandria, Egypt

Correspondence: T. Elsefi

Intensive Care Medicine Experimental 2020, **8(2)**:000195

Introduction: Traumatic brain injury (TBI) is a major public health problem. It is considered to be one of the leading causes of death and disability worldwide (1). After TBI cerebral blood flow (CBF) becomes extremely low approaching ischemic threshold (2). Concurrently, cerebral blood flow velocities become strongly correlated to CBF itself post injury. Identification of such haemodynamic disturbances can be used to predict outcome in severe TBI when measured immediately post-injury using Transcranial Doppler (TCD). TCD permits non invasive assessment of different CBF velocities as well as pulsatility index (PI) (3). Abnormal measurement of such indices is believed to correlate to poor outcome.

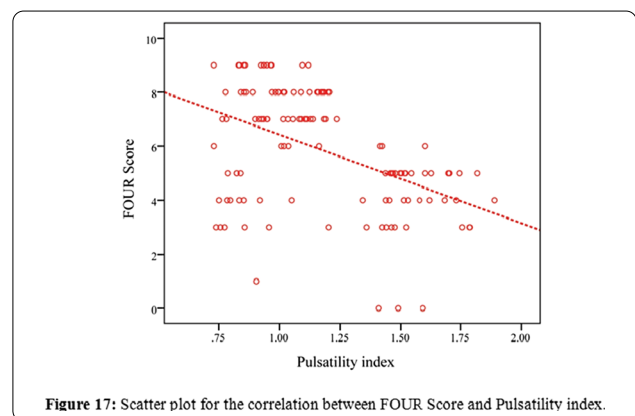

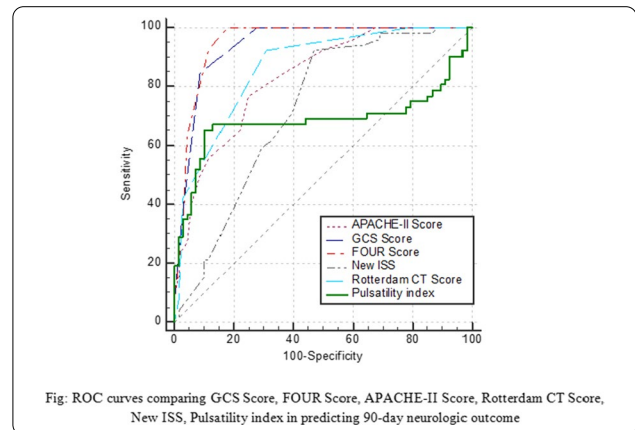

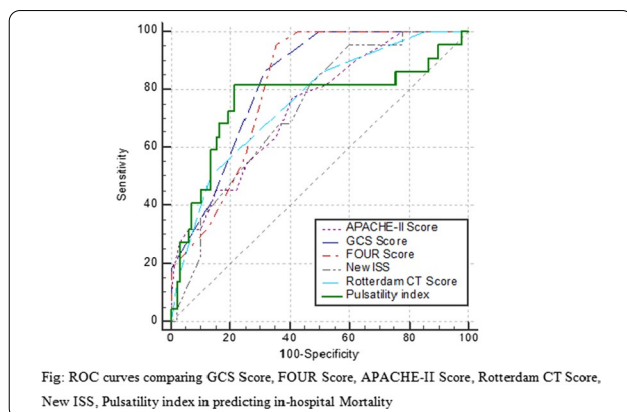

Objectives: The aim of the work was to assess the predictive value of early TCD in patients with severe TBI in terms of mortality and GOSE at 3 months, and also to correlate different TCD measurements with GCS score and FOUR score

Methods: 120 patients with severe TBI, according to GCS, underwent TCD within 24 hours post trauma. Middle cerebral artery (MCA) velocities and pulsatility index, as well as other clinical and neuroimaging data, were recorded and accordingly patients were divided into 3 groups: patients with normal TCD measurements, patients

with hypoperfusion and patients with vasospasm. Hypoperfusion was defined by meeting two out of three criteria: mean flow velocity (MFV) of MCA < 35 cm/sec, End diastolic velocity (EDV) of MCA < 20 cm/sec, PI > 1.4. Vasospasm was defined as MFV > 120 cm/sec. (4-9) Outcome was evaluated using the Glasgow Outcome Scale extended (GOSE) at 3 months, as well as in-hospital mortality. TCD measurements were also correlated to GCS and FOUR score.

Pearson's correlation coefficients(r) were calculated to test the relation between TCD and other clinical variables. A binary logistic regression analyses were performed then variables that showed statistically significant result under univariate analysis were entered into a multivariate analysis to identify independent predictors of outcome measures. Discrimination of the logistic models was assessed by calculating the area under (ROC) curve (10). All hypotheses were constructed two-tailed and $p \leq 0.05$ was considered significant

Results: There was a significant correlation between PI and GOSE 3 months. There was also significant correlation between PI and mortality. However, different MCA velocities did not show any correlation with GOSE or mortality. Strong negative correlation was recognized between PI and GCS and FOUR score.

Conclusion: Pulsatility index, when measured within the first 24 hours post-trauma, is considered a good predictor of mortality as well as functional outcome at 3months. Abnormal pulsatility index values correlate with the severity of injury (in terms of GCS and FOUR score).

Intensive Care Medicine Experimental 2020, **8(2)**:000267

Introduction: Creating ICU "surge capacity" was essential for the COVID-19 pandemic but takes time to implement and is costly and disruptive. A short-range forecast was needed in early March 2020 to guide costly and ethically challenging decisions in England and justify immediate service re-configuration from early epidemiological data. The design, construction, testing, implementation, documentation, dissemination and peer-review of a computer model is typically a lengthy process. Here we describe the use of agile techniques to develop a COVID-19 strain forecasting tool from ultra-early epidemiological data building a working tool within a week.

Objectives: To develop and implement a region-specific, short-range ICU demand forecast based on case data from the commissioning regions in England using agile software development techniques to build a public-facing tool as rapidly as possible.

Methods: We modelled the likely increases in regional ICU bed demand over a 14-day horizon under an exponential assumption. Daily COVID-19 cases were extrapolated from cumulative data using log-linear regression. Stochastic models for ICU admissions and length of stay linked expected case incidence to excess bed occupancy. Mortality and admission rates were regionally standardised. In parallel we developed a web application to publish updated predictions daily (Figure 1), with an explanatory manuscript on medRxiv [1] and code on GitHub [2].

Figure 1: Our interactive web application. The user can alter the model assumptions as well as interact with the plots for more detail.

Results: We delivered an interactive web application along with explanatory notes and versioned code in 7 days. Community feedback allowed for a crowd-sourced review of manuscript and code. Users could explore the effect of changing various modelling assumptions interactively at a regional level. Over the preparatory time period, cumulative case data was well fitted by an exponential model. We predicted that ICU bed occupancy would grow very quickly with London and the Midlands predicted to be particularly hard-hit, motivating an immediate effort to create as much capacity as possible.

Conclusion: Uncertainties in modelling early epidemiological data notwithstanding, we accurately predicted that surge capacity would be required from the end of March. We were able to leverage software development techniques to deliver a working application on a time-scale which was still actionable in the preparatory phase for COVID-19 in England. Our approach demonstrates that data-driven approaches to emergency healthcare planning can be highly agile.

Intensive Care Medicine Experimental 2020, **8(2)**:000278

Introduction: During the early post-operative period, children with congenital heart disease can suffer from inadequate cerebral perfusion. Cerebral perfusion can be monitored non-invasively with the near-infrared spectroscopy (NIRS) cerebral oximeter, which measures local cerebral tissue oxygen saturation (SctO₂) of the frontal lobe. In this study, we hypothesized that reduced SctO₂ and increased dose of desaturation during the early post-operative period, may independently increase the probability of reduced total IQ score 2-years after Pediatric Intensive Care Unit (PICU) admission.

Methods: The study included 90 children (median age (IQR) 4 (1 to 13) months) admitted to the PICU of the University Hospitals Leuven (Belgium) and included in the PEPaNIC trial [1] and NIRS study [2], after cardiac surgery for congenital heart disease. Inadequate post-operative cerebral perfusion was characterized by computing the mean SctO₂ and dose of desaturation (defined as SctO₂ < 65%) from the first 12 hours of SctO₂ monitoring after surgery. Trained psychologists assessed the total IQ at 2-years follow-up with the Wechsler Intelligence Quotient (IQ) tests. The independent association between mean SctO₂, dose of desaturation and total IQ at 2-years follow-up was evaluated with a Bayesian linear regression model adjusted for age, syndrome, nutrition strategy (early vs late parenteral nutrition), cyanotic cardiopathy and severity of illness with Pediatric Index of Mortality 3 score.

Results: The results of the Bayesian model, summarized in Table 1, showed that reduced mean SctO₂ and increased dose of SctO₂ desaturation below 65% during the first 12 hours of SctO₂ monitoring, independently increased the probability of a lower total IQ at 2-years follow-up. For example, a difference of 10% in the mean SctO₂ during the first 12 hours of SctO₂ monitoring would result in a loss of 0.3 to 4 IQ points, with an 80% probability. Similarly, a dose of desaturation of 300 %-minutes (resulting, for instance, from a SctO₂ of 60% for 1 hour) would correspond to a loss of 0.3 to 4.8 IQ points with an 80% probability.

	β estimates [80% credible interval]	Probability that the β estimates for the population is strictly negative(-)/positive(+)
Desaturation dose	-0.009 [-0.016 to -0.001]	90% (-)
Mean SctO₂	0.227 [0.037 to 0.412]	90% (+)

Table 1. The β estimates [80% credible interval] resulting from the Bayesian model are reported in the table together with the cumulative probability that the β estimate of the population are strictly negative (-) or positive (+). The 80% credible interval indicates the range to which the β estimates of the population belong with 80% probability. Results were obtained by using a noninformative prior.

Conclusion: Reduced mean SctO₂ and increased dose of SctO₂ below 65% during the first 12 hours of SctO₂ monitoring, independently increase the probability of having a lower total IQ, 2 years after PICU admission. However, given the observational design of the study, no causal relations are proven. Whether intervention to improve SctO₂ would result in better outcomes is still unclear.

Introduction: Mechanical chest compressions (CC) are frequently used during prolonged cardiopulmonary resuscitation in out-of-hospital cardiac arrest (OHCA), particularly in patients who do not have early return of spontaneous circulation (ROSC) on the scene. However, little is known about the characteristics of this population of OHCA patients, particularly after hospital admission.

Objectives: We hypothesized that the decision to initiate mechanical CC could identify, by itself, a specific subgroup of cardiac arrest patients with more severe clinical features.

Methods: This is a post hoc analysis of a sub-group of patients in the TTH48 trial (NCT01689077) who received or did not receive mechanical CC during resuscitation manoeuvres. Baseline characteristics included age, sex, height, weight, neurological function before cardiac arrest and a prespecified set of comorbidities. Relevant data regarding OHCA were recorded following Utstein templates. Resuscitation outcomes included survival at ICU discharge, survival at hospital discharge, 6-months survival and 6-months survival with good neurological outcome (CPC 1-2). Continuous variables are presented as median [IQR] and nominal variables as percentage. Mann-Whitney u-test and chi-square test were used for groups comparison, accordingly. A $p < 0.05$ was considered as statistically significant.

Results: Out of 351 patients included in the analysis, 25.6% received mechanical CC. No major difference in baseline characteristics were observed between groups. Compared to patients that receive manual CC, mechanical CC patients showed significant prolonged time to ROSC (26 [20;38] vs 20 [15;25] min, $p < 0.01$). Accordingly, a greater percentage of patient received resuscitation drug (adrenaline: 80 vs 57%, $p < 0.01$; amiodarone: 53 vs 37%, $p < 0.01$) and percutaneous coronary intervention (93 vs 79%, $p < 0.01$). After hospital admission, mechanical CC patients demonstrate worse hemodynamic and acid-base status compared to patient who received manual CC; more specifically they showed lower systolic arterial pressure (104 [91;120] vs 114 [97;132] mmHg, $p < 0.01$), higher blood lactate (5.8 [2.8;10] vs 3.2 [1.8;5.1] mmol/l, $p < 0.01$) and lower base excess (-8.4 [-12.3;-4.0] vs -5.8 [-8.5;-3.5] mmol/l, $p < 0.01$). During hospital stay, mechanical CC patients develop adverse events more frequently, such as generalized seizure/myoclonus (27 vs 15%, $p = 0.03$), various grade of hypotension ($p = 0.02$) and arrhythmias ($p < 0.01$), greater incidence of acute renal failure needing continuous renal replacement therapy (17 vs 5%, $p < 0.01$). Finally, mechanical CC patients showed increased mortality (ICU: 22 vs 14%, $p = 0.07$; in-hospital: 34 vs 20%, $p = 0.01$; 6-months 27 vs 15%, $p < 0.01$) and worse neurological outcome after 6 months (CPC 1-2 52 vs 71%, $p < 0.01$).

Conclusion: This descriptive analysis identified an association between patient receiving mechanical CC and worse clinical status after hospital admission. Moreover, mechanical CC patients demonstrated poorer 6-months survival and neurological outcome. The longer duration of no-flow/low-flow time observed in the mechanical CC group could partially explain the increase severity in post-cardiac arrest syndrome observed in this subgroup of patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 000285

Introduction: Families of critically ill persons face uncertainty and psychological distress during and after their close other's stay on an intensive care unit (ICU). Poor communication, insufficient shared-decision making, and inadequate emotional support negatively affect their ICU

experience and mental health. To increase quality of care and reduce adverse outcomes, guidelines recommend proactive family engagement and support. We thus implemented an advanced practice nurse-led family support intervention in a 12-bed surgical-transplant ICU in Switzerland.

Objectives: To examine the impact of the intervention on family members' satisfaction with ICU care, sense of well-being, and post-ICU psychological distress.

Methods: We used a mixed methods approach with a quasi-experimental before and after design and an embedded qualitative study. Participants were family members of patients treated in ICU before and after introduction of the intervention, which consisted of relational family engagement, therapeutic family conversations, and facilitation of communication between the family and the ICU team. Data were collected post-ICU with the Family Satisfaction in ICU-24 Survey, Hospital Anxiety Depression Scale, Impact of Event Scale-Revised-6 and semi-structured interviews. Outcome variables of the matched groups were analysed with linear mixed-effects models, and qualitative data using inductive content analysis.

Results: 139 family members in the control and 75 in the intervention group (51% response rate) returned a questionnaire, and 19 participated in an interview. Families in the intervention group showed a trend for increased overall satisfaction (difference of 5.544, 95% CI: -0.11 to 11.20), a statistically significant increase in satisfaction with decision-making (7.258, 95% CI: 0.89 to 13.63), and a non-significant increase in satisfaction with care (4.178, 95% CI: -1.53 to 9.89). Psychological distress was higher in the intervention group, with more pronounced for depression (difference of 1.706, 95% CI: 0.16 to 3.25), which may be explained by considerably longer ICU stays and higher proportion of deaths in the intervention group. Qualitative findings indicated that the intervention was beneficial for family well-being, as families reported to feel acknowledged, cared for, well informed, and supported as an individual and a family living through critical illness. Families experienced the intervention as essential to ICU care. They appreciated to have a person to turn to who was easily accessible, knowledgeable, and part of the ICU team.

Conclusion: Our study suggests that family members appreciate a specific family nursing role that offers supportive interventions and facilitates interaction and communication with the ICU team, and experience it as beneficial for their well-being. It increased their satisfaction with ICU care, but was unable to demonstrate a beneficial impact on psychological distress.

Photoacoustic mapping of tissue hypoxia after myocardial infarction in mice

H. DAVID¹; A. Ughetto¹; P. Gaudard¹; N. Paiyabhroma²; S. Richard²; P. Colson³; P. Sicard²

¹Phymedexp inserm u1046; department of anesthesiology and intensive care, CHU Arnaud de Villeneuve, Montpellier, France; ²Cardiovascular research, PhyMedExp, Montpellier University, INSERM, CNRS, IPAM, Montpellier, France; ³Department of anesthesiology and intensive care, CHU Arnaud de Villeneuve, Montpellier, France

Correspondence: H. DAVID

Intensive Care Medicine Experimental 2020, **8(2)**: 000293

Introduction: Early alterations of microvascular blood flow after myocardial infarction (MI) may participate in the development of multiple organ failure.

Objectives: The aim of this study was to assess the contribution of photoacoustic imaging, a hybrid technology based on laser and ultrasound energy coupling, to detect early oxygen saturation (sO₂) impairment in peripheral organs (kidney, liver) after MI in mice.

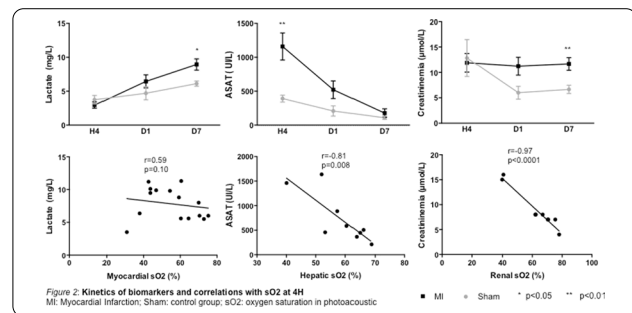

Methods: An experimental preclinical study was carried out on two groups of six week BALB/c mice: Sham (n = 22) versus MI (n = 40). MI

was obtained by permanent ligation of the left anterior descending artery within 7 days of follow-up. High resolution ultrasound was used to assess left ventricular (LV) function (ejection fraction (EF), Cardiac Output (CO) and longitudinal strain). Photoacoustic imaging (VevoL-AZR, VivalSonic[®]) was used to measure kinetics of the heart, kidney and liversO₂ after MI. Plasma biomarkers (ASAT, ALAT, creatinine, lactate) were assessed.

Results: LV function was altered 4 h post-MI (LVEF: Sham 61.7% n = 16, MI 25.7% n = 32, p < 0.0001; longitudinal strain: Sham -19.6% n = 13, MI -7.1% n = 31, p < 0.0001; CO: Sham 11.6 mL/min n = 13, MI 7.4 mL/min n = 24, p = 0.003). These alterations persisted after 7 days. A strong correlation was observed at 4h and on day 1 between LV sO₂ and longitudinal anterior myocardial strain (r = -0.46, p < 0.0001, n = 81). Photoacoustic mapping showed a significant early decrease in sO₂ level in both renal and hepatic tissues at 4h and 1 day post-MI but this was normalized after 7 days (Figure 1).

The kinetics of the biomarkers ASAT, ALAT and creatinine were correlated to a tissue alteration of sO₂ at 4h. There was no correlation between alteration of sO₂ and lactate (Figure 2).

Conclusion: Post-MI heart failure generates moderate hypoxia of the peripheral organs in mice. Photoacoustic imaging enables early detection of sO₂ multi-organ desaturation. The mapping of sO₂ organs in real time seems to be an accurate marker to identify microcirculation alteration. This emerging imaging technology could be used to improve and evaluate early microvascular therapeutics.

Intensive Care Medicine Experimental 2020, **8(2)**: 000303

Introduction: The incidence of AKI in surgical patients varies according to the type and severity of surgery, with reported rates of 19%

after cardiac surgery and approximately 12-13% after general and thoracic surgery. In a large epidemiological study of patients undergoing major noncardiac surgery in intensive care units (ICUs) in Brazil, 30% of patients had postoperative complications, and AKI was the postoperative complication with the second-highest occurrence rate. Postoperative complications are common in high-risk patients after major surgery.

Therefore, our hypothesis is that perioperative AKI is common and is associated with a worse prognosis. Thus, evaluating the incidence and characteristics of patients with previously normal kidney function who underwent major noncardiac surgery and developed postoperative AKI, in addition to determining whether perioperative volemic adjustments correlate with AKI, is relevant for adequately improving the therapeutic management of these patients.

Objectives: The main objective of this study was to evaluate the incidence, impact on outcomes and main risk factors for developing AKI in patients with previously normal kidney function who underwent noncardiac surgery and developed AKI after admission to the ICU. Because of the importance of fluid balance in surgical patients, we also evaluated the association between this variable and the development of AKI.

Methods: A multicenter, prospective cohort study with patients admitted to intensive care units (ICUs) after noncardiac surgery was conducted to assess whether they developed AKI. A total of 29 ICUs participated and provided data on 25,500 surgeries, of which 904 involved high-risk surgical patients who were included in the study. On the 28th day after surgery, the number of survivors and length of stay in the ICU and hospital were analyzed.

Results: The occurrence of AKI in the postoperative period was 15.8%, and the mortality rate of postoperative AKI patients at 28days was 27.6%, which represented 5.2% of the overall mortality of the study population. AKI was strongly associated with 28-day mortality (OR = 2.91; 95% CI 1.51-5.62; P = 0.001), and the assessment of ICU, hospital and 28-day postoperative survival identified significant differences between patients with and without postoperative AKI (log-rank test, P < 0.0001). Independent factors for the risk of developing AKI were preoperative anemia (OR = 7.01; 95% CI 1.69- 29.07), elective surgery (OR = 0.45; 95% CI 0.21 - 0.97), SAPS 3 (OR = 1.04; 95% CI 1.02-1.06), postoperative vasopressor use (OR = 2.47; 95% CI 1.34-4.55), postoperative infection (OR = 8.82; 95% CI 2.43-32.05) and need for reoperation (OR = 7.15; 95% CI 2.58-19.79). Additionally, regarding fluid adjustment during the perioperative period, patients with higher fluid balance values presented an increased risk of developing AKI (OR = 1.001; 95% CI, 1.000-1.002). It was noted that starting on the second day after surgery, the higher the fluid balance is, the more likely AKI is to develop.

Variable (daily median)	Univariate		Multivariate		OR (95% CI)
	All patients	No AKI	AKI	P-value	
Total volume (mL)	1900 (1253-2502)	1820 (1250-2500)	2000 (1500-2927)	0.007	1.000 (0.998-1.001)
Fluid balance (mL)	800 (183-1500)	786 (126-1459)	840 (300-1506)	0.04	1.001(1.001-1.002)
0.9% saline solution (mL)	1044(720-2000)	1000 (642-1750)	1500 (1000-2527)	0.000	0.999 (0.999-1.001)
Lactated Ringer's solution (mL)	1500(1000-2500)	1500 (1000-2500)	1500(1000-2500)	0.337	1.000 (0.999-1.001)
Plasma-Lyte (mL)	1500 (1000-2164)	1500 (1000-2500)	1150 (500-2000)	0.121	0.999 (0.998-1.001)
Hydroxyethylamide 130/0.4 (mL)	500 (500-1000)	500 (500-1000)	1000 (750-1000)	0.137	-----

OR: odds ratio; 95% CI: 95% confidence interval. Values are expressed as the median (interquartile range); adjusted OR in the multivariate analysis.

Conclusion: AKI is a major complication in high-risk surgical patients and is associated with risk of death. Patients with anemia prior to surgery who underwent elective surgery, had a higher SAPS 3, needed a vasopressor during the postoperative period or had postoperative infection or needed reoperation were more likely to develop AKI, as were those with an elevated perioperative fluid balance.

Intensive Care Medicine Experimental 2020, **8(2)**: 000312

Introduction: Overproduction of nitric oxide (NO) plays an important role in sepsis-induced hypotension (1). However, a phase III study of L-NMMA, a non-selective NO synthase (NOS) inhibitor, was terminated early due to increased mortality (2). A new class of NOS inhibitor acts via inhibition of dimethylarginine dimethylaminohydro-lase-1 (DDAH1). This increases levels of asymmetric dimethylarginine (ADMA), an endogenous methyl-arginine, which blocks NOS activity (3). Using a septic, hypotensive rat model, we hypothesized that indirect NOS inhibition would improve haemodynamics without detrimental effects on cardiac output that is associated with non-selective NOS inhibition.

Methods: Anaesthetized male Wistar rats underwent right jugular venous cannulation for fluid/drug administration. Sepsis was induced by intraperitoneal faecal slurry (T = 0 h). Animals were recovered and fluid (1:1 mix of 5% glucose and Ringer's lactate [RL]) was infused at 10 ml/kg/h from 2 h. At 6 h, animals were re-anaesthetized with cannulation of the carotid artery for BP monitoring and a tracheostomy to secure the airway. A further bolus of RL bolus (20 ml/kg) was given. At 8 h, baseline measurements of BP, cardiac output (by echocardiography) and blood gas analysis were taken. Animals were then randomized to receive either direct (L-NMMA) or indirect (L-257) NOS inhibition, or to act as controls (equivalent volumes of RL). Treated animals received a bolus over 5 mins followed by infusion over 2 hours (to T = 10 h). Blood pressure was measured before and after the bolus. All other variables were measured hourly.

Results: Data shown as mean (± SE). B = bolus over 5 minutes. Inf = infusion. Index of systemic vascular resistance (SVR) calculated as Blood pressure (BP)/Cardiac output (CO). Statistics: 2-way RM-ANOVA

and post-hoc Tukey's test. * $p < 0.05$ or ** $p < 0.01$ between controls and drug-treated animals ($n = 6/\text{group}$). L-257 bolus = 30 mg/kg, inf = 3.75 mg/kg/h. L-NMMA bolus = 3 mg/kg, inf = 2.5 mg/kg/h.

Conclusion: In hypotensive, septic rats, both direct and indirect NOS inhibition significantly increased blood pressure. While we did not use doses of either drug that significantly impacted on cardiac output, indirect NOS inhibition showed a lesser increase in SVR, in keeping with a more desirable safety profile.

Brain tissue oxygenation guided therapy in poor grade aneurysmatic subarachnoid haemorrhage patients

E. Bogossian¹; D. Diaferia¹; N. Ndieugnou¹; M. Menozzi¹; JL. Vincent¹; J. Creteur¹; FS. Taccone¹

¹Soins intensif, ULB Erasme, Brussels, Belgium

Correspondence: E. Bogossian

Intensive Care Medicine Experimental 2020, **8(2)**: 000342

Introduction: Aneurysmatic subarachnoid hemorrhage (aSAH) is responsible for severe disabilities and death (1). Tissue hypoxia can occur after SAH, even with normal levels of intracranial pressure (ICP) (2). As such, brain tissue oxygen (PbtO₂) monitoring has become widely used. Low PbtO₂ has been associated with delayed cerebral ischemia and worse neurologic outcome(3-4).

Objectives: The aim of this study was to assess the impact of PbtO₂-guided therapy on patients' outcome.

Methods: Single center retrospective cohort study from January 2014 until March 2019 including adult patient admitted to the ICU with poor grade aSAH, that required invasive neurologic monitoring (ICP + /- PbtO₂ catheter) within the first 48 hours of admission. Patients monitored with combined PbtO₂ + ICP monitoring were compared with patients monitored with ICP alone. We considered as "PbtO₂-guided therapy", a bundle of interventions aiming to increase PbtO₂ > 20 mmHg. Primary outcome was the presence of PbtO₂ < 20mmHg and burden of tissue hypoxia.

Results: Of a total of 259 patients admitted to the ICU due to aSAH during the study period, 152 patients were included in the study: 96 were monitored with ICP alone and 56 with PbtO₂ + ICP; of those 47(83.9) had at least one episode of PbtO₂ < 20 mmHg and 22 (39.3%) received a PbtO₂-guided therapy. PbtO₂-guided therapy was associated with a reduction of the risk of unfavorable outcome (OR 0.03 CI 95% 0.002-0.46, $p = 0.01$) and mortality (OR 0.01 CI 95% 0.16, $p = 0.002$). PbtO₂ < 20 mmHg was an independent predictor of poor neurological outcome(OR 24.48 CI 95% 1.49-470.77).

Conclusion: In this cohort of poor grade SAH, PbtO₂-guided therapy was an independent predictor of neurological recovery.

Intensive Care Medicine Experimental 2020, **8(2)**: 000353

Introduction: Acute respiratory distress syndrome (ARDS) is a life threatening complication of various illnesses such as sepsis, pneumonia or cardiogenic shock. As there is no causal therapy available which is why the mortality of > 40% could not be significantly reduced within the last decades.

Activated polymorphonuclear (PMN) cells with systemic uncontrolled inflammatory responses and consecutive respiratory failure play a central role in the pathogenesis of acute respiratory distress syndrome. The leukocyte integrin $\alpha\text{M}\beta\text{2}$, which can be blocked activation specific by novel binding protein (Designed Ankyrin Repeat protein, DARPIn) is a promising novel therapeutic target for acute respiratory distress syndrome as it has recently been shown to inhibit leukocyte transmigration and systemic inflammation.

Methods: ARDS was induced by intratracheal LPS instillation (5 $\mu\text{g/g}$). Recombinant anti- $\alpha\text{M}\beta\text{2}$ DARPins were produced in *E. coli*. Purity of DARPins was assessed by SDS-Page electrophoresis. Activation specific binding of DARPins to activated mouse PMN cells was measured *ex vivo* using standard flow cytometry protocols. Disease severity was quantified through protein concentration and FACS analysis of bronchial lavage fluid. Animals were analysed on day 4 (acute phase) and on day 10 (chronic phase). Mice were weighed every day and eliminated if the weight loss was 20 % over baseline. Animals were treated daily i.p. with anti- $\alpha\text{M}\beta\text{2}$ DARPIn ($n = 11$), PBS ($n = 16$) or control DARPIn ($n = 18$). Statistical analysis was performed with one-way ANOVA and post hoc analysis, the survival curves were compared with Mantel-Cox test.

Results: 4 day survival was 100% (healthy controls) vs. 90% (anti- $\alpha\text{M}\beta\text{2}$ DARPIn) vs. 38% (control DARPIn) vs. 56% (PBS) ($p = 0.0035$). Absolute neutrophil number per ml BAL fluid was 10 ± 4.8 (healthy controls) vs. $6,026 \pm 4,103$ (anti- $\alpha\text{M}\beta\text{2}$ DARPIn) vs. $19,582 \pm 19,132$ (control DARPIn) vs. $38,621 \pm 37,791$ (PBS) ($p = 0.0031$). The protein concentration in the BAL fluid was lower in the anti- $\alpha\text{M}\beta\text{2}$ DARPIn group indicating a strong therapeutic effect in mice with acute respiratory distress syndrome (healthy controls vs. anti- $\alpha\text{M}\beta\text{2}$ DARPIn vs. control DARPIn vs. PBS: 0.16 ± 0.08 mg/ml vs. 0.3 ± 0.12 mg/ml vs. 0.62 ± 0.38 mg/ml vs. 0.77 ± 0.34 mg/dl, $p = 0.0002$).

Conclusion: Treating murine acute respiratory distress syndrome with the novel activation specific anti- $\alpha\text{M}\beta\text{2}$ DARPIn significantly reduces disease severity and improves survival.

The effect of short-chain fatty acid butyrate on metabolism, immune and mitochondrial function in sepsis

V. Peters¹; N. Arulkumaran¹; C. Gaupp¹; T. Roger²; M. Shankar-Hari³; M. Singer¹

¹Bloomsbury institute of intensive care medicine, University College London, London, United Kingdom; ²Infectious diseases service, Lausanne University Hospital, Lausanne, Switzerland; ³Peter gorer department of immunobiology, Kings College London, London, United Kingdom

Correspondence: V. Peters

Intensive Care Medicine Experimental 2020, **8(2)**: 000358

Introduction: Sepsis induces changes in cellular metabolic, immune and mitochondrial function [1]. The effect of nutrition on these changes is mostly overlooked. In addition to a caloric source, short-chain fatty acid butyrate may affect metabolism, immune and mitochondrial function.

Objectives: To examine the therapeutic effect of butyrate in *in vitro* and *in vivo* models of sepsis.

Methods: Human peripheral blood mononuclear cells (PBMCs) from six healthy donors were incubated overnight with LPS (100 ng/ml), heat-killed *Staphylococcus aureus* or *Escherichia coli* O18 (PBMC:bacterium ratio 5:1) in the presence or absence of butyrate (1.8 mM). Supernatants were collected and IL-6, IL-10 and TNF concentrations quantified by ELISA. Mitochondrial respiration was assessed using high-resolution respirometry.

A rat model of faecal peritonitis was developed to study the impact of butyrate *in vivo*. Rats were cannulated and received intraperitoneal injection of faecal slurry. Rats were housed in metabolic cages and, alongside fluid resuscitation, received intravenous butyrate infusion (0.6 g/kg/h) commencing 6 hours following sepsis induction. 24 hours following sepsis induction, splenocytes were isolated and oxygen consumption measured. Splenocyte membrane potential, reactive oxygen species (ROS), and intracellular cytokines (IL-10 and TNF) were assessed using flow cytometry. Non-parametric one-way ANOVA tests with Dunn's correction were used for statistical analyses.

Results: Butyrate significantly reduced IL-6, IL-10 and TNF secretion by PBMCs. Maximal respiration and spare-respiratory capacity were non-significantly increased. *In vivo* butyrate infusion stimulated fatty acid metabolism as shown by a fall in the respiratory exchange ratio. *Ex vivo* splenocytes from septic rats showed significantly increased TNF production, which was not affected by butyrate infusion. Butyrate infusion decreased mitochondrial respiration, increased mitochondrial ROS production and membrane potential.

Conclusion: Butyrate had anti-inflammatory and mitochondrial respiration stimulating effects *in vitro*. However, *in vivo* butyrate infusion caused mitochondrial stress in immune cells and did not impact immune function. Hence, beneficial effects of butyrate on immune cells *in vitro* could not be reproduced *in vivo*.

Intensive Care Medicine Experimental 2020, **8(2)**: 000389

Introduction: Acute respiratory distress syndrome (ARDS) is a heterogeneous syndrome with high mortality. Personalized medicine approaches targeting patients based on their molecular phenotypes of ARDS might help to identify effective pharmacotherapies. The inflammasome-caspase-1 pathway contributes to the development of ARDS via IL-1 β and IL-18 production. Recent studies indicate that tetracycline (TET) can be used to treat inflammatory diseases mediated by IL-1 β and IL-18 while the molecular mechanism by which TET inhibits inflammasome-caspase-1 signaling remains unknown.

Objectives: To identify patients with ARDS characterized by IL-1 β and IL-18 production and investigate the ability of TET to inhibit inflammasome-caspase-1 signaling.

Methods: IL-1 β and IL-18 levels were quantified in bronchoalveolar lavage fluid (BALF) from 62 patients from two ARDS referral centers with direct (viral, COVID-19 and bacterial pneumonia) or indirect (non-pulmonary) ARDS via multiplex assay. TET's effect on lung injury and inflammation were assessed in a LPS-induced mouse model of

direct ARDS. Murine lung injury was determined by measurement of i) albumin concentration by ELISA, ii) neutrophil population by FACS (both in BALF) and iii) histopathology. Concentration of IL-1 β , IL-6, IL-18 and TNF α was measured by multiplex assay in BALF. The effect of TET on caspase-1 was tested in BMDMs after stimulation with LPS plus nigericin. Concentration of IL-1 β and TNF α was determined by ELISA and cleavage of caspase-1 via western blot. Alveolar leucocytes were obtained from BALF of patients with direct ARDS and the effect of TET on IL-1 β and IL-18 production was measured *ex vivo*.

Results: BALF levels of IL-1 β and IL-18 are significantly higher in patients with direct than those with indirect ARDS ($p < 0.05$). In experimental direct ARDS, TET treated mice showed significantly reduced weight loss and mortality (43% vs. 7%; $p < 0.001$) compared to PBS treated animals. TET treatment diminished lung injury in terms of lower albumin (325 ± 35 vs $144 \pm 16 \mu\text{g/ml}$; $p < 0.01$) concentration and number of neutrophils. Histopathology showed reduced lung injury in TET-treated animals. TET decreased exclusively the concentration of IL-1 β (152 ± 16 vs 86 ± 8 pg/ml; $p < 0.01$) and IL-18 (92 ± 7 vs 31 ± 2 pg/ml; $p < 0.05$) in BALF. Immunoblot showed that TET reduced cleavage of the p45 caspase-1 precursor into its p20 subunit. TET inhibited in a dose-dependent manner production of both IL-1 β and IL-18 from alveolar leucocytes obtained from patients with direct ARDS including COVID-19 by up to 85% ($p < 0.01$).

Conclusion: This work demonstrates that i) patients with direct ARDS have significantly higher IL-1 β and IL-18 levels in their lungs than individuals with indirect ARDS, ii) TET may be effective in the treatment of direct ARDS including COVID-19 and iii) TET blocks the inflammasome-caspase-1 pathway by selective inhibition of caspase-1.

Intensive Care Medicine Experimental 2020, **8(2)**: 000391

Introduction: Traumatic brain injury (TBI) has been increasing with greater incidence. It remains a leading cause of death (1). Cerebral pressure autoregulation impairment is a well-known pathology after TBI that worsens the prognosis and outcome (2). Transcranial Doppler (TCD) can be used to assess Transient Hyperaemic response ratio (THRR) after carotid compression which is a well demonstrated valid index for cerebral autoregulation (3,4). A relative increase in mean flow velocity (MFV) of middle cerebral artery (MCA) above the baseline following the release of carotid compression denotes preserved autoregulation and sequentially predicts good outcome, whereas absence of such response indicates altered autoregulation with poor outcome (5).

Objectives: The aim of the work was to assess cerebral autoregulation and its relation to outcome in patients with moderate and severe TBI using TCD. The primary end point is the Glasgow outcome score (GOS) (6) as a measure of outcome to assess THRR after carotid compression as an indicator of cerebral pressure autoregulation and as a predictor of GOS as well as a being prognostic tool. Other measures of TCD as MFV of MCA and Pulsatility Index (PI) were also used as predictors of GOS and correlated with THRR. The length of stay as well as mortality were recorded and correlated to THRR.

Methods: 120 patients with moderate or severe TBI according to Glasgow Coma Score (GCS) (7) underwent daily TCD, after initial hemodynamic and respiratory stabilization, for 5 days post trauma. All patients were managed according to guidelines for the management of head injury of the American Association of Neurologic Surgeons (8). A compression time of 10 seconds and a compression ratio of 40% or more, allow maximum expression of the hyperaemic response. Also carotid compression is accepted only when flow velocity is stable with no further decrease during the whole period of compression otherwise the compression will be terminated and repeated 60 seconds later (3).

The Patients were divided into those with normal TCD measurements and those with poor cerebral circulation (MFV < 40, PI > 1.2). GOS scores are dichotomized into favorable or unfavorable outcomes. Patients in the upper two GOS outcomes groups (good recovery or moderate disability) are considered favorable outcome, and patients in other groups (severe disability, vegetative state or death) are considered unfavorable outcomes.

Pearson's correlation coefficients were calculated to test the relation between TCD and other clinical variables. Discrimination of the logistic models was assessed by calculating the area under (ROC) curve (9). P value < 0.05 was considered significant.

Results: There was a significant correlation between THRR and GOS (patients with THRR ≥ 1 had favorable outcome). There was also significant correlation between THRR and mortality. Also significant correlation between THRR and MFV as well as PI was found. THRR ≥ 1 showed sensitivity of 83.3%, specificity of 72.9%, positive predictive value (PPV) of 82.2% and negative predictive value (NPV) of 74.5% in predicting patients with favorable outcome.

Conclusion: THRR provides a clinically useful index of cerebral autoregulation. THRR after carotid compression is a good predictor of GOS as well as being a prognostic tool in patients with moderate and severe TBI.

Intensive Care Medicine Experimental 2020, **8(2)**: 000400

Introduction: The widespread use of antibiotics poses a significant threat to human health because of the risk of antimicrobial resistance. While piperacillin/tazobactam (TZP) is commonly used in the empirical treatment of severe infections in the ICU, and the drug can be detected in plasma up to several days after discontinuation, it is unclear how long piperacillin is detectable in the feces of patients. Given the potential impact of antibiotics on the microbiome, we sought to investigate fecal concentrations of piperacillin in critically ill patients using a newly developed sensitive method.

Objectives: The objective of this study was to describe concentrations of TZP in the feces of critically ill patients during intravenous therapy and after treatment discontinuation.

Methods: Critical ill patients without chronic or acute abdominal disease and receiving intravenous piperacillin/tazobactam were included. The regimen consisted of a loading dose of 4,5 g of TZP injected over 30 minutes, followed by continuous infusion according to kidney function (standard therapy 16 g/24 h). Fresh stool specimens were collected after a minimum of 24 hours of antibiotic treatment, with up to ten samples per patient during therapy. Within ten minutes after collecting a stool sample, a serum sample was obtained for drug concentration analysis. Stool specimens collected up to one week after treatment discontinuation were analyzed, with a maximum of five samples. Concentrations of piperacillin and tazobactam were measured by a validated and sensitive ultra-high-performance liquid chromatography - high resolution mass spectrometric (UHPLC-HRMS) method, with a lower limit of quantitation (LLOQ) of 1 µg/g and 0,5 µg/g lyophilized (lyo) feces and 1,5 mg/L and 0,5 mg/L plasma for piperacillin and tazobactam, respectively.

Results: Ten critically ill patients with a median age of 70,5 years (interquartile range (IQR) 50-74) were included. The specimens of one patient were excluded in further analyses due to pre-analytic errors. During therapy, piperacillin concentrations ranged from 18,65 to 289,18 mg/L in plasma and 1,63 - 23000,70 µg/g in lyo feces. Tazobactam concentrations ranged from 2,57 - 38,17 mg/L in plasma and could be detected and quantified in stool specimens of six patients (67%) during therapy (range 0,08-576,18 µg/g). After discontinuation of therapy respectively 5 (56%) and 3 (33%) patients were found to have measurable fecal concentrations of piperacillin (range 5,48 - 3477,27 µg/g) and tazobactam (range 2,27 - 531,44 µg/g) for 1 to 2 days. In 2 patients, piperacillin and tazobactam were detectable in stool specimens for at least 4 to 6 days after discontinuation. Both of them suffered from acute kidney injury (AKI stage I and II).

Conclusion: Both piperacillin and tazobactam are measurable in stool during therapy; after discontinuation of therapy, piperacillin can be detected in feces for up to 6 days. This may have important consequences for disturbances of the microbiome and the impact of antibiotic therapy.

Intensive Care Medicine Experimental 2020, **8(2)**:000402

Introduction: Septic shock is one of the deadliest diseases worldwide, with a mortality rate of 30-50%. Antibiotic delay and higher microbial loads are known to increase morbi-mortality in sepsis.

Loading doses achieve faster appropriate concentrations in plasma, allowing for a better bacterial kill. Bacterial kill and patient outcomes may be further improved by synergistic combination therapy, which is best established for betalactams and aminoglycosides. However, how the sequence of antibiotic administration impacts this synergy is unknown. While *in vitro* work suggests that giving the betalactam first improves bacterial clearance, the effect of antibiotic sequence has not been studied *in vivo*.

Objectives: Determine whether the sequence of antibiotic administration impacts bacterial kill and cytokine production in a monomicrobial rat model of septic shock.

Methods: Our monomicrobial peritonitis rat model of septic shock requires the surgical implant of a gelatin capsule with a fibrinogen clot, alpha cellulose and a known bacterial inoculum (2×10^6 cfu E. coli Bort) in the peritoneum of the rat. This capsule slowly dissolves and generates a progressive peritoneal infection that evolves into septic shock in 12 hours.

After septic shock is established, we fluid resuscitate the rats, connect them to mechanical ventilation, and start vasopressors if needed to achieve a MAP goal of 70 mmHg. We experiment with the order of antibiotics (cefotaxime [cef] and gentamicin [gent]) and compare them to monotherapy, untreated controls and sham controls, for a total of 7 treatment arms and 6 rats per arm. We used two doses of antibiotics: normal (cef 60 mg/kg, gent 10 mg/kg) and high (cef 120 mg/kg, gent 20 mg/kg).

We measure bacterial blood counts, cytokine profile, lactate and renal function at different time points. Following the ethics guidelines of University of Manitoba, we euthanize the rat and measure organ bacterial counts after homogenization.

Results: Rats treated with cefotaxime monotherapy had slow initial bacterial clearance compared to those treated with gentamicin alone. This improved with the higher dose of cefotaxime. Over time the rats treated with gentamicin showed bacterial regrowth (postantibiotic effect); this was delayed in the group treated with a higher gentamicin dose. All combination arms showed a rapid initial bacterial kill and maintained bacterial clearance over time, exhibiting the strengths of gentamicin and cefotaxime, respectively. No significant differences were observed between combination arms.

All treatment arms showed similar bacterial clearance from peritoneal fluid and organs.

Conclusion: Combination therapy showed synergistic effects with a rapid and maintained bacterial clearance from the blood. Altering the antimicrobial sequence had no significant impact in our *in vivo* model of septic shock. Higher doses of antibiotics showed faster initial bacterial kill with cefotaxime monotherapy, and delayed the postantibiotic effect of gentamicin monotherapy.

Too old for the ICU? Long term prognosis of critically ill patients

A. Oliveira¹; D. Rei¹; M. Vera-Cruz²; J. Gonçalves-Pereira¹

¹Intensive Care Unit, Hospital de Vila Franca de Xira, Estrada Carlos Lima Costa, Vila Franca de Xira, Portugal, Vila Franca de Xira, Portugal

Correspondence: A. Oliveira

Intensive Care Medicine Experimental 2020, **8(2)**: 000423

Introduction: In the recent years a rapid increase in the age of patients admitted to the Intensive Care Units (ICU) was noted. Fewer limitations are now imposed on performing invasive treatments or surgery in old or even frail patients, especially when complemented by optimal supportive intensive care. However, little is known about the long term follow up of these patients.

Objectives: To evaluate the age stratified long-term all-cause mortality, after admission to the ICU. Secondly, to compare a one-year mortality rate of this cohort of critically ill patients after hospital discharge, with that of a standard population with the same age distribution.

Methods: Retrospective cohort study of all patients admitted to a multipurpose ICU between 2015-2019. Patients < 18 years or admitted for < 24 h were excluded. Only the first ICU admission was considered. Patients were followed until hospital discharge or death, whatever occurred first. One-year all-cause mortality was assessed for all patients. Standard Mortality Ratio (SMR) were determined at hospital discharge and at a 1-year follow-up.

We split the sample in 4 groups according to patients age at admission to the ICU: 18-50 (Adult); 51-65 (Senior); 66-80 (Old); > 80 (Very-old). Survival curves were plotted for all 4 groups according to the time of ICU admission. The ratio between observed and expected mortality was calculated, for patients discharged alive from the hospital and according to age-adjusted tables for the general Portuguese population.

Age Groups (years)	N	Predicted Mort. (SAPSII)	I.H Mortality	SMR	Follow-up	
					1 st year	
					Real	SMR
Adult [18-50]	372	60 (16.1%)	40 (9.2%)	0.67	56 (15%)	0.93
Senior [51-65]	507	125 (24.6%)	84 (16.5%)	0.67	136 (26.8%)	1.09
Old [66-80]	892	321 (36%)	199 (22.3%)	0.62	322 (36.1%)	1.00
Very-old >80	413	181 (43.8%)	110 (26.6%)	0.61	200 (48.4%)	1.10
Total	2184	687 (31.5%)	433 (19.8%)	0.63	714 (32.7%)	1.04

Table 1 -Mortality by Age Group. Predicted and observed in-hospital mortality (with SAPSII), and one-year follow-up SMR-Standard Mortality Ratio

Results: A total of 2184 patients were included. Male gender was predominant (57%); mean age and SAPS II Score were 66 ± 15.8 and 40 ± 18.9 . Mean ICU length of stay was 4.23 ± 4.2 days. ICU and Hospital mortality were 12.1% and 19.8% (SMR 0.63). SAPSII performance was accurate to predict one-year mortality, rather than in-hospital mortality, for all age groups (Table 1).

A Kaplan-Meier survival curve (KM) was computed to assess the differences between long term prognosis for the different age groups (Fig 1) and unveiled a statistically significant difference in the survival probability (log rank test, $p < 0.01$). A sharp drop in survival in the first days was noted, corresponding to the in-hospital mortality. A continuous decay in survival was observed in the Old and Very-old groups that was less evident in the younger population.

Age Groups (years)	N	1 st year		Ratio
		After discharge	Population Estimate	
Adult [18-50]	332	14 (4.2%)	1 (0.3%)	14
Senior [51-65]	423	51 (12.2%)	3 (0.71%)	16.9
Old [66-80]	693	125 (18.4%)	16 (2.3%)	8
Very-old >80	302	89 (29.5%)	32 (10.6%)	2.8
Total	1750	535 (30.6%)	69 (3.9%)	7.8

Table 2 - One-year mortality after discharge and age adjusted control population estimate.

One-year mortality rate after hospital discharge was higher in the older patients. The ratio between the observed and expected mortality (for an age adjusted control population) was significantly high for all age groups (Table 2).

Conclusion: The one-year mortality risk of critically ill patients of all age groups is very high, even after hospital discharge, largely above of the general population. SAPSII showed good accuracy to predict one-year mortality in this cohort. Although a continuous decline in survival is noted in the older patients, more than 50% of the Very-old patients are alive 1 year after ICU admission.

Intensive Care Medicine Experimental 2020, **8(2)**: 000426

Introduction: Hypotension is known to be the most consistent manifestation of decompensated shock leading to major organ failure, and even brief hypotension is associated with increased morbidity and mortality. Several early warning scores have been introduced to identify patients at risk for decompensation and trigger escalation of care, but most of current scoring systems are unable to provide reliable, continuous feedback to clinicians who need to make time-sensitive decisions for rapidly fluctuating conditions in critically-ill patients.

Objectives: Using common vital sign data, we aim to develop a machine learning model to predict the initial hypotension event among intensive care unit (ICU) patients, and design an alert system for bedside implementation.

Methods: From the Medical Information Mart for Intensive Care III (MIMIC-3) dataset, minute-by-minute vital signs were extracted. An initial hypotension event was defined as at least 5 measurements within a 10-minute period of systolic blood pressure ≤ 90 mmHg and mean arterial pressure ≤ 60 mmHg. The performance of various supervised machine learning models was measured with area under the receiver operating characteristic curve (AUROC) and area under the precision recall curve (AUPRC). A random forest (RF) classifier was selected, trained with 10-fold cross validation method, then applied to an *a priori* separated out-of-sample validation cohort. Risk score trajectory was built from vital signs features on overlapping windows. For an alert system, hypotension alerts were generated using a two-step (stacked) approach. First, positive alerts were identified with risk score thresholds, then a second RF model was used to reduce false alerts, followed by imposing a lock-out time for alerts to decrease alarm fatigue.

Results: We identified 1532 subjects (1946 ICU stays) as the case group (experienced a hypotension event), and 1707 subjects (2585 ICU stays) as the control group. The RF model showed AUROC of 0.93, 0.91, and 0.88 at 15, 30, and 60 minutes before hypotension, AUPRC of 0.77, and a low calibration score (Brier score 0.09). Mean risk score trajectories revealed a clear separation with 80% of cases predicted at 15 minutes before hypotension, and more than 60% at one hour before the hypotension. For the alert system, the stacked machine learning model with lock-out of 15 minutes produced on average 0.79 alerts/subject/hour for future hypotension, with a positive predictive value (probability of developing hypotension) of 65% and sensitivity of 92.4%.

Conclusion: Most clinically significant hypotension events in the ICU can be predicted from bedside physiologic monitoring at least 1 hour before the initial hypotension episode. Designing a practical alert system with high sensitivity and acceptable positive predictive value for hypotension prediction is feasible, with low rate of alerts.

Intensive Care Medicine Experimental 2020, **8(2)**:000460

Introduction: In mechanically ventilated patients, positive end-expiratory pressure (PEEP) is used to improve gas exchange and respiratory mechanics by preventing alveolar collapse. Recently, it has been demonstrated in rats, that PEEP induces diaphragm remodelling by altering the position and length of the muscle, causing longitudinal atrophy [1]. The effects of PEEP on the human diaphragm during tidal breathing are currently unknown.

Objectives: To study the effects of PEEP on diaphragm movement and configuration during tidal breathing, including velocity of muscle contraction.

Methods: Healthy subjects (n = 17) underwent dynamic magnetic resonance imaging (MRI) in five different planes during tidal breathing under non-invasive ventilation with PEEP. After 30 sec, PEEP was abruptly increased from 2 (baseline) to 5, 10 or 15 cmH₂O (randomized) for 1 minute. The diaphragm dome and zone of apposition (ZOA) were tracked semi-automatically in every MRI frame using a software routine developed in Matlab (see Fig 1). Then, subjects were instrumented with nasogastric catheters to measure diaphragm neuromechanical efficiency (NME) during tidal breathing at different PEEP levels. Parameters were analysed using mixed models.

Results: Diaphragm tracking was successful (Fig 1). Increasing PEEP from 2 to 15 cmH₂O resulted 1) in decreased end-expiratory total diaphragm length (390 (234 - 445) to 351 (295 - 408) mm respectively), mostly due to decreased ZOA length (178 (166 - 190) to 140 (124 - 155) mm respectively), 2) flattening of the diaphragm with an increase of the radius of curvature (R in Fig 1) of 1.4 cm and 1.9 cm for the right and left hemidiaphragm respectively and 3) increased peak contraction velocity (14.2 (13.3 - 15.1) to 15.4 (14.0 - 16.7) mm/s respectively) but unchanged peak relaxation velocity and 4) decreased NME of 48% (37.5 - 56.6%). All mentioned effects were significant (p < 0.03) and reported as estimated mean (95% confidence interval).

Figure 1 : Automatic tracking of diaphragm dome (blue line) and ZOA (orange line) at end-expiratory lung volume in two different imaging planes, namely sagittal right (left and middle image) and coronal mid (right image). All images were acquired in one subject. Left and middle images show diaphragm configuration at respectively 2 cmH₂O and 15 cmH₂O PEEP. The radius of curvature is shown as the white R in the middle image and was computed by fitting a fourth-degree polynomial through the top of the dome. Note the shortening of the ZOA, caudal displacement and flattening of the dome at 15 cmH₂O PEEP.

Conclusion: PEEP affects diaphragm geometry and function during tidal breathing. These findings suggest that conditions to develop longitudinal atrophy in the human diaphragm are present with the application of PEEP.

Introduction: Ventilator associated pneumonia is still a problem in the intensive care unit (ICU). Noble metal coating of endotracheal tubes reduces the adhesion of bacteria and could reduce the incidence of VAP.

Methods: A controlled prospective randomized, double blind, multicenter study was launched in November 2018 in Liège, Belgium enrolling 324 patients from 8 ICUs from 4 sites of two hospital institutions using endotracheal tubes for ventilated patients from Bactiguard. These tubes with subglottic suctioning had, for half of them, a thin coating of noble metals (gold, silver and palladium) firmly attached to their surfaces, preventing bacteria from adhering and forming biofilm. Coated tubes were indistinguishable from control tubes. Coated and control tubes were coded and remained blinded for all the participants. Patients were followed during ventilation and ICU stay up to 28 days. Tracheal colonization, incidence of VAP, and antibiotic consumption were recorded.

Results: The study ended on 5 March 2020 before the Covid-19 pandemic occurrence in Liège. Data are given as a whole because the code is not yet broken. This will be done before the European convention. Among the 324 patients with a median age of 67.5 (IQR 56,5-74,6), there were 179 men (55.4%). Their mean Charlson score was 2 (IQR 1-4) and the mean saps II score, calculated the day of intubation, was 50.5 ± 17.5. The median length of ventilation through both uncoated and coated tubes was 5 days (IQR 3-9) totaling 2202 ventilatory days. No bacteria were found in tracheal sputum from 122 patients during ventilation. Persistence of bacteria already present in tracheal sputum the day of intubation was documented in 38 patients and new bacteria were found in 76 patients. No sampling was done in 88 patients, partially because of too short ventilation (n = 26). During ventilation and 2 days after extubation, there were 55 suspected episodes of VAP. The analysis of these episodes based on the presence of new infiltrate on X-ray exam, fever, leucocytosis, increase of the FiO₂ or PEEP level, quantitative bacteriological result and CRP change, leads to reject 25 suspicions and classifies the 30 other as confirmed (n = 2), probable (n = 12) or possible (n = 16). The overall incidence of VAP was 13.7/1000 ventilatory days or 9.3/100 patients. Antibiotic from any kind was used during 68.7 % of ventilatory days and 61.7% of ICU days. ICU mortality was 41.9 % and hospital mortality was 50.8%.

Conclusion: This is the first report of a randomized double blind study with Bactiguard tubes which will allow to define the number of patients for a confirmatory larger study.

000521**Prognostic biomarkers for length of stay and mortality in patients admitted to critical care: a systematic review**YI. Wan¹; A. Brayne¹; RW. Haines¹; JR. Prowle¹¹William Harvey research institute, Queen Mary University of London, London, United Kingdom**Correspondence:** YI. Wan*Intensive Care Medicine Experimental* 2020, **8(2)**: 000521

Introduction: Large numbers of observational studies have investigated the association of pre-specified laboratory tests within subgroups of critically ill patients. This systematic review aimed to determine evidence from pre-existing literature of associations between routine blood results and outcomes of patients admitted to critical care.

Methods: The study protocol was registered with the International Prospective Register of Systematic Reviews (PROSPERO; ID CRD42019122058). We followed the Preferred Reporting Items for Systematic Reviews and Meta-analyses (PRISMA) guidelines. [1] Searches were carried out using MEDLINE (PubMed) and Excerpta Medica database from inception through 29th January 2019. Outcome measures were 1) critical care or hospital length of stay, 2) mortality during critical care or in hospital or within 90 days of critical care admission. Identified studies were insufficiently homogenous to calculate pooled effect measures and qualitative summary assessments were undertaken. For biomarkers showing consistent effects, we reviewed proposed mechanisms and underlying hypotheses. Quality of evidence and risk of bias was assessed using the Newcastle-Ottawa Scale criteria. [2] We evaluated study methodology including diagnostic test accuracy, statistical approach and covariate selection.

Results: Of 441 records identified in our search, 98 met inclusion eligibility criteria. Studies analysed biomarkers individually or using a composite measure of two related biomarkers. The majority of studies were focused within mixed medical and surgical admissions (n = 62). All studies described retrospective data collection using cohort (n = 84) and case-control (n = 14) designs. A total of 25 unique biomarkers were reported: 17 (one to four records), 5 (five to nine), and 3 (ten or more). RCDW was the biomarker most frequently assessed. Definitions varied in measurement of biomarkers and outcomes. 67.3% of studies measured admission values, 25.7% used repeated measures throughout the admission period. The biomarkers showing most consistent effects were RCDW, platelet count, NLR and albumin. A higher RCDW, a lower platelet count and a higher NLR were associated with both mortality and increased critical care length of stay. A lower level of albumin was associated with mortality. Of studies reporting statistical methods, the majority used logistic regression and Cox proportional hazards analysis. Studies which adjusted for confounders selected covariates using stepwise selection or bivariate screening.

Conclusion: Results from previous studies have limited applicability as methods of analyses tended to be restrictive and open to measured and unmeasured confounders. All identified studies focused on determining statistical significance prior to evaluating underlying pathophysiological mechanisms. Establishing a direct causal pathway among biomarkers and outcomes may be challenging and traditional statistical modelling may fail to adequately control for confounding.

000527**Potential for lung recruitment in patients with SARS-CoV2-associated acute respiratory distress syndrome**M. Combet¹; X. Monnet¹; A. Pavot¹; S. Ayed¹; A. Bertier¹; T. Creutin¹; D. Osman¹; L. Guerin¹; N. Anguel¹; JL. Teboul¹; T. Pham¹¹Médecine Intensive Réanimation, Bicetre Hospital AP-HP, Le Kremlin-Bicêtre, France**Correspondence:** M. Combet*Intensive Care Medicine Experimental* 2020, **8(2)**: 000527

Introduction: Many patients with SARS-CoV2 severe pneumonia received invasive mechanical ventilation and met the Berlin definition for ARDS. However, there is an ongoing debate regarding their respiratory mechanics. Several small studies found conflicting results: some showed a low potential for recruitability at an early stage of mechanical ventilation [1], others demonstrated a significant potential for recruitability, although with large variability between patients[2],[3].

Objectives: We aimed to assess lung recruitability in the first days of invasive mechanical ventilation in patients with SARS-CoV2 induced ARDS.

Methods: Single-center study in a French medical ICU.

We included patients undergoing invasive mechanical ventilation for SARS-CoV2 ARDS. Lung recruitability was assessed using recruitment-to-inflation ratio (R/I) measured within 72 hours after intubation. R/I ratio was obtained with a drop in PEEP over a single breath manoeuvre, as previously described[4]. We also assessed airway opening pressure (AOP) by performing a low-flow inflation[5].

Results: Twenty-three patients were included in this study; 18 (78%) were men with a mean±SD age, body mass index, SAPS II and SOFA of respectively 57 ± 13, 29 ± 6 kg/m², 45 ± 15 and 9 ± 4 at ICU admission. The majority of them (65%, N = 15) had at least one comorbidity, including hypertension (48%, N = 11), diabetes (22%, N = 5) or immunocompromised status (22%, N = 5). R/I ratio was measured 1 [0;2.5] days after intubation and 14 patients (60.9%) were considered to have recruitable lung (R/I ratio 0.76 [0.61;1.01]) with no difference in baseline characteristics as compared to the 9 patients with a R/I < 0.5. Airway opening pressure was measured in eighteen patients and 4 patients (22.2%) had an AOP > 5 cmH₂O (with a median of 6.50 cmH₂O), with no significant difference between recruiters and non-recruiters. Overall survival rate was low (43.5%), 57% in the recruiter group (N = 8) and 22% in the non-recruiter group (N = 2), not reaching statistical difference (p = 0.197).

Table 1. Respiratory parameters within 72 hours of mechanical ventilation.

	All patients, n=23	Non recruiters, n=9	Recruiters, n=14	p value
VT mL/kg predicted body weight	5.95±0.43	6.10±0.35	5.85±0.46	0.149
PEEP	15.0 [12.0;15.0]	15.0 [12.0;15.0]	14.5 [12.0;15.0]	0.972
Respiratory rate	29±4	27±4	29±5	0.275
FiO2	60.0 [50.0;80.0]	60.0 [50.0;60.0]	65.0 [50.0;80.0]	0.974
PaO2/FiO2 ratio	135±39	126±42	141±37	0.431
R/I ratio	0.59 [0.39;0.80]	0.38 [0.29;0.40]	0.76 [0.61;1.01]	<0.001
AOP	4 (22%)	2 (29%)	2 (18%)	1.000

Data are presented as median [interquartile range] or number (percentage)

VT tidal volume, R/I ratio recruitment to inflation ratio, AOP airway opening pressure.

p-values refer to the comparison between recruiters and non-recruiters.

Conclusion: Of the 23 patients with SARS-Cov2-associated acute respiratory distress syndrome included in this study, a majority (61%) were considered as recruitable according to measured R/I ratio and 22% presented an AOP > 5 cmH₂O. Given the large variability of potential for recruitment in our study, R/I ratio and AOP should be assessed to individualize PEEP settings for each patient.

Intensive Care Medicine Experimental 2020, **8(2)**: 000537

Introduction: Measuring Plateau Pressure (Pplat) with an inspiratory hold during Pressure Support Ventilation (PSV) usually gives a value higher than the set pressure. This measurement can be used with two important clinical purposes. 1) The difference between Pplat and Peak Pressure can estimate patient's inspiratory effort (1) 2) Pplat, as in controlled mechanical ventilation (CMV), can be used to compute driving pressure and the respiratory system compliance (CrS) (2). However, an inspiratory hold performed during PSV does not always reveal a reliable Pplat, due to ongoing muscular activity. The parameters defining Pplat as reliable during PSV are not established.

Objectives: To describe the features of a reliable inspiratory hold during PSV. To compare 1) the derived measure of inspiratory effort (Pressure Muscle Index, PMI) with the direct measure of muscular pressure (Pmusc) through esophageal pressure (Peso); 2) Crs measured during PSV and CMV when the two measurements are close enough in time.

Methods: This is an ancillary analysis of pressure and flow curves obtained during a multicentre observational study aimed to describe the incidence of patient ventilator asynchronies in moderate to severe ARDS (BEARDS, NCT03447288). We selected the tracings with an inspiratory hold in PSV and a reliable Peso. We analyzed the features of the readable Pplat and the correlation between 1) Crs measured during CMV and PSV 2) PMI and Pmusc. To be deemed reliable, Pplat had to be flat, flow had to be 0, if inspiratory efforts were detected, Pplat had to be flat before and after the efforts. Univariate analysis was performed through t test for parametric data, Mann Whitney for non-parametric data. Data correlation was verified by Pearson's.

Results: 91 traces from BEARDS study (11centres, 35patients) met the inclusion criteria. 69/91 holds were deemed reliable (76%), 30/35 (86%) patients had at least one readable hold, according to visual inspection. The duration of the flat part of the hold was 1845 msec [1207-2640]. The standard deviation of airway pressure (Paw) during the hold was significantly lower in readable versus non readable holds (1.6 [0.7-2.7] vs 2.1 cmH₂O [1.8-4.7], p < 0.005). The time to reach a plateau was lower in readable versus non readable holds (400 [229-850] vs 1740 ms [905-3150], p < 0.001). Peso swing was significantly lower in readable holds (6.2 ± 4.8 vs 11.4 ± 5.9 cmH₂O, p < 0.005). PMI showed a strong correlation with Pmusc (R = 0.79, p < 0.001, Figure 1). In 21 patients, a measurement of Crs in CMV was available, with a strong correlation with Crs measured during PSV (R = 0.71, p < 0.001, Figure 2).

Conclusion: A readable measurement of Pplat could be obtained in most patients during PSV. Readable holds were characterized by low variability of Paw during the hold and by a short time to reach a stable plateau. When patient respiratory effort is vigorous, a reliable plateau might be more difficult to achieve. Pplat might be used to reliably compute Crs and Pmusc during PSV.

Introduction: Liver biopsy remains the reference standard for diagnosing and quantifying steatosis. Ultrasonography is a widely accessible, cheap, harmless imaging technique for the detection of fatty liver and other relevant chronic liver diseases, but the reported accuracy and reliability have been inconsistent across studies. We aimed to determine whether or not it is a suitable tool to evaluate organ viability in potential liver donors comparing with the gold standard technique.

Objectives: Determine the utility of abdominal ultrasound in organ donors to evaluate the level of hepatic steatosis and other relevant chronic liver diseases as any structural alteration in the organ.

Methods: We studied 226 consecutive donors during three years (January 2017 to December 2019) in an Intensive Care Unit from a tertiary referral hospital.

We correlated ultrasound findings with the results from the intraoperative biopsy, so we could establish the consistency between these two diagnostic tests calculated by an inter-rater agreement statistic (Kappa).

Results: Of 226 donors reviewed, 220 (97.3%) had conducted an abdominal ultrasound and 164 (72.6%) had a liver biopsy. 65% were male donors. The mean age of the donors was 60.6 years-old. 73% of evaluated organs were transplanted. 62.4% of ultrasonography operators were junior resident doctors. Agreement between ultrasonography and biopsy to evaluate hepatic steatosis is described in Table 1. We calculated a Cohen's Kappa coefficient (κ) of 0.19 and a weighted

Kappa coefficient of 0,32. The ultrasonography was also able to detect other relevant, macroscopic findings, like space occupying liver lesions or ischemic lesions.

Table 1.

	MILD STEATOSIS n	MODERATE STEATOSIS n	SEVERE STEATOSIS n
ULTRASONOGRAPHY	13	19	0
BIOPSY	49	12	14
KAPPA	0,02	0,02	<0,01

Conclusion: In our study, hepatic steatosis evaluated by abdominal ultrasound presented very low concordance rate with anatomopathological findings. Abdominal ultrasound results a very helpful tool to evaluate incidental structural injuries, though these could be uncommon findings. The use of newer quantitative ultrasound-based imaging techniques, which also are less operator dependent than traditional ultrasound, could improve the ability of ultrasound to detect and quantify hepatic steatosis and emerge as a solution to our concern.

Introduction: Infective endocarditis (IE) is associated with considerable morbidity and mortality despite advances in diagnostic and therapeutic modalities.

Objectives: We sought to explore the epidemiology of IE in ICU patients with emphasis on severity, causes, management and outcome.

Methods: Preliminary analysis of EPENDICUS study (EPidemiology and outcome of ENDocarditis in ICU patientS: a multi-centre prospective epidemiological study on infectious endocarditis in ICU patients). Patients with a diagnosis of IE and ICU admission were included. Data

were collected between December 2018 and April 2020. Of the collected data, demographics, comorbidities, community or healthcare-onset, severity assessment on ICU admission, complications, surgical approach and ICU outcome were available for preliminary analysis. Continuous data are reported as median and interquartile range and categorical data as percentages.

Results: 73 patients were enrolled from 16 centers; median age 69 (IQR, 59-78), 69% male, 74% had at least one comorbidity, 49% presented valvular disease, 10% had a history of previous endocarditis, 7% were intravenous drug users. Median SAPS and SOFA on ICU admission were 52 (IQR, 45-64) and 9 (IQR, 5.25-11.75), respectively. Sepsis/septic shock and cardiac failure were recorded in 43% and 28% of the patients, respectively. Mechanical ventilation was performed in 67% of the patients. IE was healthcare-associated in 26% cases (63% of them were vascular catheter- or prosthetic device-associated). A native valve was involved in 60% of the cases (aortic in 56%, mitral in 28% of the cases). Embolic complications were observed in 18% of the patients (cerebrovascular in 46% of them). The predominant (52%) pathogens were Staphylococci (*Staphylococcus aureus* in 61% of them), *Enterococcus spp.* in 16%, *Streptococcus spp.* in 10%. Surgery was performed in 56% patients (emergency/urgent in 33% patients). ICU mortality was 29%.

Conclusion: The preliminary descriptive analysis of EPENDICUS showed that IE cases present important severity on ICU admission including sepsis and septic or cardiogenic shock. IE in the ICU setting is associated with comorbidities and underlying valvular disease in the majority of the cases. A considerable number of the cases were healthcare-onset and device-associated while the predominant pathogens were Staphylococci. Surgery was performed in the majority of the patients. Enrollment and further analysis are actually ongoing.

Correspondence: C. Bonetti

Intensive Care Medicine Experimental 2020, **8(2)**: 000600

Introduction: Increased intracranial pressure (ICP) is one of the major clinical complications of acute brain injuries (ABIs) and it is associated with poor outcome. ICP monitoring (ICPm) is considered the standard of care for the management of patients with intracranial hypertension, even if the procedure is not risk-free, and complications may occur. The indications for ICPm are mostly based on traumatic brain injury (TBI), whereas uncertainties remain for ICPm in non-TBI (subarachnoid haemorrhage (SAH) and intracerebral haemorrhage (ICH)).

Objectives: The main objective of the study is to describe the current practice of ICPm using a worldwide sample. Aim is to quantify practice variations in ICPm in TBI and non-TBI patients.

Methods: The SYNAPSE-ICU is an international, prospective, observational, cohort study (NCT03257904) including patients in coma after acute traumatic and non-traumatic brain damage admitted to the ICU. From March 2018 to June 2019, all patients fulfilling the following inclusion criteria were recruited: age > 18 years; ABI due to primary haemorrhagic stroke or TBI; Glasgow Coma Score (GCS) with Eyes score (E) = 1 and Motor score (M) ≤ 5 at ICU admission or within the first 48 hours. Data regarding the practice of ICPm insertion in both TBI and non-TBI patients was collected.

Results: 2504 patients were enrolled in the study (54.3% TBI, 21.7% SAH, 24% ICH), and 1358 (54%) of them received an ICPm during ICU stay (53.6% of TBI, 63.3% of SAH and 47.5% of ICH).

The most common reason for ICPm was clinical indication (n = 948, 70.1%), followed by radiology-anatomy of injury (n = 213, 15.7%),

neuroworsening (n = 152, 11.2%), with no significant differences among primary diagnosis. Considering the type of device, in most TBI patients (n = 144, 72.3%) an intraparenchymal catheter was inserted, whereas in SAH and ICH patients DVE was the most frequently used (in n = 179, 53.8% and n = 151, 54.5% of patients, respectively).

In the majority of patients, the catheter was inserted in operating room (61.9%). Alternatively, the insertion was performed in ICU (26.9%) or in emergency department (5.5%). The procedure was performed by neurosurgeons in more than 90% of cases, rarely by intensivists (2.3%) or other medical specialists (0.7%).

The mean length of ICPm was 8.7 days (standard deviation, SD = 16.9) in TBI, 14.6 days (SD = 10.7) in SAH and 10.4 days in ICH patients (SD = 8.6). During ICU stay, the catheter was changed in 366 patients (14.1%) due to fault or break (25.5%), neurosurgery procedures (22.9%), catheter displacement (19.8%) or accidental removal (15.1%), site infection (4.2%) and other reasons (12.5%) including insertion of another device, clinical worsening and hydrocephalus. The catheter has been changed, on average, after 5 days from the insertion.

Conclusion: A great variability regarding ICPm practice was observed. The results stress the need of evidence-based recommendation regarding ICPm worldwide.

Intensive Care Medicine Experimental 2020, **8(2)**:000603

Introduction: Mechanistic studies of sepsis-induced myopathy are rare because of their complexity, both ethical and practical. Proteomics and metabolomics are high throughput technologies that aim to identify and quantify proteins and metabolites at a large scale. The analysis of protein and pathways that are involved at the cellular level, combined with metabolomic analysis of these pathway intermediates, could unravel innovative therapeutic strategies regarding muscle dysfunction in sepsis.

Objectives: We aimed to investigate the sepsis-induced myopathy mechanisms with integrative and cutting-edge technologies.

Methods: We conducted a prospective study in three French Intensive Care Units. Muscle biopsies (*vastus lateralis* or *rectus abdominis*) were collected from 3 groups of patients: Septic Shock ("SS" group, n = 24), Cardiogenic Shock ("CS" group, n = 25) and Brain Dead ("BD" group, n = 18). The proteins/metabolites were extracted from muscle samples, then analyzed by High-Performance Liquid Chromatography-coupled to tandem Mass Spectrometry. We used enrichment analyses (differential analyses between two groups) to identify the impact of cellular pathways in muscle tissue during septic shock.

Results: Characteristics of the patients are detailed in Table 1. Proteomic and metabolomic analyses allowed the identification of 2426 proteins and 259 metabolites respectively. Despite the fact that biopsies were obtained from different muscle groups, proteomic analysis did not show any difference in the proportion of muscle fiber types. Auto-clustering methods (principal component analysis, hierarchical clustering) clearly differentiated the three groups, meaning that SS patients could be well discriminated using the proteomic and metabolomic datasets. Enrichment analysis was performed on the proteomic dataset (Figure 1). Each data point represents a biological pathway in the SS group, taking into account its significance (adjusted p-value, y-axis, logarithmic scale) and its magnitude of change (x-axis) compared to the CS group (Figure 1A) or the BD group (Figure 1B). The

dotted line represents the threshold for adjusted p-value significance. The most strongly negatively impacted pathways (adjusted p-value < 0.05) were observed in the SS group: Oxidative phosphorylation; Valine, leucine and isoleucine degradation; Citrate cycle; Propanoate metabolism; Butanoate metabolism; and Beta-oxidation. Moreover, numerous key mitochondrial transporters, e.g. proteins that shuttle metabolites across the mitochondrial membranes, were no longer detected in the SS group. In the metabolomic dataset, fatty acid biosynthesis was the only up-regulated pathway in the SS group. Finally, consistent data in the proteomic and metabolomic datasets showed that anti-oxidant mechanisms have been surpassed: we observed increased polyamine and depletion of reduced glutathione (metabolomic dataset), decreased glutaredoxin, mitochondrial thioredoxin and peroxiredoxin enzymes (proteomic dataset).

	SS (n=24)	CS (n=18)	BD (n=25)
Age, yr	62±9	56±11	66±16
Male sex, n (%)	13 (54.2)	15 (83.3)	16 (64.0)
SAPSII score	45±14	42±15	60±14
Antibiotic use, n (%)	24 (100)	6 (33)	5 (20)
Vasopressor use, n (%)	24 (100)	18 (100)	21 (84)
Median delay between admission and biopsy (IQR)	2 (1; 4)	2 (0.5; 6.5)	3 (2; 4)
Median ICU length of stay (IQR)	9 (5; 22)	17 (8; 37)	3 (2; 4)
Median number of days of ventilation (IQR)	3 (2; 5)	4 (2; 15)	3 (2; 4)
Hospital mortality, n (%)	8 (42)	8 (62)	25 (100)

Conclusion: Our data provide a detailed and integrated in depth overview of proteins and metabolic analysis, of the pathogenesis of sepsis-induced myopathy in ICU patients. Interestingly, the mitochondrial response is not as impaired in major inflammatory processes without sepsis (brain death) or processes combining inflammation and hypoperfusion without sepsis (cardiogenic shock) as it is during sepsis.

Intensive Care Medicine Experimental 2020, **8(2)**: 000607

Introduction: Catecholamine hypo-responsiveness is a hallmark of sepsis, but its pathogenesis remains elusive. The adrenergic pathway, from catecholamine binding to the adrenergic receptor (AR) to the final physiological effect is a multistep process. Knowledge about protein expression and localisation of different constituents of the

adrenergic signalling in sepsis, including adrenergic receptors themselves, is sparse.

Objectives: Using our well-characterised 72 h fluid-resuscitated rat model of faecal peritonitis (1), where accurate prognostication can be made as early as 6 h, we analysed expression and membrane localisation of the b2-AR protein in heart tissue at early (6 h) and late (24 h) timepoints.

Methods: Sepsis was induced in male Wistar rats by i.p. injection of faecal slurry under general anaesthesia. The animals were then recovered and i.v. fluid resuscitation was started 2 h after sepsis induction. Sham-operated rats (SH) were treated identically but did not receive the slurry. At 6 h, an echo-measured heart rate cut-off of 460 bpm was used to classify animals into predicted survivors (SR) and non-survivors (NSR). Rats were culled at either 6 h or 24 h with heart tissue collected and snap frozen in liquid nitrogen. To study b2-AR expression, either protein lysates of whole heart tissue or membrane fractions were prepared and analysed by Western Blot with antibodies against b2-AR and PFK or Caveolin 3. Specific signals were analysed in Image Studio Lite 5.2. Results are presented as mean \pm SE and considered significant at $p < 0.05$ (Student's t-test).

Results: The level of expression of b2-AR myocardial protein expression did not change in survivors but declined in non-survivors being significantly lower than survivors at 24 h (Table 1). Representative results of membrane localisation of b2-AR within different membrane fractions are presented in Figure 1. Lipid rafts were observed in only two of the 12 gradient fractions, namely fractions 4 and 5. This was confirmed by cholesterol distribution and caveolin 3 staining. In sham operated animals and in predicted survivors at 24h, b2-AR appeared strongly in fraction 5, associated with the lipid rafts. In predicted non-survivors, b2-AR was not detected in fractions 4 and 5 either at 6h or 24h post-sepsis.

Table 1. Relative expression of b2-AR in heart tissue, normalised to PFK expression (arbitrary units)

	Sham	Predicted survivor	Predicted non-survivor
Early sepsis (6h)	0.95 \pm 0.08	0.91 \pm 0.04	0.79 \pm 0.07
Late sepsis (24h)		1.10 \pm 0.15	0.45 \pm 0.06 *

Figure 1. b2-AR localization within different membrane fractions

Conclusion: More severe sepsis, with corresponding poor prognosis, is accompanied by increasing catecholamine hyporesponsiveness. One cause could be a decrease in adrenergic receptor protein expression. Localisation of the b2-AR within lipid rafts is also a prerequisite for their normal functioning. In predicted non-survivors myocardial b2-AR was dissociated from the lipid rafts. Further studies are necessary to identify strategies that restore adrenergic signalling in sepsis

Premorbid functional status as an outcome predictor in intensive care patients aged over 85 years

L. Pietiläinen¹; M. Bäcklund²; J. Hästbacka³; M. Reinikainen⁴

¹Department of anesthesiology and intensive care, Kuopio University Hospital, Kuopio, Finland; ²Helsinki university and helsinki university central hospital, University of Helsinki, Helsinki, Finland; ³Intensive care units, department of anaesthesiology, intensive care and pain medicine, University of Helsinki and Helsinki University Hospital, Helsinki, Finland; ⁴Department of intensive care, Kuopio University Hospital, Kuopio, Finland

Correspondence: L. Pietiläinen

Intensive Care Medicine Experimental 2020, 8(2): 000684

Introduction: Poor premorbid functional status (PFS) is associated with a twofold increase in odds of death within 12 months after intensive care unit (ICU) admission in patients aged 80 years or over [1].

Objectives: We evaluated the one-year outcome of the oldest old ICU patients (aged 85 years or over) and the impact of PFS on outcome.

Methods: We analysed data from the nationwide Finnish Intensive Care Consortium database. We defined good PFS as independence in activities of daily living (ADL) and ability to climb stairs, whereas patients who were dependent on help in ADL or unable to climb stairs were defined as having poor PFS. Using multivariable logistic regression analysis to adjust for differences in admission types and severity of illness, we evaluated the independent impact of PFS on mortality.

To assess both the premorbid situation and functional outcome one year after ICU admission, we evaluated the patient's ability to live at home and to manage five physical activities (getting out of bed, moving indoors, dressing, climbing stairs and walking 400 metres) and created a functional status score (FSS) based on the number of manageable activities.

Results: During the years 2012-2015, 2224 (3.3%) ICU patients were aged 85 years or older. PFS was available for 1431 (64.3%) patients. PFS was good for 47.7% and poor for 52.3%. Hospital mortality was 19.9% for patients with poor PFS, as compared to 13.3% for those with good PFS, $p = 0.001$. One-year mortality was 47.4% for patients with poor PFS, as compared to 30.1% for those with good PFS, $p < 0.001$.

Poor PFS was associated with increased mortality. For in-hospital death adjusted odds ratio (OR) was 1.35; 95% confidence interval (CI) 0.97-1.88; and for 12 months death OR was 1.85, 95% CI 1.45-2.37.

For one-year survivors ($n = 1244$), data on the type of accommodation and the FSS one year after ICU admission were available for 49.8% and 47.2%, respectively. Of those patients who had lived at home before ICU admission, 84.2% were still living at home one year afterwards. The FSS one year after ICU admission was the same or higher than the premorbid FSS for 69.5% of survivors. The premorbid and one-year FSS are presented in Fig. 1.

Fig. 1 Functional status scores (FSS) one year after ICU admission according to premorbid FSS

Conclusion: PFS is strongly associated with long-term outcome in ICU patients aged 85 years or older. For most survivors, functional recovery was favourable.

In which form is cholesterol present in blood?

A. Kleyman¹; C. Gaupp¹; M. Singer¹

¹University College London, Bloomsbury Institute of Intensive Care Medicine, London, United Kingdom

Correspondence: A. Kleyman

Intensive Care Medicine Experimental 2020, 8(2): 000695

Introduction: Hypocholesterolaemia (HCE) is a well-known hallmark of sepsis, a reliable biomarker of disease severity and a predictor of poor outcome. The pathogenesis of HCE in sepsis however remains elusive. The plasma cholesterol level reflects the balance between synthesis and ingestion versus metabolism. The rapid drop of cholesterol in sepsis onset suggests a leading role for metabolism in the development of HCE.

We postulate that sepsis-induced HCE is part of a big defensive re-organisation of the plasmalemma that includes activation of enzymes participating in membrane remodelling and production of bioactive lipids (phospholipases, sphingomyelinases and b-glucosidases). b-glucosidases transfer a sugar moiety, glucose or galactose, from glucosylceramide to cholesterol. The product is glycosylated cholesterol, which differs from cholesterol in its physical and chemical properties, including resistance to cleavage by cholesterol esterase, but is sensitive to alkaline hydrolysis.

Objectives: To study the chemical forms of cholesterol, we analysed cholesterol levels before and after alkaline hydrolysis in blood obtained from septic rats.

Methods: Seven awake instrumented male Wistar rats (300 ± 50 g) received an i.p. injection of faecal slurry followed by a i.v. fluid resuscitation in 2 h (1). Blood was collected before sepsis initiation (base line), and at 24 h post-sepsis. Total and free cholesterol were measured by an enzymatic method and Amplex red assay with and without cholesterol esterase. Alkaline hydrolysis was performed with 2N NaOH at 45 °C for 2 h and then neutralised by 10N HCl. Statistical analysis was performed using Student's t test

Results: Plasma cholesterol dropped markedly ($p < 0.05$) after 24 hours of sepsis (Table 1). This was more prominent for cholesterol esters (54%) compared to free cholesterol levels (21%). Of note, total cholesterol concentration increased after alkaline hydrolysis and was unchanged after 24 h sepsis.

Table 1. Cholesterol concentration in blood (mg/ml)

	Before hydrolysis		After hydrolysis	
	Total cholesterol	Free cholesterol	Cholesterol Esters	Total cholesterol
Baseline	666±45	163±14	503±31	1081±128 (c)
Sepsis 24h	348±18 (a)	129±6	219±13 (a)	905±90 (c)

a= $p < 0.01$ compared to corresponded baseline c= $p < 0.01$ compared total cholesterol before and after hydrolysis

Conclusion: These results suggest that cholesterol is mainly present in blood as neither free cholesterol nor as a cholesterol ester, but rather as a substance that cannot be directly oxidized by cholesterol oxidase (ChO). However, after alkaline hydrolysis, cholesterol could be liberated from this substance and oxidised by ChO. Total cholesterol levels after hydrolysis at baseline and 24 h post-sepsis were similar, however the levels of any form of cholesterol without hydrolysis differed significantly. This suggests that during sepsis the proportion of cholesterol in this form had increased. Further analytical studies, MS analysis and digestion by b-glucosidases are required to identify this form of cholesterol and elucidate the pathogenesis of sepsis-induced hypocholesterolaemia.

Can physiology based mathematical models better represent arterial blood in the event of transient ventilatory changes?

L. Shastri¹; S. Kjærgaard²; P.S. Thyrestrup²; S.E. Rees¹; L.P. Thomsen¹
¹Respiratory and critical care group (rcare), department of health science and technology, Aalborg University, Aalborg, Denmark; ²Department of anesthesia and intensive care, Aalborg University Hospital North, Aalborg, Denmark

Intensive Care Medicine Experimental 2020, **8(2)**:000700

Introduction: ABGs are performed in acute conditions as the reference method for assessing the acid-base status of blood. Hyperventilation and breath-holding are common ventilatory changes that can

occur around the time of sampling, rapidly altering the 'true' status of the blood.

Objectives: To determine whether mathematically calculated "arterialised" venous values (1) represent a more stable measure of arterial blood during rapid, transient, changes in ventilation.

Methods: 14 patients without cardiovascular and respiratory illnesses scheduled for elective surgery were studied. Following anaesthesia and before the start of the surgery, ventilator settings were altered to achieve + 100% or - 60% change in alveolar ventilation ('over-' or 'under-ventilation'), thus simulating a transient change in ventilation. Blood samples were drawn simultaneously from indwelling arterial and peripheral venous catheters at baseline and every 15s for 1min following the ventilatory change. Venous values were used to calculate arterial equivalents of acid-base status, using the mathematical arterialisation method (1).

Results: Figure 1 illustrates measured arterial and calculated arterialised values, shown as changes from baseline for pH and PCO₂, for over- and underventilation. Arterial blood changes rapidly within the first 15 - 30s with arterialised values remaining relatively constant until 45s.

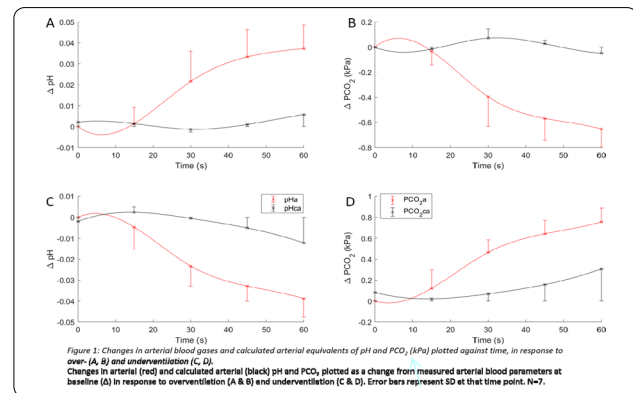

Figure 1: Changes in arterial blood gases and calculated arterial equivalents of pH and PCO₂ (kPa) plotted against time, in response to over- (A, B) and under-ventilation (C, D). Changes in arterial (red) and calculated arterial (black) pH and PCO₂ plotted as a change from measured arterial blood parameters at baseline (A) in response to over-ventilation (A & B) and under-ventilation (C & D). Error bars represent SD at that time point. N=7.

Conclusion: In situations prompting transient changes in ventilation, viz. anxiety in the emergency department or spontaneous breathing with assisted ventilation, mathematically arterialised venous values may provide a more stable value of arterial acid-base status closer to baseline values, prior to the transient change in ventilation.

Intensive Care Medicine Experimental 2020, **8(2)**:000715

Introduction: Acute upper gastrointestinal bleeding (UGIB) is a common condition associated with significant morbidity and mortality. Previous studies in trauma patients have shown low ionized calcium

(Ca⁺⁺) levels to be associated with an increased need for transfusion of blood products and adverse outcome in this population.

Objectives: We hypothesized that admission Ca⁺⁺ levels could predict the need for blood transfusion and surgical/angiographic intervention in patients with UGIB.

Methods: We conducted a population-based retrospective cohort study, using the data of patients admitted to Rambam Medical center, Haifa, Israel due to UGIB for whom Ca⁺⁺ was measured within 24 hours before or after the endoscopy and before administration of blood transfusion. Patients on anticoagulants, with known varices or chronic liver disease were excluded as these cause complex alterations in coagulation and hemostasis. The primary outcome of this study was a composite of transfusion of two or more packed red blood cells (PC) or a need for urgent surgical or angiographic intervention during the index admission. Secondary outcomes included individual components of the composite outcome. Multivariable logistic regression was performed to determine whether Ca⁺⁺ was an independent predictor of these outcomes.

Results: A total of 1345 patients were included in the final analysis. Hypocalcemia (Ca⁺⁺ < 1.16) was recorded in 604 (45%) patients and 88 (7%) had Ca⁺⁺ below 1 mmol/L. The rates of composite adverse outcome were significantly higher in the low Ca⁺⁺ group, 14.4% vs. 5.1%, $p < 0.001$. In addition, multiple transfusions (9.9% vs. 2.3%, $p < 0.001$), need for surgical/angiographic interventions (5.3% vs. 2.8%, $p = 0.03$) and mortality (33.3% vs. 24.7%, $p < 0.001$) were significantly increased in the hypocalcemia group. Multivariable logistic regression analysis identified Ca⁺ < 1.16 as an independent predictor of the primary and secondary adverse outcomes. Ca⁺⁺ performed better than modified Glasgow Blatchford score in predicting the need for multiple PC transfusion (AUC 0.72 95% CI 0.69-0.74 vs. AUC 0.55 95% CI 0.53-0.58, $p = 0.001$). There was a trend towards a better performance of Ca⁺⁺ measurements on the composite adverse outcome (AUC 0.66 95% CI 0.63-0.69 vs. AUC 0.58 95% CI 0.56-0.61, $p = 0.07$).

Conclusion: Low calcium in patients with UGIB is common and associated with an increased requirement of PC transfusion and need for surgical or angiographic interventions. Admission calcium levels may facilitate the rapid identification of high-risk patients with UGIB. As Ca⁺⁺ plays a key role in the coagulation cascade, coagulopathy may occur as Ca⁺⁺ levels drop. In addition, low cardiac contractility and reduced systemic vascular resistance also occur when calcium levels drop. Correcting hypocalcemia may serve as an additional goal in the treatment of the bleeding patient. Further studies should evaluate the impact of correcting hypocalcemia on UGIB patients' outcome. Until definitive studies are available, clinicians should consider monitoring Ca⁺⁺ levels and maintaining it within the normal range in patients with UGIB.

Effects and complications of neostigmine for acute colonic ileus in critical care patients

SN. Jansen¹; J. De Metz¹; RJ. Bosman¹; B. Van Den Bogaard¹

¹Intensive care medicine, OLVG location East, Amsterdam, Netherlands

Correspondence: S.N. Jansen

Intensive Care Medicine Experimental 2020, **8(2)**: 000724

Introduction: Neostigmine is used to treat critical illness related colonic ileus in the intensive care unit (ICU). Data on the effectiveness and possible complications of intravenous administration of neostigmine in critically ill patients are scarce. Specifically data concerning patients with recent intestinal anastomosis are lacking.

Objectives: The primary objective of this study was to assess the effectiveness of neostigmine treatment on passing stool. The secondary objective was to assess the rate of hemodynamic and abdominal complications of neostigmine treatment in critically ill patients.

Methods: In this single-centre retrospective cohort study, all consecutive patients treated with neostigmine on the ICU of the OLVG hospital (Amsterdam, the Netherlands) between 2007 and 2019 were included. The primary outcome was the effectiveness of neostigmine treatment defined as the percentage of patients with ≥ 100 ml stool, 6 and 24 hours after the start of neostigmine. The secondary outcome was the rate of complications, such as bradycardia and abdominal complications. Bradycardia was defined as heart rate < 50/min and/or the use of atropine after administration of neostigmine. Abdominal complications such as bowel perforation and anastomotic leakage were assessed by automatic database extraction and consequently manually reviewing all relevant patient files. We studied the incidence of abdominal complications between patients with- and without a recent (within 10 days) intestinal anastomosis.

Results: Between 2007 and 2019 a total of 1008 patients were treated with neostigmine. 71% of these patients were male, mean age was 66 years (SD 13), mean SOFA score 10 (SD 3,8), mean APACHE IV 0,4 (SD 0,3). In 414 patients (41%) ≥ 100 ml stool was passed after 6 hours, and in 784 patients (79%) after 24 hours. Bradycardia was seen in 58 patients (6%) and atropine was administered to 15 patients (1.5%). A total of 148 patients (15%) had abdominal surgery within 10 days prior to neostigmine treatment. Forty-nine (5%) of them had an intestinal anastomosis. Twelve of these 49 patients (24,5%) developed an abdominal complication requiring surgery during their treatment on the ICU. In eleven patients an anastomotic leakage was found, and one patient experienced a spontaneous perforation of an diverticula. In 1.65% of patients (13 out of 784) without recent abdominal surgery a spontaneous perforation or bowel ischemia requiring a surgical intervention was observed after neostigmine treatment. In the patients who underwent recent abdominal surgery without an intestinal anastomosis, 7% developed an abdominal complication.

Conclusion: Neostigmine seems to be an effective treatment to resolve acute colonic ileus in critically ill patients. Bradycardia requiring atropine was observed rarely. However, in 24.5% of patients with recent abdominal surgery with an intestinal anastomosis treated with neostigmine anastomotic leakage or diverticular perforation was observed.

External validation of a Gaussian Process model for the prediction of elevated intracranial pressure on the Center-TBI datasetG. Carra¹; F. Güiza¹; B. Depreitere²; G. Meyfroidt¹¹Department and laboratory of intensive care medicine, KU Leuven, Leuven, Belgium; ²Department of neurosurgery, KU Leuven, Leuven, Belgium**Correspondence:** G. Carra*Intensive Care Medicine Experimental* 2020, **8(2)**: 000725

Introduction: Intracranial pressure (ICP) is continuously monitored in patients with severe Traumatic Brain Injury (TBI). Güiza et al. [1] developed a prediction model able to predict elevated ICP (defined as ICP > 30 mmHg for more than 10 minutes) with useful forewarning. The model, which was developed on the Brain-IT database [2], presented good calibration (Cox calibration slope 1.02, calibration-in-the-large = -0.02) and good discrimination (AUC = 0.87).

It is good practice to periodically validate the performance of a prediction model on new and preferably external databases. First, it is important to assess whether the performance of the model have deteriorated as a result of the changes in the clinical practice that followed the new Brain Trauma Foundation guidelines for TBI of 2007 and 2016. Second, external validation allows to assess the model generalizability capacities. In this study, we validated the prediction model developed by Güiza et al. [1] on the Collaborative European NeuroTrauma Effectiveness Research in Traumatic Brain Injury (CENTER-TBI) dataset [3]. This validation follows a previous external validation performed on data prior to 2013 [4].

Methods: The external validation included 257 patients with continuous ICP and mean arterial blood pressure signals. Patients were prospectively recruited between January 2015 and December 2017 as part of the Center-TBI dataset. In accordance with the original publication [1], the performance of the model was quantified in terms of Area Under the ROC Curve (AUC) and calibration. Discrimination curve analysis was additionally performed to quantify the clinical utility of the model.

Results: On the external validation dataset, the model was still able to predict future episodes of elevated intracranial pressure with good calibration (Cox calibration slope 1.22, calibration-in-the-large = -0.04, see panel A) of Fig.1) and discrimination (AUC = 0.93). The discrimination curve showed clinical usefulness for almost all risk thresholds (respectively from 4% to 96%), as shown in panel B) of Fig. 1.

Conclusion: These results demonstrate the robustness of the prediction model for elevated ICP developed by Güiza et al. [1]. The model shows good calibration and good discrimination even when evaluated on an external multi-center dataset collected 10 years later than the original development cohort. Future intervention studies are required to assess the impact of this model on patient outcome when used in clinical practice.

Introduction: Microvascular thrombosis has recently been diagnosed in patients with COVID-19, and it has been proposed to mediate the pathogenesis of organ injury in this disease. While widespread pulmonary microvascular thrombosis was demonstrated, reports about the compromise of extrapulmonary microvessels are controversial.

Objectives: To evaluate the characteristics of sublingual microcirculation and skin perfusion in patients with acute respiratory distress syndrome (ARDS) secondary to COVID-19.

Methods: We prospectively included 27 patients with diagnosis of ARDS secondary to COVID-19 (positive PCR testing of nasopharyngeal or tracheal samples), from 4 intensive care units in Argentina. All patients were intubated and mechanically ventilated, received infusions of midazolam, fentanyl and atracurium, and anticoagulant prophylaxis from their hospital admission. Blood pressure, heart rate and norepinephrine infusion remained unchanged for 3-h before the measurements. Sublingual microcirculation was assessed by means of hand-held videomicroscopy and software-assisted analysis (1). The respective institutional review board approved this study and waived patient informed consent.

We present continuous variables as median [IQR] or mean (SD), and categorical variables as numbers (%).

Results: PaO₂/FiO₂ was 122 ± 43, and APACHE II and SOFA score were 12 [9-17] and 6 [3-8]. Norepinephrine (0.03 [0.01-0.17] µg/kg/min) was required in 12 patients (44%). D-dimer was elevated (1.30 [0.58-2.93] µg/mL. Median plasma lactate was normal (1.8 [1.6-2.5] mmol/L). Capillary refill time was prolonged (3.5 [3.0-5.0] s).

Compared to reported normal values (1), total and perfused vascular density and heterogeneity flow index were high, and the proportion of perfused vessels, microvascular flow index, and red blood cell velocity were reduced (Table 1). The proportion of perfused vessels was inversely correlated with total vascular density (Pearson $r = -0.41$, $P = 0.03$).

Sublingual microcirculatory variables	
Total vascular density, mm/mm ² (normal values=16.7±1.6)	21.9±3.9
Perfused vascular density, mm/mm ² (normal values=16.7±1.6)	21.0±3.5
Proportion of perfused vessels (normal values=1.00±0.00)	0.96±0.03
Microvascular flow index (normal values=2.97±0.03)	2.79±0.10
Red blood cell velocity, μm/s (normal values=1331±190)	1124±161
Heterogeneity flow index (normal values=0.04±0.03)	0.91±0.24

Conclusion: Although most patients were hemodynamically stable, they had alterations in sublingual microvascular flow and capillary refill time. Microcirculatory abnormalities consisted in an increased number of unperfused vessels. Although these changes seem minor, compared to those described in septic shock, they represent a several time increase from normal values. In addition, heterogeneity was severely augmented and flow velocity was reduced. These abnormalities might contribute to the development of multiple organ failure. The most striking result was the increase in vascular densities, a finding that might be related to enhanced angiogenesis or hypoxia-induced capillary recruitment. The association of microthrombosis and increased angiogenesis has been found in COVID-19 and in other conditions.

In summary, patients with severe COVID-19 pneumonia showed subtle but consistent alterations in sublingual microcirculation and skin perfusion.

Intensive Care Medicine Experimental 2020, **8(2)**: 000755

Introduction: Patient-ventilator asynchronies occur when there is a mismatch between the ventilator's setting and patient's breathing pattern, and could trigger major consequences. Asynchronies are difficult to characterize when supported only by visual assessment carried out by inexperienced personnel, since different types may develop in

a short time period or may even overlap with each other. Therefore, it would be extremely useful to have access to a method for assessing irregularity and complexity which could detect Complex Patient-Ventilator interactions (CP-VI), including not only asynchronies of any kind but also changes in the respiratory rate, in an automated, non-invasive and personalized fashion.

Sample Entropy (SE) is a non-linear method which measures complexity and regularity. Lower SE value indicates more self-similarity in a time series of data. SE has proved to be an effective tool for investigating different types of time series data derived from various biological conditions in the human body. We hypothesized that analyzing transient complexity of CP-VI may provide clinically relevant information about asynchronies and changes in respiratory rate during invasive mechanical ventilation.

Objectives: Develop and validate a non-invasive method based on SE measurement using the entire airway pressure (Paw) and airway flow (Flow) waveforms to detect CP-VI, defined as the occurrence of asynchronies and changes in the respiratory rate.

Methods: SE of airway flow (SE-Flow) and airway pressure (SE-Paw) waveforms from 92 15-minute-long segments obtained from 27 critically ill, mechanically-ventilated patients were used to develop and validate an automated algorithm for detecting CP-VI, defined as a > 50% change in the respiratory rate, and/or > 30% asynchronous breaths of any type (ineffective expiratory efforts, double cycling, premature cycling, prolonged cycling, or reverse triggering) over a 3-minute period.

The algorithm's performance was compared versus CP-VI scored visually by three experts, and measured through Fleiss's Kappa interrater agreement. A repeated holdout cross-validation procedure using the Matthews correlation coefficient (MCC) as a measure of effectiveness was used for optimization of different combinations of SE settings (embedding dimension, m , and tolerance value, r), derived SE features (mean, [SE-Flowmean and SE-Pawmean] and maximum values, [SE-Flowmax and SE-Pawmax]), and the thresholds of change (Th) from patient's own baseline SE value, applying different values of Th (15%, 20%, 25%, 30%, 35%, 40%, 45%, 50%). We hypothesized that SE values would be higher in periods with CP-VI than in periods with regular patient-ventilator interactions

Results: Fleiss' kappa for inter-rater agreement was 0.90 (0.87-0.93), indicating almost perfect agreement. SE was highly sensitive to changes in the irregularity of the respiratory pattern occurring during ventilation. The most accurate results for the automated detection of CP-VI were obtained using the maximum values of SE-Flow ($m = 2$, $r = 0.2$, $Th = 25%$, [SE-Flowmax25]) and SE-Paw ($m = 4$, $r = 0.2$, $Th = 30%$, [SE-Pawmax30]) which report MCCs of 0.85 (0.78-0.86) and 0.78 (0.78-0.85), and accuracies of 0.93 (0.89-0.93) and 0.89 (0.89-0.93), respectively. Once we had determined the settings that best detected CP-VI, we evaluated the performance of the algorithm in the 15 repetitions of the cross-validation procedure. Both SE-Flowmax25 and SE-Pawmax30 yielded their highest MCC values in 13 of the 15 repetitions.

Conclusion: Our non-invasive method based on SE measurement of Paw and Flow is able to detect with high accuracy CP-VI, defined as the occurrence of clusters of asynchronies and changes in the respiratory rate, with high accuracy. Clinical relevance and usefulness of identifying Complex Patient-Ventilator Interactions in different clinical scenarios deserves to be explored.

The mechanical power before and after initiation of VV-ECMO; the importance of correct calculations

V. Baartmans¹; J. Goedegebuur¹; A. Schoe¹

¹Intensive Care, Leiden University Medical Center (LUMC), Leiden, Netherlands

Correspondence: V. Baartmans

Intensive Care Medicine Experimental 2020, **8(2)**: 000775

Introduction: Ventilator induced lung injury (VILI) is associated with the amount of energy the ventilator transfers to the patient, which is called the mechanical power (MP) [1]. In a previous study, Schmidt et al. demonstrated that veno-venous extra corporal membrane oxygenation (VV-ECMO) can reduce the amount of energy transferred to the lungs to maintain adequate oxygenation and ventilation [2]. However, they used a formula developed for volume controlled ventilation (VCV) [1], whereas 40% of the population was ventilated with a pressure controlled mode (PCV) before start of VV-ECMO. This percentage was even a greater after the start of ECMO.

It is of utmost importance to use the right methods to calculate the MP. Using the formula for VCV on patients ventilated with PCV will lead to a systemic bias in which the MP will be underestimated.

Objectives: To describe the change of MP before and after initiation of ECMO using the correct calculations and to demonstrate the systemic bias when using the wrong calculations.

Methods: We performed a retrospective cohort study in all patients admitted to the adult ICU of the LUMC on VV-ECMO for respiratory indications between 2011 and 2020. We calculated the mean MP during 6 hours pre ECMO and 6 hours after initiation of ECMO with a pause of ca. 2 hours after placing the patient on ECMO. Mechanical power was calculated with the formula $MP-PCV = 0.098 * RR * Vt * [PEEP + \Delta P_{insp} * (1 - e^{-(T_{insp}/(R * C))}]$ as described by van der Meijden et al. [3], which is suitable for PCV. We also calculated the MP in all patients using the formula described by Gattinoni et al. [1] $MP-VCV = 0.098 * RR * Vt * [P_{peak} - 0.5 * \Delta P_{insp}]$ which is suitable for VCV and used by Schmidt et al. on all patients.

All patients were ventilated with an Evita -XL (Dräger, Lubeck, Germany) or Hamilton 6 ventilator (Hamilton Medical, Bonaduz, Switzerland). Statistics were done with SPSS 25 (Armonk, NY: IBM Corp).

Results: See Table 1. for the population characteristics. The mechanical power before ECMO was 34.5 J/min (sd 13.4), after start of ECMO the mean MP was 6.8 J/min (sd 4.0). When calculated with the VCV method the MP was 27.2 J/min (sd 11.1) before and 5.3 J/min (sd 3.0) after ECMO. Ventilator settings and gas exchange parameters are shown in table 2. The mean difference of the MP before ECMO between the two calculations was 7.3 J/min and after ECMO 1.5 J/min.

Table 1. population characteristics

Number of patients	40
Mean age (sd)	51 (15.9)
Gender - Male / female	77.5% / 22.5%
ECMO indication - ARDS	37.5%
- Bacterial pneumonia	30%
- Asthma / COPD / other	32.5%
Mean RESP score (sd)	1.3 (3.2)
ECMO survival	75%
ICU survival	62.5%
Hospital survival	62.5%

Table 2. Results

	Before ECMO;	After ECMO;
	mean (sd)	mean (sd)
MP-PCV (J/min)	34.5 (13.4)	6.8 (4.0)
Wrong calculation: MP-VCV (J/min)	27.2 (11.1)	5.3 (3.0)
Mean difference MP-PCV and MP-VCV	7.3 (4.6)	1.5 (1.4)
Percentage MP-VCV lower than MP-PCV	21%	22%
pH	7.20 (0.15)	7.30 (0.10)
pCO2 (kPa)	9.1 (3.2)	6.5 (1.6)
pO2 (kPa)	10.8 (6.7)	9.8 (3.3)
PEEP (cmH2O)	13.4 (5.1)	10.5 (3.7)
	Before ECMO;	After ECMO;
	mean (sd)	mean (sd)
Ppeak (cmH2O)	33.8 (5.6)	23.2 (5.7)
RR (/min)	29.6 (5.1)	15.0 (7.3)
Vt (L)	0.395 (0.103)	0.224 (0.092)
fiO2 (%)	82.9 (17.3)	49.6 (13.2)

Conclusion: VV-ECMO lowers the mechanical power while maintaining adequate oxygenation and ventilation reducing the MP with 80%. The MP calculation with the wrong formula underestimated the MP by more than 20% in this study. This study underlines that it is mandatory to use the correct methods to calculate the MP.

Tracheal and Enteral Aspirate pH Study: The beginning of the end to pH testing for confirmation of enteral tube placement?J.P. McNally-Reilly¹; S. Giannarakis¹; J. Wilcox¹; N.A. Barrett¹; L. Wandrag¹¹Adult critical care, Guy's and St Thomas' NHS Foundation Trust, London, United Kingdom**Correspondence:** J.P. McNally-Reilly*Intensive Care Medicine Experimental* 2020, **8(2)**: 000788

Introduction: Delivering enteral feed or medications through an enteral feeding tube placed into the lung causes major morbidity. (1) To prevent this from occurring an accurate means of assessing enteral tube placement is essential. In the UK, the National guidelines for assessment the of enteral feeding tube position includes the measurement of gastric aspirate pH (< 5.5) and assessment of tube placement using x-ray if indeterminate. (1) However there is little evidence to support this as a safe approach in critically ill patients. (2,3)

Objectives: • Establish the prevalence of acidic pH aspirates (defined as a pH < 5.5) within the critical care ventilated patient cohort. • Provide clarity on the use of pH strip testing as a method confirming nasogastric (NG) tube position in the critically ill patient cohort.

Methods: Simultaneous pH measurements were taken for aspirates obtained from the NG tube, subglottic port and tracheal samples in 106 ventilated patients from June - November 2019 at a university-affiliated, tertiary hospital. The pH from the three sites was obtained and recorded once per nursing shift and electronically entered. Any sample taken as a non-directed bronchial lavage (NBL) also had the pH recorded. Baseline demographic data, relative time of NBL to sampling, and presence of medications used to suppress gastric acid production were recorded. Patient's notes were reviewed by the authors for history or suspicion of aspiration, and documented episodes of emesis. Institutional approval was given for this work. Statistical plan: The distribution of pH from each site was described using descriptive statistics. Specific note was made of any instances of pH < 5.5. Spearman's correlation was performed between subglottic and tracheal aspirate data.

Results: Data were included for 106 patients. Demographics include: mean age of 58.9 years, 78.3% referred from a medical speciality, average APACHE II score 14.6, average SOFA score 7.2, and 28.9% mortality rate overall. Analysis of all aspirates collected demonstrated a significant proportion within both subglottic and sputum aspirates of a pH < 5.5, 5.3% and 6.3% respectively, see Table 1. Fifteen patients accounted for the 27 acidic subglottic aspirates and four patients for the 7 sputum aspirates. Of note, there was a large proportion of NG aspirates with a pH > 5.5, 70.8%.

Table 1. Summary of data points collected from subglottic, nasogastric and sputum aspirates

	Subglottic	Nasogastric	Sputum
Count	513	510	111
Mean pH	6.5	5.3	6.9
Standard Deviation	1.4	1.8	1.6
Median pH	6.5	6.0	7.0
Lower Range pH	6.0	5.0	6.0
Upper Range pH	7.0	6.5	8.0
No. pH < 5.5	27	149	7
Percentage pH < 5.5	5.3	29.2	6.3

Analysis of simultaneous sputum and subglottic demonstrated a positive correlation, $r = 0.52$ (Confidence Interval 0.31 - 0.69), $p < 0.0001$.

Conclusion: From this study we have demonstrated a large number of acidic samples outside of the gastrointestinal tract, 5.3% subglottic and 6.3% sputum, with a simultaneously high proportion of aspects from the gastrointestinal tract not being acidic (70.8%). Given that the pH in tracheal and subglottic examples was strongly correlated, it is

possible that the acidic pH in the airway was due to micro-aspiration past the cuff of the endotracheal tube. (4,5) This raises the possibility that any patient with significant glottic dysfunction and either macro- or micro-aspiration may have an acidic tracheal pH and raises doubts about the validity of pH testing as a means of confirmation of correct placement of an enteral feeding tube in this population. The elevated pH in the gastric samples is to be likely due to the use of protein pump inhibitors as a medication for stress ulcer prophylaxis in the critically ill patient cohort.

The data presented here suggests that pH testing as a means of confirmation of enteral tube placement will not prevent feed installation into the lungs if the tube is misplaced and the patient has poor glottic function and a risk of aspiration.

Ventilatory Ratio: a useful prognostic tool for ARDS due to SARS-CoV-2M. Monti¹; P. Pugni¹; M. Di Matteo²; L. Gandini¹; FM. Russo¹; L. Manesso¹; A. Martinelli²; L. Zacchetti²; I. Bianchi²; L. Grazioli²; L. Longhi²; F. Previdi³; FL. Lorini²¹Anestesia, rianimazione e terapia intensiva e del dolore, University of Milan, Milano, Italy; ²Dipartimento di emergenza urgenza e area critica, ASST Papa Giovanni XXIII, Bergamo, Italy; ³Ingegneria, Università Degli Studi Di Bergamo Ingegneria Ed A, Dalmine, Italy**Correspondence:** M. Monti*Intensive Care Medicine Experimental* 2020, **8(2)**: 000813

Introduction: Increased dead space, as a reflection of global lung injury, is an independent predictor of mortality in both the early and intermediate stages of Adult Respiratory Distress Syndrome (ARDS) (1). Ventilatory ratio (VR) is a bedside index of impaired ventilatory efficiency with significant association with dead space and outcome in ARDS (2). Severe Adult Respiratory Syndrome Coronavirus-2 (SARS-CoV-2) disease partly differs from traditional ARDS; high dead space fraction may be a specific pathophysiological characteristic (3).

Objectives: To describe VR, its trend and association with mortality in a cohort of SARS-CoV-2 patients.

Methods: A cohort of consecutive patients affected by SARS CoV-2 admitted to Papa Giovanni XXIII Hospital ICU (Bergamo) from February 22th to March 22th and requiring invasive mechanical ventilation was retrospectively analysed. VR, defined as [minute ventilation (ml/min)*PaCO₂ (mmHg)]/[predicted body weight *100 (ml/min)*37.5 (mmHg)], was calculated within 48 hours since intubation. Patients were divided into two groups, low VR (< 2) and high VR (≥ 2) (2). Demographics, ventilatory parameters (Mann Whitney test) and 28-day mortality (Fisher's exact test) were compared between the two groups.

Results: 86 of the 115 patients enrolled had a baseline VR, with a mean value of 2.05 (± 0.59). VR remained high over the first 15 day of ICU admission (mean value always ≥ 2 , Figure 1). Low VR group included 45 patients with mean VR 1.58 (± 0.34); high VR group included 41 patients with mean VR 2.53 (± 0.40). The groups were similar for age, SOFA-score, baselines ventilatory setting and gas exchange (Table 1). High VR was associated with significantly increased 28-day mortality (odds ratio 2.83, 95% CI 1.08-7.39, $p = 0.03$). Comparing survivors and non-survivors median VR was respectively 1.87 (1.55-2.35) versus 2.22 (1.72-2.71) ($p < 0.05$).

Table 1. Baseline characteristics in the two groups.

	VR<2 (n ^o 45)	VR \geq 2 (n ^o 41)	p-value
Age	57(51-66)	64(55-69)	0.07
SOFA score	6(4-8)	7(4-9)	0.1
Driving Pressure	11 (10-13)	11(10-14)	0.5
PEEP	15(13-16)	15(14-17)	0.2
Compliance	41(35-46)	41(32-46)	0.4
PaO ₂ /FiO ₂	117(98-151)	98(76-135)	0.09

Conclusion: Patients with baseline VR ≥ 2 had significantly higher 28-day mortality in ARDS due to SARS-CoV-2; VR could be a useful prognostic tool.

Intensive Care Medicine Experimental 2020, **8(2)**: 000814

Introduction: Anecdotal evidence suggests COVID-19 may be associated with severe insulin resistance in critical care. Indeed, a group of leading diabetologists have recently established a COVID-19-Diabetes registry to catalogue cases of new onset diabetes and severe insulin resistance associated with COVID-19, positing that COVID-19 may be a uniquely diabetogenic virus. However, to date there has been no longitudinal evaluation of insulin requirements in critically ill patients with COVID-19 and there is no evidence to suggest these observations represent anything other than stress hyperglycaemia.

Methods: To address this, we conducted a retrospective observational study of contemporaneous electronic medical records of insulin requirements and glycaemia in patients admitted to our intensive care unit (ICU) with COVID-19 in March and April 2020.

Results: 54 patients with COVID-19 were admitted to our unit for > 24 hours during the study period and included in the analysis. We reasoned that the high insulin requirements observed in COVID-19 may represent the high prevalence of severe illness. To test this, we analysed insulin requirements according to interventions employed to treat respiratory failure, namely mechanical ventilation, neuromuscular blockade, nebulised epoprostenol and proning. Increased Insulin requirements (units/day) and worsening glycaemia were clearly associated with severity of illness as indicated by intensity of salvage therapies required for respiratory failure ($P < 0.01$ for all, ordinal regression). In a multivariate model adjusted for age and sex, being proned during ICU admission and pre-morbid Type 1 or Type 2 diabetes, but not steroid exposure or obesity, were independently associated with insulin requirements. To determine if COVID-19 had unique effects on glucose metabolism we compared insulin requirements and glycaemia in COVID-19 to a cohort of non-viral pneumonitis patients admitted to our ICU between 2018 and 2020, matched for age, sex, BMI and diabetes status. Insulin requirements (Mean Insulin Dose (Units/day), COVID-19: 19.8 ± 8.3 , Non-COVID-19: 24.8 ± 11.2 , $P = NS$, $N = 17$ per group) and glycaemic control (Time in range 4-10mmol/L (%), COVID-19: 81.2 ± 26.2 , Non-COVID-19: 82.1 ± 20.9 , $P = NS$, $N = 17$ per group) were comparable between groups (Figure 1). Finally, we examined the short term metabolic sequelae of COVID-19 by looking at anti-hyperglycaemic use in 31 patients discharged from our hospital after their ICU admission for COVID-19. All patients who were commenced on insulin in ICU had insulin successfully withdrawn and there was no new initiation of oral anti-hyperglycaemic agents in this cohort.

Conclusion: Insulin requirements in severe COVID-19 are positively associated with severity of respiratory failure and pre-existing diabetes. They are comparable to those seen in non-COVID-19 viral pneumonitis and resolve in convalescence. We did not find evidence to support the emerging hypothesis that SARS-CoV-2 is a uniquely diabetogenic virus.

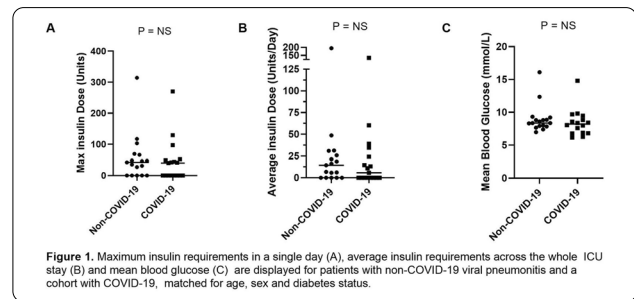

Figure 1. Maximum insulin requirements in a single day (A), average insulin requirements across the whole ICU stay (B) and mean blood glucose (C) are displayed for patients with non-COVID-19 viral pneumonitis and a cohort with COVID-19, matched for age, sex and diabetes status.

Introduction: Diuretic therapy to obtain a negative fluid balance is often used in patients with acute respiratory distress syndrome (ARDS) but its aggressive application can result in decreased renal perfusion and kidney injury (AKI). Since skin blood flow (SBF) is highly sensitive to a reduction in blood flow, we hypothesized that a reduction in SBF during an attempt to decrease fluid balance could be associated with the development of AKI.

Methods: We included hemodynamically stable (mean arterial pressure (MAP) ≥ 65 mmHg without an increase in norepinephrine (NE) dose in the least 6 hours at least) ARDS patients (Berlin criteria) in which intravenous furosemide administration was used in order to reach a negative fluid balance. Patients with AKI at baseline were excluded. SBF (Periflux 5000, Perimed; index finger; Perfusion unit: PU) together with hemodynamic variables, the ratio of arterial oxygen partial pressure to fractional inspired oxygen (PaO₂/FiO₂), central venous oxygen saturation (ScvO₂) and blood lactate concentrations were obtained at baseline (T0) and after 24 hours (T24). Relative changes in SBF during first 24 hours (ΔSBF₂₄) was recorded. Patients were separated by the occurrence of acute kidney injury (AKI) (AKIN criteria) within 7 days after T0. Receiver operating characteristic (ROC) curves were constructed and reported as areas under the curve (AUC) with 95% confidence intervals to predict AKI.

Results: Of the 36 ARDS patients (pneumonia (26), abdominal infection (8), pancreatitis (2)) we studied, 14 developed AKI (12 stage 3 and 2 stage 1). A strategy to achieve a negative fluid balance was initiated 73 (50-96) hours after ARDS diagnosis. At baseline, there were no significant difference between patients with and without AKI in SOFA score (8 (6-11) vs 11 (7-12), p = 0.2), PaO₂/FiO₂ (p = 0.5), MAP (p = 0.9), cardiac index (p = 0.4), lactate concentration (p = 0.1), ScvO₂ (p = 0.3) and SBF (p = 0.1) (Table 1). At T24, lactate concentration increased and SBF decreased in both groups. However, ΔSBF₂₄ was greater in patients who developed AKI than in those who did not (Table 1). ΔSBF₂₄ had the highest AUROC (0.90 ± 0.06 [0.76-0.1]) (p < 0.01) to predict the occurrence of AKI, with a cut off value of 45% (sensitivity 74%, specificity 89%) (Figure 1)

Table 1 Hemodynamic variables, lactate concentration, SBF and ΔSBF₂₄ before (T0) and after the negative fluid balance strategy (T24)

	All patients (N=36)			No AKI (N=22)			AKI (N=14)		
	Before	After	p	Before	After	p	Before	After	p
MAP (mmHg)	71 (69-72)	71 (69-73)	1.0	71 (69-72)	71 (69-73)	0.6	72 (69-72)	72 (69-75)	0.8
Cardiac index (L/min/m ²)	2.9 (2.5-3.3)	3.0 (2.7-3.4)	0.1	2.8 (2.5-3.3)	2.9 (2.7-3.4)	0.2	3.0 (2.5-3.3)	3.0 (2.7-3.5)	0.9
Norepinephrine dose (mcg/kg/min)	0.2 (0.1-0.2)	0.1 (0.05-0.3)	0.8	0.1 (0.02-0.2)	0.1 (0.02-0.2)	1.0	0.2 (0.1-0.3)	0.2 (0.1-0.4)	0.3
PaO ₂ /FiO ₂ (mmHg)	163 (122-209)	166 (134-224)	0.1	151 (126-197)	166 (133-204)	0.02	180 (123-220)	166 (137-227)	0.2
Lactate levels (mmol/L)	1.2 (0.8-1.5)	1.5 (1.0-1.8)	<0.01	1.1 (0.8-1.2)	1.3 (1.0-1.4)	<0.01	1.4 (0.9-1.8)	1.7 (1.5-2.1)	0.04
ScvO ₂ (%)	71 (70-74)	72 (71-73)	0.1	70 (70-72)	72 (71-73)	0.04	73 (70-75)	72 (71-73)	0.7
SBF (PU)	120 (62-167)	64 (20-116)	0.01	153 (87-210)	105 (56-187)	<0.01	91 (51-134)	45 (14-79)	<0.01
ΔSBF ₂₄ (%)	36 (19-51)			21 (11-36)			51 (34-64)		

Conclusion: Monitoring of SBF can be valuable to decrease the risk of AKI during a negative fluid balance strategy for ARDS.

Introduction: Randomised controlled trials represent the cornerstone of modern evidence-based medicine [1]. There is increasing interest in the reporting of randomized controlled trials to ensure that research is transparently described [2]. Currently, the quality of reporting within the critical care literature is unclear.

Methods: A systematic search was undertaken to identify all randomized controlled trials published within the four highest impact factor critical care journals between 1st January 2013 and 31st December 2016. Randomised controlled trials involving children were excluded. Two researchers independently selected articles and marked them against the Jadad scale and the CONSORT reporting guideline to determine if any domains were lacking.

Results: 306 trials met the inclusion criteria over the four-year study period. Just under half were blinded randomized controlled trials (139 of 298; 46.6%), and the median number of participants was 95 (IQR: 175.25); nine trials enrolled in excess of 1000 participants. Median compliance with CONSORT was 75% (IQR: 15.7%). The three best reported items were background and rationale (298/298; 100%), Interpretation consistent with results (99.3%) and statistical methods comparing groups for primary/secondary outcomes (99.4%). The three worst reported items were any changes to commencement with reasons (4.3%), important changes to methods after trial recruitment, with reasons (11.2%) and where the full trial protocol is if available (17.6%). There was an improvement in reporting over time, blinded trials had better reporting than unblinded trials, and trials with a trial registration had higher compliance.

Conclusion: Randomised controlled trials in critical care journals are typically well reported but some clear weaknesses should be addressed. These include location of a full protocol and a detailed description of any changes to the study after commencement.

Intensive Care Medicine Experimental 2020, **8(2)**: 000884

Introduction: COVID19 pandemic and the consequent surge of patients with acute hypoxemic respiratory failure has been challenging for intensive care departments around the globe.

Objectives: To describe the main clinical characteristics and ICU outcomes in a cohort of adult patients with severe acute hypoxemic respiratory failure due to COVID19 admitted between 15 March and 15 April in the ICU Catalan network.

Methods: Consecutive patients admitted between 15 March and 15 April in 26 ICUs, who tested positive for SARS-Cov-2 (RT-PCR in a nasopharyngeal swab) and had severe acute hypoxemic respiratory failure (need of at least 10 L/min oxygen flow to keep an oxygen arterial saturation -pulsioximeter- above 90%, and presenting with bilateral infiltrates in the chest X-ray). Demographic and relevant clinical and physiological data were collected within the first 24h of ICU admission. Follow-up time was till ICU discharge. Study was approved by the Ethics Committee of the the coordinating center (Hospital Universitari de la Santa Creu i Sant Pau).

Results: A total of 1704 patients (1187 men and 517 women) were admitted. Median age was 63 yr (IQR 54-70) and median BMI was 28 kg/m² (IQR 26-32). Most frequent comorbidities were cardiovascular conditions (n = 480), diabetes (n = 90), cancer/immunosuppression (n = 74) and COPD (n = 31). ICU mortality was 505/1704 (29,6%). Among patients who required invasive mechanical ventilation (82% of the cohort), ICU mortality was 35% (491/1388). ICU mortality very much differed between patients up to 60 yr (n = 705) and older than 60 yr (n = 999): 12,8% (90/705) and 41,5% (415/999) respectively, p < 0.001. The median length of ICU stay was 13 days (IQR 7-25).

Conclusion: COVID19 severe hypoxemic respiratory failure mainly affects men, the vast majority will require invasive mechanical ventilation for a long period of time and the overall mortality is substantial. People older than 60 yr have a dismal prognosis.

Intensive Care Medicine Experimental 2020, **8(2)**: 000887

Introduction: The declaration of the Novel Coronavirus (COVID-19) as a pandemic lead to the implementation of surge plans and an increase in the number of intensive care units beds across most healthcare facilities. Health care workers (HCWs) in the ICU are frontlines of this crisis as they deal with critically ill patients affected by COVID-19 which can potentially affect their mental wellbeing and causes different levels of stress and psychological disorders.

Objectives: We aimed to determine the prevalence of stress among HCWs involved in the management of critically ill COVID-19 patient, identify the risk factors associated with stress, and highlight the availability of psychological support provided to HCWs and its effectiveness.

Methods: A cross sectional multicenter, international study using a web-based questionnaire of 27 questions including the Perceived Stress Scale [PSS] for assessment of stress level. Questions to identify the risk factors for stress and the psychological support provided by each health care facility in addition to the socio-demographic characteristics were included.

Results: We received a total 1501 response from 59 countries, 526 (35%) were from Europe, 432 (28.7%) from Asia, 283 (18.85%) from Africa and 159 (10.59%) from North America. A total of 657 (43.95%) were senior doctors, 455 (30.43%) were nurses, 278 (18.60%) were junior doctors and 105 (7.04%) others (clinical pharmacists, physiotherapists and respiratory therapists). Most responders were male 844 (56.22%). The overall average stress level was 22 points on the PSS denoting moderate stress, while 508 (33.36%) respondents had a severe level of stress, 788 (51.87%) respondents had moderate level of stress and only 223 (14.61%) had mild stress.

Fear of infection was the major concern for more than 80% of all the respondents, where 717 (58.5%) reported that fear of getting infected with COVID-19 increased their stress level while 290 (23.67%) reported that the fear of transmitting the infection to their families was the main cause of their stress. Other contributing factors to stress were, the increased duty hours, the increased work load and shortage of staff as reported by 89 (7.26%) while the lack of (personal protective equipments) PPEs accounted for stress in 68 (5.63%) respondents. Social media and triaging COVID patients were the least causes of staff stress as quoted by 39 (3.1%) and 38 (3.1%) respectively.

Although 805 (53.67%) of respondents reported receiving psychological support from their facility, 689 (45.93%) reported not receiving any support. 302 (26.24%) received psychiatric counselling, 613 (53.26%) received phone calls and motivational emails/messages, 515 (44.74%) received phone calls for psychological support from their facility, 428 (37.19%) reported active listening to their concerns, 208 (18.07%) received psychological support from the community in the form of positive words and applauses. 444 (38.61%) reported the psychological support was somewhat effective, 371 (32.26%) said that it was very effective while 335 (29.19%) said that it was not effective at all. 829 (55.45%) tried some ways to decrease their stress like religious services, anxyolytics, exercise and watching movies

Conclusion: Stress level was rated to be moderate to severe among intensive care HCWs during this pandemic, many risk factors were identified emphasizing the importance of psychological support during that unprecedented pandemic and adjusting different ways for mitigating such stress.

The Presence of Psychological Safety Within the Intensive Care Environment: A Qualitative Interview and Questionnaire Study

K. Grailey¹; E. Murray²; S.J. Brett³

¹Imperial College London, London, United Kingdom; ²Said business school, University of Oxford, Oxford, United Kingdom; ³Critical care, Imperial College Healthcare NHS Trust, London, United Kingdom

Correspondence: K. Grailey

Intensive Care Medicine Experimental 2020, **8(2)**: 000893

Introduction: Psychological safety is defined as an environment “safe for interpersonal risk taking” (1). It allows staff to voice concerns without fear of negative repercussions. This can reduce clinical error, lead to workplace innovation and enhance staff wellbeing (2).

The importance of psychological safety has led to the study of its antecedents across many sectors (2-4). This understanding needs to be built upon, focusing on the specific needs of each workplace.

Objectives: Our study had 3 objectives:

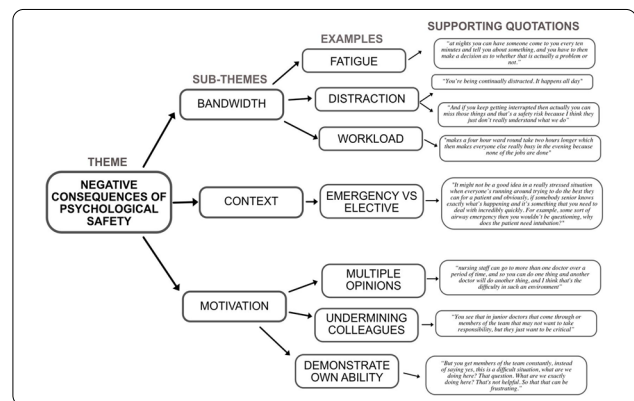

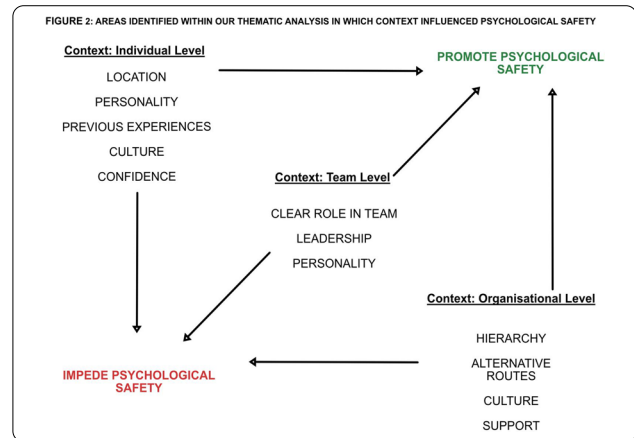

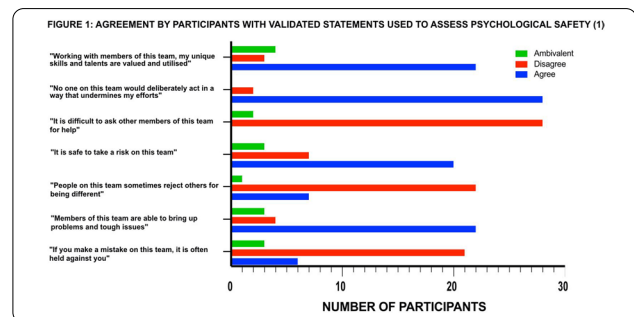

1. How psychologically safe is our intensive care (ICU) workforce?
2. How does context influence psychological safety?
3. Are there any negative consequences of psychological safety?

Methods: Participants were recruited from the multidisciplinary teams of 3 ICU’s within Imperial College NHS Trust. Semi-structured interviews were conducted, exploring attitudes towards psychological safety. Quantitative data were collected in the form of verbal agreement with 7 statements (1) and the completion of the Safety Attitudes Questionnaire (SAQ) (5). Qualitative audio files were transcribed and analysed within NVIVO software using a thematic analysis approach. Quantitative data were analysed using Microsoft Excel & Graph Pad Prism.

Results: Interviews, verbal surveys and SAQ’s were completed by 30 participants. 28 were in agreement that it was easy to ask for help, with

20 agreeing that it is safe to take a risk on the team. 6 reported feeling that a mistake would be “held against” them [Figure 1]. The SAQ data corroborated this - 28 felt encouraged to report safety concerns. However, 11 were unsure this would be acted upon by management. Our thematic analysis highlighted areas where the context influenced an individual’s psychological safety [Figure 2]. These contextual factors included personality, culture & leadership. Counterintuitively - psychologically safe teams in which individuals are encouraged to participate can lead to negative consequences for the team leader. This can take the form of distraction and fatigue. It was also reported that time taken for increased discussion and raising concerns could reduce the time available for other clinical work.

We demonstrated that psychological safety can be influenced by motivations other than patient safety – such as undermining others or self-promotion. [Figure 3]

Conclusion: Our study demonstrates reassuring levels of psychological safety within our sample of ICU staff. It also highlighted room for improvement – 1/3 felt at risk of repercussions after speaking up. We have created a model demonstrating how the context of each clinical scenario can influence psychological safety, and how this varies across different levels within the organisation. This allows leaders to identify contexts that can be modified in order to promote psychological safety.

Understanding the negative consequences of psychological safety and when they occur is important – if a clinician's bandwidth is overloaded this can have implications both for employee well-being and patient safety. Team leaders can use this data to help foster a culture of openness whilst minimising the risk of negative implications.

Intensive Care Medicine Experimental 2020, **8(2)**: 000909

Introduction: Increased use of technology in Intensive Care Medicine has become integral to the specialty over the last 50 years (1). This, accompanied by advances in medical practice, has led to larger quantities of data amongst ventilated patients and a need to accurately record ventilator parameters to make clinical decisions (2). It is important to evaluate traditional paper-based data entry with new automated data capture in intensive care units to ensure continued best practice.

This audit aims to assess data collection failures in ventilator setting recordings amongst intubated and ventilated COVID-19 patients and directly contrast failures of hourly recording amongst the ICCA system and data entered in paper ICU flow sheets. We analysed 13,355 data entries over a one-week period in our ICU to compare recording failure of computer-based records and traditional flow sheet entry.

Objectives: The objective of this audit is to directly compare and analyse the performance of paper-based nurse led data entry against computer based patient recording. Primary end points were hourly recordings of the following values: FiO₂, SpO₂, EtCO₂, Respiratory Rate, Ventilator Mode, Tidal Volumes, Minute Volume, Peak Airway Pressure and Positive End Expiratory Pressure over a one-week period. By analysing the results, we aim to gain insight into the benefits and potential failures of automated computing in data recording as its use is further incorporated into clinical practice.

Methods: Hourly ventilator data record entry was retrospectively analysed for intubated patients from the 13th -19th of April in a Dublin teaching hospital ICU. The IT system and patient flow sheet for each patient were analysed. All data was available for inclusion. Patients who were extubated during the week were included until the hour

of extubation. Hours when a result was not available for FiO₂, SpO₂, EtCO₂, Respiratory Rate, Ventilator Mode, Tidal Volumes, Minute Volume, Peak Airway Pressure and PEEP were recorded. These 13,355 data points were separated by patient hours when either the ICCA system or Nurse led patient flow sheet was used with 9270 patient hours in the ICCA arm and 4283 patient hours in the Paper recording arm, further analysis was based upon time of day, (day shift 0800-2000 and night shift 2000-0800). These data were then entered onto a database for analysis.

Results: 13,355 data entries were collated. Within the IT based ICCA system 4% (368 hours of 9270 hours) of data entries were unrecorded compared to paper flow sheet entries 7.6%, (487 hours of 4283 hours data entries). Of ICCA recordings that were missed 62.5% were missed during day shifts, (0800-2000) and 37.5% during night shifts, (2000-0800). This contrasts with paper flow sheet entry in which 39.5% of data entries missed during day shifts and 60.5% during night shifts.

Results were also separated by parameter missed as percentage of total recorded hours. The ICCA system resulted in: End Tidal (2%), Peak Airway Pressure (0.728%), Minute Volume (0.65%), Tidal Volume (0.287%), SpO₂ (0.12%), PEEP (0.12%), FiO₂ (0.077%), Ventilator Mode (0.066%) Respiratory Rate (0%). Percentages refer to hours missed as a proportion of total hours.

Paper flow sheets recording resulted in: End Tidal CO₂(2.1%), SpO₂ (1.5%), Ventilator Mode (1.42%), FiO₂ (1.12%), PEEP (1%), Minute Volume (0.21%) Peak Airway Pressure (0.163%), Tidal Volume (0.14%), Respiratory Rate (0.02%).

Of note a range of data entry failures occurred across multiple parameters simultaneously. This was consistent with patient movement for diagnostic tests and procedures and was not removed from the data set.

EtCO₂ performed poorly in both groups. It is hypothesised that air temperature and humidity change within the unit during the COVID-19 epidemic contributed in part to these results.

Conclusion: Accurate data collection provides clinicians with the ability to make informed decisions on patient care. Our study concludes that ventilation parameters are recorded more accurately with the use of digital computer systems when total data failures are compared to total patient hours, (4% and 7.6%). The improved performance is even more clear if EtCO₂ is removed as it results in 2.1% of 4% of the ICCA computing failures. While this confers more accurate data available for clinicians there were parameters where paper flow sheets had improved recording over automated data entry. These include peak airway pressure, tidal volume and minute ventilation while ICCA had improved performance in FiO₂, SpO₂, ventilator setting and PEEP. EtCO₂ had the worst recording rate amongst both modalities. We can conclude that the use of automated computing provides superior overall recording rates, however, nurse led paper flow sheets had improved recording in some parameters and recorded less proportion of data misses during daylight hours.

Does the rate of administration of a fluid challenge have a haemodynamic impact?

V. Bennett¹; H. Farrah¹; A. Messina²; HD. Aya¹; A. Rhodes¹; N. Fletcher¹; M. Cecconi²

¹Intensive care medicine, St George's University Hospitals NHS Foundation Trust, London, United Kingdom; ²Anaesthesia and intensive care units, Humanitas Research Hospital, Rozzano, Italy

Correspondence: V. Bennett

Intensive Care Medicine Experimental 2020, **8(2)**: 000953

Introduction: Peri-operative fluid management has long been identified as key to reducing post operative morbidity and mortality. Assessment of fluid responsiveness following administration of a fluid challenge can form part of a review of whether that patient requires additional fluid volume. (1) How the optimal fluid challenge should be delivered remains an area of ongoing research. Previous work has shown that 4 ml/kg is the minimum volume to reliably challenge the circulation but the rate at which the fluid should be given has not been fully investigated. (2)

Objectives: The primary objective was to determine if the rate of administration of a fluid challenge influences the percentage of responders and non-responders to fluid administration.

The secondary objective was to investigate whether the rate of administration influences the pharmacodynamic response to fluids in terms of maximum change and duration of change in haemodynamic variables including Pmsf and CO.

Methods: A prospective study of 40 post-operative patients was conducted in the intensive care units at St George's Hospital, London. They were randomized to receive a post operative 4 ml/kg fluid challenge over either 5 or 20 minutes. Stability criteria were assessed and then baseline observations including heart rate (HR), blood pressure (BP), mean arterial pressure (MAP), stroke volume (SV), cardiac output (CO), mean systemic filling pressure (Pmsf) and central venous pressure (CVP), where available, were recorded. These were repeated on completion of the fluid challenge and after a 5 and 10 minute interval. Cardiac output measurements were recorded using a calibrated LiDCOplus™ monitor. Patients were considered fluid responsive if SV increased by more than 10% following a fluid challenge. Adequacy of fluid challenge was assessed as an increase in Pmsf of more than 14%. The proportion of fluid and Pmsf responders were compared using Fisher's exact test. ANCOVA models adjusted by baseline values and fluid responsiveness, were used to assess the impact of rate on haemodynamics. P values less than 0.05 were considered significant.

Results: Of the 40 patients randomized 7 were excluded from analyses, as they did not meet stability criteria. In the group that received a fluid challenge over 5 minutes, 40% were fluid responsive and 11.1% were fluid responsive in the 20 minute cohort. This difference was not statistically significant, $p = 0.1$. In the 5 minute group 73.3% showed an increased in Pmsf of more than 14%, and 72.2% in the 20 minute group, $p = 0.8$. The rate of fluid administration does not affect the change in Pmsf, but has a significant effect on change in MAP (8.3 vs -0.2 mmHg, $p = 0.03$), CO (0.6 vs -0.3 L/min, $p = 0.02$) and SV (9.6 vs -6.4 mL, $p = 0.02$).

Conclusion: No statistically significant difference between the rate of responders and non responders could be demonstrated with varying the rate of administration of the fluid challenge. However, a potentially clinically significant difference was seen. The changes in Pmsf seen in both groups, suggests no difference in the adequacy of fluid challenge with varying rates. This may indicate a potential effect of the fluid challenge on venous resistance and highlights an area for future work.

The potential magnitude of endogeneity bias in the evidence base of an international sepsis guideline

Intensive Care Medicine Experimental 2020, **8(2)**: 000979

Introduction: It has been shown that observational studies often lead to biased results, even when statistical methods such as logistic regression and propensity score matching are used to adjust for confounding. This has specifically been shown for intensive care-related inferential problems [1, 2].

In observational critical care studies, the initiation or dose of the investigated treatment is often associated with baseline severity of illness and mortality risk. This causes *endogeneity* in estimation models (a correlation between the investigated treatment and the error term), which biases the analysis results. Endogeneity is a separate entity from confounding by indication, which arises through omitted variables. It arises from *measurement error* (imperfect calibration of severity-of-illness scoring systems) and *simultaneity* (the decision to initiate treatment or the dose is influenced by the severity of illness but also influences the severity of illness) [2, 3].

We aimed to investigate the potential magnitude of endogeneity bias in the evidence base of a major intensive care guideline.

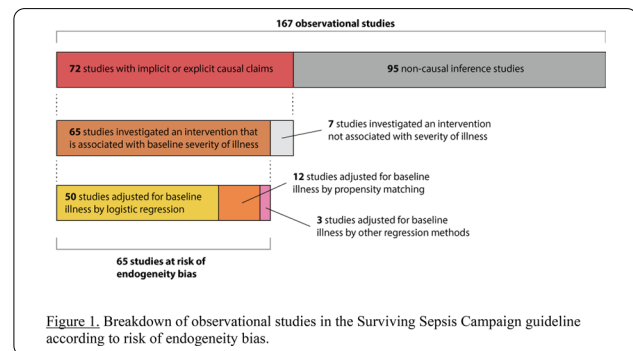

Objectives:

1. To identify which observational studies in the Surviving Sepsis Campaign (SSC) Guidelines' evidence base are at risk of endogeneity and spurious causal inferences [4].
2. To identify which topics in the SSC Guidelines are most affected by these potentially biased studies.

Methods: We screened all references in the Surviving Sepsis Campaign (SSC) Guidelines. We considered studies to be at risk of endogeneity bias when five conditions were met:

1. Observational non-randomized study design, and;
2. Investigated an intervention whose initiation or dosing is positively or negatively associated with baseline severity of illness or mortality risk, and;
3. Aimed to analyse the relationship between the intervention and a clinical outcome, and;
4. Adjusted for baseline severity of illness by regression methods (such as linear, logistic or proportional hazards regression) or propensity matching, and;
5. Made implicit or explicit causal statements.

Results: We identified 167 observational studies in the guidelines' evidence base. Sixty-five (39%) of these studies were at risk of endogeneity bias (Figure 1). None of these studies used a validated causal inference method to reduce endogeneity (e.g. an instrumental variable approach.) Studies at risk of endogeneity bias were most prevalent among the guideline topics Fluid Therapy (5 studies) and Glucose Control (9 studies).

Conclusion: We found that 39% of the observational studies in the SSC Guidelines made causal statements while being at risk of endogeneity bias. The most affected topics were Fluid Therapy and Glucose Control. Their inclusion in a major guideline means these studies are not merely 'hypothesis-generating' and may influence treatment decisions. Biased results caused by endogeneity may thus lead to patient harm. Clinicians and authors of guidelines should be aware of this potential bias.

000991**Endothelial glycocalyx disruption and impaired microvascular flow following liver resection surgery**E. Potter¹; B. Creagh-Brown²; L. Forni³; J. Mcvey⁴¹Intensive Care Unit, Royal Surrey County Hospital, Guildford, France;²Intensive care and perioperative medicine, Royal Surrey County Hospital, Guildford, United Kingdom; ³Intensive care, Royal Surrey County Hospital, Guildford, United Kingdom; ⁴Biochemical sciences, University Of Surrey, Guildford, United Kingdom**Correspondence:** E. Potter*Intensive Care Medicine Experimental* 2020, **8(2)**: 000991

Introduction: The endothelial glycocalyx is a bio-active structure which lines blood vessels. Its importance in critical and peri-operative care is increasingly recognised.1 Shedding of key components of the endothelial glycocalyx such as syndecan-1, a proteoglycan, which binds glycosaminoglycans, has been found to be associated with impaired microvascular blood flow following cardiac bypass surgery.2 Glycocalyx degradation has also been found in ischaemia – reperfusion in trauma patients with shock.3 Animal models have found antithrombin to reduce endothelial dysfunction following ischaemia-reperfusion injury.4 In our centre we use a low central venous pressure (CVP) anaesthetic for liver resection surgery to decrease intra-operative blood loss, which is then followed by goal-directed fluid therapy.5 We investigated whether there was impairment of microvascular blood flow, evidence of endothelial glycocalyx shedding or changes in antithrombin concentrations in patients undergoing liver resection surgery.

Objectives: To establish:

- if there is evidence of endothelial glycocalyx shedding by measuring serum concentrations of: syndecan-1, thrombomodulin, vascular endothelial growth factor receptor (VEGF-R) or e-selectin in patients undergoing liver resection surgery
- if there were changes in antithrombin concentrations during liver resection surgery
- if endothelial glycocalyx shedding was related to microvascular blood flow.

Methods: This was a prospective observational study (REC no 14/NE/1150) enrolling patients undergoing elective liver resection surgery. Microvascular blood flow, measured using the MicroScan device (MicroVision Medical, Amsterdam) and physiological measurements were taken at pre-specified time points throughout the peri-operative period (T1, awake on day of surgery pre-operatively, T2 following induction of anaesthesia, T3 on exposure of the liver, T4 completion of liver resection prior to fluid resuscitation, T5 arrival at ICU, T6 completion of goal directed fluid therapy (GDFT)). Serum samples were taken from a subset of 20 patients at T2, T4 and T6. ELISA's were carried out in duplicate for each sample at two dilutions. Results which fell outside of the standard curve were excluded from analyses.

Results: A total of 55 data sets were included in the analyses, 28 male and 27 female, mean age was 58 years (S.D. 13) and BMI 28.1 kg/m² (S.D. 5.4), 18% were smokers, 13% were diabetic and 76% had neoadjuvant chemotherapy.

Microvascular flow measurements decreased post-operatively and this fall was sustained after completion of GDFT. There was a fall in microvascular flow index (MFI), proportion of perfused small blood vessels

(sPPV) and perfused small blood vessel density (sPVD) from time 1 to T6 of 2.78 (2.42 – 2.98) vs 2.58 (2.08 – 2.83) $p < 0.0001$, 95.6 (87.4 – 99.8) vs 65.1 (61.3 – 66.8) $p < 0.0001$ and 4.85 (3.69 – 5.9) vs 5.77 (4.91 – 7.2), $p < 0.0001$ respectively.

There was a significant increase in syndecan-1 shedding and fall in antithrombin concentrations on completion of goal directed fluid therapy. Other markers of endothelial glycocalyx disruption decreased.

Table 2 – Markers of endothelial disruption (results displayed as median (IQR). Wilcoxon signed rank test is used to establish difference between groups)

Biomarker	Baseline (T2)	Post-operative (T6)	
syndecan-1 (pg/mL)	52.6 (42.7 – 52.6)	18456 (10047 – 24301)	$p < 0.0001$
Thrombomodulin (ng/mL)	6.73 (5.6 – 7.6)	3.3 (2.5 – 3.7)	$p < 0.0001$
e-selectin (ng/mL)	21.9 (10.1 – 21.9)	4.5 (2.2 – 7.5)	$P = 0.0001$
vascular endothelial growth factor receptor (VEGF-R) (ng/mL)	10.4 (9.7 – 10.5)	1.7 (1.3 – 2.5)	$p = 0.001$
Antithrombin	110 (106 – 115)	96 (92 – 114)	$P = 0.04$

Syndecan-1 and other biomarkers were not related to microvascular perfusion parameters, morbidity or length of stay.

Conclusion: Microvascular blood flow decreased post-operatively and this was sustained despite completion of GDFT. There was a significant increase in syndecan-1 concentration post-operatively, which may be due to disruption of the integrity of the endothelial glycocalyx membrane. However, there was a fall in other biomarkers, this could be dilutional. There was a fall in circulating antithrombin concentration which may be related to increased infiltration and binding to the endothelial glycocalyx following hypoperfusion. Further study of the glycocalyx in the peri-operative setting and its relation to microvascular blood flow is required.

Sánchez-Bayton Griffith¹¹Intensive care medicine, University Hospital 12 de Octubre, Madrid, Spain;²Intensive care medicine, Hospital Universitari Son Llàtzer, Palma, Spain;³Intensive care medicine, Ourense University Hospital, Ourense, Spain**Correspondence:** H. Fernández-Hervás*Intensive Care Medicine Experimental* 2020, **8(2)**: 000996

Introduction: The COVID 19 pandemic outbreak in Madrid overwhelmed the capacities of our regional and local health system. Despite the local efforts to increase the critical care capacity we were faced with difficult decisions regarding allocation of a scarce resource. The optimal method for allocating critical care resources during a pandemic remains questionable [1].

Objectives: To describe the cohort of patients evaluated with COVID 19 disease and the associated factors with ICU eligibility. This study could provide relevant information to optimize benefits from critical care resources in future COVID 19 outbreaks.

Methods: This prospective observational study was conducted in a specialised trauma and emergency department ICU of a level-3 hospital in Madrid, Spain. Our ICU staff evaluated adult patients with respiratory failure due to suspected COVID 19 infection at the ED. The decision about eligibility for ICU admission was guided using an institutional protocol including age, comorbidities and disease severity. We also collected data regarding gender, severity scores at time of evaluation (SOFA, CURB65), decision about eligibility (with independence of ICU admission), ICU admission and in-hospital mortality. Data was analyzed using the software RStudio Version 1.2.5042 for windows. For the univariate analysis we used Chi square test for categorical variables and student T Test or Mann Whitney U Test for continuous variables. Multivariate analysis was performed with a logistic regression model.

Results: Between March 4th and April 20th 2020 we evaluated a total of 221 patients. In the univariate analysis, age, comorbid state and disease severity were inversely associated with ICU eligibility with statistical significance. The number of events in the non eligible group limited the number of explanatory variables in the multivariate model, we created an index of comorbid state simply adding the main comorbidities of each patient, SOFA score was excluded due to lack of linearity. The resultant logistic regression model showed adequate goodness of fit and predictive accuracy (Likelihood ratio test $\chi^2(4) = 94.945$ $p < 0.001$. Pseudo R McFadden: 0.3837. Classification rate 0.85. Area under the curve for the ROC curve 0.8875 (95% CI [0.8365; 0.9385]). In this model only age and comorbidities retained statistical significance (Table 1).

	Non eligible (56)	Eligible (165)	p value (Uni)	OR (95% CI Multi)
Age (years)	66.7 (SD 10.7)	52.3 (SD 11.8)	<0.001	0.91 (0.86-0.95, $p < 0.001$)
Female	22 (39.3%)	44 (26.7%)	0.082	0.60 (0.25-1.41, $p = 0.233$)
Hypertension	29 (51.8%)	47 (28.5%)	0.002	
Diabetes	20 (35.7%)	19 (11.5%)	<0.001	
OSA	12 (21.4%)	11 (6.67%)	0.004	
COPD	10 (17.9%)	3 (1.82%)	<0.001	
Obesity	20 (35.7%)	41 (24.8%)	0.125	
Heart Disease	17 (30.4%)	6 (3.64%)	<0.001	
Number of comorbidities * †	3.00 [1.75; 4.00]	1.00 [0.00; 2.00]	<0.001	0.46 (0.33-0.65, $p < 0.001$)
SOFA*	3.00 [2.00; 3.00]	2.00 [2.00; 3.00]	0.012	-
CURB65*	2.00 [1.00; 3.00]	1.00 [0.00; 2.00]	<0.001	0.71 (0.42-1.15, $p = 0.170$)

Conclusion: The variables most associated with ICU eligibility were age and comorbid state proving that age was not the only factor accounted for. Female gender and CURB 65 was inversely associated with eligibility however this association was not significant in multivariate models.

Intensive Care Medicine Experimental 2020, **8(2)**: 001002

Introduction: Samples for diagnostic tests for SARS-CoV-2 can be obtained from the upper (nasopharyngeal/oropharyngeal swabs) or lower respiratory tract (sputum or tracheal aspirate or broncho-alveolar lavage - BAL). Data from different testing sites indicates different rates of positivity¹. Real-time polymerase chain reaction (RT-PCR) allows for semi-quantitative estimates of viral load as time to crossing threshold (Ct) is inversely related to viral load.

Objectives: The objective of our study was to evaluate SARS-CoV2 RNA loads between paired nasopharyngeal (NP) and deep lung (endotracheal aspirate or BAL) samples from critically ill patients.

Methods: SARS-CoV-2 RT-PCR results were retrospectively reviewed for 51 critically ill patients from 5 intensive care units in 3 hospitals; Addenbrookes Hospital Cambridge (3 units), Royal Papworth Cambridge (1 unit), and Royal Sunderland Hospital (1 unit). At the times when paired NP and deep lung samples were obtained, one patient had been on oxygen only, 6 patients on non-invasive ventilation, 18 patients on ECMO, and 26 patients mechanically ventilated.

Results: Results collected showed significant gradient between NP and deep lung viral loads (Figure 1). Median Ct value was 29 for NP samples and 24 for deep lung samples. Of 51 paired samples, 16 were negative (below limit of detection) on NP swabs but positive (above limit of detection) on deep lung sample, whilst 2 were negative on deep sample but positive on NP (both patients were on ECMO).

Figure 1 : Comparison of viral load of paired samples from nasopharynx (NP) and deep lung (endotracheal aspirate or BAL). Red line indicates median value. P value by Wilcoxon matched pairs test

Conclusion: It has been suggested that whilst SARS-CoV1 tends to replicate in the lower respiratory tract, SARS-CoV2 replicates more vigorously in the upper respiratory tract². These data challenge that assumption. These data suggest that viral migration to, and proliferation in, the lower respiratory tract may be a key factor in the progression to critical illness and the development of severe acute respiratory syndrome (SARS). Factors which promote this migration should be examined for association with severe COVID-19. From a practical point

of view, patients with suspected severe COVID-19 should have virological samples obtained from the lower respiratory tract where-ever possible, as upper respiratory samples have a significant false-negative rate.

Caregivers resilience during CoVID 19 pandemic, Return from experience

Y.L. Nguyen¹; C. Baillard¹; M. Samama¹

¹Anesthesiology and critical care department, Cochin Hospital, Paris, France

Correspondence: Y.L. Nguyen

Intensive Care Medicine Experimental 2020, **8(2)**: 001038

Introduction: The CoVID19 pandemic led to a complete reorganization of our anesthesiology and critical care medicine department (composed of 8 ICU beds, 12 intermediate care unit beds (IMCU) and 32 operating rooms (OR))(1). In order to face the increasing demand of ICU beds, our 12 IMCU beds were transformed into ICU beds, 40 ICU beds were created within the 3 post-anesthesia care units of our hospital, leading to a total of 60 ICU beds and only 13 OR remaining opened. The majority of caregivers working usually in the OR worked in these new ICUs outside the walls from March 23d to May 7th 2020.

Objectives: One month after the end of the pandemic, we conducted an anonymous e-survey among caregivers of our department, with the aim of identifying what happened, what went right, what went wrong and what to do in the case of a second wave of CoVID19 infections.

Methods: This project received the approval of the research ethics committee of the French Society of Anesthesiology and Intensive Care Medicine (SFAR). Participation was free. Our survey was composed of 10 questions with rating scales (0 to 10) to assess job satisfaction, quality of care delivered and quality of life at work, with tick box categories and free text to evaluate the main positive/negative points related from their experience and the main actions to be taken in case of a second wave, with Likert scales to evaluate the relationships between caregivers and on demographic data.

Results: 130 people answered our questionnaire, mainly women (n = 84; 65%), the majority younger than 40 years old (n = 94; 72%) and the majority with a past experience in critical care (n = 92; 71%). The participation rate varied across professions: 100% for head of nurses (n = 3), 65% for nurses (n = 44), 45% for anesthetist nurses (n = 22), 47% for nurse assistants (n = 20), 100% for physiotherapists (n = 6); 100% dieticians (n = 2); 50% for residents (n = 16), 70% for physicians (n = 14). The levels of job satisfaction, quality of care delivered and quality of life at work were respectively 6.9 (± 2), 7.2 (± 2) and 5.8 (± 2). The main positive points reported were the collaboration and solidarity between colleagues (n = 76; 58%) and the feeling of being useful (n = 62; 48%). The main negative points reported were the working conditions difficulties (environment, logistics, material protection) (n = 95; 73%) and the lack of visibility of their schedule or hospital ICU organization (n = 36; 27%). The two main areas for improvement suggested were the optimization of logistics organization (n = 74; 57%) and working within the same unit (n = 59; 45%). The majority were satisfied with their relationships with physicians (n = 123; 89%), nurses (n = 127; 98%) or other allied health workers (n = 95; 73%).

Conclusion: During the epidemic, the 3-fold increase of ICU beds and the closing of the majority of OR were associated with a big change in the work habits of our caregivers. Despite the difficulties related to working conditions, caregivers have been strongly resilient with the complete reorganization of our department during the CoVID19 pandemic. The existence of an association with this new organization and patient outcomes must be explored.

Intensive Care Medicine Experimental 2020, **8(2)**: 001048

Introduction: Despite some new evidence, the use of noninvasive continuous positive airway pressure (nCPAP) during coronavirus disease 2019 (COVID-19) is still an issue. In a large population of COVID-19 patients treated with nCPAP we aimed to identify early factors associated with intubation.

Methods: Post hoc analysis of an observational prospective-retrospective multicentre study performed in six Italian hospitals. We included in this analysis all patients treated with nCPAP outside ICU due to COVID-19 and candidate to intubation in case of nCPAP failure. We collected demographic and clinical data at hospital entrance and PaO₂/FiO₂ percentage increase between Venturi mask (PaO₂/FiO₂VENT) and nCPAP (PaO₂/FiO₂nCPAP) i.e., ΔPaO₂/FiO₂, calculated as (PaO₂/FiO₂nCPAP - PaO₂/FiO₂VENT)/ PaO₂/FiO₂VENT × 100.

Results: From March 1st to April 15th, a total of 397 patients with confirmed COVID-19 were treated with nCPAP with a full treatment therapeutic goal. Of these, 8% of the patients were excluded from the analysis as intubated on the same day nCPAP was started. Univariate analysis showed that among the demographic and clinical patients' characteristics, age (65 (IQR, 55-71) vs. 68 (IQR 58-73) years), lactate dehydrogenase (LDH) (518 (IQR, 360-676) U/L vs. 654 (IQR, 486-922) U/L), white blood cells (6.75(IQR, 5.11-8.91) × 10³/μL vs. 7.04 (IQR, 5.17-10.00) × 10³/μL) resulted significantly lower in patients succeeding nCPAP compared to those who failed nCPAP and were intubated. Percentage increase in PaO₂/FiO₂ (87(IQR, 7-203) vs. 44(IQR, 12-120)) was higher in patients who succeeded nCPAP compared to those who failed. Male gender was also significantly associated with intubation. A multivariate analysis adjusting for age, gender, Charlson comorbidity index, percentage increase in PaO₂/FiO₂, lactate, white blood cell count, LDH and C-reactive protein levels led to an area under the curve of 0.77 and confirmed that age (relative risk, 1.023; 95% CI, 1.005-1.043), LDH (relative risk, 1.001; 95%CI, 1.000-1.001), and PaO₂/FiO₂ (relative risk, 1.002; 95%CI, 1.001-1.003), were strong predictors of intubation.

Conclusion: In patients with acute hypoxemic respiratory failure due to COVID-19 receiving nCPAP outside ICU PaO₂/FiO₂, LDH at hospital entrance and age were predictors of intubation.

Incidence of acute kidney injury and provision of renal replacement therapy in critically ill patients with COVID-19

R. Fisher¹; J. Clarke¹; K. Al Arfi¹; R. Saha¹; C. Sharpe²; K. Bramham²; SD. Hutchings¹

¹Critical care, King's College Hospital, London, United Kingdom; ²King's kidney care, King's College Hospital, London, United Kingdom

Correspondence: R. Fisher,

Intensive Care Medicine Experimental 2020, **8(2)**: 001077

Introduction: Amongst patients admitted to intensive care (ICU) with COVID-19 the reported incidence of acute kidney injury (AKI) ranges from 3% to 66%. [1] In the United Kingdom (UK) 26% of patients admitted to ICU with COVID-19 required renal replacement therapy (RRT). [2] At our institution RRT in ICU is usually exclusively provided as Continuous Venovenous Haemodiafiltration (CVVHDF). During early stages of the pandemic it became apparent that demand for RRT - driven by a surge in ICU admissions, high rates of AKI and shorter than usual filter lifespan - threatened our ability to provide timely organ support to critically ill patients with COVID-19, a situation that was being replicated globally. [3] During the first 2 months of the pandemic in the UK we introduced a number of measures designed to extend our ability to provide RRT, including introduction of acute peritoneal dialysis (aPD) and intermittent haemodialysis (IHD).

Objectives: To describe the incidence of AKI in patients admitted to ICU with COVID-19 at a large teaching hospital in London, UK. To evaluate how the introduction of alternative modalities of RRT (aPD and IHD) - not usually offered in our ICU - were able to reduce dependence on CVVHDF. To report any complications associated with using aPD and IHD in these critically ill patients.

Methods: We carried out a retrospective review of patients' electronic medical records as part of a departmental service evaluation (ref: KCC06052020AIA). We recorded baseline demographics, incidence of AKI (defined using KDIGO serum creatinine criteria) [4] and details regarding RRT received and complications of RRT for all patients admitted to our ICU with a diagnosis of COVID-19 between 10/03/2020 (date of first patient admitted with COVID-19) and 10/05/2020.

Results: 177 patients with COVID-19 were admitted to the ICU. Excluding patients who were transferred from other institutions (n = 34) and patients with established End-Stage Kidney Disease (ESKD, n = 7) the incidence of AKI was 79%. Most (86%) developed severe (stage 3) AKI. 63% of patients required RRT, which was initiated a median of 4.5 (IQR 2-7) days after ICU admission. As of 16/06/2020, of patients who developed severe AKI, 49% had died, 8% were still admitted to the ICU, 22% had been discharged from the ICU but were still in hospital and 22% had been discharged home. Almost all ICU survivors had recovered renal function to the point of being free of RRT (95%). Median duration of RRT in those who recovered was 21 (IQR 13-29) days. Peritoneal dialysis catheter insertion was attempted in 41 patients and successful in 34 (83%). 15 patients (44%) were subsequently exclusively treated with aPD, whilst 19 required some supplemental CVVHDF. Common reasons for reverting to CVVHDF included: clinical deterioration not attributed to PD (n = 5); elevated urea (n = 5); fluid overload (n = 4); hyperkalaemia (n = 3). No patients were reported to have had deterioration in ventilatory parameters or peritonitis. A reverse osmosis (RO) plant was installed within the ICU on 18/04/20, and IHD began on 20/04/20. 82 HD sessions were delivered to 15 patients. Transient hypotension was reported during 11 sessions (13.4%). On one occasion the session was terminated due to marked hypotension. At the start of the pandemic 100% of RRT was delivered as CVVHDF. With the introduction of aPD and IHD this fell to a nadir of 39%. During the study period a total of 463 patient days of CVVHDF were replaced with either aPD or IHD.

Conclusion: In our study most patients admitted to ICU with COVID-19 developed severe AKI. It was only possible to provide RRT to these patients by expanding the range of RRT modalities offered to include aPD and IHD. Through close collaboration between the critical care and nephrology departments this was achieved rapidly, effectively and with no serious adverse events during pandemic conditions.

Intensive Care Medicine Experimental 2020, **8(2)**: 001097

Introduction: The energy delivered to the respiratory system during mechanical ventilation can be measured as mechanical power (i.e. work over time) and has been associated with increased in-hospital mortality. [1] A previously proposed concept of mechanical power (here referred to as *Respiratory System-directed Power*) [2] is easy to calculate but includes energy dissipated into the chest wall as well as static work from positive end-expiratory pressure (PEEP), both probably not causal to lung injury. These issues could be addressed by excluding PEEP as well as using transpulmonary pressure (PL) instead of airway pressure (Pao).

Objectives: To compare and assess the agreement between *Respiratory System-directed Power* and two alternative calculations in mechanically ventilated patients suffering from ARDS.

Methods: Using data from a previous, randomized trial (EPVent) [3], mechanical power was calculated from pressure-volume loops: (1) *Respiratory System-directed Power* based on Pao and including static work from PEEP; (2) *Respiratory System-directed Driving Power* based on driving pressure (Pao-PEEP); (3) *Lung-directed Driving Power* based on PL change from end-expiration. Estimates were compared at baseline using repeated measures ANOVA and Bland-Altman analysis. We further investigated how the study intervention - a PEEP titration to achieve positive PL - affected agreement among the estimations.

Results: In 4,803 breathing cycles from 53 patients, *Respiratory System-directed Power* yielded a median 37.2 [IQR 24.1;51.4] J/min, followed by *Respiratory System-directed Driving Power* (14.2 [11.0;19.8]) and *Lung-directed Driving Power* (13.4 [9.9;18.8]) J/min, overall p < 0.001). There was poor agreement between *Respiratory System-directed Power* and the other two estimates (bias 24.2 [20.8; 27.7], limits -0.2 [-6.1;5.7] to 48.7 [20.8;27.7] J/min against *Respiratory System-directed Driving Power* and 25.6 [21.9;29.2], limits -0.5 [-6.8;5.9] to 51.7 [45.3;58.0] J/min against *Lung-directed Driving Power*) and good agreement between *Respiratory System-directed Driving Power* and *Lung-directed Driving Power* (bias 1.4 [95% CI 0.8;1.9], limits -2.3 [-3.2;-1.4] to 5.0 [4.1;5.9] J/min). In a subgroup of 21 patients, *Respiratory System-directed Power* increased after PL-guided PEEP titration by 5.8 ± 12.4 J/min (p = 0.033) with no change in the other estimates, increasing bias and limits of agreement between *Respiratory System-directed Power* and the other two estimates.

Conclusion: In mechanically ventilated patients without spontaneous breathing activity, inclusion of PEEP into calculation of mechanical power may greatly increase the estimate. Calculations including PEEP show poor agreement with calculations excluding PEEP or made based on PL. Clinical data are required to elucidate how these different concepts relate to patient outcome.

Intensive Care Medicine Experimental 2020, **8(2)**: 001103

Introduction: For many decades red blood cells (RBC) transfusion remains the main treatment for acute and even chronic anemia. However, numerous clinical trials estimated the risks of RBC transfusion as comparable with those of anemia and associated with increased mortality [1]. Recognition of the fact promotes search for more rigorous and less formal transfusion triggers.

Objectives: To compare blood transfusion effectiveness assessment based on oxygen extraction ratio (ExRO2), arterial-venous oxygen difference (A-Vdiff) and central venous oxygen saturation (ScvO2) with those using only blood hemoglobin (Hb) level.

Methods: Prospective observational study included 59 patients with mean age of $57 \pm 14,3$ years and initial Hb $72 \pm 12,0g \times l^{-1}$. ScvO2, ExRO2 ((CtaO2–CtvO2)/CtaO2) 100%, A-Vdiff (CtaO2–CtvO2) and serum lactate were measured and calculated before and after RBC transfusion. According to the initial ExRO2 all the patients were divided between two groups – I ($\geq 40,0\%$, $n = 20$) and II ($< 40\%$, $n = 39$).

Results: After transfusion, in group I ExRO2 significantly decreased by $9,1 \pm 2,5\%$ ($p < 0,05$), ScvO2 increased by $7,0 \pm 2,6\%$ ($p < 0,05$), while in group II both ExRO2 and ScvO2 changes were less ($5,9 \pm 1,0\%$ and $5,9 \pm 1,1\%$ respectively, both $p < 0,05$). A-Vdiff after transfusion did not drop significantly in both groups: $0,8 \pm 2,8$ and $0,7 \pm 1,2ml \times l^{-1}$ respectively (both $p > 0,05$). Serum lactate decrease was significant in group I ($0,5 \pm 0,2mmol \times l^{-1}$, $p < 0,05$) and negligible in group II ($0,3 \pm 0,1mmol \times l^{-1}$, $p > 0,05$). Notably, Hb levels were similar among the two groups with different ExRO2 levels before and after transfusion. These results are presented in Table 1.

Parameters	Group I		Group II	
	Before transfusion	After transfusion	Before transfusion	After transfusion
ExRO2, %	43,7±5,6	34,6±8,7	34,0±5,6	28,1±5,8
ScvO2, %	55±5,3	62±8,6	64,2±6,2	70,1±5,8
A-Vdiff, ml×l ⁻¹	40,7±8,4	38,6±12,7	28,6±7,2	28,8±7,1
Lac, mmol×l ⁻¹	1,3±1,0	0,8±0,5	1,1±0,7	0,8±0,7
Hb, g×l ⁻¹	72,7±12,4	81,2±13,0	70,0±12	82,0±12,5

Spearman correlation between ExRO2 and ScvO2 showed strong negative relationship in both groups (before 0,9 and 0,8; after 1,0 and 0,9 respectively); the same coefficient between ExRO2 and A-Vdiff was 0,5 before and 0,8 after transfusion. ExRO2 and Hb demonstrated weak negative connection: $-0,2$ before transfusion in both groups, $0,1$ and $-0,2$ after transfusion in groups I and II respectively.

Conclusion: ExRO2 assesses anemia severity and compensation degree more correctly in comparison to Hb level only. This parameter reveals effectiveness of transfusion, and can be used as the alternative transfusion trigger. ScvO2 has also showed some value as blood transfusion trigger, while having certain restrictions as systemic oxygen balance criterion because of unreliable correlation with mixed venous oxygen saturation.

Intensive Care Medicine Experimental 2020, **8(2)**: 001121

Introduction: Title

Analysis of the STRIVE Phase 2 Trial of Once-Weekly Rezafungin for Treatment of Candidemia and Invasive Candidiasis Compared with Caspofungin: Outcomes by Body Mass Index (BMI)

Authors

Jose A. Vazquez1; Shawn Flanagan2; Peter G. Pappas3; George R. Thompson III4; Taylor Sandison2; Patrick M. Honoré5

1Medical College of Georgia at Augusta University, Augusta, Georgia, USA; 2Cidara Therapeutics, Inc. San Diego, CA, USA; 3University of Alabama, Birmingham; 4University of California-Davis, Davis, California, USA; 5CHU Brugmann University Hospital, Brussels, Belgium

Objectives: There is increasing evidence of antifungal underdosing in the treatment of invasive disease, particularly in special populations such as the obese. Body size is often an important variable affecting drug exposure, and pharmacokinetic (PK) models of antifungal dosing have suggested size-based dose adjustments to achieve target drug exposure.

Rezafungin (RZF) is a novel echinocandin in Phase 3 development for treatment of candidemia and invasive candidiasis (IC) and for prevention of invasive fungal disease caused by *Candida*, *Aspergillus*, and *Pneumocystis* in blood and marrow transplant recipients. Distinctive PK properties of RZF (e.g., long half-life, extensive tissue distribution, and front-loaded drug exposure) lend themselves to RZF once-weekly (QWk) dosing and antifungal efficacy.

Methods: To evaluate outcomes of the Phase 2 STRIVE trial of RZF QWk for the treatment of candidemia and/or IC compared with caspofungin (CAS) once-daily (NCT02734862)1, based on patient BMI.

Results: The STRIVE trial (NCT02734862) compared the safety and efficacy of RZF QWk compared with once-daily caspofungin. For this sub-analysis, data were stratified by BMI categories of $< 30 \text{ kg/m}^2$ and $\geq 30 \text{ kg/m}^2$. Efficacy (overall response [resolution of clinical signs of infection + mycological eradication], mycological response, and investigator assessment of clinical response) and safety (treatment-emergent adverse events [TEAEs]) endpoints by treatment group were evaluated, as well as PK data (area under the curve [AUC]) from RZF-treated patients

Mean BMI values were similar across treatment arms ($26,9 \text{ kg/m}^2$ in RZF Group 1 and $26,8 \text{ kg/m}^2$ in RZF Group 2 and CAS arms). Efficacy outcomes at Day 14 were similar between BMI categories (Table 1). Rates of TEAEs were generally similar between BMI categories as well (Table 2), with no concerning safety trends. Following one dose of RZF 400 mg (Week 1), the ranges of AUCs by BMI category overlapped and there was a minor mean difference of $\sim 20\%$ (lower for those with BMI $\geq 30 \text{ kg/m}^2$).

Conclusion: The safety, efficacy, and PK of RZF in the Phase 2 STRIVE trial was consistent across BMI categories. These results suggest that dose adjustments in obese patients are not necessary. These findings contribute to the evaluation of RZF in a range of patient populations and its ongoing development.

Introduction: A hospitalization due to COVID-19 in the intensive care units (ICU) is challenging for patients, their families, and ICU professionals. In addition to coping with the uncertainties of a widely unknown disease, visits is limited or even prohibited during a pandemic. These restrictions require special attention and trigger unconventional ways for personal contact among ICU professionals with families in order to provide required informations and support.

Objectives: This Delphi study aimed 1) to explore the opinions and experiences of experts during the COVID-19 pandemic in relation to supporting ICU patients and their families; and 2) to provide recommendations for supporting families during a pandemic.

Methods: A two-round modified Delphi process assessed the opinions and experiences of experts from Germany, Switzerland, Austria and Lichtenstein between May and June 2020. Experts included ICU professionals, patients, and family members. 120 experts answered anonymously the first online questionnaires with 33 questions based on a literature review and recommendations of ICU experts. Each question contained an additional comment section. The answers were analyzed and transformed into a second questionnaire with 16 questions and comment sections, which was answered by 131 experts. Data analysis will include descriptive statistics and content analysis of the answers in all comment sections.

Results: First results indicate that experts perceived family support on ICU as highly important during the COVID-19 pandemic. Enabling contact amongst patients, families and clinicians is regarded essential to build hope and confidence. The role of a designated contact person, who delivers frequent and consistent information and builds a supportive and professional relationship, may even be more important. The extraordinary situation leads to the implementation of new communication structures to support families and to document the patients' ICU stay for future processing. The use of video calls, or other forms of communication are mostly wanted under the condition that data security is guaranteed, and that enough personnel and technical resources are available. Some experts see a potential for application of such new resources beyond the current pandemic.

Conclusion: During a pandemic, virtual contacts are essential for COVID-19/ICU patients and respective families to gain and maintain faith confidence in ICU professionals and ICU treatment. Ethical considerations are crucial in deciding what forms of communication would be most appropriate, considering data security, resource distribution, and the information need of patients and their families.

001166**Profiling the physical rehabilitation of COVID-19 patients admitted to critical care**J. Dowds¹; G. Sheill¹; K. O'Brien¹; N. Murphy¹; C. Bannan²; I. Martin-Loeches³

¹Department of physiotherapy, St James's Hospital, Dublin, Ireland; ²Department of genito urinary medicine and infectious disease and school of medicine, St James's Hospital and Trinity College Dublin, Dublin, Ireland; ³School of medicine, Trinity College Dublin, Dublin, Ireland

Correspondence: G. Sheill*Intensive Care Medicine Experimental* 2020, **8(2)**: 001166

Introduction: The COVID-19 pandemic brings a large number of people experiencing critical care admissions. It is important to profile the physical rehabilitation required by patients admitted to hospital with COVID-19 in order to identify the physical side-effects of critical care admission and to determine the rehabilitation services required by this patient group.

Objectives: The aim of this study is to profile the acute rehabilitation pathway of people with COVID-19 admitted to critical care.

Methods: This study was a retrospective patient chart audit of all patients admitted to critical care with COVID-19 between March 16th and May 2nd, 2020. Ethical approval was granted for this study. Demographic information and information regarding critical care stay was collected for each patient. Physical rehabilitation was assessed against standardised rehabilitation milestones as per the ICU Mobility Scale.

Results: A total of 64 patients were admitted to critical care (65% male, mean age 60 years SD 14.1). 56 had a confirmed diagnosis of COVID-19 on testing, while 8 patients were classified as 'highly suspicious' for COVID-19. A total of 14 patients died in critical care and 1 patient remains in critical care, leaving 49 patients for inclusion in the rehabilitation audit. 33 (67%) of these patients were intubated, with an average critical care length of stay of 16 days (SD 15.1, range 2-69 days). All patients were referred for physical rehabilitation during their critical care stay (range: 0-49 sessions).

On average, patients began active rehabilitation sitting over the edge of the bed 11 days (range 3-46 days) after ICU admission. Patients progressed to step transfers from bed to chair a mean of 1.35 days later and mobilised away from the bedside a mean of 4.05 days later. In total 26 (53%) participants experienced a documented oxygen desaturation during physical rehabilitation, the majority while transferring out of bed and mobilising (SaO₂ 90-95% n = 9, SaO₂ 85-90% n = 11, SaO₂ 80-85% n = 4, SaO₂ 75-80% n = 2).

A total of 43 (88%) patients had independent mobility before admission to critical care, while 6 (12%) required mobility aid/assistance with mobility. On discharge from hospital 34 (69%) patients had returned to baseline mobility levels, while 6 patients required increased aids/assistance with mobility when compared to baseline levels. A further 9 patients (18%) were still receiving inpatient rehabilitation at the time of this audit.

Conclusion: Findings of this study indicate that patients with COVID-19 who survived a stay in critical required inpatient physical rehabilitation. Once rehabilitation began, a large proportion of patients progressed quickly through functional mobility classifications to become independently mobile. A sub-set of patients in this audit have required extensive inpatient physical rehabilitation following a critical care stay.

001193**Thrombo-embolic events associated with Covid-19 ARDS – Epidemiology and risk factors**E. de Montmollin¹; D. Faille²; J. Patrier³; M. Marzouk³; L. Lefevre³; S. Ruckly⁴; G. Franchineau³; L. Bouadma³; K. Peoch⁵; V. Andrieu⁶; R. Sonneville³; N. Azjenberg²; J.F. Timsit¹

Correspondence: J.F. Timsit*Intensive Care Medicine Experimental* 2020, **8(2)**: 001193

Introduction: Covid-19 severe ARDS is frequently associated with venous thrombosis and pulmonary emboli. The first events we diagnosed led us to recommend a high heparin prophylaxis (4000 IU enoxaparin bid or 6000 IU bid if weight > 120 kg; targeted anti-Xa activity 0.3-0.5 UI/mL) or an immediate use of curative anticoagulant therapy (enoxaparin 100 IU/kg bid or unfractionated heparin 500 IU/kg/d; targeted anti-Xa 0.5-0.7 UI/mL).

Objectives: To evaluate the risk factors and epidemiology of deep venous thrombosis (DVT) and pulmonary emboli (PE) when this strategy is applied to all the Covid-19 patients with ARDS.

Methods: All the consecutive patients with severe ARDS due to SARS-Cov2 were systematically followed until hospital discharge or day60. Doppler US of the vein was routinely performed to all patients. IV CT scan was performed as clinically indicated. We recorded daily clinical and biological covariates as well as antimicrobial, anticoagulant and anti-inflammatory therapies from ICU admission to ICU discharge. Patients were followed until hospital discharge or day 60. No patient was lost to follow-up.

We use a competing cause-specific risk model to evaluate the risk of DVT/PE during the follow-up (SAS 9.X, SAS system NC, USA). We tested variables at ICU admission and variables collected daily as time-dependent covariates. Variables collected at time t-1 were used to model even occurring at time t. A p value of 0.05 or less was considered significant. The impact of time-dependent DVT/PE on patients' survival was tested using a Cox model.

Results: Of the 134 patients with Sars-Cov2 ARDS admitted in our ICU (age 59.5 [51; 69]; SAPSII: SOFA 5 [4; 7]), 47 (35.1%) died at day 28. 21 developed a DVT/PE (10/21 ultimately died), 45 died without DVT/PE and 68 were censored alive without DVT/PE. Main characteristics of the patients and anticoagulant therapy used at ICU admission are on Table.

The cause specific model identified high SOFA score, use of central vein catheter, hypothermia less than 36 °C, high BUN, high ALAT, high LDH, low hematocrit, high neutrophils count as risk factors of DVT/PE. Neither anticoagulant therapy (curative vs prophylaxis) given the day before nor anti-Xa activity were related with DVT/PE risk. Platelet count, prothrombin time, fibrinogen level, fibrin monomers, D-dimer, troponin levels were not related to DVT/PE risk.

DVT/PE was not related to survival even after adjusting on comorbidities and SOFA score at ICU admission HR = 1.679; 95%CI [0.802; 3.512], p = 0.17

ALAT (U/L)	36 (17; 94.4)	42 (17; 121)	69 (32; 96)	49 (19; 78)
LDH (U/L)	47 (28; 94)	49 (34; 88)	41 (27; 62)	48 (30; 84)
LDH (U/L)	48.2 (19.8; 197.5)	53 (24; 69)	51.0 (16.9; 69.4)	38.9 (33.0; 48.3)
Alkaline phosphatase (U/L)	70 (34; 94)	79 (34; 112)	70 (34; 98)	70 (31; 88)

Conclusion: Even when using a high-risk prophylaxis, curative anticoagulant therapy, DVT/PE occurred in 16% of cases. The risk is higher in patients with high SOFA score, renal and hepatic failure, high neutrophil count suggesting that other mechanisms than coagulation (i.e. endothelial activation and/or hypofibrinolysis) may concur to thromboembolic events.

Intensive Care Medicine Experimental 2020, 8(2): 001197

Introduction: Severe Acute Respiratory Syndrome Coronavirus 2 has spread at great speed throughout the world. Between 15 and 25% of hospitalized patients infected with COVID-19 develop acute kidney injury (AKI).

Objectives: To describe the incidence, evolution and prognosis of Acute Kidney Injury (AKI) in critically ill patients with the COVID-19 disease.

Methods: A multicenter, descriptive, observational study including COVID-19 patients admitted to 19 Catalan UCIs. Usual demographic variables, drugs, AKI development, several therapies, mortality and ICU/hospital stay were collected.

Descriptive statistics and logistic regression analysis for AKI development and mortality were used.

Results: A total of 936 patients were enrolled, of whom 66% were men and mean age was 64(17) years. APACHE II and SOFA scores were 13(8) and 5(4), respectively. Viral pneumonia with ARDS was observed in 88% of the patients. MV was required by 76% of patients, and in addition, 56% required prone position, 66% received vasopressors and 51% treatment with glucocorticoids. AKI prevalence at ICU admission was 28.4% and increased during ICU stay up to 43.6%: 29.4% was developed in the first 72 hours and 36% in the following 7 days. Only 88 (9.3 %) required RRT.

AKI occurred more frequently in older patients (66 years vs 59 years), males (74% vs 61%), those with higher ICU scores (APACHE II: 15 vs 10, SOFA: 6.5 vs 5), hypertension (58% vs 42%), CPOD (9.7% vs 5.9%), CKD (10% vs 1, 3%), diabetes mellitus (29% vs 18%) and chronic ischemic heart disease (7% vs 4%).

AKI was more frequent in ARDS severe patients (59% vs 43%, p < 0.001), in MV patients (91.5% vs 78%, p < 0.001) and required more prone position (69% vs 58%, p < 0.001). The treatment included Remdesivir (2.3% vs 0.5%, p < 0.039), interferon (32% vs 23%, p < 0.009), glucocorticoids in patients with shock (6% vs 1.1%, p < 0.001) and vasopressors (86% vs 63%, p < 0.001).

AKI patients developed more infections during ICU stay: ventilator associated pneumonia (VAP) (35% vs 22%, p < 0.001) and catheter related bloodstream infections (17% vs 11%, p < 0.021).

Risk factors associated with AKI development were age (IC 1.02-1.05), gender (male IC 1.4-2.9), APACHE II (1.02- 1.07), SOFA (1.1-1.2), CKD (3.13-21.6), Shock (2.03-4.4) and VAP (1.11-2.3).

Mortality in ICU stay was 30% and overall in-hospital mortality 33%. Mortality was increased in AKI patients in both groups: ICU stay (47% vs 15%, p < 0.001) and in-hospital (51.7 % vs 16.5 %, p < 0.001).

AKI was an independent factor associated with mortality (IC 1.5 – 3.45). Mortality was higher in patients that required RRT both in the ICU (57 % vs 44 %, p < 0.04) and in-hospital (62.5% vs 48%, p < 0.03). The duration of ICU stay was longer in AKI patients (22 vs 16 days, p < 0.001).

Conclusion: There is a high incidence of AKI in critically ill patients with COVID 19 disease and it is associated with higher mortality, increased organ failure, nosocomial infections and prolonged ICU stay.

001203**Delirium Prediction in COVID-19 Intensive Care Unit: A Bayesian Model with Informed Priors (DELIPIOUS)**A. Al-Hindawi¹; J. Sokhi¹; F. El-Hibri¹; A. Hill¹; A. Sisson¹; M. Vizcaychipi¹¹Intensive care unit, Chelsea and Westminster Hospital, London, United Kingdom**Correspondence:** A. Al-Hindawi*Intensive Care Medicine Experimental* 2020, **8(2)**: 001203

Introduction: Patients infected with COVID-19 are recognised to have a spectrum of neurological complications. In a systematic review, of those who survived, 65% developed delirium during their intensive care stay [1]. Current models assessing delirium in the Adult Intensive Care Unit (AICU), such as E-PRE-DELIRIC, lacks discriminant variables for the prediction of delirium in patients with COVID-19 [6]. Furthermore; the increased in length of stay (LOS) for those with COVID-19 (average 20 days) invalidates models such as E-PRE-DELIRIC which has been modelled on an average LOS of 6 days.

The pathogenesis of delirium in AICU is thought to be a combination of disease severity, hypoxia, highinflammatory response and thrombosis; all elements present in patients with COVID-19 [3–5]. Consequently, further research into mental health surrounding COVID-19 has been set as a priority [6].

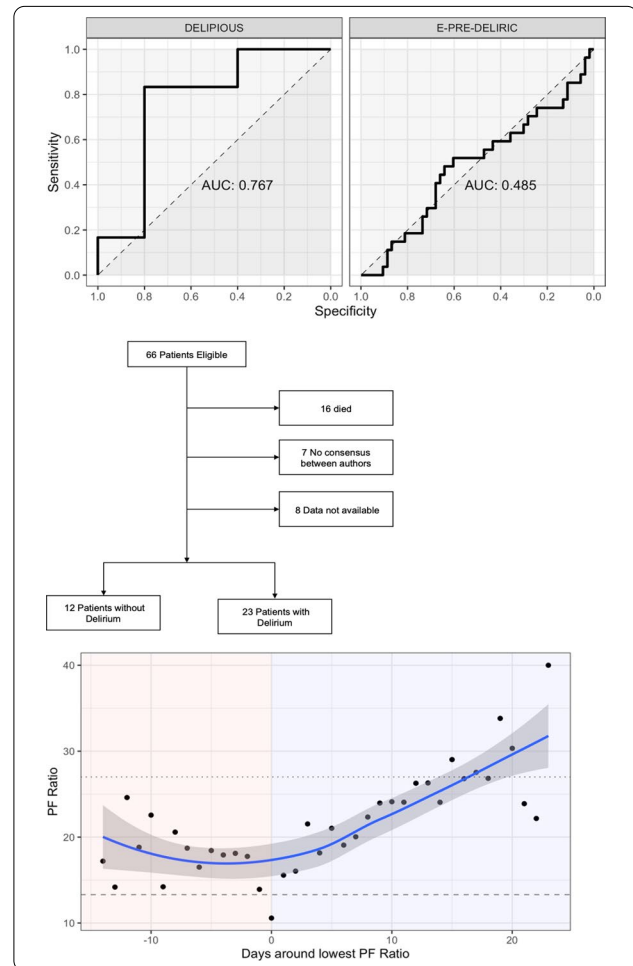

Objectives:

1. To test the validity of E-PRE-DELIRIC in patients with COVID-19.
2. Develop an internally valid, COVID-19 specific, delirium prediction model using Bayesian Hamiltonian Markov Chain Monte Carlo methods.

Methods: Anonymised data from SARS-CoV-2 positive patients admitted to AICU at Chelsea and Westminster Hospital was collected from the 9th of March to the 18th of May 2020. CAM-ICU or author consensus was used to identify patients who underwent delirium assessment. Observational, pathological, and ventilatory variables from patients were extracted from electronic patient records. Forward variable selection strategy was used in the patient's recovery phase; this phase was identified through dichotomisation of their AICU stay following an alignment procedure that centres the patients' stay, such that day 0 is the day with their lowest PaO₂/FiO₂ (PF) ratio. The resulting dataset was split into a training cohort (80%) and a validation cohort (20%). Analysis was performed in R version 4.0. Candidate variables were standardised to a mean of 0 and a standard deviation of 1 prior to the use of BRMS as an interface to Stan. Receiver Operator Curves (ROC) and the Area Under the Curve (AUC) are used to demonstrate model performance.

Results: 66 patients were screened of which 31 were excluded resulting in the identification of 23 patients with delirium and 12 patients without delirium (Figure 1).

The alignment procedure successfully identified the recovery phase with U-shaped PF ratio pattern centred on the lowest ratio (Figure 2). E-PRE-DELIRIC was found to be inaccurate in the prediction of delirium in patients with COVID-19 with an AUC of 48.6%. DELIPIOUS, a Bayesian model with priors informed from both the delirium and COVID-19 literature, was developed demonstrating good performance with an AUC of 76.7% (Figure 3). The proposed model uses biologically plausible variables that reflect the pathogenesis of delirium in COVID-19. By defining the recovery period and using values within, temporal relationship between the timing of the variables' values and onset of delirium is maintained. This reduces the lag-time between variable value and outcome given the prolonged stay of COVID-19 patients resulting in higher accuracy.

Conclusion: E-PRE-DELIRIC has a poor performance in those with COVID-19. DELIPIOUS uses biologically plausible variables that reflect the pathogenesis of delirium in COVID-19 resulting in an accuracy of 76.7%. It requires external and prospective validation prior to its clinical use.

Intensive Care Medicine Experimental 2020, **8(2)**: 001264

Introduction: A substantial proportion of Intensive Care unit (ICU) survivors develops psychological impairments in the aftermath of ICU treatment, such as post-traumatic stress disorder (PTSD), anxiety and depression (1). These impairments are the major determinant for decreased health-related quality of life (HRQoL) (2), and it is hypothesized that an unmet need for information regarding ICU-treatment might be an important contributing factor (3). An effective evidence-based treatment for these psychological impairments and this need for information is still lacking. Virtual reality (VR) exposure therapy for several psychological disorders is effective and safe and could provide an adequate method to deliver the desired information of the ICU period (3). To date, it is unknown whether Intensive Care specific VR exposure in survivors of critical illness decreases psychological sequelae.

Objectives: To examine the effect of ICU-specific Virtual Reality (ICU-VR) on psychological sequelae and quality of life.

Methods: We conducted a multicenter, randomized pilot study in ICU patients admitted with sepsis or septic shock and mechanically ventilated for ≥ 24 hours. A week after ICU discharge, patients were randomized into the control or intervention group. The intervention group received ICU-VR, providing both exposure to the environment traumatizing them in combination with information regarding several aspects of their ICU treatment. The control group received a static VR environment for the same duration of time. Safety of ICU-VR was assessed by monitoring vital signs and the simulator sickness questionnaire (SSQ). Psychological sequelae and HRQoL were assessed at baseline (T0) and 2 days (T1), 7 days (T2), 1 month (T3) and 6 months (T4) after initial exposure to VR. Depression was assessed using the Beck Depression Inventory (BDI), and PTSD using the Impact of Event Scale - Revised (IES-R). HRQoL was assessed using the Short-Form 12 (SF-12) and the EuroQol 5 dimensions (EQ-5D).

Results: We included 50 patients, median age 61 years (IQR: 51-68), median APACHE IV score of 77 (IQR: 57-106) and an median ICU length of stay of 16 days (IQR: 8-31). During VR exposure, no changes in vital signs were observed and none of the individual SSQ items were scored as severe. After 1 month (T3), patients in the intervention group scored significantly lower on PTSD (IES-R sum score, median (IQR): 8 (3-13) vs. 17 (12-26), $P = 0.003$) and depression (BDI sum score, median (IQR): 8 (6-12) vs. 12 (8-18), $P = 0.04$). This effect persisted at 6 months after ICU discharge (T4) for PTSD (IES-R sum score, median (IQR): 5 (1-13) vs. 23 (10-27), $P = 0.01$), but not for depression (BDI sum score, median (IQR): 4 (2-12) vs. 10 (6-17), $P = 0.07$) (Figure). Subsequently, although we observed no difference in the physical quality of life between groups, patients in the intervention group reported a better mental quality of life 1 month after VR exposure (Mental Component Scale (MCS-12), median (IQR): 57 (53-61) vs. 47 (39-49), $P = 0.002$), but not at 6 months after ICU discharge (MCS-12, median (IQR): 50 (41-58) vs. 47 (39-56), $P = 0.43$).

Conclusion: We demonstrate that ICU-VR decreases PTSD and depression up to 6 months after ICU discharge, is safe and improves mental quality of life. Further research is needed to confirm these effects on a larger scale.

Intensive Care Medicine Experimental 2020, **8(2)**: 001268

Introduction: Although patients with SARS-CoV-2 infection have several risk factors for ventilator-associated lower respiratory tract infections (VA-LRTI), the reported incidence of hospital-acquired infections is low.

Objectives: We aimed to determine the relationship between SARS-CoV-2 pneumonia, as compared to influenza pneumonia or no viral infection, and the incidence of VA-LRTI. Secondary objectives were to determine the relationship between SARS-CoV-2 infection and the etiology and outcomes of VA-LRTI.

Methods: Multicenter retrospective European cohort performed in 36 ICUs. All adult patients receiving invasive mechanical ventilation for more than 48h were eligible for this study if they had: SARS-CoV-2 pneumonia, influenza (A or B) pneumonia, or no viral infection at ICU admission. VA-LRTI, including ventilator-associated tracheobronchitis (VAT) and ventilator-associated pneumonia (VAP), were diagnosed using clinical, radiological and quantitative microbiological criteria. All VA-LRTI were prospectively identified, and chest-X rays were analyzed by at least two physicians. Cumulative incidence of first episodes of VA-LRTI was estimated using Kalbfleisch and Prentice method, and

compared using Fine-and Gray models. This study is registered on ClinicalTrials.gov, NCT04359693.

Results: 1576 patients were included (568 in SARS-CoV-2 group, 482 in influenza group, and 526 in no viral infection group). VA-LRTI incidence was significantly higher in SARS-CoV2 patients (287, 50.5%), as compared to influenza patients (146, 30.3%, adjusted sub hazard ratio (SHR) 1.60 (95% confidence interval (CI) 1.27 to 2.00)) or patients with no viral infection (133, 25.3%, adjusted SHR 1.65 (95% CI 1.22 to 2.22)). VA-LRTI were mainly caused by Gram-negative bacilli (*Pseudomonas aeruginosa*, *Enterobacter* spp., and *Klebsiella* spp.). VAP was associated with increased adjusted HR for 28-day mortality in SARS-CoV-2 and influenza groups, and for duration of ICU stay in all study groups.

Conclusion: The incidence of VA-LRTI is significantly higher in patients with SARS-CoV-2 infection, as compared to patients with influenza pneumonia, or no viral infection.

Zarit Burden Interview to evaluate main caregivers overload in Intensive Care Chronic patients

O. Moreno Romero¹; A. Carranza Pine¹; M. Muñoz Garach¹

¹Intensive care unit, Hospital Universitario Clínico San Cecilio, Granada, Spain

Correspondence: O. Moreno Romero

Intensive Care Medicine Experimental 2020, **8(2)**: 001279

Introduction: Critically ill patients survival is increasing nowadays parallel to fragility and morbidity in long term surviving ICU patients, thus the role of caregivers in some cases has become essential.

Objectives: First, to evaluate the main caregiver overload of chronic patients roled in our Home Mechanical Ventilation Unit (driven by intensive care physicians) using the Zarit Burden Interview. Secondly, to describe the characteristics of our caregivers and patients.

Methods: The evaluation was perform with a presential interview to the main caregiver of all the patients included in our program during 12 months, from January 2018 to January 2019. We applied the Zarit Burden interview, which classifies the caregiver as a sum of various items, in 3 grades: absence of overload (< 46 points), mild overload (46-55), heavy overload (> 56 points) (Figure 1). Epidemiological data of caregivers (age, sex, number of carers, state economical help) and patients (age, sex, Barthel Index, diagnostic).

THE ZARIT BURDEN INTERVIEW

Please circle the response the best describes how you feel.

	Never	Rarely	Sometimes	Quite Frequently	Nearly Always	Score
1. Do you feel that your relative asks for more help than he/she needs?	0	1	2	3	4	
2. Do you feel that because of the time you spend with your relative that you don't have enough time for yourself?	0	1	2	3	4	
3. Do you feel stressed between caring for your relative and trying to meet other responsibilities for your family or work?	0	1	2	3	4	
4. Do you feel embarrassed over your relative's behaviour?	0	1	2	3	4	
5. Do you feel angry when you are around your relative?	0	1	2	3	4	
6. Do you feel that your relative currently affects our relationships with other family members or friends in a negative way?	0	1	2	3	4	
7. Are you afraid what the future holds for your relative?	0	1	2	3	4	
8. Do you feel your relative is dependent on you?	0	1	2	3	4	
9. Do you feel strained when you are around your relative?	0	1	2	3	4	
10. Do you feel your health has suffered because of your involvement with your relative?	0	1	2	3	4

12. Do you feel that your social life has suffered because you are caring for your relative?	0	1	2	3	4	
13. Do you feel uncomfortable about having friends over because of your relative?	0	1	2	3	4	

Results: In 12 months, 49 patients and caregivers were roled in our study. Zarit Burden Scale of caregivers: 6 (12,2%) absence of overload, 28 (57,1%) mild overload and 15 (30,6%) with heavy overload.

Caregiver Characteristics: mean age 53,58 ± 15,61, women 38 (77,5%); one single caregiver in 28 (57,1%); state economical significant help in 26 (53%).

Patient data: mean age 43,73 ± 13,1, man 33 (67,3%), Barthel Index 45,42 ± 33,2 (IC95% 36,1-54,7), diagnostic: Amyotrophic Lateral Sclerosis ALS in 22 (45%), other myopathies and neuromuscular diseases 16 (32,6%), difficulty in weaning 11 (22,4%) due to mechanical ventilation dependency: COPD (6), critical patientpolineuromiopathy (4), others (1). From these, NIMV (6), IMV (5).

Conclusion: In our caregivers using the Zarit Burden Scale shows that more than 85% have moderate-severe overload. Women is the prevalent carer (77%). Neumomuscular diseases is the most importante cause for roling our unit, becoming ALS the most prevalent disease (45%). This unit has become a great alternative for patients with difficult in weaning in our in intensive care units, 11 patients (22,4%) can be treated at home with their families, even so, bigger efforts needs to be performed to improve overload in caregivers.

Correspondence: T.J. McClelland

Intensive Care Medicine Experimental 2020, **8(2)**: 001303

Introduction: ICU-acquired infections (ICU-AI) are associated with substantial morbidity and mortality, but there are few large-scale epidemiological studies and investigations of risk factors, including predictive biomarkers, are currently limited. Genomic-led approaches identified two distinct Sepsis Response Signatures (SRS1 and SRS2) using hierarchical clustering of leucocyte genome-wide gene

expression in patients admitted to ICU with sepsis [1]. The SRS1 endotype is characterised by features of immunosuppression and increased mortality.

Objectives: To elucidate the risk factors for ICU-AI, compare outcomes between those with or without ICU-AI, and assess the influence of SRS endotype on ICU-AI.

Methods: Patients in whom ICU-AI was clinically diagnosed at any time during ICU admission were identified from a cohort of 2054 patients admitted with sepsis to 34 ICUs in the UK [2]. 1697 (82.6%) patients with an ICU length of stay > 48 hours were included in the analysis. Univariate analysis comparing between those with and without ICU-AI was calculated for continuous variables using linear model ANOVA and Kruskal-Wallis test (for non-normally distributed data), and Pearson's Chi-squared test (X²) (categorical variables). Logistic regression modelling used all potentially significant independent variables from univariate analysis ($p < 0.2$), with backward selection of significant variables for the final models. A weighted Cox-regression model was used to assess effect of ICU-AI on 6-month mortality.

Results: A total of 687 ICU-AIs were recorded. 462 (27.2%) patients developed one or more ICU-AI. The most common were ventilator-associated pneumonia ($n = 208$, 12.3% of all patients), line-related infection ($n = 115$, 6.8%), and wound infection ($n = 111$, 6.5%). These accounted for 63.2% of all ICU-AIs. Patient demographics (age, race, sex, Charlson score) did not differ between those with or without ICU-AI. Those with ICU-AI had higher severity scores on admission (APACHE II score [median 18 vs 16, $p < 0.001$], SOFA score [median 8 vs 6, $p < 0.001$]). ICU-AI was significantly associated with the level of organ support and steroid therapy [$p < 0.001$]. In those in whom SRS endotype had been assigned ($n = 871$), the last available SRS endotype was significantly associated with ICU-AI. In patients with the SRS1 (immunosuppressed endotype), 30.8% ($n = 89$) developed an ICU-AI compared to 20.8% ($n = 121$) of those with the SRS2 (immunocompetent endotype) ($p = 0.002$, X²). Renal replacement therapy (RRT) (OR 1.85, 95% CI 1.11-3.09, $p = 0.019$) and inotropic support (OR 1.84, 95% CI 1.17-2.91, $p = 0.009$) were independent risk factors for ICU-AI. ICU-AI was associated with increased risk of death at six months (HR 1.31, 95% CI 1.08 - 1.61, $p = 0.0056$).

Conclusion: Risk factors for ICU-AI include illness severity, level of organ support, steroid therapy and the SRS1 transcriptomic endotype. RRT and inotropic support were independently associated with ICU-AI. ICU-AI is associated with increased mortality.

Intensive Care Medicine Experimental 2020, **8(2)**: 001307

Introduction: Patients admitted to intensive care units (ICUs) are at higher risk of death because of their underlying illness, often worsened by the occurrence of healthcare associated infections (HAIs). The

Simplified Acute Physiology Score (SAPS) II is one of the most used scoring systems to evaluate the severity of illness of patients admitted to ICU and to predict their risk of dying.

Objectives: The main aim of this study was to evaluate the ability of SAPS II to predict the risk of 7-day mortality of patients admitted to ICU, and to compare its performance with a machine learning algorithm combining the SAPS II with additional patients' characteristics at ICU admission.

Methods: For this purpose, we used data from seven biennial editions (i.e. from 2006-2007 to 2018-2019) of the "Italian Nosocomial Infections Surveillance in Intensive Care Units" (SPIN-UTI) project. Overall, 3,782 patients staying in ICU for at least 7 days and those who died within the same timeframe constituted the test set. The training set, instead, was made of 4589 recovered and synthetic records. The accuracy of the SAPS II for predicting 7-day mortality was evaluated using the receiver operating characteristic (ROC) curve and computation of the Area Under the Curve (AUC). Next, the Support Vector Machine (SVM) algorithm was applied to improve the predicting performance of the model, by combining the SAPS II with the following variables collected at ICU admission: gender, origin of the patient, trauma patient, impaired immunity, antibiotic treatment, patient needed acute coronary care, surgery before ICU admission, presence of intubation, presence of urinary catheter, presence of central vascular catheter.

Results: The proportion of deaths was 23.1% in the test set and 43.4% in the training set, respectively. No differences in the SAPS II and other patient's characteristics at ICU admission were evident. The SAPS II was able to discriminate patients who died from those who did not, with an accuracy of 69.3% and AUC of 0.678 (95%CI = 0.657 - 0.700). However, the SVM algorithm improved the predicting performance of the model, reaching an accuracy of 83.5% and AUC of 0.896 (95%CI = 0.881 - 0.910). Notably, the SAPS II was the predictor which weighted more on the model. Indeed, both accuracy and AUC dropped to 68.4% and 0.653 (95%CI = 0.632 - 0.675) by removing the SAPS II from the algorithm.

Conclusion: The SVM algorithm - which combined the SAPS II with additional patients' characteristics at ICU admission - exhibited higher predicting performance than the SAPS II alone. This model represented a simple tool to quickly predict patients at the highest risk of death at ICU admission, allowing them to be prioritized and potentially reducing the mortality rate.

Introduction: Severe Acute Respiratory Syndrome Coronavirus 2 has spread at great speed throughout the world. Between 15 and 25% of hospitalized patients infected with COVID-19 develop acute kidney injury (AKI).

Objectives: To describe renal replacement therapy (RRT) in COVID-19 patients at the admission in intensive care units (ICU).

Methods: A multicenter, descriptive, observational study of COVID-19 patients admitted to 19 Catalan ICUs. Patients with acute kidney injury (AKI) and RRT requirements were included. Data of descriptive variables including severity and evolution of the AKI, associated complication, circuit permeability, filter duration and need of RRT at discharge were analyzed. Frequency and percentage (categorical) and mean (SD) or median (RI) (quantitative) are presented. X²/T-Fischer or T-Student/U-Mann Whitney were applied. Data were presented as frequency (percentage) and mean (standard deviation) or median (95%RI).

Results: A total of 934 patients were included, 66% men, mean age 64(16.8) years. APACHE II and SOFA at admission were 13(8) and 5(4) respectively. Information was collected on the following comorbidities: arterial hypertension (45%), obesity (34%), diabetes mellitus (20%) and COPD (7%). Chronic kidney disease was present in 4.5% of patients. AKI at the ICU admission was 28.4% and increased to 44% during ICU stay. NSAIDs were administered to 25.9%, contrast-media to 18.8% and ACE inhibitors to 10.5%. AKI patients presented ventilator-associated pneumonia VAP (35.7%), UTIs (16.6%) and intravascular catheter-related infection (14%).

A total of 88 patients (9.3%) required RRT. At the initiation of RRT patients presented with KDIGO I: 2.5%, II: 6.2%, III: 91.4% (creatinine mean was 3.91(1.6) mg/dL). Indications of RRT initiation were: anuria (62%), fluid overload (51.1%), hyperkalemia (33%), sepsis (20.5%) and uremic syndrome (14.8%). RRT duration was 7 (RI 9) days (CVVHDF (62.4%), CVVHD (35.3%), CVH (2.4%)); and iHD 3 (RI 6.5) days.

Heparin was the most commonly prescribed anticoagulant for use during continuous RRT (61.4%), followed by ARC (45.5%) and a minor percentage of no anticoagulation (6.8%). Filter/patient median was 3 (RI 4); filter life with ARC was 2 (RI 1.23), with heparin 1.71(1.53) and without anticoagulation 1(1.63) days. Complications: catheter dysfunction (26.1%), early/non expected coagulation (23.9%), thrombocytopenia (14.8%), bleeding (5.7%) and hypothermia (5.7%). Only one patient required adsorption techniques. A quarter of patients (24.7%) needed RRT at ICU discharge. Overall ICU mortality was 57.1% in RRT patients, 44.3% in AKI without RRT and 14.9% in patients without AKI.

Conclusion: A high percentage of patients required RRT for AKI at the admission or during ICU stay, with a mortality rate exceeding 50%.

Management and complications are not different from the usual clinical practice.

Introduction: Surgery initiates inflammation which contributes to postoperative morbidity and mortality.

Objectives: We aimed to assess the effects of dexamethasone on postoperative complications in patients undergoing major surgery.

Methods: In a multicenter, randomized, double-blind trial, patients over 50 years of age undergoing non-cardiac surgery with expected duration of more than 90 minutes were recruited from 34 centers. We randomly assigned patients to dexamethasone (0.2 mg.kg⁻¹ immediately after the procedure, and on day + 1) or to placebo. Randomization was stratified on two criteria: cancer and thoracic procedure. The primary outcome was a composite of major complications (including sepsis, pneumonia and the need for mechanical ventilation) and all-cause mortality occurring within the first 14 days following surgery.

Results: Of the 1,222 patients, 613 patients were randomized to dexamethasone, and 609 to placebo. In intention-to-treat analysis after multiple imputation for missing data, 104 patients (17.1%) in the dexamethasone group and 123 patients (20.4%) in the placebo group had major complications or died within 14 days after surgery (adjusted odds ratio, 0.78; 95% confidence interval [CI], 0.59-1.04; P = 0.09, crude odds ratio 0.79; 95%CI, 0.60-1.07, P = 0.13). The hazard ratios with dexamethasone for sepsis (including pneumonia) and for mechanical ventilation were respectively 0.82 (95%CI 0.61-1.12, P = 0.21) and 0.68 (95%CI 0.53-0.88, P = 0.003). In the a priori defined randomization stratum of patients with non-thoracic surgery, primary outcome occurred less frequently in the dexamethasone group than in the placebo group (P = 0.04). Adverse events were reported in 47% and 48.6% of patients who received dexamethasone or placebo (odds ratio: 0.92; 95%CI 0.74-1.15).

Conclusion: After major non-cardiac surgery, dexamethasone did not result in significantly less mortality or fewer major complications 14 days after surgery. (Funded by French Ministry of Health, PHRCN 2016, number clinicaltrials.gov NCT03218553).

Intensive Care Medicine Experimental 2020, **8(2)**: 001320

Introduction: It is unclear when the effects of the coronavirus will subside and a surge in demand for critical care follow-up is anticipated. The requirement to provide a rehabilitation service within the context of social distancing and reconfigured outpatient infrastructure presents a set of new challenges to the delivery of optimal patient care.

Objectives: 1. To explore the feasibility of managing critical care recovery via remote coaching enabled by smartwatch technology. 2. Report physical measures at the point of hospital discharge and on follow-up

Methods: The use of smartwatch ambulatory health monitoring technology in COVID-19 critical care discharges was set up across eight trusts in Surrey, Sussex and Kent, UK. Worthing Hospital also implemented a digitally integrated multidisciplinary team (MDT) approach (physiotherapists, exercise physiologist, critical care, respiratory and general practice clinicians) using this smart watch data to support our critical care COVID-19 survivors. Smartwatch data was shared by the patient with the MDT via synchronisation with a smartphone app. The MDT met remotely every 4 weeks to review patients' progress and discuss goal setting. Baseline data was collected at discharge and follow up data points are at 3 months and 12 months respectively.

Results: From the first 13 patients reviewed (mean age 58, SD 10), mean heart rate per minute has slowed from 98 (SD 11) at hospital discharge to 75 (SD 5) at six weeks, whilst daily step count has increased from 1187 (SD 486) to 5407 (SD 3153). Shuttle walk test distance increased from 69 metres (SD 78) at hospital discharge to 364 (SD 221) on three-month follow-up, with air oxygen saturations increasing from 86% (SD 8) to 93% (SD 3). The MDT were able to provide a patient personalised follow up pathway, providing earlier intervention than would have occurred with a face-to-face patient follow up.

Patient engagement with the programme was high with over 90% of patients regularly wearing and uploading smartwatch data. Patients responded well to the technology and incorporated the feedback from the devices into their personalised rehabilitation programmes. As further patients return for follow up this dataset will increase substantially over time.

Conclusion: Remote rehabilitation is feasible and offers an alternative to traditional post critical care follow-up. Regular, proactive review of smartwatch data combined with a remote MDT facilitated a unique, personalised and sustainable model for post critical care follow up. Future work will aim to expand this model to a wider cohort of critical care survivors.

Intensive Care Medicine Experimental 2020, **8(2)**: 001322

Introduction: During novel coronavirus disease (COVID-19) pandemic outbreak, a large number of patients required respiratory support due to severity of the respiratory involvement. Noninvasive ventilation delivered as continuous positive airway pressure (CPAP) for de novo acute hypoxemic respiratory failure (ARF) is still debated. To face the overwhelming wave of patients, hospitals converted many general wards in respiratory intermediate units (RICU), where COVID-19 patients requiring respiratory support could be treated with CPAP outside intensive care unit (ICU).

Objectives: The study aims to investigate the role of CPAP outside ICU during COVID-19 pandemic, describing the clinical characteristics of patients and ascertaining whether the CPAP duration affects outcome in patients requiring endotracheal intubation.

Methods: We performed a multicenter, retrospective observational study in six hospitals of Eastern Piedmont Region in Northern Italy. All patients admitted to one of the participating hospitals from March 1st to April 15th 2020 with hypoxemic ARF secondary to COVID-19 infection were eligible. Inclusion criteria were: 1) age \geq 18 years, 2) respiratory distress and partial pressure of arterial oxygen to fraction of inspired oxygen ratio $<$ 200 mmHg during low flow oxygen therapy, 3) CPAP initiation outside ICU. Patients were classified according to predefined CPAP therapeutic goal in two subgroups: 1) full treatment, i.e. patients scheduled to receive intubation in case of CPAP failure; and 2) do-not-intubate (DNI), when CPAP was the ceiling of treatment.

Results: During the study period, 537 patients received CPAP outside ICU in the six Eastern Piedmont hospitals. The median age was 69 (IQR, 60-76) years. Median CPAP duration was 4 (IQR, 1-8) days, while hospital LOS 16 (IQR, 9-27) days. According to predefined CPAP therapeutic goal, 397 (74%) patients were included in full treatment subgroup, and 140 (26%) in the do-not intubate (DNI) subgroup. Sixty-day in-hospital mortality was overall 34% (95%CI, 0.304-0.384), 21% (95%CI, 0.169-0.249) and 73% (95%CI, 0.648-0.787) for full treatment and DNI subgroup, respectively. In the full treatment subgroup, in-hospital mortality was 42% (95%CI, 0.345-0.488) for 180 (45%) CPAP failures requiring intubation, while 2% (95%CI, 0.008-0.035) for the remaining 217 (55%) patients who succeeded. Delaying intubation was associated with increased mortality [HR, 1.093 (95%CI, 1.010-1.184)].

Conclusion: Our study suggests that CPAP is feasible outside ICU even during COVID-19 outbreak. In-hospital mortality is related to therapeutic goal and patients with pre-set therapeutic limitations showing a higher mortality rate. Intubation delay is an independent risk factor for mortality.

Serum leptin is associated with hypercoagulation measured by thromboelastometry (ROTEM) in COVID-19 disease

N. Van Veenendaal¹; T. Scheeren²; K. Meijer³; P. Van Der Voort⁴

¹Department of critical care/department of anaesthesiology, University Medical Center Groningen, Groningen, Netherlands; ²Department of anaesthesiology/department of critical care, University Medical Center Groningen, Groningen, Netherlands; ³Department of hematology, University Medical Center Groningen, Groningen, Netherlands; ⁴Department of critical care, University Medical Center Groningen, Groningen, Netherlands

Correspondence: N. Van Veenendaal

Intensive Care Medicine Experimental 2020, **8(2)**: 001333

Introduction: Coronavirus disease 2019 (COVID-19) is associated with coagulation abnormalities leading to numerous thromboembolic complications. Obesity is a risk factor for severe COVID-19 disease and patients with obesity have relatively high leptin serum levels. In addition, high serum leptin levels are associated with hypercoagulation. Rotational thromboelastometry (ROTEM[®]) is a digitized modification of thromboelastography reported to be useful in identifying hypercoagulable conditions.

Objectives: The aim of this study was to determine the correlation between serum leptin levels and ROTEM[®] profiles of COVID-19 patients.

Methods: In a cross-sectional design, we included patients who were treated in the Intensive Care Unit with COVID-19 at the same time.

Blood samples were collected for serum leptin measurement (ELISA kit MD53001 IBL International, Hamburg, Germany, performed according to the manufacturer's instructions) and ROTEM® thromboelastometry. Coagulation patterns were analyzed using extrinsic and intrinsic rotational thromboelastometry activators (respectively EXTEM and INTEM). The following variables were recorded and analyzed: clotting time (CT), clotting formation time (CFT), clot firmness' amplitude after 5 minutes (A5) and after 10 minutes (A10), and maximum clot firmness (MCF). Spearman's correlation coefficients were determined for all variables.

Results: Thirty-one COVID-19 patients were included, of which 23 (74%) were male. The mean age was 62.5 years (Standard Deviation (SD) 9.7), and the mean BMI was 31.2 kg/m² (SD 5.7). The median serum leptin level was 12.2 (range 1.0 – 85.2) ug/L. BMI was significantly correlated to serum leptin level $r = 0.49$; $p = 0.001$. Table 1 shows the correlation of leptin and ROTEM variables.

Table 1.	Spearman's correlation	P-value
EXTEM clot formation time (CFT)	-0.410	0.022
EXTEM maximum clot firmness (MCF)	0.210	0.258
INTEM CFT	-0.422	0.018
INTEM MCF	0.262	0.154
FIBTEM CFT	-0.108	0.563
FIBTEM MCF	0.023	0.904

Table 2 shows the correlation of leptin and conventional coagulation variables.

Table 2.	Spearman's correlation	P-value
Platelet function	0.168	0.367
Activated Partial Thromboplastin Time	-0.277	0.139
Prothrombin	0.143	0.350
Fibrinogen	-0.010	0.960
Antithrombin III	0.244	0.129

The only variable that was significantly correlated with serum leptin level was clot formation time, both for EXTEM and for INTEM tests. An inverse correlation was found, meaning that higher leptin levels were correlated with a shorter clot formation time. The conventional clotting tests were not significantly correlated with serum leptin level.

Conclusion: ROTEM® measurements of clot formation time were significantly inversely correlated with serum leptin levels, which may indicate that leptin plays a role in the hypercoagulable state that is present in COVID-19 patients treated in the ICU.

Correspondence: M. Pellegrini

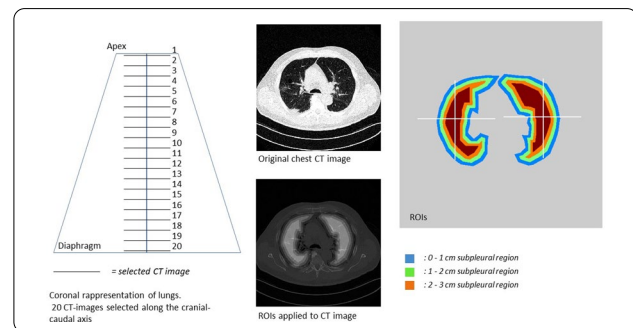

Intensive Care Medicine Experimental 2020, **8(2)**: 001344

Introduction: Specific features differentiate SARS-CoV2-induced acute respiratory failure from the classical definition of acute respiratory distress syndrome (ARDS) [1]. By lung computed tomography (CT) it is possible to characterize extension and severity of lung damage

and infer regional lungs mechanics during ARDS [2]. The role of lung CT for SARS-CoV2 related lung engagement remains to be confirmed.

Objectives: A primarily subpleural distribution of lung infiltrates induced by SARS-CoV2 has been hypothesized. The correlation between the extent of lung infiltrated and days of spontaneous breathing has never been tested before.

Methods: This study has been performed on CT images collected from 20 patients affected by a severe form of SARS-CoV2 infection in need of intensive care. Chest CT, acquired during static conditions and without contrast agent were selected. For each CT, twenty equally spaced images between apex and diaphragmatic dome were analyzed. Each CT image was divided into three subpleural regions of interest (ROIs - between 0 and 1 cm; 1 and 2 cm; 2 and 3 cm) concentric to the visceral pleura. Four quadrants (external non-dependent, internal non-dependent, internal dependent, external dependent) were delineated for each lung, depending on figures centroids (Figure). Quadrants were used to differentiate between atelectasis, affecting dependent regions, and SARS-CoV2 specific lung infiltrates in the external and non-dependent regions. Four lung Hounsfield units (HU) compartments were defined [3]: hyper (– 1,000 to – 800 HU), normally (– 800 to – 500 HU), poorly (– 500 to – 100 HU) and not inflated (– 100 to + 100 HU). Friedman's test (α -value < 0.05) was used for statistics. Days of spontaneous breathing with and without ventilatory support were defined for each patient. Correlations between HU compartments and days of spontaneous breathing were performed (Spearman correlation, r_s , α -value < 0.05).

Results: Twenty-three chest CT were analyzed. Hypo-inflated and not-inflated compartments were significantly more represented in the subpleural regions of the lung (0-1 cm) compared to more central ones (2-3 cm), both in dependent and not dependent quadrants. Consistently, the amount of normo-inflated lung was more represented in deeper regions of the lung. The hyper-inflated compartment was significantly more represented in non-dependent subpleural lung regions (0-1 cm). A positive correlation was found between days of spontaneous breathing and hypo-/not- inflated lung compartments, in not-dependent ($r_s = 0.54$, $p = 0.017$) and external regions ($r_s = 0.49$, $p = 0.032$).

Conclusion: The primarily subpleural distribution of SARS-CoV2 specific lung infiltrates has been confirmed using objective lung-CT analysis. Further, it subsequently extends towards more central regions of the lung. A direct correlation between extent of SARS-CoV2-induced lung infiltrated and days of spontaneous breathing was shown.

Intensive Care Medicine Experimental 2020, **8(2)**: 001357

Introduction: In late 2019, the virus responsible for Covid-19 was identified and called SARS-CoV-2. In China, 5% of Covid-19 patients were admitted in ICU, 2,3% were ventilated and 1,4% died. In early 2020, Covid-19 quickly spread in Europe and was responsible for high mortality. Since the start of the SARS-CoV-2 pandemic, the need for trials to assess the benefit of antiviral treatment, anti-cytokine drugs, convalescent plasma and hydroxychloroquine has been advocated by the world health organization. However, evidence of the efficacy of such strategies is still lacking.

Objectives: This observational multicentric study aimed to identify prognostic factors and therapies which could be valuable in mechanically ventilated Covid-19 patients for respiratory insufficiency.

Methods: The method consisted in a multicentric retrospective analysis in all consecutive Covid-19 patients admitted to intensive care unit (ICU) and mechanically ventilated for more than 24 hours from March 1 to April 25, 2020, in 12 hospitals. The study protocol was approved by our Ethics Committee and, due to the retrospective nature of the data collected, no consent from the patient was required.

Admission date, age, sex, body mass index, underlying conditions, treatments, physiological values, use of vasopressors, renal replacement therapy (RRT) and extracorporeal membrane oxygenation (ECMO), duration of mechanical ventilation, length of ICU stay, ICU and ventilator-free days at day 42 were collected during May 2020. A second call for missing data was done during June 2020 in each center. The primary outcome was survival during the hospital stay. Secondary outcomes included use of vasopressors, RRT or ECMO, ICU and ventilator-free days at day 42, and evolution of the main physiological values between days 0 and 7. Quantitative variables were reported as median and interquartile range (Q1-Q3). Categorical variables were expressed as number (%). Simple and multiple time-dependent Cox regression models were used to assess the effects of factors on survival. All the variables which had a p-value lower than the critical level of 0.1 were selected for the multivariate model. A p-value < 0.05 was considered significant.

Results: From March 1 to April 25, 2020, out of 2003 adult patients hospitalized for SARS-CoV-2 pneumonia, 361 were admitted to the 12 participating ICUs for acute respiratory failure. Of these, 257 patients were ventilated for more than 24 hours and 247 were included in the data base. The median age of the 247 patients was 65 (57-72), and 172 (70%) were men. On admission, the median sequential organ failure assessment (SOFA) score was 6 (4-8), the median PaO₂/FiO₂ ratio was 103 (82-132) and 128 (52%) patients were treated with norepinephrin. The median length of stay in ICU was 21 (12-32) days, the median survival time was 82 days, and the mortality rate was 45%. Sixty-nine (28%) patients needed RRT and 215 patients (87%) were treated with norepinephrine during

their ICU stay. Four patients (1,6%) were on ECMO. Corticosteroid therapy was started in 58 (23%) patients between days 0 and 7 of ICU admission and 225 (91%) patients received hydroxychloroquine alone or in combination with corticosteroid and/or azythromycin. The mortality rate of the patients who received corticosteroid was 34% (20/58) while it was 48% (91/189) for patients who did not (p = 0,01).

As opposed to survivors, non-survivors were older and suffered more often from chronic kidney disease. On admission in ICU, non-survivors had higher SOFA score and serum creatinine value, lower mean arterial pressure and diuresis. Non-survivors were also more often treated with norepinephrine during the first day in ICU. Survivors received more frequently corticosteroid and hydroxychloroquine.

Using multiple regression, the predictors of mortality were age, creatinine value, mean arterial pressure lower than 70 mmHg, lymphocytes count on day 0 and absence of corticosteroid use during the first week of mechanical ventilation. Survival probability was significantly higher in patients who received corticosteroid (p = 0,01). Survival probability was 75% by day 23 for patients who received corticosteroid versus by day 10 for those who did not.

Conclusion: Retrospectively analyzing the data of a multicenter cohort, we observed that mortality of patients with SARS-CoV-2 pneumonia-treated with mechanical ventilation was as high as 45% and median survival time was 82 days. In this series, the risk factors for mortality included age, renal and circulatory dysfunction, lymphopenia and the absence of corticosteroid use during the first week of mechanical ventilation. Corticosteroid therapy during the first week of mechanical ventilation was associated with a lower mortality (34% vs 48%) (p = 0,01).

Intensive Care Medicine Experimental 2020, **8(2)**: 001363

Introduction: In mid-February 2020, an outbreak of atypical pneumonia caused by Severe Acute Respiratory Syndrome CoronaVirus 2 (SARS-CoV-2) represented the beginning of COVID-19 epidemic in Italy. Since then, the number of admissions in intensive care units (ICU) due to bilateral pneumonias progressing to Acute Respiratory Syndrome (ARDS) rose substantially. Lombardy, due to the high number of cases, created a network called 'COVID-19 Lombardy ICU Network' to manage the exponential surge of patients. With all the Data gathered in these patients, we hypothesized that machine learning models could predict the mortality risk in these patients.

Objectives: Predicting mortality at 7, 14 and 28 days from ICU admission in COVID-19 patients using machine learning models.

Methods: Data comprises medications, comorbidities and daily ventilation of 1503 ICU patients from Lombardy affected by COVID-19 during the early phase of the epidemic.

Two machine learning models were built: the first machine learning model was trained only with features available before ICU admission to investigate the predictive power of pre-existing conditions; the second one was integrated with all the data available during the first day of admission in ICU.

Results: The majority (51%) of the cohort faced death; survivors were characterized by significantly lower age, higher length of stay and a minor number of comorbidities at admission. Kaplan-Meier curves reveal a survival percentage drop of 30% within the first 10 days, 45% after 20 days and reaches a plateau around day 30 where the population is halved. As age increases, the percentage of survivors decreases, with lowest survival in the age cohort between 80 and 90.

Best model performance was reached when predicting mortality at 28 days, where average area under the curve (AUC) after multiple

cross-validations were respectively 0.77 and 0.79. There was no major difference in sensitivity and specificity between the two models (around 70% for both). Shortening the interval of time at 7 days led to a decrease in performance (AUC 0.68 and 0.72) with the model including data from the first day in ICU performing worse overall. Mortality predictions at 14 days performed in between with an AUC 0.72 and 0.73.

Conclusion: Mortality prediction performances at 28 days showed promising results based merely on patient information that could be gathered at ICU admission. Further training on the model could improve more its ability to assess and give a score of severity at admission to patients for better resource management during the pandemic.

Intensive Care Medicine Experimental 2020, **8(2)**: 001366

Introduction: The COVID-19 pandemic has led to unprecedented numbers of critically ill patients requiring prolonged mechanical ventilation [1]. Professional societies advocated the delay of tracheostomies or discouraged them altogether given the expected increase in risk of aerosol-generating procedure (AGP) [2]. We performed tracheostomy in an effort to deal with predicted pandemic related resource shortages and to reduce ICU weakness and hospital stay [3]. We developed a modified technique for the performance of percutaneous and surgical tracheostomies to reduce AGP potential, with a dedicated team performing them, presented as another abstract.

Methods: A prospective, single centre, observational study took place between March and July 2020. Patients underwent tracheostomy if expected to require prolonged mechanical ventilation and were either unready for trial extubation or unfit for extubation after failing a dedicated protocol for extubation within 7-15 days of intubation.

Results: Between March 2020 and July 2020, 74 patients were admitted to our ICU due to COVID-19 pneumonitis. Of these, 13 patients (17.6%) required CPAP only and 61 patients (82.4%) were intubated. No patient met the extubation criteria, so 34 underwent tracheostomy (15 percutaneous, 19 surgical). Patients were predominantly

male (63.6%), with a median age of 64 years (IQR: 58-68) (Table 1). Only 85.3% were confirmed cases of COVID-19. The rest could not be tested for antibodies, but had a strongly suggestive clinical picture. At the time of tracheostomy, 25% were receiving vasopressor support and 17.9% requiring renal replacement therapy (RRT) (Figure 1). Duration of oro-tracheal intubation prior to tracheostomy was 7.5 days (IQR: 5-12) and length of cannulation was then 12 days (IQR: 6-17). ICU-LOS was 23 days (median, IQR: 15-34.5) and ward-LOS was 9 days (median, IQR: 5-17). Mortality was 20.6% (7 patients); death occurred at a median of 9 days (IQR: 4-14). Twenty six patients (78.8%) were discharged home and one remains in hospital. Three patients required a more protracted weaning phase with prolonged ICU and ward stay; all of them had developed fibrosis in HRCT. After treatment with high dose steroids, they were successfully decannulated. Predictors of survival were: age ≤ 67 years OR = 10.5 (1.5-70.8; IQR; $p < 0.05$) and PEEP at day 4 post tracheostomy < 10 cmH2O OR = 13.8 (1.9-97.2; IQR; $p < 0.01$). Comorbidity was a risk factor for death (Charlson's comorbidity index OR = 0.43 [0.18-0.99; IQR; $p < 0.05$]). See Figure 2 for Kaplan-Meier curves. Previous CPAP was not associated with worse outcomes. **Conclusion:** In a selected cohort of COVID-19 patients tracheostomy is associated with good outcomes. Predictors of ICU survival in these patients were age ≤ 67 years and the ability to wean respiratory support 4 days after tracheostomy, whereas greater comorbidity is associated with worse outcomes. Patients with prolonged weaning might benefit from being investigated for development of pulmonary fibrosis.

Intensive Care Medicine Experimental 2020, **8(2)**: 001375

Introduction: Covid-19 ARDS progress from hospital oxygen requirement to severe ARDS requiring ECMO, to final hospital discharge or death. The impact of antiviral therapy, corticosteroids (CS) and other immunomodulatory agents on the path between states is not known.

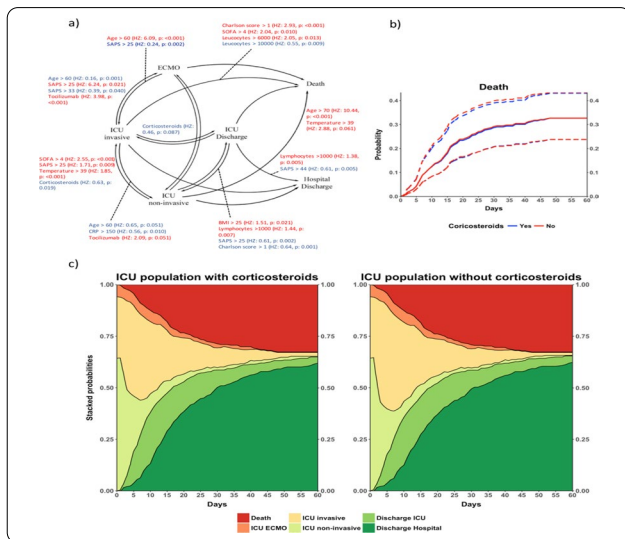

The Recovery trial [1] found a better day 28 prognosis when using dexamethasone low dose (DXM-6mg) but results are only preliminary and CS adverse effects not followed.

Objectives: To model COVID-ARDS states transitions from ICU admission to day 60 prognosis and evaluate the CS impact on transitions and final outcome.

Methods: A prospective data collection of severe COVID-19 patients admitted in 10 ICUs in France. Patients were followed daily until hospital discharge for a maximum of 60 days. We considered a multistate model shown in Figure 1. The 17 possible transitions are modeled via a Cox proportional hazard model (Breslow method, robust variance). Continuous variables are discretized via nested coding using quartiles values and tested on transitions with more than 10 events. Covariates with a p-value ≤ 0.2 in univariate analysis are retained and the final model is achieved via stepwise selection (BSC criterion). CS effect is tested using G-computation. Confidence intervals are obtained via a probabilistic sensitivity analysis (500 runs).

Results: From 401 patients in OutcomeRea, 6 are excluded since COVID-19 was acquired in the hospital. 77.5% are male, the median age is 61 years. Charlson score is greater than 0 in 61% of patients, the median BMI is 28.3, median SAPS II is 33. The median duration first symptom-ICU admission is 10 days, and the median hospital stay before ICU is 2 days. Median lymphocytes count is $0.9 \times G/L$, median C-reactive protein serum value is 157 mg/L and the median leucocytes is $9G/L$. 28.6% have temperature $> 39^\circ C$, 26.3% received CS at admission (8.3% with dose ≤ 10 mg of Dexamethasone or equivalent and 18% with DXM 20mg or equivalent), 34.7% lopinavir/ritonavir, 6.8% tocilizumab, 6.3% anakinera and 11.1% hydroxychloroquine. 20% received more than one therapy.

64.3% were admitted in ICU with non-invasive oxygenation, 30.9% with invasive mechanical ventilation and 5.8% in ECMO. Overall day 60 mortality was 32.9% and 13.4% of patients were censored. Transition selected variables are shown on Figure 1. Antiviral therapies did not result in significant impact. CS decrease the risk of invasive ventilation but decreased the risk of successful extubation. G computation suggests no significant effect on day 60 prognosis (32.7% CI: 23.8-43.1% and 32.7% CI:23.8-43.4% of being dead for CS and no CS, respectively). Low and high doses of CS provide similar effect.

Conclusion: Using a multistate model, we found that CS decrease the risk of invasive ventilation need but is associated with a lower chance of being extubated. Impact on prognosis is not significant. Possible causes of this delayed adverse impact (infections or other adverse effects) require further analyses.

Intensive Care Medicine Experimental 2020, **8(2)**: 001406

Introduction: The Recovery trial [1] found a better day 28 prognosis while using dexamethasone (DXM) low dose (DXM-6 mg) but results are only preliminary and not specific of the patients already admitted in ICU. Consequently, the benefit of Corticosteroids (CS) for the Covid-19 pneumonia patients admitted in ICU on death is still under debate.

Objectives: The objective of this study was to assess a non-biased effect of early CS in COVID-19 pneumonia patients admitted in ICU on the occurrence of death by the 60-day.

Methods: We selected patients from 11 ICUs included in the French OutcomeReaTM group. We included patients over 18 years, with COVID proved by PCR, entered in database from January 2020 to May 2020, with an ICU stay longer than two days, not transferred from another ICU and without decision to forego life-sustaining therapies on admission. We excluded patients treated with CS before ICU admission. The primary outcome was death before day 60. The intervention was an early administration of CS in ICU defined by the initiation of a new treatment by CS at day 1 or 2 after ICU admission. We used Cox proportional-hazard models with ponderation with inverse probability of treatment weighting (IPTW) to model the risk of death (IPTWHR > 1 in favor of death).

Results: 302 patients were included. Their median age was 61.6 (53-70) years; 78.8% were male; 58.6% had at least one comorbidity. On admission, SAPS II was 33(25-44); the PaO₂/FIO₂ ratio was under 200 mmHg in 74.2%; 34.8% of the patients received invasive mechanical ventilation, 31.8% had a temperature over 39 °C.

66 (21.8%) patients were in the Early CS subgroups (11 (3.6%) with dose less than 10mg of DXM or equivalent and 55 (18.2%) with DXM 20mg or equivalent). In the No Early CS subgroup, 96 (40.7%) received CS after day 2. Patients in the Early CS subgroup received more often anti-viral therapy and Anakinra (p < 0.01), had more hyperglycemia (p < 0.01) and needed more daily insulin dose (p < 0.01) during the ICU stay and tended to have more bacteremia and HAP-VAP (p = 0.06 and 0.16, see table).

The mortality at day 60 was 29.4% in the study population, 34.8% in the early CS and 28% in the non Early CS (p = 0.28). In the IPTW analysis, on day 60, early CS was not associated with an increase risk of death (IPTW-HR = 1.06, CI 95%, 0.67 to 1.68, p = 0.79). The results were similar limiting the analysis to high doses CS (IPTW-HR = 1.24, CI 95%, 0.83 to 1.87, p = 0.29).

ICU Death	85 (28.2)	63 (26.7)	22 (33.3)	0.29
Death at day 60	89 (29.4)	66 (28)	23 (34.8)	0.28

Conclusion: For the COVID-19 patients just admitted in ICU, in a prospective cohort with daily follow-up and a use a causal inference model, we were not able to unmask any positive impact of early CS therapy on patients' survival. Early CS was associated with hyperglycemia. The absence of benefit is not related to CS doses and may reflect difference in case-mix and/or standard of care used. Further studies are required to confirm the results of the RECOVERY trial.

Correlation between ventilatory parameters and gas exchange response to prone ventilation in SARS-CoV-2 ARDS

M. Chotalia¹; JE. Alderman¹; M. Bangash¹; D. Parekh¹; J. Patel¹
¹Birmingham acute care research group, University of Birmingham, Birmingham, United Kingdom

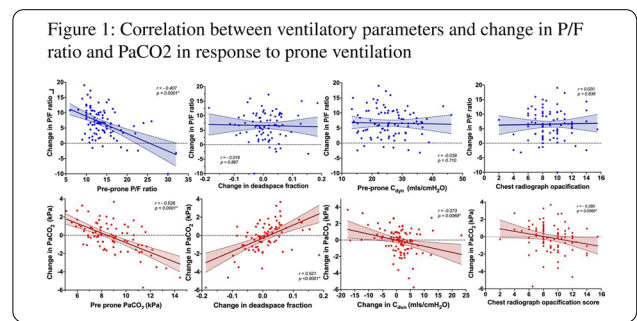

Correspondence: M. Chotalia
 Intensive Care Medicine Experimental 2020, **8(2)**: 001416

Introduction: Prone ventilation has a demonstrated mortality benefit in moderate-severe ARDS [1]. It has been argued that the majority of patients with SARS-CoV-2 ARDS have preserved lung compliance and low lung weight and have minimal response to prone ventilation due to a low amount of recruitable lung tissue. [2]

Objectives: To determine the pre-prone parameters that correlate with P/F ratio and PaCO2 response to prone ventilation in SARS-CoV-2 ARDS.

Methods: This is a single-centre, prospective study from the Queen Elizabeth Hospital Birmingham, UK. Patients undergoing invasive mechanical ventilation with SARS-CoV-2 pneumonia between the 11th March and 21st April that received at least one episode of prone ventilation were included. Prone ventilation was encouraged in patients who had an FiO2 concentration of greater than 0.6. Ventilatory parameters six hours before and during the first episode of prone ventilation were collected. Severity of opacification on chest radiography was graded by two independent reviewers using a validated, semi-quantitative opacification score ranging from 0 to 16. [3] Deadspace fraction was estimated using the unadjusted Harris-benedict equation. [4] Statistical analysis was performed using GraphPad Prism v.8.0. Continuous data are presented as median (IQR). Correlation between variables was analysed using a nonparametric spearman correlation test. A p value < 0.05 was used to determine significance.

Results: 143 patients were admitted to the ICU, of which 94 (66%) received at least one episode of prone ventilation for a median time of 16 (14 – 20) hours. P/F ratio increased by 6.6 (3.5 – 10.1) and PaCO2 decreased by -0.03 kPa (+0.9 – -1.0) in response to prone ventilation.

Conclusion: The P/F ratio response to prone ventilation correlated with the degree of hypoxia prior to proning, indicating that stratifying the receipt of prone ventilation by the degree of hypoxia is entirely appropriate. The P/F ratio response did not correlate with changes in deadspace fraction, pre-prone compliance or chest radiograph opacification, indicating that part of the response may be independent of lung recruitment, potentially due to improvements in cardiac output, distribution of blood flow and shunt fraction, as suggested by Gattinoni. [5] The PaCO2 response to prone ventilation correlated with markers of lung recruitment, such as changes in dynamic compliance, deadspace fraction and pre-prone severity of chest radiograph opacification, similar to findings from previous ARDS cohorts. [5] In summary, the majority of patients with SARS-CoV-2 ARDS had positive P/F ratio responses with prone ventilation and receipt of this ventilation strategy should be stratified by the degree of hypoxia.

Intensive Care Medicine Experimental 2020, **8(2)**: 001440

Introduction: COVID19 pandemic and the consequent surge of patients with acute hypoxemic respiratory failure has stretched the intensive care departments capacity to provide supportive treatment.

Objectives: To describe the baseline ventilator settings of adult patients with severe acute hypoxemic respiratory failure due to COVID19 admitted in the Catalan ICU network.

Methods: Consecutive patients admitted between 15 March and 15 April in 26 ICUs, who tested positive for SARS-Cov-2 (RT-PCR in a nasopharyngeal swab) and had severe acute hypoxemic respiratory failure, presenting with bilateral infiltrates in the chest X-ray and requiring invasive mechanical ventilation. Relevant data were collected in stable conditions shortly after intubation. Follow-up time was till ICU discharge. Study was approved by the Ethics Committee of the coordinating center (Hospital Universitari Sant Pau, Barcelona).

Results: A total of 1704 patients (1187 men and 517 women) were admitted, and their median age was 63 yr (IQR 54-70). Of these, 1388 (82%) required invasive mechanical ventilation. Median duration of mechanical ventilation was 14 days (IQR 7-24). Overall UCI mortality was 35% (491/1388). Prone position was implemented in 77% (1070/1388). ARDS criteria was met by 1220 intubated patients (88%, 1220/1388). Cumulative survival over ICU time is shown in the Kaplan-Meier plot.

Intensive Care Medicine Experimental 2020, **8(2)**: 001469

Introduction: The spectrum of kidney damage in COVID-19 has been mostly limited to autopsies and case reports. Here, we report the first case series of patients with COVID-19 who developed kidney injury and underwent a kidney biopsy in the Paris and its metropolitan area. The spectrum of kidney damage in COVID-19 has been mostly limited to autopsies and case reports. Here, we report the first case series of patients with COVID-19 who developed kidney injury and underwent a kidney biopsy in the Paris and its metropolitan area.

Methods: We included all patients with COVID-19 who underwent a kidney biopsy between March 08 and May 19, 2020. Data were obtained through the review of the medical records.

Results: Forty-seven patients (80.9% men) with COVID-19 were included in the present study. Median age was 63 years IQR [52-69]. Comorbidities included hypertension (66.0%), diabetes mellitus (27.7%), previous history of chronic kidney (25.5%), cardiac (38.6%) and respiratory (27.3%) diseases. Initial symptoms were fever (85.1%), cough (63.8%), shortness of breath (55.3%), and diarrhea (23.4%). Almost all patients developed acute kidney injury (97.9%) and 63.8% required renal replacement therapy. Kidney biopsy analysis showed two main histopathological patterns, including isolated acute tubular necrosis in 22 (46.8%) patients, and dominant glomerular injury consisting of collapsing glomerulopathy or focal segmental glomerulosclerosis in 17 (36.2%) patients. Eight (17%) patients had alternative diagnosis, which were most likely unrelated to COVID-19. Acute tubular necrosis occurred almost invariably in the setting of severe forms of COVID-19, whereas patients with glomerular injury had various profiles of COVID-19 severity and collapsing glomerulopathy was only observed in patients harboring a combination of *APOL1* risk variants. At last follow-up, 16 of the 30 patients who initially required dialysis were still on dialysis, and 9 died from COVID-19 or related-adverse events.

Conclusion: The present study describes clinico-pathological spectrum of kidney lesions in yet-alive patients with COVID-19. While acute tubular necrosis is correlated with COVID-19 severity, the pattern of glomerular injury is intimately associated with the expression of *APOL1* risk variants. Whether SARS-CoV-2 directly underlies renal damage remains a major but unsolved issue.

Baseline settings and parameters (mean± std deviation)				
	All (n=1388)	Alive (897)	Dead (491)	p (alive vs dead)

Evaluation of oXiris in COVID-19 patients on VV-ECMO with AKIK. Aitchison¹; R. Lewis¹; R. Browning¹; L. Thakuria¹; J. Doyle¹¹Intensive care, Royal Brompton & Harefield NHS Foundation Trust, London, United Kingdom**Correspondence:** K. Aitchison*Intensive Care Medicine Experimental* 2020, **8(2)**: 001472

Introduction: COVID-19 caused many deaths through a dysregulated immune response, with resultant “cytokine storms” contributing to multi-organ failure [1]. Patients with severe respiratory failure have required extra-corporeal membrane oxygenation (ECMO) as a rescue therapy [2]. The oXiris adsorptive haemofilter has the capacity to adsorb cytokines while delivering continuous renal replacement therapy (CRRT) [3]. Therefore, patients with multi-organ failure secondary to COVID-19 could be managed with ECMO and haemoadsorptive therapy as a novel approach [4]. Minimal evidence currently exists of its effectiveness or safety.

Objectives: To evaluate the safety and efficacy of oXiris in COVID-19 patients on VV-ECMO with AKI.

Methods: A single-site prospective observational case series was conducted from March to June 2020. Inclusion criteria were: COVID-19, age > 18, VV-ECMO, CRRT and severe septic shock. Data was collected at baseline and over three successive oXiris filters. Data included vaso-pressor requirements, biochemical markers and vital signs. Variables at baseline and completion of therapy were compared using Wilcoxon Signed Ranks Test, two-tailed p-values (significance $p < 0.05$).

Results: Eight patients were included; 7 males and 1 female with a mean age of forty-seven. None had pre-existing renal disease and mean baseline creatinine on admission was 230 $\mu\text{mol/L}$. Mean CRP was 252 mg/dL with a mean lactate of 3.12 mmol/L . The median vaso-pressor dose fell significantly from 0.02 units/min to 0.00 units/min ($p = 0.031$), median noradrenaline dose fell significantly from 0.23 mcg/kg/min to 0.06 mcg/kg/min ($p = 0.039$) and median urine output significantly improved from 0 ml/day to 151 ml/day ($p = 0.008$). There were no adverse events reported.

Conclusion: The use of oXiris adsorbent membrane in patients requiring VV-ECMO for COVID-19 with clinical evidence of a “cytokine storm” was safe, with no adverse events. There was also significant improvement of haemodynamic stability and initial renal recovery. Further evaluation through a large randomised control trial is warranted.

The use high levels of positive end-expiratory pressure in patients with massive non-traumatic subarachnoid hemorrhages and initially increased intracranial pressureED. Mekhia Mekhia¹; A. Savenkov¹; A. Solodov¹; S. Petrikov¹; V. Krylov²¹Neurosurgical ICU, Sklifosovsky Research Institute for Emergency Medicine, Moscow, Russia; ²Neurosurgery, Sklifosovsky Research Institute for Emergency Medicine, Moscow, Russia**Correspondence:** A. Solodov*Intensive Care Medicine Experimental* 2020, **8(2)**: 001478

Introduction: Positive end-expiratory pressure (PEEP) is one of the main parameters for preventing lung damage and ensuring gas exchange during mechanical ventilation. The use of high PEEP levels can lead to increase of intracranial pressure (ICP) in patients with

massive non-traumatic subarachnoid hemorrhages (SAH). Therefore, the use of high levels of PEEP is limited in patients with initially high ICP.

Objectives: To determine the efficacy and safety of different levels of PEEP in patients with intracranial hemorrhage with initially increased ICP.

Methods: We analyzed the state of systemic and cerebral hemodynamics in different levels of PEEP in critically ill patients with SAH in situations with initially increased ICP ($n = 31$). The study was not performed in patients with intracranial pressure of 20 mmHg and more. The examined patients had Glasgow coma scale below 9. Invasive ICP monitoring, transpulmonary thermodilution, respiratory monitoring were used in all patients. The studied parameters were determined with an increase in PEEP from 5 $\text{cm H}_2\text{O}$ to 10, 15 and 20 $\text{cm H}_2\text{O}$. Minute ventilation volume and PaCO_2 were stable at all stages of the study.

Results: The initial level of ICP was 17 (16; 18) mmHg , cerebral perfusion pressure (CPP) - 93 (86; 107) mmHg . A decrease of global end-diastolic index and compensatory increase of systemic vascular resistance index with normal mean arterial blood pressure indicated a state of latent hypovolemia. Increase of PEEP to 10 and 15 cmH_2O had no negative effects on ICP and CPP. We determined the tendency to decrease cardiac index, cardiac preload and to increase systemic vascular resistance index, stroke volume variation. High levels of PEEP did not lead to obstruction of extracranial venous outflow; the jugular bulb pressure were stable (Table 1). We identify increase ICP and decrease CPP, cardiac index, global end-diastolic index, systemic vascular resistance index when PEEP were 20 cmH_2O . Hypovolemia limited the compensatory reserves of hemodynamics, which resulted a decrease in arterial and cerebral perfusion pressures.

Table 1. Parameters of systemic and cerebral hemodynamics during different levels of positive end-expiratory pressure in patients with high baseline intracranial pressure

Parameters	PEEP 5 cmH_2O	PEEP 10 cmH_2O	PEEP 15 cmH_2O	PEEP 20 cmH_2O
Intracranial pressure, mmHg	17 (16;18)	17,5 (16;18)	18 (16;19,5)	19 (17;20) *#
Mean arterial pressure, mmHg	110 (102;122)	109 (100;119)	105 (98;114)	99 (92;110) *#
Cerebral perfusion pressure, mmHg	93 (86;107)	92 (84;102)	89 (80;97)	81 (75;90) *#
Cardiac index, litres/min/m ²	3,5 (3,0;3,7)	3,3 (2,9;3,4)	3,1 (3,0;3,3)	3,0 (2,8;3,3)
Global end diastolic index, ml/m ²	608 (598;701)	556 (523;666)	564 (527;653)	588 (514;662)
Systemic vascular resistance index, $\text{dyn} \cdot \text{s} \cdot \text{cm}^{-5} \cdot \text{m}^2$	2450 (1980;2925)	2645 (2107;3073)	2590 (2193;3000)	2725 (2248;3119)
Stroke volume variation, %	10,5 (8;14)	13 (9;21,3)	18 (12;22,8)	21,5 (14;22,8) *
Extravascular lung water index, ml/kg	4,9 (4,6;7,7)	5,3 (5,7;6)	5,3 (4,8;7,8)	6 (5,2;7,3)
Central venous pressure, mmHg	5 (4;7,5)	6 (4;7)	6 (3;11)	8 (5,5;12)
Jugular bulb pressure, mmHg	14 (13;19)	15 (13;18)	14 (13;18)	15 (12,5;16,8)
$\text{PaO}_2/\text{FiO}_2$	352 (294;390)	364 (276;402)	382 (323;429)	397 (313;440)

(* - $p < 0,05$ compared with PEEP 5 cmH_2O , # - $p < 0,05$ compared with PEEP 10 cmH_2O).

Conclusion: Increase PEEP up to 15 cmH_2O does not have a negative effect on ICP and CPP in patients with initially increased intracranial pressure. Further increase PEEP up to 20 cmH_2O can lead to increase ICP, to decrease mean arterial pressure and CPP. The increase ICP is on average 2-3 mmHg , which may be acceptable for use high PEEP in

conditions of stable blood pressure and significant improvement in pulmonary gas exchange.

A Good Death: A Complete Audit Cycle of End of Life care in the Intensive Care Unit at The Hammersmith Hospital

S. Bakare¹; J. Irwin²; R. Towning²; R. Stumpf³

¹Anaesthetics and intensive care medicine, Northwick Park Hospital, London, United Kingdom; ²Foundation programme, Imperial College Healthcare NHS Trust, London, United Kingdom; ³Intensive care, Hammersmith Hospital, London, United Kingdom

Correspondence: S. Bakare

Intensive Care Medicine Experimental 2020, **8(2)**: 001485

Introduction: Despite advances in medicine, death rates in Intensive Care Units (ICU) remain high (1). ICU patients are admitted for life saving organ support; however when this fails, it is vital to provide patients with dignified deaths. The ICU brings about unique circumstances that make palliative care challenging, highlighting the importance of auditing current practices. The aim of this project was to audit the provision of end of life care, identify areas for improvement and develop interventions to ensure we provide optimum care. This was particularly important during the COVID-19 Pandemic surge where we had higher than average ICU mortality rates and unique sets of challenges. Interventions included raising awareness through multidisciplinary education at various forums. We increased awareness of existing available tools such as electronic end of life care forms and prescription order sets. Trainees also had access to electronic copies of simple guides to facilitate discussions with patient and their families (2). Videoconferencing proved invaluable in allowing spiritual and psychological support for parents and their families.

Methods: A retrospective initial audit was carried out by reviewing the electronic medical records (ISCCA) of patients who died between April and September 2019, following the implementation of interventions, a re-audit was carried out between March and May 2020. Data was collected based on NICE and FICM guidelines for end of life care and summarised into 6 main criteria (3,4,5). This included; Identification of dying patients, Treatment escalation and Resuscitation planning, Patient and Family Involvement, Symptom management, Comfort care, and Psychological and Spiritual needs. The data was analysed using simple statistical tests.

Results: There were 61 deaths during the initial audit period and 28 during the re-audit. The re-audit showed 93% (92% initial audit) of patients were identified as dying in a timely manner with 86% having clearly documented treatment escalation and appropriate resuscitation planning. 93% (77% initial audit) of patients had clearly documented Patient and Family Involvement with end of life discussions. Spiritual & Psychological support and Comfort Care was documented in all patients. This was a significant improvement compared to 41% for Spiritual & Psychological support and 26% for Comfort Care recorded in the initial audit. Symptom management also significantly improved from 13% to 100%.

Conclusion: Despite the additional challenges posed by the COVID-19 Pandemic these results show our ICU Team continued to provide high quality and compassionate End of Life Care. We intend to continue carrying out multidisciplinary teaching sessions with input from Palliative care and Pharmacists. We will also encourage the use of the palliative care form on ISCCA to provide prompts and enable accurate documentation. A laminated aide memoire flow chart (4) will also be available in clinical areas. End of life care is an essential skill for all members of the critical care team, because a good death is as important as a good life (4).

Intensive Care Medicine Experimental 2020, **8(2)**: 001489

Introduction: Circulatory shock and infections are known to be among the major causes of mortality in the ICU. These critical states are often associated with vasodilation, which could cause a significant drop in blood pressure, reduced tissue oxygenation and eventually organ failure.

A common physiological index of metabolic dysfunction and tissue oxygenation is blood lactate level. In particular, vasopressor need and lactic acid level have been proven to provide an accurate severity of illness classification system [1] in predicting out-of-hospital mortality.

Objectives: The goal of this study is to identify effects of the initiated vasopressor therapy as related to Lactate levels. To this extent, we developed a model to predict a change in blood lactate level 12 hours after the administration of vasopressors by combining baseline features extracted from the electronic health records with measures of vasopressor responses estimated from continuously recorded ECG and arterial blood pressure (ABP) waveforms.

Methods: The data used in this study comes from the MIMIC-III database [2]. The study was carried out on a cohort of 123 patients resulting from selection of all patients undergoing vasopressor administration that passed waveform signal quality annotation and had matching clinical data.

Selected features were extracted from the waveform recordings considering 15-minute windows before and after vasopressor administration, as shown in Figure 1.

Clinical measurements from laboratory tests, blood gas analyses, pathologies, treatments and demographic information were also

extracted for each patient within a 12 hour window before vasopressor onset.

We used all features to predict whether lactate level was normal (< 2 mmol/L) or abnormal (= > 2mmol/L) 12 hours after the vasopressor onset.

The dataset was divided into a training set (80%) and testing set (20%). A Random Forest classifier was trained through a hyperparameter optimization with a 10-fold cross validation and grid search procedure.

Results:

Results (Figure 2) showed an AUROC = 0.84 and AUPRC = 0.57. Feature importance analysis indicated that changes of the cardiovascular interaction between heartbeat and blood pressures after vasopressor administration are predictive of an abnormal lactate 12 hours after the start of vasopressor therapy.

Conclusion: Autonomic measures reveal an association between the response of the cardiovascular system to vasopressor therapy and changes in blood lactate level, suggesting that ECG- and ABP-derived indexes may be useful for predicting lactate level changes, i.e. tissue oxygenation level, after initiation of vasopressor therapy.

Intensive Care Medicine Experimental 2020, **8(2)**: 001507

Introduction: Tracheostomy is a life-saving intervention and facilitates prolonged ventilation in critical care. However, the negative consequences of tracheostomy include thirst and difficulty communicating which can be the most well recalled and distressing experiences for patients [1–3]. Above cuff vocalisation (ACV), also known as ‘talking tracheostomy’ and ‘external subglottic airflow (ESAF)’, has been used for > 50 years [4]. A flow of oxygen or air is applied via the subglottic port of the tracheostomy to restore airflow through the vocal cords and enable vocalisation [5–7]. Some research has also reported improvements to swallowing and cough, hypothesised to be a result of improved laryngopharyngeal sensation [5,8].

Objectives: To explore the extent of ACV use internationally, implementation approaches, risks, and benefits.

Methods: Ethical approval was obtained (MREC: 18-037). An international online survey was disseminated May–November 2019 via social media and professional networks. The survey included 73 questions covering topics such as: tracheostomy management, prevalence, practicalities, barriers, resource use, and personal experiences and opinions. Quantitative data was analysed using Microsoft Excel® (2016) and reported descriptively.

Results: The survey was completed by 244 healthcare professionals (HCPs), with one exclusion, from 9 different HCP groups and 25 countries. Respondents were primarily from critical care (85%; n = 205). ACV was used by 94 HCPs (39%). Most respondents had limited ACV experience; 54% (n = 50) had used ACV with < 10 people. There was a varied approach to ACV implementation (Figure 1). Most respondents wait > 72 hours post-tracheostomy insertion prior to commencing ACV (n = 45; 48%), but 13 (14%) commence ACV at 0–48 hours. The most common complications or symptoms observed with ACV were patient reported discomfort (n = 54; 58%), strained vocal quality (n = 39; 42%), and air escape via the stoma (n = 32; 34%) (Figure 2). Various benefits were reported including: communication (n = 76; 82%), mood (n = 62; 67%), laryngeal sensation (n = 49; 53%), swallowing frequency (n = 43; 46%), reduced volume of subglottic secretions (n = 39; 42%), expectorating secretions (n = 37; 40%), and earlier commencement of oral intake (n = 16; 17%). Incidences of more serious complications were observed less frequently, sub-cutaneous emphysema in 1–4 patients (n = 7; 8%), air trapping in 1–6 patients (n = 10; 11%), and bleeding in 1–30 patients (n = 10; 11%). The most extreme barriers to ACV implementation were lack of access to knowledgeable staff (n = 92; 38%), lack of access to training (n = 73; 30%), and not using tubes with subglottic ports (n = 74; 31%).

Figure 1 – Percentage of respondents that implemented procedures or documentation for ACV

Figure 2 – Complications or symptoms observed that were suspected to be a result of ACV

Conclusion: There is a varied approach to ACV implementation and delivery. The benefits are diverse, but minor complications are common. Future research should focus on establishing optimal implementation of ACV and developing a standardised approach to maximise benefits and minimise risks.

Delays in initiating the weaning process: Insights from the WEAN SAFE Study

T. Pham¹

¹Service de médecine intensive-réanimation, Hôpital de Bicêtre, Le Kremlin-Bicêtre, France

Correspondence: T. Pham

Intensive Care Medicine Experimental 2020, **8(2)**: 001514

Introduction: Prolonged weaning from invasive mechanical ventilation (MV) is associated with poorer patient outcomes, including longer length of stay in the ICU and in the hospital and higher patient mortality [1]. It is recommended to start weaning based on general respiratory criteria (PEEP, FiO₂...) to avoid potential delays which may contribute to prolonged ventilation and poor outcomes.

Objectives: To evaluate the prevalence and types of delays in initiating the first separation attempt (SA) from invasive MV in patients enrolled in the WEAN SAFE study (Worldwide Assessment of Separation of pAtients From ventilatory assistance; NCT03255109).

Methods: WEAN SAFE is a global, multi-centre prospective observational study that enrolled 6,167 patients in 476 centres receiving mechanical ventilation for at least 2 days. The time to initiation of the first SAs was examined in patients meeting general criteria. We considered the patients met criteria for initiating the weaning process when they were not receiving neuromuscular blocking agents, were on low dose or no vasopressors, had a PEEP < 10 cmH₂O and a FiO₂ < 50%. Patients were classified according to the WIND classification, which describes three different duration of weaning [2]. WIND groups were defined as the time from the first SA to successful weaning or death: group 1 within 24h; group 2: more than 1 day and less than a week; group 3: weaning not completed 7 days after the first SA.

Results: Of the 6167 patients enrolled, 4646 had at least 1 SA and could be grouped according to the WIND classification: 70% in group 1; 14% in group 2 and 16% in group 3.

Of 4,212 patients that met criteria for weaning initiation, the median (interquartile range) time from these criteria to the first SA was 2 days (0;4). In the whole cohort, 30% of the patients had a SA the very day they met these criteria (n = 1257) whereas this delay was longer than 6 days in 16% (N = 669). This delay statistically differed according to the WIND group (Table 1). We then assessed the time difference between the first day patients had spontaneous breathing activity and the first SA. In the whole population (n = 4646) this delay was 0 (0;3) days and was also significantly different across the WIND groups

(Table). Delay from the first SA to the weaning termination (successful weaning or death) was associated with the outcomes: hospital mortality was 15.6% in group 1, 38.2% in group 2 and 35.4% in group 3 (P < 0.001 between groups).

Delays in Initiating weaning attempts				
	Group 1 (n = 3231)	Group 2 (n = 650)	Group 3 (n = 765)	P value
Time to 1st SA in patients fulfilling weaning criteria, days, median (IQR)	1.00 [0.00;4.00]	2.00 [0.00;5.00]	2.00 [0.00;6.00]	<0.001
Time to 1st SA since spontaneous breathing, days, median (IQR)	0.00 [0.00;2.00]	1.00 [0.00;3.00]	1.00 [0.00;4.00]	<0.001

Conclusion: Delays in initiating the weaning process in patients may contribute prolonged mechanical ventilation and subsequent higher mortality. The reasons underlying these delays in initiating weaning need to be explored.

Introduction: Inflammation-driven “endothelitis” appears to contribute to acute heart failure (AHF). We aimed at evaluating the proinflammatory status and endothelial activation, as well as their correlation, in human AHF, cardiogenic shock (CS) and to differentiate the same processes in patients with the diagnosis of non-cardiogenic shock (NCS), namely septic shock.

Methods: Patients with AHF (n = 23), CS (n = 25) and NCS (n = 20) were included and blood and urine samples were collected at days 1-2, days 3-4 and days 5-8. Blood donors were used as controls (n = 22) at a single time point collection. Serum IL-1β, IL-6, tumoral necrosis factor-α (TNF-α), intercellular adhesion molecule-1 (ICAM-1), vascular cell adhesion molecule-1 (VCAM-1) and E-selectin were determined using Multiplex Immunoassays. Endocan was evaluated by ELISA kit.

Results: At admission, we found no significant differences in IL-1β concentration between groups. Admission IL-6 values (pg/mL) were higher in patients' groups (controls: 2.0 ± 0.9; AHF:40.0 ± 22.3; CS: 95.9 ± 26.4, NCS: 598.1 ± 311.5; controls vs AHF, p < 0.01; controls vs CS or NCS, p < 0.001). Admission TNF-α concentration (pg/mL)

was higher in NCS (controls: 5.4 ± 0.6 ; AHF: 11.9 ± 3.1 ; CS: 9.4 ± 1.5 ; NCS: 46.9 ± 8.7 , controls vs NCS, $p < 0.001$; NCS vs CS, $p < 0.001$). Admission endocan (ng/mL) were higher in all patients' groups (controls: 1.4 ± 0.2 ; AHF: 6.1 ± 1.8 ; CS: 12.9 ± 1.9 , NCS: 10.6 ± 1.4 ; controls vs AHF, $p < 0.01$; controls vs CS or NCS, $p < 0.001$, CS vs AHF, $p < 0.01$). Admission ICAM-1 values (ng/mL) were increased in CS and NCS compared to controls and AHF (controls: 474.9 ± 70.7 ; AHF: 412.4 ± 60.3 ; CS: 665.5 ± 72.6 , NCS: 726.6 ± 55.3 , controls vs CS, $p < 0.05$; controls vs NCS, $p < 0.01$). Admission VCAM-1 (ng/mL) was higher in all patients' groups (controls: 705.8 ± 51.0 , AHF: 1840.0 ± 290.0 , CS: 3425.0 ± 645.6 , NCS: 4462.0 ± 449.7 , controls vs AHF, $p < 0.01$; controls vs CS, $p < 0.001$, controls vs NCS, $p < 0.001$), while E-selectin presented higher values in NCS (controls: 28.7 ± 1.6 , AHF: 33.1 ± 2.3 , CS: 37.9 ± 3.7 , NCS: 207.4 ± 28.6 , controls vs NCS, $p < 0.001$, CS vs NCS, $p < 0.001$). During hospitalization, there was an overall decrease in TNF- α values ($p = 0.02$) and also a decrease in all endothelial biomarkers (ICAM-1, VCAM-1 and E-selectin concentration - $p = 0.04$ and $p = 0.001$ and $p < 0.01$, respectively) in NCS. Withinpatients, we observed significant positive correlations between endocan and IL-6 and VCAM-1, between ICAM-1 and IL-1 β , IL-6, VCAM-1 and E-selectin, between VCAM-1 and IL-6, TNF- α and all the endothelial biomarkers, and between E-selectin and IL-6, TNF- α , ICAM-1 and VCAM-1.

Conclusion: Proinflammatory status and endothelial cell activation are interrelated and significantly increased in all patient's groups. During hospitalization, there is significant decrease in all endothelial biomarkers only in NCS patients. This suggests that inflammation-driven "endothelitis" is constant in AHF and CS which might perpetuate and aggravate the prognosis heart failure.

Intensive Care Medicine Experimental 2020, **8(2)**: 001579

Introduction: Since the outbreak of the SARS-CoV-2 pandemic, there has been a surge of clinical risk prediction scores developed, mostly at the first epicentre in China [1][2][3][4]. Predicting risk of deterioration or severe COVID-19 related illness is of significance, both as part of a clinical treatment guidance as well as to highlight the likely groups benefitting from novel disease modifying therapies. Although many of the risk prediction tools were developed in multi-centre studies, their external clinical utility and face validity has not been established in independent cohorts [5].

Objectives: We attempted to validate three previously published risk-stratification tools in a multi-centre study.

Methods: Anonymised patient data was collected as part of a service evaluation and audit project by the Secondary Care Group Members of the Welsh Government COVID-19 response from patients admitted to the University Hospital of Wales, a tertiary academic centre and to the two district general hospitals in Aneurin Bevan UHB. Due to the anonymised nature of the data collection, formal written consent was waived.

Data was collected to enable to calculate the CALL-score, the COVID-GRAM risk score and a nomogram developed by Gong et al [1][2][3]. Primary outcome was a composite outcome of development of severe COVID-19 disease leading to ICU admission or death as described by the original publications. The outcome was censored at hospital discharge or 30-days.

For statistical analysis receiver operating characteristics (ROC) curves were used to establish predictive ability. Data is presented as n (%), median (IQR) or ROC (95%CI) as appropriate.

Results: We collected data from 169 patients. Patients were 73 (59-82) years old, 66 out of 169 (39.1%) were female, 32 (18.9%) had no significant co-morbidities, 57 (33.7%) had one and 80 (47.3%) had two or more comorbidities. Most prevalent comorbid conditions were diabetes in 42 (24.9%), COPD in 32 (19.0%) and ischaemic heart disease in 26 (15.4%) of patients. 81 (47.9%) of patients had reached the composite outcome of ICU admission or death, the hospital mortality was 33.7%. Neither of the three risk-prediction tools were able to accurately predict outcome. ROC (95%CI) for the COVID-GRAM score was 0.636 (0.550-0.722) $p = 0.003$, for the CALL-score 0.500 (0.411-0.589) $p = 0.997$ and for the nomogram 0.628 (0.543-0.714) $p = 0.005$ (Fig 1).

Conclusion: With respect to the composite outcome of ICU admission or death within our cohort, the discriminative value of all three predictive tools was poor. This is likely due to a variety of factors. The absence of calibration data to address the overfitting of the COVID-GRAM leaves the fine-tuning of regression coefficients as potentially overlooked [6]. Furthermore, each of the tools had relatively small and homogenous training and validation cohorts, despite being multi-centred in nature, in contrast to the international datasets now available. Moreover, our cohort differed as older, predominantly white and carrying a higher comorbidity burden.

Intensive Care Medicine Experimental 2020, **8(2)**: 001586

Introduction: COVID-19 outbreak has represented a new challenge for intensivists worldwide in terms of patient and resources management. The decision of which ventilation strategy to adopt in each patient has been crucial and not guided by existing outcome evidence.

Objectives: We described the clinical characteristics and outcomes of hospitalized COVID-19 patients according to the adopted ventilatory strategy.

Methods: All COVID-19 patients hospitalized within the Rimini province (340,000 residents) from February 26 to April 18, 2020 were included in the present observational population-based study. Patients were classified according to the maximum level of ventilation support (oxygen, non-invasive ventilation (NIV), mechanical ventilation (MV)). Sixty-day mortality was computed and patient's risk of death was estimated with a Cox proportional hazard analysis adjusted by age, sex, and administration of steroids, canakinumab, and tocilizumab.

Results: 1,424 symptomatic patients were identified; 522 (36.7%) were hospitalized, the remaining 902 (63.3%) were treated at home with no deaths at 60 days. 408 (78.5%) patients were treated only with standard care and oxygen supplementation during hospitalization (G1), 46 (8.8%) patients underwent only NIV (G2), 25 (4.8%) failed a NIV trial and received MV (G3), and 41 (7.9%) only/or MV (G4). There was no significant difference in the P/F at MV inception among G3 and G4 (p -value 0.9). Overall 60-day mortality was 24.2% and was 23.0% in G1, 19.6% in G2, 32.0% in G3, and 36.6% in G4 ($p = 0.165$). Compared with G1, corresponding adjusted HRs progressively increasing from G2 to G4 (HR 1.78, 95% CI 0.79–3.98; HR 2.78, 95% CI 1.14–6.73; HR 2.97, 95% CI 1.55–5.65, Figure).

Conclusion: Our study suggested that patients who failed a NIV trial did not have a worse prognosis than patients treated directly with MV, but the adopted strategy has helped with the optimization of the resources allocation.

Intensive Care Medicine Experimental 2020, **8(2)**: 001597

Introduction: Critically ill COVID-19 patients often required mechanical ventilation (MV) support. For ICU nursing staff, COVID-19 patients' management presented a relevant increasing in workload, especially during pronation. In this emergency scenario Clinica Luganese Moncucco, identified as a COVID-19 Center by the Swiss Health Department, decided to introduce a specialized *ICU Physiotherapy Team* (IPT) to support nursing staff during pronations.

Objectives: Primary outcome was to analyze complications rate in critically ill COVID-19 patients managed by this specialized team during pronations. Secondary outcomes were to analyze all correlations between the incidence of minor complications, like pressure sores, and clinical data to find any potential protective factor.

Methods: A retrospective analysis on consecutive critically ill COVID-19 patients from March 16th to April 16th, 2020. The purpose of this study was to analyze the rate of major and minor complications related to pronation performed by the IPT.

Results: Forty-two patients were treated by specialized IPT. Pronation maneuvers were performed on 81% of patients with 296 pronations, with an average of 3.52 cycles per patient (SD 2.47). The average BMI was 28.3 kg/m²(SD 5.1); 36 (86%) patients were on MV (66% ventilated by OTI and 19% by tracheotomy), with a mean duration of MV days of 10.5 days. The mean age was 65.61 (SD 10.95), 35 (83.3%) were male. The nurse workload was increased, with a median NEMS score of 34.5, compared to previous year ($p < 0.001$).

One major complication (0.3%) identified as a dislocation of endotracheal tube was observed; 14 patients (33.3%) were burdened by minor complications like pressure sores. The number of pressure sores was correlated with ICU LOS ($p = 0.001$) and MV days ($p = 0.001$); the presence of pressure sores was also related to ICU LOS ($p = 0.029$) and MV days ($p = 0.015$). No other significant correlations were found. To better estimate the effect of the observed data, the propensity score was applied, given the retrospective study design and the imbalance between treatment and pronation number. The propensity match score showed no protective pronation factor regarding the presence of ulcers (1.0, $p = 0.448$).

Conclusion: Specific pronation team resulted in a lower rate of major complications. The persistent high amount of minor complications appeared to be related rather to the disease severity than to pronation

gesture, suggesting that minor complications were not protected by pronation.

Machine Learning to tackle COVID-19: the collection of multicenter intensive care data from electronic health records during a crisis

L. Fleuren¹; B. Vonk²; M. Fornasa²; DB. Aletta²; W. Herter²; H. Hovenkamp²; T. Guo¹; L. Roggeveen¹; P. Thorai¹; E. Swart³; ARJ. Girbes¹; M. Hoogendoorn⁴; PWG. Elbers¹

Intensive Care Medicine Experimental 2020, **8(2)**: 001598

Introduction: The Corona virus disease 2019 (COVID-19) pandemic touches health care systems worldwide and surpasses intensive care capacity in many areas. Since COVID-19 is an emerging disease, high quality evidence about the course of the disease and optimal treatment is sparse. We envision that combining efforts of the intensive care community through knowledge and data is paramount to accumulate insight into this novel disease.

Objectives: We set out to gather data from COVID-19 patients for machine learning studies from all intensive care units in the Netherlands. We outline the process of data collection under European privacy law in times of crisis.

Methods: We devised a multidisciplinary report on the lawful collection of data from electronic health records during the COVID-19 pandemic in close collaboration with data protection officers (DPO), hospital lawyers, and intensivists. Similarly, a data sharing agreement was drafted based on a nation-wide template for sharing data between healthcare institutions. Documentation was reviewed by the institutional review board (IRB). All hospitals in the Netherlands with an intensive care unit were approached, and documentation was reviewed locally before permission was granted.

Results: Under European law, patient privacy is regulated in the General Data Protection Regulation (GDPR) (1). Both the GDPR and Dutch national law provide that data subjects have to give explicit consent for the processing of their data. We argue that during the COVID-19 crisis, asking consent cannot be reasonably expected from health care workers due to a) the large number of expected patients and associated time burden in an already overstrained health care system, b) the danger of spreading or contracting the virus upon contact with patients or their families, and c) the poor clinical condition of many patients in the intensive care. Consent is therefore not only impractical, but often impossible. In addition, alternative forms of data collection are unavailable and selection bias would lead to unreliable data. As under non-crisis circumstances, we may gather COVID-19 data necessary for scientific purposes when we “provide for suitable and specific measures to safeguard the fundamental rights and interests of the data subject” (GDPR, Article 9, paragraph j1). Therefore, we a) pseudonymized data in the providing hospital, b) informed patients through media and local hospital outlets about the possibility to opt out, and c) signed data sharing agreements regulating privacy of patients. We currently have data sharing agreements in place with 38 hospitals, and have received data from 32 hospitals. With this study we

aspire to set an example for the lawful collection of data in times of a health crisis.

Conclusion: In times of the COVID-19 crisis, we consider large scale data collection pivotal to combat this novel disease and to improve patient outcomes. Data collection in times of crisis may be possible and lawful under European privacy laws.

Intensive Care Medicine Experimental 2020, **8(2)**: 000065

Introduction: One of the most common adverse events during continuous renal replacement therapy (CRRT) is hypothermia, < 35.0 °C, reported in 44% of all cases. Hypothermia may be less common over time, but available data is scarce. Hypothermia is associated with higher mortality rates; in a time series analysis of over 15000 admissions during 8.5 years, the incidence of hypothermia (< 36.0 °C) decreased from 29% to 21% during the study period and was associated with ICU mortality in both medical and surgical patients. The older Prismaflex CRRT system uses the Barkey blood warmer, also known as Prismacomfort. It operates by covering the blood return flow with a silicon tube heat exchanger and the heat is transferred by the contact of the resistance heating system. The Thermax blood warmer on the newer Prismaflex CRRT system responds to changing treatment parameters by repeatedly adjusting heating to fulfil the prescribed return blood temperature. We wanted to characterize the occurrence of hypothermia in CRRT patients and to compare whether the newer Thermax warmer was more effective in protecting against hypothermia compared to its predecessor Barkey.

Methods: The study was registered at Clinical Trials.gov (NCT03973814) and approved by the Swedish Ethical Review Authority (Dnr 2019-04388). A total of 9046 patients admitted to the Intensive Care Unit at Skåne University Hospital, Lund, Sweden during the years 2006-2019 were screened and 342 patients undergoing CRRT were identified and included. The old Prismaflex with the Barkey warmer was used until November 2018, thereafter the Prismaflex with the Thermax was used. Data was extracted from the electronic patient database management system ICCA (IntelliSpace Critical Care and Anesthesia, Philips, the Netherlands) which contains complete clinical datasets generated during the ICU stays. Inclusion criteria: > 18 years of age and admission to the adult intensive care unit at Skåne University Hospital, Lund during the period from November 2006 to August 2019 and treatment with CRRT during the ICU stay. Hypothermia was defined as < 36.0 °C. The temperature measurements (bladder, ear, blood) were carried out hourly. The fraction of hours in hypothermia were compared between the two warmers. A sensitivity analysis was performed where the first two hours of CRRT treatment were excluded in order to test if the phase of starting CRRT was the main driver of overall hypothermia. Means and standard deviations are presented. Significance was tested by using the chi squared test. For all calculations the SAS software version 9.4 (Statistical Analysis Software, Cary, USA) was used. Significance level was defined as p < 0.05.

Results: In total, 57741 hours were available for evaluation in the cohort. Prismaflex patients spent 11.43% (6112 treatment hours below 36 °C /53465 treatment hours in total) of their time in hypothermia, as compared to the novel Prismaflex CRRT system, where 10.06% (430 treatment hours below 36 °C/4276 treatment hours in total) were below 36.0 °C (Chi-Square p = 0.0063). In the sensitivity analysis significant differences between the historic and novel systems prevailed; 12.7% as compared to 11.2% hypothermia hours (p = 0.0216). The Thermax blood warmer was associated with less heat loss compared to the Barkey warmer. This was highlighted by a mean patient temperature of

37 °C vs 36.5 °C correspondingly, but also by the fact that the mean set return temperature was 37.9 °C vs 40.9 °C. This difference in mean set return temperature translates to a significant ($p < 0.001$) difference in the historic Barkey system compared to the new Thermax system. Seemingly, an overcorrection was needed in the Barkey system, probably because of its insufficiency to maintain the sought blood temperature in the patient. In addition, the use of adjacent Bairhugger bodywarmer was significantly less in the Thermax group compared to the Barkey group; 17/32 (53.1%) patients had Bairhugger compared to 285/310 (91.9%) ($p < 0.001$) and for those patients with Bairhugger there were more Bairhugger free hours in the Thermax group compared to the Barkey group; 99.7 ± 93.4 hours without (16.7 ± 16.4 h with) in the Thermax group compared to 73.2 ± 107.3 h without (40.3 ± 45.7 h with) in the Barkey group ($p < 0.01$).

Conclusion: In conclusion, every tenth hour during CRRT was spent in hypothermia. There was a signal that the Prismax CRRT system and the Thermax blood warmer significantly decreased the risk of hypothermia as compared to historic controls with the older Prismaflex and Barkey warmer, in this pilot study. Furthermore, achieving target temperature was easier with the new system and use of auxiliary Bairhugger bodywarmer was significantly less.

Intensive Care Medicine Experimental 2020, **8(2)**: 000109

Introduction: After acute phase of circulatory failure, some authors suggest to have a derresuscitation strategy to avoid side effects of fluid overload, involving mechanical or diuretic's induced fluid removal (1). According to frank starling, hypovolemia should induce a decrease in cardiac index. We hypothesized that an absence of refilling detected by an hemoconcentration, or a preload responsiveness before fluid removal could predict cardiac index (CI) decrease during mechanical fluid removal induced by renal replacement therapy.

Methods: We conducted a single center prospective diagnostic accuracy study in an intensive care unit of an academic French hospital. Primary aim of the study was to evaluate diagnostic performance of haemoconcentration based on proteinemia variation to detect CI decrease $\geq 12\%$ during mechanical fluid removal. Secondary aims were to evaluate diagnostic performance of passive leg raising (PLR) or CI trending by pulse contour analysis to detect CI decrease, and to describe hemodynamic variations observed during mechanical fluid removal. Patients were adults treated with continuous renal replacement therapy, and fluid removal; and monitored by transpulmonary thermodilution technique. Non inclusion criteria were needs to sedation or vasoactive drug adjustment, compartment abdominal syndrome, pregnancy. Patients experienced a fluid removal challenge

(FRC), consisting in a mechanical fluid removal of 500 mL during one hour. Fluid removal was stopped if hypotension occurred. Biological samples with proteinemia and haemoglobin, PLR and transpulmonary thermodilution were carried out just before and just after the FRC. We constructed Receptor Operative Characteristics (ROC) curves with computation of area under the curve (AUC) to evaluate diagnostic performance of different variables. 95% confidence interval was determined by bootstrap technic with 2000 repetitions. Comparisons between groups were analysed with a Mann-Whitney U test. All tests were two-sided, and p-value below 0.05 defined statistical significance.

Results: We included sixty-nine patients between December 2016 and April 2020. Sixteen patients had a significant CI decrease (23% [CI95% 14-35]). Patient's age was 64 [52, 72], 46 (67%) were cardiac surgical patients, 41 (59%) benefited from mechanical ventilation, 29 (42%) presented arrhythmia, cumulative fluid balance at baseline was 7% [- 1, 16], SOFA score was 12 [8, 14]. To compare with patient without CI decrease, patients with significant CI decrease presented: no variation concerning arterial pressure or heart rate; a preload decrease (global end diastolic volume index decrease -8% [CI95% - 20, - 5] vs 0 [CI95% - 4, 6]); a systemic vascular resistance index increase (29% [CI95% 14, 30] vs 2% [- 7, 14]); a more important decrease in cardiac function index (- 9% [CI95% - 16, - 2] vs - 4% [CI95% - 8, 3]). Hemoconcentration evaluated by proteinemia or haemoglobin variations, PLR before or after FRC, and CI trending by pulse contour analysis failed to predict CI decrease with AUC under ROC curve > 0.75 .

Conclusion: Haemoconcentration variables, preload responsiveness status and CI trending by pulse contour analysis failed to predict a CI decrease during FRC. As we observed several events of CI reduction, monitoring cardiac index with transpulmonary thermodilution technique might help to prevent deleterious effect of fluid removal.

The duration of acute kidney injury is an additional parameter to predict 1-year survival in very elderly patients

F. ZHOU¹; L. Qinglin¹; M. Zhi¹; T. Sheng¹

¹Department of critical care medicine, Chinese PLA General Hospital, Beijing, China

Correspondence: F. ZHOU

Intensive Care Medicine Experimental 2020, **8(2)**: 000178

Introduction: Acute kidney injury (AKI) severity is classified into three stages on the basis of either the increase in serum creatinine (Scr) level or the duration and extent of oliguria by KDIGO criteria. However, the diagnostic and staging criteria do not take into account the duration of Scr elevation, which reflects the time to renal function recovery and could be an important potential dimension of AKI along with severity.

Objectives: We sought to explore the association between the duration of AKI based on Scr and 1-year mortality and to examine whether the duration of AKI offered any additional prognostic information over the magnitude of elevation in Scr.

Methods: This retrospective study was conducted from 2007 to 2018 with very elderly patients (≥ 75 years) from the Chinese PLA General Hospital. AKI was stratified by magnitude according to KDIGO stage and duration (1-2 days, 3-4 days, 5-7 days, and > 7 days). The primary outcome was the 1-year mortality rate after AKI.

Results: During the study period, a total of 688 AKI patients were included in the analysis. The median age was 88 (84-91) years. According to the KDIGO criteria, 317 patients (46.1%) had stage 1 AKI, 169 (24.6%) had stage 2 AKI, and 202 (29.4%) had stage 3 AKI. Of the 688 study subjects, we stratified patients by duration of AKI: 1-2 days (61; 8.9%), 3-4 days (104; 15.1%), 5-7 days (140; 20.3%), and > 7 days (383; 55.7%).

The Kaplan-Meier survival plot demonstrates that 1-year survival was significantly different according to both AKI stage and duration. As the duration of AKI increased within each strata of AKI severity as defined by the KDIGO criteria (magnitude), 1-year survival decreased, but no significant differences were found for patients with stage 1 and stage 2 AKI (stage 1, $P = 0.526$; stage 2, $P = 0.818$; stage 3, $P = 0.016$).

However, survival significantly changed within each strata of AKI classified by duration. Notably, the 1-year mortality rates were greater for those with a duration of 3–4 days, a duration of 5–7 days, and a duration of > 7 days of AKI. These relationships were confirmed when we examined the stratified survival plots. When patients were stratified by the stage of AKI, patients with increasing duration of AKI had significantly worse 1-year survival in the group with AKI stage 3 (log-rank test: $P < 0.001$), but no differences were found in the group with stage 1 or stage 2 (log-rank test: both $P > 0.05$). In contrast, when patients were stratified by the duration of AKI, the magnitude of Scr increase as classified by KDIGO was significantly associated with 1-year mortality (log-rank test: $P < 0.05$ for all four strata).

According to the multivariate regression analysis, both AKI duration (3–4 days: HR = 3.184; 95% CI: 1.733–5.853; $P < 0.001$, 5–7 days: HR = 1.915; 95% CI: 1.073–3.416; $P = 0.028$; > 7 days: HR = 1.766; 95% CI: 1.017–3.065; $P = 0.043$) and more advanced AKI stage (stage 2: HR = 3.063; 95% CI: 2.207–4.252; $P < 0.001$; stage 3: HR = 7.333; 95% CI: 5.274–10.197; $P < 0.001$) were independently associated with 1-year mortality.

Conclusion: In conclusion, the duration of AKI in geriatric patients is independently associated with 1-year mortality and may add prognostic value in addition to that provided by the magnitude of Scr alone. These data need to be validated in other settings of AKI, and if found to be valid, the duration of AKI should be incorporated into the consensus definitions of AKI and target AKI duration for clinical management.

Intensive Care Medicine Experimental 2020, **8(2)**: 000334

Introduction: Acute kidney injury (AKI) is common and serious complication in critically ill. AKI treated with continuous renal replacement therapy (CRRT) may alter trace element levels in critically ill patients and at risk for disturbances in plasma levels of trace elements due to the underlying illness, AKI, and dialysis 1.

Objectives: We aimed to determine trace element balances during CRRT in critically ill patients.

Methods: The study was conducted prospectively in intensive care unit (ICU). The study included patients aged ≥ 18 years who were admitted in ICU with AKI and required CRRT support (continuous venovenous hemodiafiltration, CVVHDF). Serum trace elements (copper, zinc, selenium, chromium and cobalt) measured were measured using the high performance liquid chromatography on the first three days of CVVHDF and first two days after CVVHDF.

Results: We enrolled 50 patients. The median (min-max) age was 64(18-88) years. The most common reasons for ICU admission were respiratory failure (34%) and metabolic disorders (20%). The median (min-max) baseline APACHE II score and NUTRIC score of the patients was 24.0 (6.0-33.0) and 5 (0-8), respectively. The mean days on CRRT was 2.4 ± 0.5 days. Serum copper, zinc, selenium, chromium and cobalt levels at all times and reference range showed Table 1. Serum trace elements was not significantly different from baseline at all times ($p > 0.05$).

Table 1. Serum copper, zinc, selenium, chromium and cobalt levels

Variable	Value	Reference range
Copper, µg/dl		
In dialysis, ±SD		
Baseline	79.5±32.56	
Day 1	80.27±32.50	
Day 3	86.04±27.82	75–145 µg/dL2
After dialysis, ±SD		
Day 1	66.63±28.34	
Day 2	69.43±29.86	
Zinc, µg/dl		
In dialysis, ±SD		
Baseline	51.71±22.60	66-110 µg/dL2
Day 1	53.00±25.50	
Day 3	47.13±25.92	
After dialysis, ±SD		
Day 1	51.19±30.72	
Day 2	48.07±30.01	
Selenium, µg/dl		
In dialysis, ±SD		
Baseline	2.09±1.36	
Day 1	1.92±1.15	5.8–23.4 µg/dL2
Day 3	2.30±0.90	
After dialysis, range		
Day 1	2.70(0.30-98.80)	
Day 2	2.60(1.30-41.50)	
Chromium, µg/dl		
In dialysis, ±SD		
Baseline	11.20±3.40	
Day 1	11.19±3.25	
Day 3	10.93±2.48	0-5 µg/dL3
After dialysis, ±SD		
Day 1	11.07±5.01	
Day 2	12.65±4.04	
Cobalt, µg/dl		
In dialysis, ±SD		
Baseline	1.03±0.76	
Day 1	1.06±0.72	0-12 µg/dL3
Day 3	0.67±0.47	
After dialysis, range		
Day 1	0.7(0.3-13.0)	
Day 2	0.6 (0.3-4.7)	

Conclusion: End of the study, serum chromium and selenium was tended to increase on follow-up while cobalt, copper and zinc was tended to decrease on follow-up. However, the difference in these parameters was not statistically significant.

Intensive Care Medicine Experimental 2020, **8(2)**: 000369

Introduction: Acute kidney injury (AKI) is common in surgical patients. We aimed to investigate the validity of plasma and urine neutrophil gelatinase-associated lipocalin (NGAL) in the early detection of AKI and prediction of outcomes in patients undergoing major elective colorectal surgery.

Methods: This was a post-hoc analysis of a randomized controlled trial comparing oesophageal doppler and Lithium dilution cardiac output monitoring for intraoperative haemodynamic monitoring in high risk patients undergoing major colorectal surgery in a tertiary care hospital. Plasma and urine samples were collected before surgery (T1), immediately after surgery (T2), and on postoperative day 1 (T3) and NGAL levels were measured. We collected baseline demographics, perioperative parameters, hospital and long-term mortality. We identified patients with AKI according to KDIGO criteria and compared them with patients without AKI.

Results: A total of 89 patients were included, of whom 12 (13.5%) developed AKI. Plasma NGAL significantly increased from T1 to T3 in both AKI ($P < 0.001$) and non-AKI ($P = 0.048$) patients, while urine NGAL did not change over time. There were no significant differences in plasma and urine NGAL in patients with and without AKI at all time points. Baseline plasma NGAL and post-operative urine NGAL were higher in 8-year non-survivors than survivors. AKI patients with raised plasma or urine NGAL had a higher long-term mortality than AKI patients without a raised NGAL.

Conclusion: Plasma and urine NGAL poorly predicted AKI post-colorectal surgery. Both plasma and urine NGAL were higher in non-survivors although further studies are needed to determine the association between NGAL and long-term outcomes.

Reference(s) and grant acknowledgment(s)

1. The authors acknowledged BioPorto Diagnostics A/S for assistance with urine and plasma NGAL measurement. Data collection was collated by the Colorectal Enhanced Recovery Team – Marie Morris, Lucy Morris, and Jane Varghese. Perioperative care was predominantly provided by the following consultant anaesthetists and surgeons – Emin Carapeti, Amir Darakhshan, Vivek Datta, Mark George, David James, Stuart McCorkell, Veda Ponnaiah, Emma Taylor, Andy Williams, and Georgina Wilson – and staff in the Overnight Intensive Recovery Unit. Linda Tovey and the ICU technicians processed the NGAL samples.
2. The study was funded by a New Services and Innovation Grant awarded by the Guy's & St Thomas' Charities. A full-time research assistant was funded jointly with contribution by the medical device manufacturer, Deltex Medical (Chichester, UK).

Impact of a computerized decision support tool and care bundle on critical care costs of acute kidney injury (AKI) patients

L. Atallah¹; E. Ghosh¹; J. Rivers²; C. Bourdeaux²
¹Connected care and personal health, Philips Research North America, Cambridge, United States of America; ²Department of intensive care, University Hospitals Bristol NHS Foundation Trust, Bristol, United Kingdom

Correspondence: E. Ghosh

Intensive Care Medicine Experimental 2020, **8(2)**: 000509

Introduction: Acute kidney injury is one of the most common complications in critical care. It is associated with high mortality, increased length of stay and adverse long-term outcomes. Clinical decision support (CDS) tools have provided means of alerting clinicians to deteriorating patients leading to better management and improved outcomes. A study was conducted in two ICU units in University Hospitals Bristol, UK. It involved integrating a CDS intervention based on Acute Kidney Injury Network (AKIN) guidelines and a care bundle consisting of alerts, dashboard and order sets.

Objectives: The study involved a before (control) and after (intervention) phases. It investigated the effect of the intervention on the number of patients deteriorating to higher AKI levels as well as measuring medication adherence. This work investigates the in-ICU costs relating to the length of stay of AKI patients before and after the intervention.

Methods: AKI score was calculated anytime a new urine output or Serum Creatinine was measured. The costs for each stage of AKI (1-3, according to AKIN) were calculated as the number of patients per stage, multiplied by the average LOS and the average cost of an ICU day in intensive care based on hospital averages (£1981). This provides a minimal value, as the costs associated with higher AKI levels are higher.

Results: Each arm of the study was run for 1 year with 2523 ICU admissions in the control phase followed by 2521 ICU admissions in the intervention phase. The prevalence of patients developing any AKI decreased from 43.1% (control) to 37.5% (intervention). There was a reduction in the proportion of patients in each stage of AKI. This was accompanied with a reduction in LOS for the three levels. In control cohort, the mean LOS for AKI stage 1 was 6.4 days which reduced to 5.0 days in intervention. For stage 2 and stage 3, the reduction was (8.2 days; control to 7.3 days; intervention) and (10.8 days; control to 10.2 days; intervention) respectively. Overall, minimal ICU costs for all AKI patient days were £14,459,874 for 1018 AKI patients in the control phase and £10,163,738 for 870 AKI patients in the intervention phase.

Conclusion: In comparison to the control phase, the study showed that the introduction of AKI guidelines and care bundle increased AKI vigilance, leading to proactive measures in managing AKI. This led to a reduction of patients with AKI in the intervention phase, accompanied by an overall shorter length of stay. ICU costs were reduced by 30% if only length of stay were to be considered as a contributing factor. This, however, is a rather simplified view of ICU costs. Further work should include the effect of treatments, long-term follow-up and readmission on costs.

Introduction: COVID 19 community acquired pneumonia is a recent and frequent cause of admission in European intensive care units. Currently, there are many open questions regarding the management

and prognostic factors of these patients. Among them, its association with acute renal failure in patients on mechanical ventilation.

Objectives: Analysis of acute renal failure in COVID 19 patients on mechanical ventilation. Prognosis and factors related to its development.

Methods: Retrospective observational study carried out in the intensive care unit of a University Hospital during the COVID 19 pandemic. We analysed patients admitted to the ICU with the diagnosis of Respiratory Failure due to pneumonia COVID 19 between 6/3/2020 and 21/4/2020. Demographic data (age, sex), APACHE II, comorbidities, analytical data (ferritin, total bilirubin), length of stay, treatments administered (mechanical ventilation, muscle relaxant, vasoactive drugs, prone) and its association to acute renal failure were analysed.

Results: 67 patients received complete treatment in our hospital. 67.2% males with an average age 60 years, length of stay (days) 14.1 ± 10 , APACHE II 14.3 ± 5.2 . Maximum creatinine mean value (mg/dl) 1.48 ± 1.26 , maximum ferritin mean value (ng/ml) 2310 ± 3322 , maximum total bilirubin mean value (mg/dl) 2 ± 2.2 . 100% of the patients required mechanical ventilation. 65.7% prone positioning, 74.6% neuromuscular blockers and 98.5% required vasoactive drugs. Establishing renal failure as creatinine values greater than 1.2 mg / dl, the results shown in Table 1 were obtained.

	Creatinine > 1,2 mg/dl	Creatinine < 1,2 mg/dl	P
Age (years)	61,3	59	0,37
APACHE II	15,8	13,3	0,128
Ferritine (max)	3421	1535	0,035
D-Dimer (max)	23,5	15	0,19
Bilirubine (max)	3	1,4	0,012

Table 2 shows the mean creatinine values in patients, who require prone positioning, muscular blockers, have cardiovascular disease, dyslipidaemia, survivors, and non-survivors.

	Level of creatinine (mg/dl)		P
	Yes	No	
Prone	1,51	1,43	0,8
Muscular bloq.	1,49	1,46	0,9
Sex (male)	1,81	0,8	0,002
CV disease	1,69	1,3	0,22
Dyslipidemia	1,92	1,22	0,026
Suoerinfecction	1,62	1,3	0,29
Survivors	1,07	1,96	0,003

Conclusion: In our sample, we have associated acute renal failure with higher ferritin values. Likewise, we have observed higher creatinine values in the group of non-survivors, those with dyslipidaemia and men, with statistical signification.

Intensive Care Medicine Experimental 2020, **8(2)**: 000837

Introduction: Astrointestinal dysfunction may lead to increased mucosal permeability and leakage of endotoxin. Although coronaviruses are known mainly as respiratory pathogens, up to 60% of COVID-19 patients show gastrointestinal symptoms at admission or developed during hospitalization. Recent published data show how endotoxemia and bacterial DNA are frequently found in patients with COVID-19 pneumonia, indicating that loss of intestinal barrier function

can contribute to the pathogenesis of COVID-19. In addition, patients who are hospitalized for extended periods in an ICU are more prone to superimposed infections.

Objectives: In this retrospective analysis we report our experience of Polymyxin B hemoperfusion (PMX-HP) as complementary therapy for unresponsive endotoxic shock management in 5 patients with COVID-19 hospitalized in our ICU ward between February and April 2020. To the best of our knowledge, there is no data published yet concerning PMX-HP use in COVID-19 patients.

Methods: In the present case series, we evaluated the impact of PMX-HP as adjunctive therapy in a population of patients affected by COVID-19 and confirmed endotoxic shock identified my measurement of endotoxin activity at enrollment. Hemodynamics and main clinically relevant outcome parameters were monitored. PMX-HP treatment consists of 2 hemoperfusion sessions, the second session performed 24 hours after the first one, at a blood flow rate of 100 ml/min. Unfractionated heparin was used as standard anticoagulant.

Results: PMX-HP treatment was associated with rapid hemodynamic stabilization with reduction of Vasopressors Inotropic Score (VIS) – (from a mean value of $29 \pm 15,17$ to $2,60 \pm 2,88$ at 120 hours, $p < 0,05$), reduction in blood lactate levels (from $2,84 \pm 1,43$ to $1,08$ mmol/l $\pm 0,54$ at 120 hours – $p < 0,05$), rapid decrease in Endotoxin Activity (EA) levels (from a mean EA value of $0,70 \pm 0,10$ to $0,49 \pm 0,13$ at 48 hours – $p < 0,05$) in a population affected by SARS-CoV-2 and endotoxic shock. PMX-HP treatment resulted safe and well-tolerated with no device related adverse events during or after hemoperfusion sessions. All patients received 2 hemoperfusion sessions.

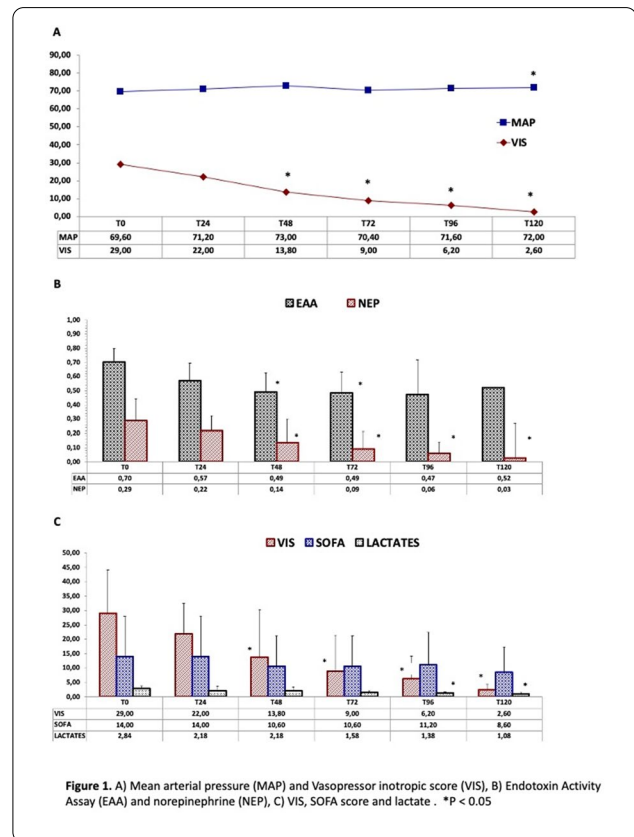

Figure 1. A) Mean arterial pressure (MAP) and Vasopressor inotropic score (VIS), B) Endotoxin Activity Assay (EAA) and norepinephrine (NEP), C) VIS, SOFA score and lactate . *P < 0.05

Conclusion. Endotoxic shock could be associated to SARS-CoV-2. PMX-HP can be considered for management of unresponsive endotoxic shock. In our cases, PMX-HP treatment was associated with rapid hemodynamic improvement associated with a rapid decrease in vasopressor use, blood lactates and EAA levels. PMX-HP treatment was safe with no device-related adverse events.

Intensive Care Medicine Experimental 2020, **8(2)**: 000839

Introduction. Acute Kidney Injury (AKI) is a common complication in trauma with 24% of incidence in intensive care unit and it is independently associated with increased morbidity and mortality, but also prolonged length of stay. The high incidence of AKI in trauma patients should lead to early identification of those at risk of AKI to establish a resuscitation strategy that aims at preventing AKI.

Methods: Detailed data of trauma patients between May, 2017 and May, 2019 were retrieved from icu medical records. In particular, patients' demographics, hemodynamic parameters, biochemical parameter and fluid balance, urinary output, sCr values at baseline, 24 hrs, 48 hrs, and 72 hrs. Short and long terms outcomes had been analysed.

Results. Based on KDIGO criteria, 45 patients developed AKI (29.4%). 29 patients (19.9%) developed stage 1 AKI, 16 patients (10.5%) stage 2-3 AKI. Patients with elevated urinary biomarkers alone undergoing therapeutic interventions had 8.5% stage 2-3 AKI compared to 33% of patients with creatinine elevation only, and 50% of patients with both increased creatinine and AKI risk score. A number of 19 patients (23%) with urinary markers driven interventions progressed to higher stages of AKI, while 7 (8.5%) improved AKI stage.

Outcome	No AKI (N=29)	AKI stage 1 (N=16)	AKI stage 2-3 (N=29)	AKI (all patients) N=45
RRT	0	0	0	5 (11%)
Ventilation free days	1.8(2.1)	1.7(1.4)	2.0(2.5)	1.8(1.9)
MV length	5.9(9.3)	4.7(6.6)	7.4(10.1)	5.9(8.6)
ICU stay	7.7(9.3)	6.3(6.7)	9.4(9.8)	7.7(8.0)
Hospital stay	18.1(16.3)	19.3(15.6)	18.5(19.6)	19.1(17.3)
Renal recovery	NA	26(89%)	11(68.5%)	37(82.2%)
Survival over 24 hrs from ER arrival	108(100%)	29(100%)	16(100%)	45 (100%)

Conclusion: AKI is a frequent complication following trauma. Although the reduction of stage 2/3 AKI based on therapeutic interventions driven by elevated urinary biomarkers was observed in 8% of patients, the use of biomarkers represent an important tool for the early detection of patients at high risk of AKI behind the local ICU experience based on multidisciplinary team.

Can dexmedetomidine reduce the incidence of AKI?

M. Giovini¹; M. Barbera¹; E. Antonucci¹

¹Intermediate care unit, Ospedale "Guglielmo da Saliceto", Piacenza, Italy

Correspondence: E. Antonucci

Intensive Care Medicine Experimental 2020, **8(2)**: 000886

Introduction: Dexmedetomidine (DEX) is a common sedative agent that may protect against organ dysfunction such as acute kidney injury (AKI) by reducing inflammatory response. A recent post-hoc analysis¹ has found that DEX treatment is associated with reduced AKI and mortality rate among septic patients. However, no human study has ever explored confounding factors that could increase AKI-risk in NO-DEX group (i.e. nephrotoxic drugs; chronic kidney disease, CKD). For these reasons, we analyzed a well stratified cohort of septic patients that need sedative agents and have been exposed to similar risk factors for AKI development.

Objectives: We hypothesized that DEX could reduce AKI incidence when compared to NO-DEX sedative agents in septic patients.

Methods: We performed a retrospective analysis, reviewing all patients admitted for sepsis to our intermediate care unit (IMCU) from January 1st 2018 to December 31st 2019. The inclusion criteria were: age ≥ 18 years old; diagnosis of sepsis at admission; need of sedative agents for delirium. Exclusion criteria were: chronic need of hemodialysis; use of sedative agents beyond delirium. NO-DEX agents included benzodiazepines, quetiapine and haloperidol. AKI was identified by KDIGO criteria. We analyzed two groups (DEX and NO-DEX) matched for age, SAPS2 score, SOFA score and CKD. We investigated rates of AKI and mortality at 90 days in the two groups. We also analyzed some confounding factors such as circulatory failure (CF), use of iodinated contrast media (ICM), aminoglycosides, glycopeptides, colistin, ACEi/sartans and non steroidal anti-inflammatory drugs (NSAID).

Results: We reviewed 34 patients and 22/34 respected the inclusion criteria (11 in DEX group; 11 in NO-DEX group). The two groups were well matched (SAPS 2 score: 33 ± 1 (DEX), 33 ± 3 (NO-DEX) p = 0.5; SOFA score: 4 ± 1 (DEX), 4 ± 4 (NO-DEX) p = 0.4; age: 70 ± 11 (DEX), 70 ± 3 (NO-DEX) p = 0.5; CKD: 3/11 patients (DEX), 2/11 patients (NO-DEX). We found that DEX significantly decreases AKI rate (DEX 1/11 patients; NO DEX 6/11 patients; OR 0.08, 95% CI 0.008-0.895, p = 0.04). We also found no significant difference in mortality at 90 days between the two groups (NO DEX 2/11 patients; DEX 5/11 patients; OR 3.75, 95% CI 0.54-26.05, p = 0.2). In the Table 1 we have reported AKI characteristics for every single patient. About confounding factors, only a patient in NO DEX group received ICM, ACEi/sartans and NSAID all together. Remaining 5 AKI patients in NO-DEX groups did not receive any nephrotoxic drug. Only a patient in DEX group showed AKI and received colistin and DEX treatment at the same time. In conclusion, the higher AKI rate in NO-DEX group was not significantly linked to confounding factors.

	DEX	NO-DEX		
KDIGO STAGE 1		x	x	
KDIGO STAGE 2	x		x	x
KDIGO STAGE 3/RRT				x x
ALTERED RENAL FUNCTION AT DISCHARGE	x		x	x x
ICM				x
ACEi/Sartans				x
NSAI drugs				x
CF				
Colistin	x			
Aminoglycosides				
Glycopeptides				

Table 1 - AKI characteristics and confounding factors. Every column represents a single patient - RRT, renal replacement therapy.

Conclusion: DEX could reduce the incidence of AKI in septic patients when compared with other sedative agents. Future large randomized studies are necessary to confirm these preliminary findings.

Intensive Care Medicine Experimental 2020, **8(2)**: 000928

Introduction: Hemodynamic instability is a frequent complication of continuous renal replacement therapy (CRRT) in intensive care patients. Postural tests (i.e. passive leg raising in the supine position or Trendelenburg in the prone position) combined with continuous measurement of cardiac output are highly reliable to identify preload dependence and may provide new insights into the mechanisms involved in hemodynamic instability related to renal replacement therapy (HIRRT).

Objectives: We aimed to assess the prevalence and risk factors of HIRRT associated with preload-dependence in ICU patients.

Methods: We conducted a single-center prospective observational study in ICU patients with acute kidney injury KDIGO 3, started on CRRT in the last 24 hours, and monitored with a PiCCO® device. The primary endpoint was the rate of HIRRT episodes associated with preload dependence during the first 7 days of CRRT. HIRRT was defined as the occurrence of a mean arterial pressure below 65 mm Hg requiring any of the following therapeutic intervention (initiation or increase in vasopressor dose, discontinuation or decrease of fluid removal by CRRT, or fluid administration). Preload dependence was assessed every 4 hours, and during each hypotensive episode, and was deemed present if the continuous cardiac index increased by at least 10 % during a passive leg raising test in supine patients, or 8 % during Trendelenburg in prone patients. Data are expressed in median [1st quartile-3rd quartile], unless stated otherwise.

Results: 32 patients (59% male, age 67 [58-75] year, SAPS-2 71 [49-78]) were included 8 [1-14] hours after CRRT initiation and studied continuously for 99 [55-144] hours. 29 [18-40] hemodynamic evaluations per patient were performed for a total of 903 hemodynamic evaluations. Preload-dependence was present in 42% of the hemodynamic evaluations. RRT modality was CVVH during 91% of the hemodynamic evaluations and CVVHD in 9%. Ultrafiltration rate was 27 [24-31] mL.kg⁻¹.hr⁻¹ in CVVH-treated patients, dialysate rate was 26 [20-29] mL.kg⁻¹.hr⁻¹ in CVVHD-treated patients, and net UF was 100 [0-200] mL.hr⁻¹. All patients experienced at least 1 episode of HIRRT. A median of 4 [3-7] HIRRT episodes occurred per patient, for a pooled total of 173 episodes. 94 episodes (54% [CI95%: 47-62%]) were associated with preload-dependence, 75 (43%, [CI95%: 36-51%]) without preload-dependence, and 2 were unclassified. Therapeutic management of HIRRT episodes is reported in the figure below. Multivariate analysis (using variables collected prior to HIRRT) identified the following variables as risk factors for the occurrence of HIRRT associated with preload-dependence: preload-dependence before HIRRT (odds ratio = 3.66, $p < 0.001$), delay since last HIRRT episode of at least 4 hours (OR = 0.35, $p < 0.01$), lactate (OR = 1.22 per 1.9 mmol/L increase, $p < 0.01$), cardiac index (0.58 per 1 L.min⁻¹.m⁻² increase, $p < 0.01$) and SOFA at ICU admission (0.90 per 1 point increase, $p < 0.01$).

Conclusion: In this single center study, HIRRT associated with preload dependence was slightly more frequent than HIRRT without preload dependence in ICU patients undergoing CRRT. Testing for preload dependence to adjust fluid removal could help preventing HIRRT incidence during CRRT.

Intensive Care Medicine Experimental 2020, **8(2)**: 000971

Introduction: TIMP2 and IGFBP7 are specific biomarkers of structural renal injury in critically ill patients. The composite of [TIMP-2]-[IGFBP7] in urine is suggested to better detect and stratify acute kidney injury (AKI). To date, there is not enough data in medical-surgical ICUs where renal critical care is essentially led by primary intensivists. We designed an observational study to define our population as a first step of an ongoing quality improvement project in AKI in Catalonia.

Objectives: To assess the prognostic value of a single [TIMP-2]-[IGFBP7] determination for predicting mortality at ICU admission.

Methods: Prospective, observational study in five tertiary university intensive care units. We included medical and surgical adult patients with an expected ICU stay more than 24 hours. We excluded those pregnant, post cardiac surgery, with severe acute kidney injury (KDIGO3) at admission or requiring bladder washouts. Epidemiological, clinical and laboratory variables were collected during more than 7 days of stay. [TIMP2]-[IGFBP7] ((ng/mL)²/1000) was analysed in an admission urine sample by Nephrocheck® Vitros 3600 platform (NC). Descriptive and survival analysis were made using Stata v.16. The descriptive results are shown in median and interquartile range (IQR). We stratified patients in three groups according acute kidney injury risk: low, NC1 < 0.3; high, NC2 0.3-2; very high, NC3 > 2 (ng/mL)²/1000).

Results: The sample included 476 patients (Table 1), with median age of 61 (IQR 48-71.5) years; 271 (57%) were women. Median ICU length of stay was 7 (IQR 4-17) days. Patients in NC3 group had a hazard ratio for mortality of 2.8 compared to NC1 group (CI 95% 1.5-5.2; $p = 0.001$). According to the Kaplan-Meier curve, the probability of death at 28

days of admission of patients in NC3 group was 52% (CI 95% 24-68%) (figure 1).

Table 1. Main characteristics of study population. Values expressed as either % or median with interquartile range (IQR)

VARIABLE	TOTAL (n = 476)
Age (years)	61 (IQR 48-71.5)
Female	57% (271/476)
ICU length of stay (days)	7 (IQR 4-17)
Hospital length of stay (days)	17 (IQR 9-32)
ICU mortality	17% (81/476)
Days on mechanical ventilation	4 (IQR 2-10)
SOFA day 1	5 (IQR 1-8)
APACHE II	20 (IQR 14-26)
Baseline serum creatinine (umol/L)	76 (IQR 63-98)
[TIMP2]-[IGFBP7] in (ng/mL)2/1000	0.07 (IQR 0.04-7.52)
AKI (KDIGO >0) at 48 hours	30% (143/476)
Renal replacement during ICU stay	5.5% (26/476)

Figure 1. Kaplan-Meier graph depicting overall survival stratified by AKI groups risk NCI, NC2 and NC3 depending on [TIMP2]-[IGFBP7] cut-offs 0.3 and 2 (ng/mL)2/1000.

Conclusion: In our study, patients with NC > 2(ng/mL)2/1000 had a significant higher mortality rate compared to those with low NC values.

Introduction: TIMP2 and IGFBP7 are specific biomarkers of structural renal injury in critically ill patients. The composite of [TIMP2]-[IGFBP7] in urine is suggested to better detect and stratify acute kidney injury (AKI). To date, there is not enough data in medical-surgical ICUs where renal critical care is essentially led by primary intensivists. We designed an observational study to define our population as a first step of an ongoing quality improvement project in AKI in Catalonia.

Objectives: To analyse the predictive value of urinary [TIMP2]-[IGFBP7] to predict acute kidney injury in critically ill patients.

Methods: Prospective, observational study in five tertiary university intensive care units. We included medical and surgical adult patients with an expected ICU stay more than 24 hours. We excluded those pregnant, post cardiac surgery, with severe acute kidney injury (KDIGO3) at admission or requiring bladder washouts. Epidemiological, clinical and laboratory variables were collected during the first 7 days of stay. [TIMP2]-[IGFBP7] ((ng/mL)2/1000) was analysed in an admission urine sample by Nephrocheck[®] Vitros 3600 platform (NC). Descriptive and predictive analysis were made using Stata v.16. The results are shown in median and interquartile range (IQR), sensibility (S) - specificity analysis (E), and predictive capability with ROC and area under the curve (AUC).

Results: Of 476 patients in our cohort, we selected 287 who did not present AKI (table 1). Median age was 59 (IQR 46-71) years; 54% were women. Patients with NC > 0.3 had a higher ICU mortality rate (45% vs 20%, $p = 0.032$). The AUC ROC curve to predict AKI KDIGO 2-3 of NC during the first week of ICU stay was 0.68 (IC 95% 0.48-0.89; $p < 0.001$) (figure 1). The negative predictive value for NC < 0.3(ng/mL)2/1000 was 98% (S 44.4%, E 86.3%). The positive predictive value for NC > 2 was 50% (S 11.1%, E 99.6%).

Table 1. Main characteristics of study population. Values expressed as either % or median with interquartile range (IQR)

VARIABLE	TOTAL (N=287)
Age (years)	59 (IQR 46-71)
Female	54% (155/287)
ICU length of stay (days)	5 (IQR 3-10)
Hospital length of stay (days)	17 (IQR 9-32)
ICU mortality	13.9% (40/287)
Days on mechanical ventilation	3 (IQR 2-7)
SOFA day 1	4 (IQR 1-7)
APACHE II	18 (IQR 13-24)
Baseline serum creatinine (umol/L)	76 (IQR 62-94)
[TIMP2]-[IGFBP7] in (ng/mL)2/1000	0.07 (IQR 0.04-7.52)

Figure 1. ROC curve and area under the curve (AUC) for [TIMP2]-[IGFBP7] to predict AKI KDIGO 2-3 during the first ICU week

Conclusion: Although in our study [TIMP2]-[IGFBP7] had a low predictive capacity to diagnose severe AKI, it showed a very high negative predictive value.

Dimopoulos*Intensive Care Medicine Experimental* 2020, **8(2)**: 000999**Introduction:** Acute kidney injury (AKI) occurs frequently in patients after cardiac surgery and has been associated with poor outcome.**Objectives:** To assess prevalence of AKI in patients admitted to intensive care unit (ICU) post-cardiac surgery during an immediate postoperative period of 24 hours, evaluate predisposing risk factors and its association with outcome.**Methods:** 199 (60 women) consecutive patients admitted to ICU post-cardiac surgery participated in this study. Kidney function evaluated pre-operatively and at 24 hours after procedure. An increase in serum creatinine by 0.3mg/dl was considered as AKI, according to KDIGO classification.**Results:** 46 patients (23.1%) developed AKI 24 hours after ICU admission. These patients received more vasoactive drugs (noradrenaline, vasopressin), (54% vs 26%, $p < 0.001$). They also had longer cardio-pulmonary bypass (CPB) time [AKI group: 119(104 – 164) min vs no-AKI group: 106(80 – 142) min, $p < 0.027$], longer administration of sedation [490(300 – 780) min vs 300(240 – 540) min, $p < 0.001$] and longer duration of mechanical ventilation support [1084(732 – 1913) min vs 720(534 – 1073) min, $p \leq 0.0001$]. Finally, patients that developed AKI had significantly higher positive fluid balance during the first 24 hours [1038(363 – 1859) ml vs 501(23 – 1239) ml, $p = 0.005$].**Conclusion:** There is a high prevalence of AKI in patients post cardiac-surgery admitted to ICU. AKI is associated with vasoactive treatment, positive fluid balance, duration of CPB and duration of administration of sedation and duration of mechanical ventilation support.

Early detection of serum biomarkers for sepsis-induced acute kidney injury through metabolomicsF. Ping¹; Y. Guo¹; Y. Cao¹; J. Shang¹; J. Zhang¹; Y. Li¹¹Department of critical care medicine, Shanghai Jiao Tong university affiliated sixth people's hospital, Shanghai, China**Correspondence:** Y. Guo*Intensive Care Medicine Experimental* 2020, **8(2)**: 000572**Introduction:** Sepsis-induced acute kidney injury (AKI) causes high mortality in critical ill patients owing to elevated levels of endotoxin. This situation might be partially attributed to the delayed recognition of AKI because the current diagnosis is based on either an elevation of serum creatinine levels or the detection of oliguria. Metabolomics including diverse detection platforms and multiple analysis methods is a potential tool for identifying small molecule biomarkers of renal diseases.**Objectives:** This study intends to study the alterations of serum metabolomics in rats with sepsis-induced AKI and to find earlier biomarkers of sepsis-induced AKI for early clinical diagnosis and treatment through gas chromatography time-of-flight / mass spectrometry (GC-TOFMS).**Methods:** A rat model of sepsis-induced AKI was established by intraperitoneal injection of Lipopolysaccharide. Thirty SD rats were randomly divided into control group, LPS 2h group and LPS 6h group with 10 rats in each group. Non-targeted metabolomics screening was performed on serum samples of control group and sepsis-induced AKI groups based on Gas chromatography time-of-flight / mass spectrometry (GC-TOFMS) techniques. Combining multivariate and univariate statistical analysis, the comparisons between every two groups were analyzed to screen out the serum metabolites that were statistically altered in the early stage of AKI in rats with sepsis. Finally

differential metabolites obtained from each intergroup comparison are summarized.

Results: Orthogonal partial least square discriminant analysis (OPLS-DA) showed the obvious separation between the control group and the LPS 2h group, the control group and the LPS6h group, the LPS 2h group and the LPS 6h group. Each intergroup comparison can obtain a series of differential metabolites that meet the set threshold in the "potential biomarkers" section. The results of differential metabolites obtained from each intergroup comparison are intersected and summarized, which suggested that three metabolites were always significantly different in the development of sepsis-induced AKI. The potential three biomarkers for sepsis-induced AKI were Malic acid, Methionine sulfoxide and Petroselinic acid.**Conclusion:** Our findings suggested that the levels of Malic acid, Methionine sulfoxide and Petroselinic acid in the serum are expected to be candidates for early diagnosis of sepsis-induced AKI in rats.**Reference(s) and grant acknowledgment(s)**

Cystatin C is a good predictor of acute kidney injury after elective aortic surgeryS. Maricic Prijic¹; A. Uvelin¹; N. Andjelic¹; A. Plecas Djuric¹; G. Jovanovic¹; S. Vickovic¹; M. Lukic Sarkanovic¹; R. Popovic¹; T. Tubic¹¹Department of anesthesiology, intensive therapy and pain therapy, clinical centre of vojvodina, Faculty of Medicine, University of Novi Sad, Novi Sad, Serbia**Correspondence:** S. Maricic Prijic*Intensive Care Medicine Experimental* 2020, **8(2)**: 000113**Introduction:** Acute kidney injury is frequent and serious complication after aortic surgery which increases length of hospital stay, costs, morbidity and mortality. Earlier recognition of patients at risk by predictive factors and identification of acute kidney injury could have important role on right timing of preventive and therapeutic measures and lower mortality of these patients.**Objectives:** To investigate the most important preoperative and intraoperative predictive factors for acute kidney injury 72 hours after elective infrarenal aortic surgery.**Methods:** This prospective observational study was performed at Clinic of Anesthesia, Intensive Care and Pain Therapy and Clinic of Vascular and Transplantation Surgery, Clinical Centre of Vojvodina, during the period of 18 months, from October 2017 till April 2019. It includes 140 adult patient who underwent elective infrarenal aortic surgery. Potential predictive factors were identified out of medical records such as: patient history, anesthesia lists, daily therapeutic lists, vital parameters and laboratory values lists. The occurrence of acute kidney injury was noted according to AKIN criteria. IBM SPSS version 21 (Chicago, Illinois) was used for statistical analysis. The results were presented in tables and graphs, statistical significance was set at p value of less than 0,05. Standard statistical tests were applied. Multivariate logistic regression model was used for potential predictive factors.**Results:** The cut off value of cystatin C serum concentration of 1,14 mg/l has the highest sensitivity (82,5%), and specificity (76%) in the differentiation of patients who will develop acute kidney injury. The final model for predicting acute kidney injury in patients who underwent elective infrarenal aortic surgery contains the following variables: presence of chronic kidney disease, preoperative serum concentration of cystatin C > 1,14 mg/l, application of colloid solutions in volume > 500 ml during the operation and total intravascular fluid replacement volume > 59 ml/kg in intraoperative period. The strongest predictor of

AKI development was cystatin C concentration above 1,14 mg/l with a probability ratio of 17,811.

Conclusion: Presurgical value of cystatin C is a good predictor of acute kidney injury after elective infrarenal aortic surgery.

Intensive Care Medicine Experimental 2020, **8(2)**: 000238

Introduction: Acute kidney injury (AKI) is a common complication among patients undergoing cardiopulmonary bypass (CPB) [1-3], leading to prolonged stay in the intensive care unit (ICU) and higher postoperative mortality [4]. Early identification paired with effective intervention has reduced the frequency and severity of postoperative AKI [2], indicating that early diagnosis is extremely warranted.

Currently, AKI diagnosis is based on KDIGO criteria evaluating serum creatinine (SCr) and urine output [5]. However, SCr has been challenged as it rises slowly after an initial insult (usually 48-72 h) and is influenced by numerous non-renal factors [6-8]. Urinary biomarkers have been extensively studied as promising strategy for early diagnosis. However, the following issues may limit urinary biomarkers from being widely used: (1) The detection needs specific testing facilities, which may not be available in all the hospitals; (2) The visible elevation can only be observed several hours after surgery [9], which still delayed the treatment to get maximum clinical benefit; (3) Most studies involved with urinary biomarkers [9-12] have been limited by the absence of statistical methods to account for overfitting due to small sample size [13] and non-linear correlation [14], leading to poor generalizability and flexibility; and (4) Urinary biomarkers prominently manifest tubular epithelium injury. New biomarkers for AKI induced by open-heart surgery are needed.

Hemolysis with subsequent free hemoglobin (fHb) released by red-blood cells is a significant contributor to AKI among patients undergoing CPB [15, 16]. Levels of fHb peaked 15 min after weaning of CPB [17] and patients with AKI display significantly higher fHb levels compared to patients without AKI [16]. In addition, the difference between levels of fHb at the end of CPB and baseline (Δ fHb) was associated with AKI in pediatric patients [18]. Whether Δ fHb or fHb ratio, defined as levels of fHb at the end of CPB divided by fHb at baseline, are independent risk factors of AKI in adult patients requires further investigation. Moreover, whether Δ fHb or fHb ratio could predict AKI remains unclear.

Therefore, we performed a secondary analysis on the control arm of a randomized controlled trial [3] to determine whether Δ fHb or fHb ratio, an easily detected surrogate of hemolysis, could be identified as an early biomarker for postoperative AKI after open-heart surgery and whether incorporation of fHb ratio could improve predictive performance, compared with using urinary biomarkers alone.

Objectives: To determine whether free hemoglobin (fHb) ratio could predict AKI immediately after open-heart surgery.

Methods: This is a secondary analysis of a randomized controlled trial comparing the effect of nitric oxide (intervention) versus nitrogen (control) on AKI after cardiac surgery (NCT01802619) [1]. 110 adult patients in the control arm were included. First, we determined whether fHb ratio (i.e., levels of fHb at the end of CPB divided by baseline fHb) was associated with AKI via univariable and multivariable analyses.

Second, we verified whether fHb ratio could predict AKI and incorporation of fHb ratio could improve predictive performance of AKI at an early stage, compared with prediction using urinary biomarkers alone. We conducted restricted cubic spline in logistic regression for model development. We used bootstrap-based internal validation to account for overfitting. We also employed concordance (c) statistic, area under curve (AUC) test, resampling model calibration, and likelihood ratio test to compare the predictive performance (i.e., discrimination and calibration) between competing models.

Results: Data stratified by median fHb ratio showed that subjects with an fHb ratio > 2.23 presented higher incidence of AKI (80.0% vs. 49.1%, $p = 0.001$), more need of renal replacement therapy (10.9% vs. 0%, $p = 0.036$), and higher 28-day mortality (10.9% vs. 0%, $p = 0.036$) than subjects with an fHb ratio \leq 2.23. fHb ratio was associated with AKI after adjustment for pre-established factors. Among the four biomarkers, fHb ratio outperformed other biomarkers with the highest AUC of 0.703 (0.600-0.806), best calibration, and minimal optimism (bootstrap-adjusted AUC 0.704, 95% CI 0.592-0.804). Incorporation of fHb ratio achieved better predictive performance in terms of better discrimination (0.771 versus 0.653, $p = 0.012$) and calibration ($p < 0.001$) at an early stage, compared with prediction using urinary biomarkers alone.

Conclusion: fHb ratio at the end of CPB is a novel, widely applicable biomarker for AKI after open-heart surgery and incorporation of fHb ratio can achieve better predictive performance at an early stage, compared with prediction using urinary biomarkers alone.

Comparison of AKI epidemiology using measured versus calculated baseline creatinine in ICU patientsD. Smaghe¹; E. Hoste²¹AZ West, Veurne, Belgium; ²Icu, Ghent University Hospital, Gent, Belgium**Correspondence:** D. Smaghe*Intensive Care Medicine Experimental* 2020, **8(2)**: 000331

Introduction: Acute kidney injury (AKI) occurs in over half of ICU patients and is associated with an increase in ICU and hospital mortality. The KDIGO consensus definition for AKI is based on an episode of oliguria or an increase of serum creatinine (Scr) above baseline Scr. In case no representative baseline Scr is available, an alternative based on the MDRD equation for estimated glomerular filtration rate (eGFR) may be used. In this study we evaluated the use of an MDRD estimated baseline Scr (MDRD-Scr) versus the use of a measured baseline Scr (BL-Scr) on the incidence of AKI in critically ill patients.

Methods: We analysed data collected during a four-year period in all consecutive admitted patients in the 5 different adult ICUs of the Ghent University Hospital. We excluded patients who did not have a BL-Scr available. AKI was assessed using the KDIGO criteria for serum creatinine based on MDRD-Scr and BL-Scr during the first week of ICU admission. Precision was calculated as $(BL-Scr - MDRD-Scr)/BL-Scr \times 100\%$, bias as $BL-Scr - MDRD-Scr$, and accuracy as the proportion of MDRD-Scr within 10%, 20%, 30% or 50% of BL-Scr (Acc10-20-30-50).

Results: Of 9,333 patients admitted, BL-Scr was available in 5,925 patients. Of these, 43.5% developed AKI based on Scr. AKI was correctly classified in 87.2% patients. No-AKI was correctly classified in 89% of no-AKI patients, and AKI stage 3 was correctly in 96.1% of AKI-3 patients. AKI-1 and AKI-2 was only correctly classified in 50.5 resp 54.7% (table 2). In 11.5% of patients MDRD-Scr led to classification of AKI in a higher stage, and in 7.5% to classification of AKI in a lower stage. MDRD-Scr had a sensitivity of 84.2% and specificity of 89.0% for diagnosis of AKI. Positive predictive value was 81.5%, and negative predictive value 90.7%. Precision was 27.5%, bias -0.09, and Acc10-20-30-50 was 20.0%, 38.9%, 53.6%, and 75.3%. In Cardiac Surgery ICU patients precision and bias were less and Acc was higher compared to Surgical ICU, Medical ICU and Burn Unit ICU patients.

Conclusion: The use of an MDRD estimated baseline Scr resulted in adequate classification of AKI in almost 90% of patients. There was an important bias and a limited accuracy when estimating baseline serum with the MDRD-Scr formula. For AKI stage 1 and 2 there was a high rate (49.5% and 45.3% respectively) of over- or underclassification. In stage 3 AKI the accuracy was 96.1% using MDRD-Scr. When available, a recorded baseline creatinine value should be used as a reference of baseline Scr.

Introduction: Acute kidney injury (AKI) is a prevalent and detrimental condition in the intensive care unit (ICU) (Silver and Chertow 2017). Its impact can be prevented or mitigated by timely intervention. We hypothesized that boosting models could accurately predict the impending development of AKI and provide interpretable information to clinicians regarding AKI risk.

Methods: We used a large cohort of 98,051 ICU encounters admitted to Mayo Clinic ICUs between 2005 and 2017 to train abstain-Boost (Schapire and Singer 1999) models to predict two classes of AKI patients: any-AKI or moderate/severe AKI (AKI stage > 1). Models predicted any-AKI six hours in advance of its onset, and moderate/

severe AKI 12 hours in advance of its onset. We removed encounters with insufficient data prior to AKI onset, and divided the remaining cohort into 'clean' encounters (agreement between urine output [UO] and creatinine [Cr] for maximum AKI stage) and 'noisy' encounters (disagreement between UO and Cr for maximum AKI stage). The clean encounters were further divided into training and testing cohorts. Encounters had a total of 388 predictive features measured during ICU stay, including laboratory results, vital signs, medications, and interventions. We compared the area under the ROCs (AUROCs) of this model with parsimonious models (30 features for any-AKI, 31 features for moderate/severe AKI) selected by the Boruta method (Kursa and Rudnicki 2010; Homola, Daniel, n.d.). We evaluated the importance and contribution of the most predictive features.

Results: Features selected by Boruta yielded nearly the same performance as using the entire feature set. On the test set, the any-AKI model had an AUROC of 0.8301 vs. 0.8303 (all features vs. feature subset), while the moderate/severe model had an AUROC of 0.889 vs. 0.891. On the noisy cohort, the models using the feature subset had AUROC of 0.74 (any-AKI) and 0.70 (moderate/severe AKI). Top features from the feature subset for predicting both any AKI and moderate/severe AKI included urine output and creatinine levels measured before AKI onset, as well as mechanical ventilation, lactate levels, and heart rate. The dosage of furosemide was predictive of any AKI, while pH and fluid balance were predictive of moderate/severe AKI.

Conclusion: This study demonstrated that parsimonious, interpretable models could accurately predict AKI in advance of its development or progression, allowing clinicians time to implement timely preventative measures. They provide a list of individualized risk factors for precision medicine.

Discharge Documentation and Nephrology Follow-up of Critical Care Patients Requiring RRTX.Y. Choon¹; N. Lumlertgul²; L. Tovey²; A. Dixon²; A. Jones²; M. Ostermann²

¹Nephrology, Guy's and St Thomas' NHS Foundation Trust, London, United Kingdom; ²Intensive care, Guy's and St Thomas' NHS Foundation Trust, London, United Kingdom

Correspondence: X.Y. Choon*Intensive Care Medicine Experimental* 2020, **8(2)**: 000374

Introduction: An episode of acute kidney injury (AKI) with a requirement for renal replacement therapy (RRT) is associated with excess short- and long-term mortality, and chronic comorbidities, including chronic kidney disease (CKD). Follow-up after discharge from hospital is recommended. This requires detailed information transfer from Critical Care to the nephrology and primary care team.

Objectives: We set out to examine data from a single-centre population of critically ill patients who received RRT during a stay in Critical Care and were discharged from hospital alive. We sought to ascertain the following:

- a) Comprehensiveness of discharge documentation;
- b) Rates of renal follow-up;
- and c) Survival outcomes at 1 year

Methods: We performed a retrospective review of electronic medical notes and patient records of patients admitted to a 54-bedded critical care unit at a Tertiary Care Centre in the UK between June 2017 to May 2018 and who received RRT.

Exclusion criteria included: end-stage renal disease already receiving RRT; transfer from other catchment areas; and patients who died in hospital.

Results: A total of 433 patients received RRT, of whom 91 met the inclusion criteria.

Underlying co-morbidities included: hypertension (54%), diabetes mellitus (25%), pre-existing renal impairment (24%) and coronary artery disease (21%).

Review of discharge documentation from Critical Care showed: AKI was mentioned in 86% and need for RRT in 82% of discharge letters. Nephrology follow up was recommended in 47% of discharge letters. Only 22 of 91 patients (24%) were followed-up by the renal team. 69 patients (76%) received medical follow-up from other specialties.

The overall survival rate was 82% at 1 year, and 70% at 2 years.

In the group followed-up by nephrologists, survival rate at 1-year was 86%, versus 81% in the group with no follow-up. There was no difference in survival in patients followed-up by other medical specialties, compared to those with no follow-up.

The average serum creatinine at point of hospital discharge was 160 $\mu\text{mol/L}$, and in survivors at 1 year it was 115 $\mu\text{mol/L}$. 7 patients were dependent on RRT at point of discharge, with 3 recovering renal function sufficiently to be independent of dialysis at 1 year. 2 out of these 7 patients were deceased at 1 year. 2 patients became newly dependent on RRT after 1 year.

Conclusion: Despite a large critical care capacity and a robust specialist renal service, our data points towards sub-optimal follow-up rates for this high risk patient cohort. Robust pathways at the point of discharge from Critical Care may help mitigate this and ensure consistent follow-up.

"Acute kidney injury in COVID-19 positive patients in the Mater Misericordiae University Hospital Critical Care"

R. Nolan¹; B. Marsh²; R. Turner²

¹Anaesthesia, The Mater Misericordiae University Hospital, Dublin, Ireland;

²Critical care, The Mater Misericordiae University Hospital, Dublin, Ireland

Correspondence: R. Nolan

Intensive Care Medicine Experimental 2020, **8(2)**: 000827

Introduction: Renal injury has been reported to occur in up to 60% of high-risk COVID-19 positive patients admitted to intensive care [1]. Distinct mechanisms of renal injury in COVID-19, two of those being hypercytokinaemia and hypercoagulability, have been reported.

Objectives: To compare rates of AKI in COVID-19 positive patients in the Mater Misericordiae University Hospital Critical Care and record data on hypercoagulability and hypercytokinaemia.

Methods: Concurrent cohort study of COVID-19 positive patients admitted to the Mater Misericordiae University Hospital Critical Care between February and May 2020; exclusion criterion was ESRF pre-admission. AKI was defined as per the AKIN criteria. Biochemical indicators of hypercytokinaemia (white cell count, neutrophils, leucocytes, ferritin) and hypercoagulability (d-dimer, platelets, fibrinogen) and data sets of individual patient's maximum vasopressor requirements, days pyrexial & VTE prophylaxis were collected.

Results: 45 out of 47 COVID-19 positive patient were included (26 males, 19 females, median age 59 (range 37-77)). 8 patients had pre-existing chronic renal disease. 64.4% of patients developed an AKI with patients with d-dimer > 5 at higher risk (RR = 1.44). Thrombocytosis showed no correlation whereas thrombocytopenia was weakly related (RR = 1.23). Double dose VTE prophylaxis (enoxaparin 40mg BD) was not shown to be protective (RR 0.9). 97% of patients had hyperferritinaemia & 78% of patients were pyrexial for at least 24 hours. Pyrexia was associated with AKI (RR = 2.2), as was neutrophilia (RR = 2.24). Maximum dose vasopressor requirement was taken as an indicator of severity of cytokine storm-related hypotension. 79% of patients with a maximum dose of noradrenaline of > 5mcg/min developed an AKI (RR = 2.11).

Conclusion: Hypercytokinaemia was the most significant factor in development of AKI, with more vasoplegic patients likely to develop renal injury. Hypercoagulability was not closely related with AKI and higher dose VTE prophylaxis did not appear to impact the development of renal injury in our small cohort of patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 000050

Introduction: Acute Kidney Injury (AKI) is a common complication in critical care patients. Several biomarkers, including urinary neutrophil gelatinase-associated lipocalin (uNGAL), have been used in the early detection of AKI.

Objectives: The aim of this study was to evaluate uNGAL for the diagnosis and prognosis of AKI in critical ill patients with infections.

Methods: This was a prospective observational study of critically ill patients with infections, sepsis, or septic shock in the intensive care unit. Clinical and laboratory data, including daily uNGAL levels, were assessed. The AKI stage using the KDIGO criteria was evaluated. Sensitivity, specificity, and the area under the curve-receiver operating characteristic (AUC-ROC) values were calculated to determine the optimal uNGAL level for predicting AKI. **Ethics Approval:** The study was approved by the Local Ethics Committee (#58317216.2.0000.0096).

Results: We had 38 patients who completed the study during the screening period (November 2016 to May 2018). The incidence of AKI was 76.3%. The hospitalization period was longer in the group that developed AKI, with 21 days of median, [IQR 13.5-25]; non-AKI group had a median of 13 days, [IQR 7-18], (P = 0.019). We found a direct relationship between uNGAL levels and the progression to AKI. Increased values of the biomarker were associated with the worsening of AKI (P < 0.05). The cut-off levels of uNGAL that identified patients who would progress to AKI were the following: (d1) > 116 ng/mL; (d2) > 100 ng/mL, and (d3) 284 ng/mL. The value of the fourth and last measurement was not predictive of patients who would progress to AKI. The median urinary uNGAL were also associated with mortality on days (1,3 and 4): d1, p = 0.039; d3, p = 0.005; d4, P = 0.005). The performance of uNGAL in detecting AKI patients (AUC-ROC = 0.881). There were no risk factors other than AKI that could be correlated with increased uNGAL levels on day 1.

TABLE 1. Increased uNGAL values in the progression of the KDIGO score (1,2,3) and without AKI.

AKI stage 1	6	213.0	[152.8-868.3]	259.4	[62.0-894.5]	158.2	[41.7-926.3]	63.3	[21.1-586.4]
AKI stage 2	4	317.1	[104.0-1802.4]	318.8	[117.7-895.6]	513.2	[133.8-916.2]	560.1	[145.1-928.9]
AKI stage 3	19	937.1	[504.4-1700.0]	1026.4	[368.9-2090.3]	961.6	[374.1-2377.5]	794.6	[403.9-4666.4]

Conclusion: The uNGAL had an association in its values with the diagnosis and prognosis of patients with severe infections and AKI. We suggest that studies with a greater number of patients could better establish the cut-off values of uNGAL and/or serum NGAL in the identification of infected patients who are at a high risk of developing AKI.

Intensive Care Medicine Experimental 2020, **8(2)**: 001023

Introduction: A novel coronavirus (severe acute respiratory syndrome coronavirus 2, SARS-CoV-2) emerged in early December 2019 and has subsequently spread globally causing a pandemic. There remains clinical equipoise on whether the incidence of acute kidney injury (AKI) is higher in those patients with acute respiratory failure caused by SARS-CoV-2 (Covid-19) than those without Covid-19 [1, 2, 3].

Objectives: To assess whether the incidence of AKI among patients admitted with acute respiratory failure caused by Covid-19 infection is higher than those with acute respiratory failure without Covid-19 infection. To describe the differences in AKI stages observed between the two groups.

Methods: This was a single centre, observational cohort study. Patients admitted with acute respiratory failure to the ICU at St George's Hospital were recruited to the study between December 2019 and May 2020. Covid-19 infection was detected by viral PCR of SARS-CoV-2 on nasopharyngeal or sputum samples. The presence and stage of AKI was defined as per AKIN criteria [4] and assessed on day 0, 7 and 14 of ICU admission. Univariate analysis was conducted using the Chi squared test to compare the frequency of AKI between the two groups.

Results: 256 patients were included. 132 (51.6%) were Covid-19 patients, whereas 124 (48.6%) were non-Covid-19 ICU patients. Overall, 226 (88.3%) patients had AKI over the study period; 112 (84.8%) within the Covid-19 group and 114 (91.9%) within the non-Covid-19 group (c2 (1) 3.1, p = 0.058).

On ICU admission, the distribution of AKI stages between Covid-19 and non-Covid-19 patients was similar (c2 (3) 2.0, p = 0.58).

At day 7 of admission, 127 patients were still in ICU - 88 in the Covid-19 group and 39 in the non-Covid-19 group. There were 45 (51.1%) in stage 0, 8 (9.1%) in stage 1, 6 (6.8%) in stage 2 and 29 (33%) in stage 3 within the the Covid-19 group, compared to 32 (82.1%) in stage 0, 3 (7.7%) in stage 1, 2 (5.1%) in stage 2 and 2 (5.1%) in stage 3 within the non-Covid-19 group (c2 (3) 13.0, p = 0.004). At day 14, 71 patients remained in ICU, and the distribution of stages was similar between both groups (c2 (3) 4.9, p = 0.16).

Conclusion: The incidence and severity of AKI in Covid-19 infected patients are higher after a week of ICU admission compared with non-Covid-19 patients admitted with respiratory failure.

Intensive Care Medicine Experimental 2020, **8(2)**: 000036

Introduction: Regional citrate anticoagulation (RCA) is commonly used for continuous renal replacement therapy (CRRT). Citrate accumulation (CA) is a serious potential complication of RCA, and conventional ways to diagnose CA such as increased total to ionized calcium ratio (T:I Ca ratio) are confounded by various clinical conditions and thus remains suboptimal [1, 2]. Blood citrate measurement emerges as a more direct way to determine CA but its clinical utility and optimal cut-off values for predicting CA remains undefined.

Objectives: To evaluate serum citrate kinetics of patients undergoing RCA CRRT and its correlations with clinical events and outcomes.

Methods: We prospectively recruited patients who received RCA CRRT and measured serial serum citrate levels at baseline, 2-, 6-, 12-, 24-, 36-, 48- and 72-hrs after initiation. The citrate levels were correlated with clinical parameters and patient outcomes.

Results: 91 patients were included, of which 15 patients developed CA defined as a combination of elevated T:I calcium ratio > 2.5, high anion gap metabolic acidosis and systemic hypocalcaemia < 1mmol/L or escalating calcium replacement requirement. The CA group showed higher APACHE IV score (136.5(99.5-167.0)vs 100.0(85.0-117.8), p = 0.003). Serum citrate levels in the CA group at 2-, 6- and 12-hrs after initiation of RCA CRRT was significantly higher than the non-CA group (p < 0.05, for all) (Figure 1). The peak citrate level was significantly higher in the CA group 0.78 mmol/L (0.39-0.96 mmol/L) vs 0.38 mmol/L(0.23-0.67 mmol/L) in the non-CA group, p = 0.01). The serum citrate level correlated with the T:I Ca ratio at 6, 12, 24 and 36 hrs (r = 0.52, 0.65, 0.53 and 0.59 respectively, p all < 0.05). Using a 2-hr serum citrate cut-off of 0.33 mmol/L, the sensitivity and specificity for predicting development of CA were 0.90 and 0.75 respectively (ROC AUC 0.83, p = 0.001) (Figure 2). Peak serum lactate level was higher in the CA group [10.4mmol/L (7.1 – 17.7 mmol/L) vs. 2.70 mmol/L (1.78 – 5.25 mmol/L), for CA vs. non-CA respectively, p < 0.001) and a cut-off value of 6.15 mmol/L also showed good predictive value for development of CA (sensitivity/specificity: 0.7/0.61, ROC AUC 0.82, p < 0.001).

Figure 1. Serum citrate levels over time in patients who have or have not developed citrate accumulation (CA) during regional citrate anticoagulation

Figure 2. The Receiver Operating Characteristic (ROC) curve of 2-hr citrate level in predicting the development of citrate accumulation in patients undergoing regional citrate anticoagulation.

Conclusion: Patients who develop CA show higher serum citrate levels over time, and the 2-hr citrate level shows good predictive value for subsequent development of CA in patients receiving RCA CRRT.

Continuous Venovenous Haemodiafiltration - Are we getting it right?

V.N. Gotz¹

¹Critical Care Unit, University Hospitals of Morecambe Bay NHS Foundation Trust, Lancaster, United Kingdom

Correspondence: V.N. Gotz

Intensive Care Medicine Experimental 2020, **8(2)**: 000184

Introduction: Acute Kidney Injury presents one of the most common organ failures on the intensive care unit. We consider renal replacement therapy in all patients with Acute Kidney Injury level 3 and issues of potassium homeostasis, fluid balance or metabolic acidosis. At University Hospitals of Morecambe Bay NHS Foundation Trust (UHMBT) we use continuous veno-venous haemodiafiltration (CVVHDF) as modality with citrate anticoagulation (PRISMAFLEX dialysis machines) and aim for an effluent volume of 20-25ml/kg/h as per KDIGO Acute Kidney Injury Guidelines (2012); but, once we have

decided on need for filtration and all is set up and ready to go, we often reflect on achieving prescribed target dose.

Objectives: To audit our performance of achieving the target dose of CVVHDF

Methods: We prospectively audited all patients needing CVVHDF between July 2019 to October 2019 at our critical care unit at Royal Lancaster Infirmary, UHMBT, England, UK. We recorded demographics and indications, total length of, downtime of and reasons for discontinuing CVVHDF as much as effluent flow to be achieved and delivered, type of anticoagulation used, hourly fluid removal and type of vascular access.

Results: We sampled 23 data sets, 13 male and 10 female. The average age of patients was 62 years with an actual average body weight of 86 kg. Length of stay on our critical care unit varied from 2 to 19 days with an average of 8.56 days. Indications for RRT included: 18 for acidosis, 9 for hyperkalaemia, 4 for anuria/fluid balance and 2 for uraemia. Average total length of CVVHDF was 100.39 hours (4.18 days) with actual CVVHDF delivered for an average of 72.78 hours (3.03 days). This means there was on average a 28% downtime of CVVHDF during dependency. Reasons for stopping CVVHDF during dependency included: access problems, recirculating e.g. for radiological examinations, blood flushed back, filter clotted and air in circuit. Effluent flow was prescribed as per actual body weight (kg) according to a prepopulated prescription chart supplied by PRISMAFLEX and was 37.95ml/kg/h on average. The prepopulated chart accounted for a 15% downtime. 21 patients were anticoagulated using citrate and 2 with heparin. Fluid removal varied from 0-100ml/h as per clinical need and was decided by consultants. 19 patients had internal jugular vein and 4 had femoral vein vascular access for CVVHDF, none had subclavian venous access due to risk of pneumothorax.

Conclusion: We prescribed effluent flow rates for all patients. However, we experienced a 28% downtime of CVVHDF during dependency. The prepopulated prescription chart by PRISMAFLEX only accounted for 15% of downtime. The likelihood of not achieving target effluent rates of at least 20-25ml/kg/h would have been high. We are, therefore, now recording our delivered effluent rate hourly on the critical care bedside chart and are calculating the average delivered rate per day, so adjustments to effluent rates can be made in order to achieve the recommended minimum of 20-25 ml/kg/h.

Intensive Care Medicine Experimental 2020, **8(2)**: 000377

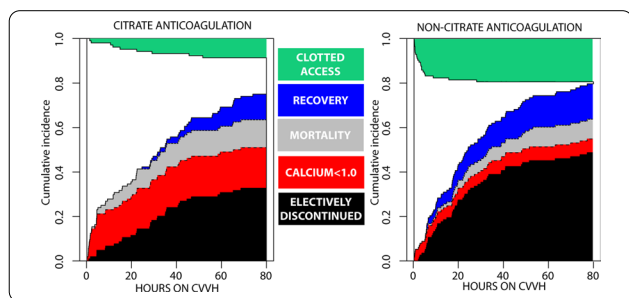

Introduction: Regional citrate anticoagulation in continuous renal replacement therapy (CRRT) offers longer filter life spans, lower bleeding complications, fewer blood transfusions and is recommended as the first line for anticoagulation despite associations with a range of metabolic complications including hypocalcaemia. 1-6 Mild hypocalcaemia is common and appears protective in critically ill patients yet severe hypocalcaemia during CRRT is associated with increased mortality. 7,8 How hypocalcaemia on CRRT competes with other endpoints according to citrate and non-citrate anticoagulation is unclear.

Methods: Patients commencing CRRT in a single centre between Mar 2016 and Feb 2018 spanned a transition from non-citrate to citrate based anticoagulation in May 2017. Patient characteristics, biochemical data and endpoints of hypocalcaemia, filter/access dysfunction, death, elective discontinuation and recovery were analysed.

Hypocalcaemia was defined as mild, moderate or severe by a systemic ionised calcium (iCa) of < 1.13, < 1.0 and < 0.9mmol/l. A competing risk analysis visualised time to events for the above endpoints and iCa < 1.0 to reflect censoring events which terminate CRRT, with log-rank tests to statistically compare the groups.

Results: 220 patients were identified during the period. 113 patients were pre citrate; of the 107 after the transition 3 were excluded for not receiving citrate based therapy. Patient characteristics by anticoagulation regime were similar. The main precipitants for renal dysfunction were septic shock 43.3%, cardiogenic shock 11.1% and hypovolaemia 9.2% ($P = 0.945$). Non-Citrate patients received a mean cumulative total of 88.2h CRRT vs 113.7h for citrate ($P = 0.128$). 28 day mortality was not significantly different (41.6% vs 37.5%, $P = 0.538$).

Pre-treatment mean iCa was 1.12 in the non-citrate and 1.15 in the citrate group ($P = 0.111$). The proportion of patients experiencing an episode of hypocalcaemia (< 1.13, < 1.0 and < 0.9) was 67.3%, 12.4%, and 2.7% for non-citrate and 93.3%, 26.0%, and 5.8% for citrate ($P < 0.02$ for < 1.13 & < 1.0). The proportion of non-citrate and citrate patients stopping CRRT on first exposure for filter/access dysfunction was 19.5% vs 8.7%, death 11.5% vs 22.1%, recovery 15.9% vs 13.5% and elective discontinuation 53.1% vs 55.8% respectively (overall $P = 0.038$). At 24h 18.6% of the non-citrate group had stopped CRRT due to filter/access dysfunction, compared to 5.7% in the citrate group ($p = 0.009$). Hypocalcaemia (< 1.0) had occurred in 5.3% vs 18.3% for the non-citrate vs citrate group ($p = 0.02$).

Conclusion: Although mild and moderate hypocalcaemia was more common in the citrate group no treatments were ceased or adverse events reported due to hypocalcaemia. The competing risk of filter/access dysfunction was significantly higher in the non-citrate group. Differences in other endpoints during the first treatment reflected longer uninterrupted CRRT delivery in the citrate group. Existing recommendations on citrate-based anticoagulation appear justified.

Intensive Care Medicine Experimental 2020, **8(2)**: 000500

Introduction: Acute kidney injury (AKI) in critically ill COVID-19 patients is common and is associated with higher mortality¹. The pandemic has placed ICUs under an unprecedented burden, and provision of RRT has been challenging.

Over 7 weeks we admitted 75 COVID-19 positive patients to our combined 59 bedded ICUs. Of those, 61% developed AKI and 40% required continuous renal replacement therapy (CRRT). In April, NHS England highlighted the difficulties with supply lines for RRT machines and disposables. Our hospital had 14 CRRT machines for the ICUs.

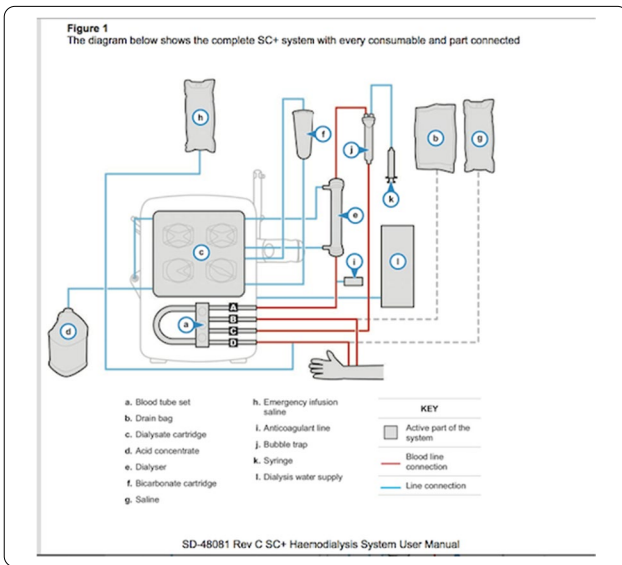

Objectives: An alternative strategy for RRT was needed, preferably effective and relatively unshackled by supply line issues of routine CRRT, usable with current infrastructure and affordable. The alternative needed to cover this crisis and provide increased future RRT capacity. Intermittent haemodialysis (IHD) and SLED were the 2 main options. SLED is modified IHD, where therapy occurs daily and has shown to be safe and efficacious².

Methods: Surge capacity meetings between intensivists, nephrologists, pharmacists and nurse managers explored alternative RRT options for their relative risk/benefit, cost/benefit strategy and feasibility assessment for its physical provision and training, with potential problems identified via web-conferencing³. Plumbing and architecture were reviewed and assessed for capability to provide reverse osmosis (RO) water interface to ICU.

A strategy to provide clinical care alongside ongoing maintenance work was devised. With manufacturer's support, a focused training programme and protocols were developed. A business plan was submitted to hospital authorities for funding approval. The current demand for RRT and available supply of disposables was assessed. An appropriate manufacturer was identified by seeking multiple quotes.

Results: SLED was chosen as it combines the benefits of IHD (less time on RRT) with those of CRRT (haemodynamic stability)⁴.

Time to proceed to setup of a SLED service was 3 days followed by 8 days to commencement of works. These were completed in two of the ICUs within 2 days, during which the areas were isolated from clinical care for RO/water softener works. In total 5 RO machines and 10 SLED machines (SC + Quanta, QD Technologies) were set up in 4 separate ICU areas, thereby increasing our number of RRT machines by 70%. The machines provide standard bicarbonate-based dialysis at high-flow (500 mL/min) and low-flow (300 mL/min) rates, supporting treatment times up to 8 hrs. The machine cost for acquisition was £25,000 including set-up. Quanta staff trained 18 nurses in 10 days including practice development nurses who will become the future trainers. ICU developed protocols for the use of SLED and prescriptions were designed into our eMR platform (Epic, WI, USA).

Conclusion: Surveillance of local and national demands on RRT alerted us to the need for surge provision of RRT. Rapid procurement and phased installation allowed introduction of a new RRT modality during a pandemic. As well as sparing stocks of RRT consumables in the short term, the longer-term improvement in ICU resilience will help manage potential future waves of COVID-19 and threats from other emerging infections. We are now disseminating this learning across the local, national and international ICU community.

Intensive Care Medicine Experimental 2020, **8(2)**: 000882

Introduction: Regional citrate anticoagulation (RCA) is the gold standard anticoagulation for continuous renal replacement therapy (CRRT) as it reduces both clotting of the circuit and systemic bleeding events. There is no clear evidence that mode of therapy improves mortality, but dialysis may be superior to filtration in improving filter life span as it removes the filtration ratio and reduces the reliance on faultless venous access and high blood flows. We present data comparing protocols for post dilution continuous veno-venous haemofiltration (CVVH) and continuous veno-venous haemodialysis (CVVHD) with or without RCA available for CRRT in critically ill patients.

Methods: 3 hospitals in the same NHS Trust (providing CRRT to general critical care patients (no cardiac surgery) for ~350 patients a year) followed the same CRRT protocols but the larger site offers a protocol with RCA as first line anticoagulation. In June 2019 all sites switched from the Nikkiso Aquarius[®] system (CVVH and RCA via post dilution method) to the BBraun OMNI[®] system (CVVHD). Recent audit (September – November 2019) coupled with historical data (September–November 2017) collected in the same way on each site, was used to compare filter life span across protocols. Heparin infusion into the filter or no anticoagulation was used when RCA was either not available or contraindicated. Only one site had data for CVVH with no RCA.

Results: In total 173 patients who used 524 filters were analysed (table 1).

When censored for reasons other than clotting, there was a significant advantage in filter survival of CVVHD over CVVH when RCA was available ($p < 0.0001$) (graph 1). There was no difference between protocols that used CVVH and CVVHD when RCA was not available ($p = 0.64$) but CVVH with RCA available, was significantly better than CVVHD when RCA is not available ($p = 0.02$).

TABLE 1	CVVH RCA	CVVH no RCA	CVVHD RCA	CVVHD no RCA
Consecutive patients	41	24	50	58
Age	56.5 (27-75)	61 (27-85)	64 (86-23)	63 (29-81)
Admission reason				
Medical	29 (70%)	15 (63%)	38 (76%)	47 (81%)
Surgical	11 (30%)	9 (37%)	12 (24%)	11 (19%)
Filters	141	63	109	211
RCA	96 (68%)	0	69 (63%)	0
Heparin	27 (19%)	27 (43%)	16 (15%)	124 (59%)
None	18 (13%)	36 (57%)	24 (22%)	87 (41%)
Filter life span (hrs)	27	20	58	20

Significantly fewer filters per patient are used with a CVVHD protocol containing RCA compared to the other protocols (2.2 (1-10); $p = 0.028$)

Conclusion: CRRT Protocols that contain RCA as first line anticoagulation significantly improve filter life span. There is a significant additional advantage in using dialysis alone over filtration.

First use of NxStage portable intermittent haemodialysis in ICU patients with AKI requiring RRT during COVID-19 pandemic in UKS. Isralls¹; G. Sartori¹; C. Edwards¹; M. Griffith¹; G. Saquing²; J. Gross³; T. Husain¹; N. Duncan²¹Intensive care unit, Northwick Park Hospital, London, United Kingdom;²Imperial college renal and transplant centre, Imperial College Healthcare NHS Trust, Hammersmith Hospital, DuCane Road, W12 0HS, London, United Kingdom; ³Intensive care, London North West University Healthcare NHS Trust, London, United Kingdom**Correspondence:** G. Sartori*Intensive Care Medicine Experimental* 2020, **8(2)**: 000895

Introduction: The Coronavirus disease (COVID-19) pandemic brought extraordinary demands on many Intensive Care Units (ICU) in the UK. Our ICU faced an unprecedented rate of admissions [ref1], with 32.7% of patients requiring Renal Replacement Therapy (RRT) for Acute Kidney Injury (AKI) [ref2]. Pre-pandemic, our conventional RRT was Continuous Venous Venous Haemofiltration (CVVHF), favoured over other modalities in view of more stable haemodynamic profile [ref3]. With a shortage of RRT machines, consumables, and trained workforce, we explored NxStage Pure Flow System and Cycler (NxS) as an alternative to provide portable intermittent haemodialysis (iHD) as RRT in ICU.

Methods: This study was designed as a service evaluation to review NxS safety and efficacy, including all patients with COVID-19 and AKI Stage 3 by KDIGO criteria treated with NxS between 24/04 and 24/06/2020. Exclusion criteria were liver failure or haemodynamic instability requiring vasopressors. Study approval SE20/015 (28/05/2020).

Results: Ten consecutive patients were included, 9/10 male, all of Black, Asian and Minority Ethnicity; mean age 54.9 years (SD 11.7). 7/10 had diabetes, 6/10 had hypertension, one had chronic kidney disease. All patients had radiological features typical for COVID-19 and 7 had positive nasopharyngeal swab. In the first 24 hours in ICU, mean APACHE II score was 19.8 (SD 5.7) and PaO₂/FiO₂ ratio 137mmHg (SD 69). All patients were intubated and ventilated during admission. 45 NxS treatments were delivered over two months, with a median of 3.5 days of NxS per patient (IQR 1.5-8), versus 14 days of CVVHDF (IQR 8-22.5). 5 of 45 treatments were aborted: 3 secondary to vascular access mechanical issues, one for change in therapeutic priority, and one for hypotension requiring metaraminol. Adverse events per patient are detailed in the table below.

PATIENT	1	2	3	4	5	6	7	8	9	10
Hypotension	0	0	0	0	0	0	0	1	0	0
Hypokalaemia	Yes	Yes	Yes	No	Yes	Yes	Yes	Yes	No	No
Dialysis catheter site bleeding	0	0	1	0	0	0	0	0	0	0
Bleeding – others	0	1	0	0	0	1	3	0	0	0
Dialysis catheters sepsis	2	0	0	1	0	0	0	0	0	0
Sepsis – others	5	3	5	3	1	0	2	2	2	2

7/10 patients developed hypokalaemia during NxS, requiring replacement in 24 of 45 treatments, without any arrhythmia. 36 treatments were delivered through standard vascath, and 9 through TesioCath. We report one bleeding episode from TesioCath site, but no episodes of catheter-associated thrombosis, nor any pneumothorax secondary to dialysis catheter insertion. We report 3 episodes of dialysis catheter associated sepsis, versus 26 septic episodes from other sources. The pH variation over NxS treatment remained stable and no patient was acidotic at the end of NxS treatment. Serum lactate level increased during all treatments, by virtue of the lactate buffer used, and decreased to the normal reference range within five hours of NxS completion in 31 of 45 cases, without clinical sequelae in the remaining cases.

Efficacy was described by achieving the target fluid balance in 40/45 treatments, and reducing blood urea nitrogen (BUN) post-NxS compared to pre-NxS in 37/45 treatments (on average 5.1 mmol/l less than pre-NxS BUN samples, $p < 0.01$ on paired t test).

8/10 patients survived to ICU discharge or last follow up; 3 have been discharged home, 2 remain in hospital and 3 in ICU. Mean ICU length of stay was 38.7 days (SD 16.8). At ICU discharge, median eGFR was 73 mL/min/1.73 m² (IQR 14 – 84) with no dialysis dependence.

Conclusion: This pilot project was developed and delivered through necessity, and it was not designed to compare or displace the use of CVVHF by iHD in ICU [ref4], but proved that NxS is safe and effective in selected patients in order to preserve the use of CVVHF for patients who are haemodynamically unstable or with liver failure.

Wells and revised Geneva scores as predictors of pulmonary embolism in critically ill patients: a prospective studyA. Muradás Girardi¹; M. Gazzana²; T. Rech¹¹Departamento de medicina intensiva, Hospital de Clínicas de Porto Alegre, Porto Alegre, Brazil; ²Departamento de pneumologia, Hospital de Clínicas de Porto Alegre, Porto Alegre, Brazil**Correspondence:** A. Muradás Girardi*Intensive Care Medicine Experimental* 2020, **8(2)**: 000112

Introduction: Critically ill patients are at high risk for pulmonary embolism (PE) (1). However, the diagnosis of this potentially fatal disease often goes unnoticed, as symptoms are nonspecific and other clinical conditions can manifest with similar features (2). Prediction rules, usually used in emergency departments, such as the Wells and Geneva scores, are not validated in this population. Therefore, the best diagnostic approach to investigate critically ill patients with suspected PE remains uncertain.

Objectives: The aim of the present study was to assess the Wells and the revised Geneva scoring systems as predictors of PE in critically ill patients.

Methods: From July 2018 to November 2019, adult patients admitted to the intensive care unit (ICU) at the Hospital de Clínicas de Porto Alegre were considered eligible for the study if they had a pulmonary computed tomographic angiogram (CTA) as a confirmatory imaging study for suspected cases of PE. Clinical data was collected and the Wells and the revised Geneva scores were calculated. The researcher who calculated the scores was unaware of the CTA result. Two radiologists independently reviewed the scans to diagnose the presence of PE based on the presence of filling defects in the pulmonary artery or its branches. The discriminative power of the Wells and revised Geneva scores to predict risk of PE was determined by receiver operating characteristic curve (ROC) analysis.

Results: Eighty critically ill patients were prospectively included in the study. The mean age of the patients was 59 ± 14 years, 52.5% were female, with a mean SAPS 3 score of 61 ± 16 . The main cause for ICU admission was acute respiratory failure (62%), followed by cardiac arrest (17%) and shock (11%). The incidence of PE was 39% ($n = 31$). Segmental PE was the most common classification (58%), followed by main artery PE (32%), subsegmentary PE (6.5%) and lobar PE (3%). Inter-observer agreement for PE diagnosis was very good ($R = 0.89$). The mean Wells score in patients without PE was 3.0 ± 1.9 vs. 4.2 ± 2.7 in patients with PE ($p = 0.027$). The mean revised Geneva score was 5.0 ± 3.0 in patients without PE vs. 6.0 ± 4.0 in patients with PE ($p = 0.08$). Figure 1 shows the ROC curves of the Wells and the revised Geneva scores, respectively. The area under the curve (AUC) for the Wells score was 0.64 (CI 0.51-0.77) and for the revised Geneva score AUC was 0.60 (CI 0.47-0.73).

Conclusion: Wells and revised Geneva scores are not reliable predictors of PE in critically ill patients. These negative results, obtained prospectively, reinforce the importance to search for alternatives for a better diagnostic approach to PE in this population.

Community acquired pneumonia in the intensive care unit

C. Serrano¹; A. Ruiz García¹; J. Higuera Lucas¹; E. Lopez Ramos¹; B. Llorente Ruiz¹; M. Trascasa Muñoz¹; E. Nevado¹

¹Intensive care unit, Hospital Príncipe de Asturias, Alcalá de Henares, Spain

Correspondence: C. Serrano

Intensive Care Medicine Experimental 2020, **8(2)**: 000133

Introduction: The term severe community acquired pneumonia (CAP) identifies the group of patients with CAP who require admission to intensive care units (ICU). The incidence of severe acquired pneumonia has increased in the last decade and is one of the main infectious causes of admission in ICU.

Objectives: The aim of this study is to review and describe severe CAP patients in a level II hospital ICU, analyzing the patients' profile, microbiology isolations and treatment.

Methods: A retrospective observational study was performed. Consecutive critically ill CAP patients receiving treatment in level II hospital polivalent ICU were reviewed from January 1, 2018 to November 30, 2019. Categorical variables were analyzed using chi-square tests, and continuous variables were analyzed by T Student or ANOVA. Significance level was established as $p < 0.05$.

Results: A total of 41 consecutive eligible individuals were reviewed. Mean age was $60.24 (\pm 8)$, mean APACHE II was $16.77 (\pm 8)$, mean hospital stay was 16 days (± 23.24). 63.45% were men. 25% were immunosuppressed. 41.5% had COPD. The main reason for admission was respiratory failure in 87.8% of patients, followed by shock (need of vasoactive drugs). 14.6% required intubation as an initial respiratory support. NIMV was initiated in 48.8%, HFO in 26.8% and conventional oxygen in 9.8%. Finally, 48.8% of patients required mechanical ventilation (20/41). There was no statistically significant difference between NIMV and GNAF failure. The initial empiric treatment was a betalactamic (ceftriaxone) and a macrolid (claritromicina) or quinolone (levofloxacin) in 78% of cases. 17% received broad spectrum treatment (piperacilina-tazobactam or imipenem). 2.5% received only ceftriaxone. In 21 cases there was microbiology isolation: respiratory virus were isolated in 10 cases (Influenza 4, VMC 3, HVS 2 and adenovirus 1). In 6 patients *S.pneumoniae* was isolated. *H. Influenzae*, *E Coli* and *P Aeruginosa* in one case each. Comparative analysis between bacterial and viral pneumonia is shown in the table below:

	Viral pneumonia n=9	Bacterial pneumonia n=9	p
Age	57	64	0.33
Gender ♂	75%	66.6%	0.56
ICU stay (days)	14.7	23.2	0.58
APACHE II	11.7	19	0.045
Diabetes Mellitus	37.5%	22.2%	0.437
CV illness previously	37.5%	44.4%	0.58
Previous respiratory illness	37.5%	33.3%	0.627
Cirrosis	0%	11.1%	0.5
Shock	37.5%	77.7%	0.12
Immunosuppression	0%	25%	0.2
Mechanical ventilation	62.5%	66%	0.63
Exitus	0%	25%	0.2

Mortality rate was 14.6%. Hospital stay, immunosuppression, vasoactive drugs requirement and mechanical ventilation requirement were found to be independent mortality risk factors.

Conclusion: In our ICU patient's profile, mortality risk factors and mortality rate are similar to other series of cases. A high percentage (48.8%) required mechanical ventilation. It should be noted that the incidence of viral and bacterial pneumonia had the same number of cases. Bacterial pneumoniae seems to lead to a longer hospital stay and mortality but more studies would be required.

Intensive Care Medicine Experimental 2020, **8(2)**: 000280

Introduction: Extracorporeal membrane oxygenation (ECMO) support in acute respiratory failure may be lifesaving, but bleeding and thromboembolic complications are common. The optimal anticoagulation strategy balancing these factors remains to be determined.

Objectives: This study was carried out to determine whether a low-dose prophylactic heparinization strategy is associated with similar rates of oxygenator changes while reducing bleeding events when compared to a high-dose therapeutic heparinization strategy.

Methods: We conducted a retrospective unblinded observational cohort study between 04/2015 – 02/2020 in two ECMO referral centres in Germany in patients receiving veno-venous (VV)-ECMO support for acute respiratory failure for > 24h and unfractionated heparin (UFH) for anticoagulation. One centre routinely applied low-dose heparinization aiming for a partial thromboplastin time (PTT) of 35–40s and the other routinely used a high-dose therapeutic heparinization strategy aiming for an activated clotting time (ACT) of 140–180s. We assessed number of and time to ECMO oxygenator changes, 15-day freedom from oxygenator change, major bleeding events, thromboembolic events, 30-day ICU mortality, activated clotting time and partial thromboplastin time, red blood cell transfusions and platelet transfusions. Primary outcome was the occurrence of oxygenator changes depending on heparinization strategy; main secondary outcomes were the occurrence of severe bleeding events and occurrence of thromboembolic events.

Results: Of 375 screened patients receiving VV-ECMO support, 218 were included in the analysis (117 high-dose group; 101 low-dose group). Disease severity measured by SAPS II score was 46 (IQR 36–57) vs 47 (IQR 37–55) and ECMO runtime was 8 (IQR 5–12) vs 11 (IQR 7–17) days ($P = 0.003$). There were 14 oxygenator changes in the high-dose group vs 48 in the low-dose group. Freedom from oxygenator change at 15 days was 73 vs 55% (adjusted HR 2.74 [95% confidence interval 1.2–6.5]; $P = 0.023$) (Figure). Severe bleeding events occurred in 23 (19.7%) vs 14 (13.9%) patients ($P = 0.256$) and thromboembolic events occurred in 8 (6.8%) vs. 19 (19%) patients ($P = 0.007$). Mortality at 30 days was 33.3% vs 30.7% ($P = 0.11$). Mean ACT in the high-dose group (158s [IQR 151–165]) and PTTs (48s [IQR 41–57] vs 38s [IQR 34–42]) corresponded well with predefined target ranges. Red blood cell and platelet transfusions were less frequent in the high-dose group (6 [IQR 2–10] vs 8 [IQR 6–19] $P < 0.001$ and 0 [IQR 0–1] vs 4 [0–10], $P < .001$, respectively).

Conclusion: Compared with low-dose heparinization, high-dose heparinization during ECMO support was associated with lower rates of oxygenator changes and thromboembolic events, but with a numerically higher number of bleeding events.

Intensive Care Medicine Experimental 2020, **8(2)**: 000315

Introduction: Acute Respiratory Distress Syndrome (ARDS) is currently diagnosed by the Berlin definition, which does not include a direct measure of pulmonary oedema, endothelial permeability, pulmonary inflammation, coagulation or oxidative stress. A diagnostic test that could capture these processes might improve the diagnosis of ARDS. We hypothesized that biomarkers of these processes have good diagnostic accuracy for ARDS.

Methods: Medline and Scopus were searched with broad keyword criteria and selection was performed by two independent researchers. Inclusion criteria were: (1) original research, (2) that reported diagnostic accuracy, (3) used a minimal invasive test for (4) pathophysiological mechanisms of ARDS and (5) compared the results to a relevant control group. The primary outcome was the diagnostic accuracy per test, categorized by pathophysiological mechanism, control group and analyzed biomaterial. Secondary, the methodological quality was assessed with Quadas-2 tool. Biomarkers that had an area under the Receiver Operating Characteristic curve (AUROC) of more than 0.75 and were studied with minimal bias against an unselected control group were considered to be promising.

Results: The search led to 929 independent articles of which 42 were included. The median AUROCC for all evaluated tests was 0.80 (25th to 75th percentile: 0.72 – 0.89). The type of control group influenced the diagnostic accuracy (Figure 1, $p = 0.01$). Higher risk of bias was associated with higher diagnostic accuracy (AUROCC 0.74 for low bias, 0.78 for medium bias and 0.84 for high bias studies; $p = 0.0021$). Club Cell protein 16 (CC16) and soluble receptor for advanced glycation end-products (sRAGE) in plasma and three biomarkers of oxidative stress in breath showed good diagnostic accuracy in low bias studies that compared ARDS patients to an unselected intensive care unit (ICU) population.

Conclusion: This systematic review revealed only three diagnostic tests that fulfilled stringent criteria for a promising biomarker in a low bias setting. For implementation into the clinical setting, prospective studies in a general unselected ICU population with good methodological quality are needed.

Correspondence: L. Hagens

Intensive Care Medicine Experimental 2020, **8(2)**: 000316

Introduction: Acute Respiratory Distress Syndrome (ARDS) is currently diagnosed by the Berlin definition, which involves subjective criteria

and leads to late diagnosis. There is a demand for a non-invasive bedside method to diagnose ARDS. Three metabolites in breath, of which octane was the most important, showed good diagnostic accuracy when analysed with gas chromatography and mass spectrometry (GCMS). However, mass-spectrometry is unsuitable for a point-of-care (POC) test. Therefore, we aimed to develop a POC test that measures octane in exhaled breath of invasively ventilated intensive care unit (ICU) patients at trace amounts (parts-per-billion). We hypothesized that the breath analyser (BA) can reliably detect octane in exhaled breath of mechanically ventilated ICU patients.

Methods: Two steps were taken in development of the BA. A laboratory BA was validated in healthy subjects with calibration measurements. Comparison to gold standard GCMS was performed in healthy subjects and in patients receiving mechanical ventilation. Subsequently, the BA was further developed into a POC BA, which was also calibrated and then used for assessment of exhaled breath of ventilated ICU patients. Accuracy of the BA was reflected by repeatability between duplicate samples and reproducibility for detecting a known amount of octane. Octane concentration was based on the area under the curve (AUC), which was extracted from the chromatogram and compared to known values from calibration measurements.

Results: Five healthy subjects and 40 patients were included for assessment with the laboratory BA, 12 patients were included for validation of the POC BA. A linear association with an R^2 of 0.99 was reached with the laboratory BA with breath samples spiked with octane. In contrast, reproducibility with GCMS was moderate ($R^2 = 0.68$). In patients 40 duplicate measurements were performed with the laboratory BA and 25 duplicate measurements with the POC BA. In 5 out of 25 measurements with the POC BA, one of the octane peaks could not be fitted due to co-elution or a noisy signal. The repeatability was strong for the laboratory- and POC-BA, with an intraclass correlation coefficient (ICC) of 0.87 and 0.95 and a coefficient of variation of 17% and 8%, respectively (Figure 1 and 2).

Conclusion: The laboratory- and POC-BA were both able to accurately detect trace amounts of octane in exhaled breath of ventilated ICU patients. Reproducibility was acceptable and repeatability was good. Further validation and implementation steps are needed to progress to a POC breath test for diagnosing ARDS in ventilated ICU patients.

Pulmonary consolidation alters the estimate of pleural fluid volume before considering chest drainage in patients on ECMOM. Maly¹; C. Mokotedi¹; M. Porizka¹; M. Otahal¹; J. Rulisek¹; M. Balik¹¹Dept of anaesthesia and intensive care, General University Hospital in Prague, Prague, Czech Republic**Correspondence:** M. Balik*Intensive Care Medicine Experimental* 2020, **8(2)**: 000347

Introduction: The estimate of pleural fluid volume on chest ultrasound (CUS) (1) helps to decide on pleural drainage in relation to weaning of the ECMO and IPPV. The method of multiplying maximum transverse pleural separation at the lung base in mm by 20 has been constructed on medical mechanically ventilated patients (1). The method may fail in severely consolidated lungs encircled by pleural fluid.

Objectives: To test the established method of pleural fluid estimation in haevily consolidated lungs and to find optimal way of the volume assessment.

Methods: 35 pleural effusions were drained in 28 mechanically ventilated patients (APACHE II 26.3 ± 5, SOFA 10.9 ± 2) with severe lung consolidation of 4th degree on CUS at least in basal lung regions and no better than 3rd degree in the apical regions. All were prospectively observed while treated on VV, VAV or VA ECMO. All drainages were performed by intensivists by blunt forceps technique, most of them with 12F chest drain (CD).

Results: The maximum pleural separation was 23 ± 6mm, correlating with separation at the lateral chest wall (19 ± 8mm, $r = 0.79$). The dorsal and frontal separations were 16 ± 7mm and 16 ± 7mm, respectively. The classic (1) method of pleural fluid estimate correlated weakly with pleural fluid volume ($r = 0.32$) and produced a mean underestimation error of - 371 ± 207ml contrasting with drained 830 ± 209ml. Better correlation was found for the frontal pleural separation ($r = 0.44, p < 0.05$). The volume of pleural fluid may be estimated with equation $V[\text{ml}] = 620 + 13 * \text{frontal separation} [\text{mm}]$ which results in a mean prediction error of 156 ± 101 ml. Similarly, the sum of basal, lateral and ventral pleural separations (51 ± 15 mm) correlated with drained volume ($r = 0.42, p < 0.05$) showing mean prediction error of 159 ± 100 ml.

Conclusion: The known CUS assessment of volume of pleural fluid largely underestimates reality in severely consolidated lungs surrounded by potentially misleadingly thin layer of circumferential effusion. The multiple measurements are feasible paying attention to a degree of lung consolidation and separation of pleural layers under the frontal chest wall.

Administration of large volume of Hydroxyethyl starch (HES) in the first 48 hours of resuscitation is associated with early ARDS development in patients with blunt thoracic traumaD. Mihajlovic¹; A. Uvelin²; M. Armus²¹Department of anesthesiology, intensive therapy and pain therapy, clinical centre of vojvodina, Medical Faculty in Novi Sad, Novi Sad, Serbia;²Department of anesthesiology, intensive therapy and pain therapy, clinical centre of vojvodina, Faculty of Medicine, University of Novi Sad, Novi Sad, Serbia**Correspondence:** D. Mihajlovic*Intensive Care Medicine Experimental* 2020, **8(2)**: 000399

Introduction: Blunt thoracic trauma is a major risk factor for development of Acute Respiratory Distress Syndrome (ARDS). Although blunt thoracic trauma is recognized as a specific risk factor for ARDS development, other predictors of early ARDS have not been precisely defined in this group patients.

Objectives: To define specific predictors that can identify patients who are at greater risk of ARDS development in an early resuscitation phase (first 48 hours) after blunt thoracic trauma.

Methods: During one-year study period, 50 patients with blunt thoracic trauma who were treated in intensive care unit after the initial resuscitation in Emergency center- Clinical center of Vojvodina were included in our study. Data were analyzed using SPSS 20.0 software. Differences between groups of patients were assessed by Student's t-test. Categorical variables were compared using chi-square test. Statistical significance (p) was set at a value of 0.05.

Results: 16 patients (32%) developed early ARDS during the first 48 hours after blunt thoracic trauma. Patients who developed ARDS received higher volumes of hydroxyethyl starch (HES) (1607 ± 594.15 vs. 678.57 ± 530.79. $p \leq 0.05$) and fresh frozen plasma (FFP) (662.85 ± 616.51 vs. 365.35 ± 894.64. $p \leq 0.05$) during the first 48 hours after the trauma. Thoracic Trauma Severity Score (TTS) and Injury Severity Score (ISS) were significantly higher in patients with ARDS in comparison to patients who did not develop ARDS (TTS: 13.29 ± 3.12 vs. 9.25 ± 4.30; ISS: 51.92 ± 20.94 vs. 34.5 ± 17.23. $p \leq 0.05$). Patients with ARDS had significantly lower values of Glasgow coma score (GCS): (9.69 ± 4.88 vs. 13.48 ± 3.05. $p \leq 0.05$).

Conclusion: Significant predictors of ARDS development in patients with blunt thoracic trauma are multiple traumatic injuries defined with higher values of ISS and TTS score, presence of traumatic brain injury with lower values of GCS and administration of higher volumes of colloids and FFP.

High dead space and dissociation between severe hypoxia and relatively low shunt might be distinguishing features of C-ARDS vs. ARDSI. Marongiu¹; E. Spinelli²; T. Mauri²; G. Colussi²; MC. Basile²; P. Tagliabue²; G. Grasselli²; A. Pesenti²¹Department of pathophysiology and transplantation, University of Milan, Milano, Italy; ²Department of anesthesia, critical care and emergency, Fondazione IRCCS Ca'Granda Ospedale Maggiore Policlinico, Milano, Italy**Correspondence:** I. Marongiu*Intensive Care Medicine Experimental* 2020, **8(2)**: 000429

Introduction: The pathophysiology of Coronavirus disease 2019 acute respiratory distress syndrome (C-ARDS) might have some peculiarities distinguishing it from ARDS of other etiology. Preliminary data suggest a unique contribution of vascular dysfunction induced by inflammation and microthrombosis to the imbalances in ventilation and perfusion within the lung [1].

Objectives: To characterize with electrical impedance tomography (EIT) the distribution of ventilation and perfusion in a cohort of patients affected by C-ARDS and to compare these findings with data collected in ARDS patients.

Methods: We included 19 patients with C-ARDS between March 2020 and April 2020 and 50 patients with ARDS between March 2019 and December 2019 admitted to the Intensive Care Unit of the Ospedale Maggiore Policlinico (Milan, Italy). Gas exchanges and the distribution of ventilation and perfusion measured by EIT were assessed at positive end expiratory pressure (PEEP) of 5 cmH₂O for C-ARDS and at clinical PEEP for ARDS patients. Perfusion was obtained through injection of 10 mL of a 5% saline bolus during end-inspiratory occlusion. Dead space fraction was calculated as the percentage of pixels ventilated but not perfused, while shunt fraction as those perfused but not ventilated. Data are presented as median [IQR], differences between groups were assessed by Mann-Whitney on ranks test.

Results: Gas exchange and respiratory data are summarized in Table 1.

	C-ARDS (n=19)	ARDS (n=50)	P value
PEEPtot (cmH ₂ O)	6 [5;6]	11 [8;15]	<0.0001
Vt/PBW (mL/kg)	7.4 [6.7;8.1]	7.3 [6.1;8.0]	0.53
Compliance (mL/cmH ₂ O)	49 [30;52]	42 [35;52]	0.61
Driving Pressure (cmH ₂ O)	10 [9;14]	11 [8;14]	0.67
Respiratory rate (breaths/min)	22 [15;26]	16 [14;22]	0.02
PaCO ₂ (mmHg)	51 [44;60]	44 [37;47]	0.0009
pH	7.39 [7.33;7.43]	7.39 [7.34;7.43]	0.90
Ventilatory ratio	2.0 [1.6;2.6]	1.4 [0.9;1.9]	0.001
PaO ₂ /FiO ₂	81 [69;137]	168 [122;241]	0.0001

*Mann-Whitney test, C-ARDS vs ARDS. *PBW*: predicted body weight
Compared to patients with ARDS, patients with C-ARDS showed no differences in tidal volume (Vt) and respiratory mechanics. Efficiency of ventilation was more impaired in C-ARDS, as indicated by higher respiratory rate, PaCO₂ and ventilatory ratio. Accordingly, EIT documented a higher dead space fraction (23% [13; 29] vs 12% [5; 19], C-ARDS vs ARDS, $p < 0.01$). (figure 1A). Hypoxemia was more severe in C-ARDS, but shunt fraction didn't differ (figure 1B).

Figure 1. EIT analysis. Mann-Whitney test, ** $p < 0.01$, C-ARDS vs ARDS

Conclusion: Compared to ARDS of other etiology, C-ARDS is characterized by more severe hypoxia and less efficient CO₂ clearance, even in the presence of preserved mechanics. The mechanisms underlying derangements of gas exchange during C-ARDS may differ from ARDS, with increased dead space likely playing a key role.

Intensive Care Medicine Experimental 2020, **8(2)**: 000435

Introduction: Since the SARS-CoV-2 pandemic, countries are overwhelmed by critically ill Coronavirus disease 2019 (COVID-19) patients. As ICU capacity becomes limited we characterized critically ill COVID-19 patients in the Netherlands.

Methods: In this case series, COVID-19 patients admitted to the ICU of the Jeroen Bosch Hospital were included from March 9, 2020. COVID-19 was confirmed by a positive result by a RT-PCR of a specimen collected by nasopharyngeal swab. Clinical data were extracted from medical records.

Results: All patients were admitted to the ICU due to acute hypoxic respiratory failure in absence of hemodynamic instability. The mean age was 64 ± 10 years, the mean BMI was 30.1 ± 7 and 73% were men. Thirty percent of patients had no comorbidities. With 33%, hypertension was the most common comorbidity.

Of the 68 admitted patients, 62 were in need of invasive respiratory support (91%). Six patients were successfully treated with high flow oxygen therapy. Six patients initially treated with a high flow oxygen cannula deteriorated requiring invasive mechanical ventilation.

Among the mechanically ventilated patients, 77% required ventilation in prone position during their stay in ICU according to our local protocol. The average length of invasive ventilation was 22.5 days (range 3-53 days). Renal replacement therapy was required in 14 (21%) patients.

Venous thromboembolism was recognized in 40% of patients. In 20 patients pulmonary embolism was diagnosed, 1 patient developed a deep venous thrombosis of the forearm and 6 patients developed a catheter related thrombus. These complications occurred despite regular thrombosis prophylaxis.

The overall mortality of our patients was 20.5%.

Conclusion: The survival rate of COVID-19 critically ill patients in our population is lower than previously reported. Dedicated selection and screening of patients before potential admission to the ICU could be a possible explanation for this low mortality. Thrombotic complications were commonly found and merit additional clinical attention.

Intensive Care Medicine Experimental 2020, **8(2)**: 000453

Introduction: Influenza A (Influenza H1N1) is one of the great epidemics of our time. It had a great repercussion due to the associated morbidity and mortality, been moderate-severe ARDS one of the most common forms of presentation that requires prolonged admission to the ICU.

Methods: Retrospective, descriptive study of patients admitted in ICU from 2009 to 2019, with H1N1 influenza diagnosis. Clinical, epidemiological and result-related variables were analyzed. Quantitative variables are expressed as mean and standard deviation, while qualitative variables are expressed as ratios and absolute value.

Results: A total of 78 patients were collected. Mean age was 47 years \pm 16.77. 53.8% were women. APACHE II average upon admission: 14 \pm 7.23 and average SOFA at admission: 5.5 \pm 3.83

Between the comorbidities: 41% of the patients presented COPD, 33.3% BPH, 32.1% Obesity and 21.3% had Heart disease and Dyslipidemia.

The 66.7% of the patients received previous NIMV; 74.4% required MV. Mean duration of MV was 15 days \pm 14.68. Most of the patients required pulmonary recruitment maneuvers, and Prone Position was needed in 35.9%. Renal failure was presented in 50% of the patients, and 21.8% of them required RRT. Tracheostomy, due to weaning, was performed in 39.7% of the patients.

Between risk factors Alcoholism (OR 9,025 p 0.042 IC 1,079 - 75.51), Malignancy (OR 41.45 p 0.001 IC 4.47 - 384,437) and Autoimmune Disease (OR 7.3 p 0.042 IC 1,075 - 49.65) were the most frequent.

When the sample was divided into two groups, survivors and non-survivors, it was observed that the deceased patients were older (Median 46 years vs. 53 years), and presented greater renal failure (38.18% vs. 78.26%) with a greater need for RRT (28.57% vs. 61.11 %) as well as greater severity in the Berlin Criteria for distress (severe ARDS 38.18% vs. 78.26%).

The length of stay in the ICU was 13 days \pm 18.47. The ICU observed mortality was 29.5% and the hospital mortality 33.33%.

Conclusion: Severe ARDS caused by H1N1 Influenza associates great morbidity and mortality, being a very relevant pathology today in Intensive Care Units.

Impact of NMBA on ventilation homogeneity and lung volume in ARDS patients

Y. Ichikawa¹; A. Shono²; M. Somei²; T. Kotani³

¹Intensive Care Medicine, Showa University, Hatanodai Campus, 1 Chome-5-8 Hatanodai, Shinagawa City, Tokyo, Japan, Shinagawa City, Japan; ²Department of Intensive Care Medicine, Showa University, School of Medicine, Tokyo, Japan; ³Intensive care medicine, Showa University Hospital, Shinagawa City, Japan

Correspondence: Y. Ichikawa

Intensive Care Medicine Experimental 2020, **8(2)**: 000486

Introduction: Excessive inspiratory effort in mechanically ventilated patients with acute respiratory distress syndrome (ARDS) increases stress and strain in the lungs leading to ventilator-induced lung injury (VILI). The use of neuromuscular blocking agents (NMBAs) can however, synchronize with ventilator, but the impact of use of NMBA on ventilation distribution and lung volume has not been fully investigated.

Objectives: The objective of this study was to examine the impact of NMBA on ventilation homogeneity and end-expiratory lung volume (EELV) evaluated by electric impedance tomography (EIT) in ARDS patients with strong inspiratory effort.

Methods: In this retrospective study, we performed off-line analysis of EIT data previously recorded before and after NMBA. The ventilation homogeneity was evaluated using EIT measures, the proportion of ventilation distribution (ventral and dorsal lung regions, expressed in percentage to a tidal volume = 100%), center of ventilation, spatial dispersion in regional distribution of tidal breath (global inhomogeneity index: GI index). End-expiratory lung impedance (EELI), which is corresponding to EELV was measured and changes in EELI from at before NMBA administration were calculated and expressed as a percentage of tidal impedance change at before NMBA administration. These EIT measures and oxygenation after NMBA administration were compared to the data measured before administration of NMBA. For the comparison, paired t-test or Wilcoxon rank sum test were used for statistical analysis as appropriate.

Results: The EIT data of 6 patients (mean age 54) were analyzed. In all the patients rocuronium was administrated because of the strong

inspiratory effort and asynchrony with ventilator. The mean proportions of ventilation distribution in ventral and dorsal region before NMBA were 39 \pm 14% (mean \pm SD) and 61 \pm 14% respectively, indicating that the active movement of diaphragm induced the predominant distribution of tidal volume to the dorsal region. After NMBA, the inspired gas distributed evenly (48 \pm 11% to ventral and 52 \pm 11% to dorsal region). GI index were decreased after administration of NMBA in 5 cases (before NMBA: 53 \pm 4% after NMBA: 44 \pm 7%). The EELI showed increase in 4 cases and decrease in 2 cases, the mean difference in EELI between before and after administration of NMBA was 26 \pm 59% (95% confidence interval, -35 to 88%). Mean difference in PaO₂/FiO₂ ratio increased after NMBA (before NMBA: 127 \pm 34 mmHg, after NMBA: 177 \pm 77 mmHg), however no significant difference was detected.

Conclusion: After administration of NMBA, the ventilation inhomogeneity was decreased by suppressing strong inspiratory effort, resulting in better oxygenation. In addition, NMBA might maintain EELV by controlling not only inspiratory effort but also active expiration.

Intensive Care Medicine Experimental 2020, **8(2)**: 000490

Introduction: In ARDS patients, mechanical ventilation should minimize ventilator induced lung injury. The mechanical power which is the energy per unit time released to the respiratory system according to the applied tidal volume, PEEP, respiratory rate and flow should reflect the ventilator induced lung injury. However similar levels of mechanical power applied in different lung size could be associated to different effects.

Objectives: Aim of this study was to assess the role both of the mechanical power and of the transpulmonary mechanical power, normalized to predicted body weight, respiratory system compliance, lung volume and amount of aerated tissue on intensive care mortality.

Methods: Retrospective analysis of ARDS patients previously enrolled in seven published studies. All patients were sedated, paralyzed and mechanically ventilated. After 20 minutes from a recruitment maneuver, partitioned respiratory mechanics measurements and blood gas analyses were performed with a PEEP of 5 cmH₂O while the remaining setting was maintained unchanged from the baseline. A whole lung CT scan at 5 cmH₂O of PEEP was performed to estimate the lung gas volume and the amount of well inflated tissue. Univariate and multivariable Poisson regression models with robust standard error were used to calculate risk ratios and 95% confidence intervals of ICU mortality.

Results: 222 ARDS patients were included, 88 (40%) died in ICU [Table 1]. Mechanical power was not different between survivors and non-survivors 14.97 [11.51-18.44] vs. 15.46 [12.33-21.45] J/min and did not affect intensive care mortality.

	Survivors N=134	Non-survivors N=88	p
Age (years)	60 [43-70]	64 [54-75]	0.005
Female N (%)	38 (31%)	31 (35%)	0.48
BMI (kg/m ²)	24.8 [22.6-28.2]	24.2 [22.2-29.0]	0.97
PaO ₂ /FiO ₂	195 [146-231]	153 [115-189]	0.001
PaCO ₂ (mmHg)	40 [35-40]	44 [39-52]	0.001
Respiratory Rate (bpm)	16 [13-20]	17 [14-20]	0.07
Tidal Volume (mL)	510 [450-600]	480 [420-550]	0.004
Clinical PEEP (cmH ₂ O)	10 [10-13]	10 [10-12]	0.68
Driving Pressure (cmH ₂ O)	12.5 ± 3.3	14.0 ± 3.5	0.004
Respiratory system elastance (cmH ₂ O/mL)	23.9 [18.4-29.2]	28.5 [22.9-34.8]	0.001
Intensive Care Unit stay (days)	19 [11-30]	15 [8-24]	0.009

The multivariable robust regression models showed that the mechanical power normalized to well inflated tissue (RR: 2.69 [95% CI: 1.10-6.56] $p = 0.029$) and the mechanical power normalized to respiratory system compliance (RR 1.79 [95% CI: 1.16-2.76], $p = 0.008$) were independently associated with intensive care mortality after adjusting for age, SAPS II and ARDS severity. Also, transpulmonary mechanical power normalized to respiratory system compliance and to well inflated tissue significantly increased intensive care mortality (RR 1.74 [1.11-2.70] $p = 0.015$; RR 3.01 [1.15-7.91] $p = 0.025$). [Figure 2].

Figure 2. Predictive performance of ventilatory variables for Intensive care unit mortality.

Conclusion: In our ARDS population there is not a causal relationship between the mechanical power itself and mortality, while mechanical power normalized to the compliance or to the amount of well aerated tissue is independently associated to the intensive care mortality. Further studies are needed to confirm this data.

Glucocorticoids as Rescue Therapy in Severe COVID-19 Respiratory Failure

T. Woodhead¹; A. Joseph¹; R. Kumar¹

¹Department of Anaesthetics and Intensive Care, Kingston Hospital, London, United Kingdom

Correspondence: T. Woodhead

Intensive Care Medicine Experimental 2020, **8(2)**: 000499

Introduction: SARS-CoV-2, the causative organism of COVID-19, is known to trigger a hyperinflammatory acute respiratory distress syndrome (ARDS) in a subset of patients leading to rapid deterioration and respiratory failure. This is associated with raised inflammatory markers and carries a poor prognosis. At present there is a paucity of interventions available to clinicians to treat this. Glucocorticoids are a plausible treatment option for this presentation given their

established application in reducing inflammatory burden and association with improved outcomes in ARDS. Targeted use of methylprednisolone in patients with COVID-19-induced ARDS has been anecdotally reported to improve outcomes but limited data to support this is available.

Objectives: To examine outcomes in patients with severe ARDS secondary to COVID-19 treated with methylprednisolone, identify predictors of favourable response and any associated risk factors with poor outcomes.

Methods: We conducted a single centre case-control study in a London district general hospital intensive care unit. 27 participants with confirmed SARS-CoV-2 infection, severe ARDS and biochemical evidence of hyperinflammation receiving invasive mechanical ventilatory support between 01/02/2020 and 26/05/2020 were included. 21 patients treated with minimum of one dose of methylprednisolone (1 g/day or 1 mg/kg/day) were identified as the case group, and compared with a control group of 6 patients requiring an FiO₂ ≥ 0.6 for > 48 hours who received no corticosteroids during ICU admission. Outcomes were measured from first dose of methylprednisolone in the case group and after requiring a fraction of inspired oxygen (FiO₂) ≥ 0.6 for 48h in the control group. Primary outcome was 28-day mortality. Secondary outcomes included FiO₂, C-reactive protein (CRP) and ferritin at 48h and day 7. Data on timing of methylprednisolone initiation, demographics and comorbidities were also collected.

Results: 28-day mortality was 38.1% (8) in the methylprednisolone group vs 66.7% in the control group (4), odds ratio 0.31 (95% CI 0.045 to 2.08, $p = 0.358$). 52.3% (11) required an FiO₂ ≤ 0.5 on day 7 in the methylprednisolone group vs 0% in the control group ($p = 0.0003$). As a predictor of 28-day survival, an FiO₂ ≤ 0.5 at day 7 had a sensitivity of 100% (95% CI: 71.5 to 100%) and a specificity of 75.0% (95% CI: 41.3 to 92.7%) ($p = 0.0002$). In participants receiving > 48 h methylprednisolone, an absolute reduction in FiO₂ requirement at day 7 of 0.25 (0.15 to 0.35, $p = 0.0002$) and an 85.1% relative reduction in CRP at day 7 (69.6 to 93.1%, $p = 0.0002$) was observed. Higher age was associated with mortality in the methylprednisolone group ($p = 0.003$).

Conclusion: Methylprednisolone may reduce early mortality in COVID-19 patients with severe ARDS and is associated with lower oxygen requirements and CRP at day 7.

Correspondence: L. Bouchant

Intensive Care Medicine Experimental 2020, **8(2)**: 000525

Introduction: Prone positioning has been proposed as a key aspect of care in ARDS (1), more than ever with emergence of COVID-19 pandemic (2), but sometimes at the cost of burdensome procedure and serious adverse events. Bed verticalization (standing upright) could be an efficient alternative to prone position. Semi-seated position (45-degree head-up, 45-degree legs-down) have already been studied and shew promising results (3, 4), but to our knowledge no study has evaluated the mechanical and physiological impacts of complete patient verticalization (standing upright) during ARDS.

Objectives: To evaluate the safety and physiological effects of bed verticalization of sedated and ventilated COVID-19 patients with ARDS (CARDS).

Methods: Patients were gradually verticalized, using a dedicated bed, at 0°, 30°, 60° and 90° by steps of 30 minutes. At each position step, multiparametric measurements were performed, including

hemodynamic data with pulmonary artery catheter, ventilatory parameters, end-expiratory lung volume (EELV), esophageal pressures and gazometric parameters.

Results: Ten out of 30 were included for this interim analysis. No serious side effects or adverse event occurred during the verticalization procedures. Mean arterial pressure, and cardiac output remained stable in different patient position. EELV of predicted body weight (PBW) increased significantly from 23 (15; 29) to 35 (28; 39) mL.kg⁻¹, between baseline to 90°. Alveolar strain was significantly lower (0.28 [0.19; 0.46] to 0.18 [0.15; 0.24]). Although static compliance decreased (36 [27; 43] to 25 [19; 32] mL.cmH₂O⁻¹.kg⁻¹, baseline and 90° position, respectively, $P = 0.01$), transpulmonary driving pressure did not increase significantly between these two steps (7 [5; 11] to 9 [5; 11] cmH₂O, $P = 0.9$), as well as total mechanical power (10 [8; 13] to 10 [9; 16] J.min⁻¹, $P = 0.5$).

Conclusion: Bed verticalization in ARDS is feasible, safe, and shows promising results on respiratory mechanic with minimal impact on hemodynamics. The rest of inclusions and data are needed to conclude on verticalization efficiency and eventually to identify some responders patients.

Respiratory pattern of critically ill patients with SARS COV 2 Infection at ICU admission

M. Perez Ruiz¹; S. Moreno Cano¹; A. Breal Flores¹; B. Gimenez Beltrán¹; B. Diez Del Corral¹; A. Estella¹

¹University hospital of Jerez, Intensive care unit, Jerez, Spain

Correspondence: M. Perez Ruiz

Intensive Care Medicine Experimental 2020, **8(2)**: 000562

Introduction: Respiratory failure is the most severe form of clinical presentation of SARS COV 2 pandemic infection. 10% of hospital admissions required to be treated in Intensive Care Units (ICU).

Objectives: To describe clinical characteristics and respiratory patterns in critically ill patients admitted in ICU with SARS COV 2 infection.

Methods: Retrospective study in a community hospital with a 17 bed ICU. We included patients with confirmed SARS COV 2 respiratory infection. Variables analyzed were clinical characteristics, respiratory support requirements, respiratory rate and inspiratory fraction of oxygen in Emergency room, PaO₂/FiO₂ ratio at admission, 24, 48 and 72 hours, peep, FiO₂ requirements and mortality.

Statistical analysis: Data were analyzed by SPSS 18 and quantitative variables were expressed as a mean ± standard deviation.

Results: Twenty consecutive patients were included. Mean age was 61,7 ± 8,25. 65% male and 35% female. Apache II at admission was 10,3 ± 4,21 and SOFA score 3,45 ± 1,87. Chest CT was performed in 20% of the patients. Predominant chest radiograph findings were bilateral lung involvement in 90% of cases. Mean PEEP at admission was 11,88 ± 1,85 and inspiratory fraction of oxygen was 65,94 ± 18,9. Non-invasive ventilation BIPAP mode was used in 5% and high flow oxygen therapy in 45% of the admitted patients. Mechanical ventilation was prescribed in 80% of patients, in 56,3% of them high flow oxygen therapy was used before intubation. Prone ventilation was indicated in most of the patients, 93,8%. Mortality was 30%, figure 1 shows PaO₂/FiO₂ ratio based on mortality.

Conclusion: Mechanical ventilation requirement and prone ventilation at ICU admission was common in SARS COV 2 critically ill patients. Improvement of PaO₂/FiO₂ in first 48 hours of ICU admission was related with better prognostic.

Therapeutic effects of high-frequency oscillatory ventilation as the rescue management for premature infants with severe refractory respiratory failure

MH. Tsai¹; SM. Chu²; JF. Hsu²

¹Pediatrics, Chang Gung Memorial Hospital, Yunlin, Taiwan; ²Pediatrics, Chang Gung Memorial Hospital, Linkou, Taiwan

Correspondence: M.H. Tsai

Intensive Care Medicine Experimental 2020, **8(2)**: 000577

Introduction: Despite wide application of high frequency oscillatory ventilation (HFOV) in neonates with respiratory distress, little has been reported about its rescue use in preterm infants

Objectives: We aimed to evaluate the therapeutic effects of HFOV in preterm neonates with refractory respiratory failure, investigate the parameters during HFOV and the independent risk factor for 120-day outcomes.

Methods: We retrospectively analyzed data collected prospectively (January 2014-December 2018) in multiple neonatal intensive care units of tertiary-level medical centers in Taiwan. All premature infants (gestational age < 34 weeks) receiving HFOV as rescue management for refractory respiratory failure were included.

Results: We analyzed the demographics, pre- and daily post-HFOV mechanical ventilation settings and use of adjunctive therapies, therapeutic responses and 120-day outcome data for 668 preterm neonates with refractory respiratory failure. The median (IQR) gestational age

and birth weight were 27.3 (25.3-31.0) weeks and 915.0 (710.0-1380.0) g, respectively. Pre-HFOV use of cardiac inotropic agents and inhaled nitric oxide were 70.5% and 23.4%, respectively. The oxygenation index (OI), FiO_2 , and AaDO₂ were markedly increased after HFOV initiation (all $p < 0.001$), and can be decreased within 24-48 hours (all $p < 0.001$) after use of HFOV. 547 (81.9%) patients had a good response to HFOV within 3 days. The final in-hospital mortality rate was 34.7%. No association was found between specific primary pulmonary disease and survival in multivariate analysis. Initial severity of respiratory failure, response to HFOV treatment, occurrence of sepsis, severe hypotension and patients with underlying perinatal asphyxia were independently associated with the 120-day mortality.

Conclusion: Nearly two-thirds of preterm infants with severe respiratory failure had well response to HFOV, mostly within the first 48 hours. For preterm infants with sepsis, severe hypotension and perinatal asphyxia, alternative strategies are warranted and urgently needed to investigate, in order to optimize outcomes.

Intensive Care Medicine Experimental 2020, **8(2)**: 000635

Introduction: Spain has been one of the most affected countries by the SARS-COV2 pandemic with thousands of cases in Madrid. The healthcare overload and excessive number of critical patients increased the capacity of the ICU. Due to assistance pressure, many of the patients with acute respiratory failure de novo had to be treated at the beginning with conventional respiratory support, CPAP systems and NIMV before their admission in ICU.

Objectives: To analyse the evolution, average hospital stay and mortality of our patients who received respiratory support with CPAP, HFOT or BiPAP before their admission in the ICU. Comparing with the critical patients admitted after conventional oxygen therapy failed.

Methods: Retrospective observational study completed in an ICU of a second degree hospital. During the pandemic, ICU beds went from 14 to 39. We analysed the patients with diagnosis of acute respiratory failure and severe atypical pneumonia by SARS-COV2 admitted from 6/3/20 to 21/4/20. Patients who are still admitted at the time of data collection are excluded. Demographic variables, medical history, APACHE II, days elapsed from hospital admission to ICU admission, presence of associated organic failure, need for rescue treatment in refractory hypoxemia (prone position, neuromuscular relaxation) were collected. We also gathered analytical parameters of bad prognosis (creatinine, bilirubin, ferritin, D-dimer), days of ICU stay and mortality. Statistical analysis is performed using the IBM®SPSS Statistics 23 tool.

Results: We analyse 90 patients. Only 67 received full treatment at our centre due to the lack of beds. All requiring invasive respiratory support, of whom 46.3% of these patients (31) received respiratory support with CPAP or NIMV systems prior to admission in the ICU. In the subgroup analysis, we did not find statistical significant differences in terms of age, gender, personal history, APACHE II or development of organ failure. No differences were found in the number of prones, tracheostomies or need of neuromuscular blockers. There were not differences in the analytical parameters nor in the number of superinfections, neither in the ICU stay nor in mortality. The only difference was in the days elapsed from hospital admission and ICU admission, being 5.6 ± 6.15 days in patients who received non-invasive

respiratory support prior to ICU admission versus 3.03 ± 2.48 days in patients who did not ($p < 0.05$)

Table 1.

	Device (n=32)	No device (n=35)	p
Age(y)	59.32±9.26	60.66±10.5	> 0.05
Sex ♂/♀ (%)	71/29	65.71/34.29	> 0.05
CV (%)	48.39	42.86	> 0.05
Medical history (%)			
Respiratory	22.58	17.14	> 0.05
Others(%)	64.52	60	> 0.05
Days before ICU admission	5.64±6.15	3.03±2.48	<0.05
APACHE II	15.08±5.8	13.16±4.56	> 0.05
Vasoactive support	100	97.14	> 0.05
Creatinine(mg/dl)	1.55±1.55	1.42±0.99	> 0.05
Bilirubine (mg/dl)	1.98±2.03	2.09±2.41	> 0.05
Ferritine (ng/ml)	1743.27±1726.38	2627.73±4216.26	> 0.05
D-dimer (mg/l)	17.13±22.15	18.85±26.59	> 0.05
Prone (%)	67.74	62.86	> 0.05
Neuromuscular blockers(%)	74.19	74.28	> 0.05
Tracheostomy (%)	45.16	43.75	> 0.05
Mortality (%)	45.16	48.57	> 0.05
Days at UCI	13.97±8.37	14.14±11.65	> 0.05

Conclusion: In our sample, the patients diagnosed with refractory hypoxemia who were treated with non invasive respiratory devices had not a worse evolution, longer ICU stay or increased mortality.

We did find a difference in the time elapsed between hospital admission and ICU admission. Patients who were treated with non invasive respiratory devices were admitted later than patients who did not require them.

Derivation of "specific population who could benefit from Rosuvastatin": A secondary analysis on randomised controlled trial to uncover novel value of Rosuvastatin for precise treatment of ARDS

S. Zhang¹

¹zhongda hospital, Nanjing, China

Correspondence: S. Zhang

Intensive Care Medicine Experimental 2020, **8(2)**: 000648

Introduction: The high heterogeneity of ARDS contributes to paradoxical conclusions from previous investigations of rosuvastatin for ARDS. Identification of the population (phenotype) who could benefit from rosuvastatin is a novel exploration for precise treatment of ARDS.

Methods: The patient population for this analysis consisted of unique patients with ARDS enrolled in the SAILS trial (Rosuvastatin vs. Placebo). Phenotypes were derived using consensus k means clustering applied to routinely available clinical variables within 6 hours of hospital presentation before receiving placebo or rosuvastatin. Kaplan-Meier statistic was used to estimate the 90 day cumulative mortality for screening specific population who could benefit from rosuvastatin, with cut-off value as $P < 0.05$.

Results: The derivation cohort included 585 patients with ARDS. Of the 4 derived phenotypes, phenotype 3 was identified as "specific population who could benefit from rosuvastatin" since rosuvastatin resulted in a significant reduction in 90 day cumulative mortality for ARDS (hazard ratio [HR] 0.29 [95% CI 0.09, 0.93]; $P = 0.027$). Meanwhile, there were no significant differences in baseline characteristics between those assigned to rosuvastatin and those assigned to placebo. Additionally, rosuvastatin markedly improved the free of cardiovascular failure (10.08 ± 3.79 in Rosuvastatin group vs 7.31 ± 4.94 in Placebo group, $P = 0.01$) and coagulation abnormality (13.65 ± 1.33 vs 12.15 ± 3.77 , $P = 0.02$) to day 14 in phenotype 3. Patients classified as phenotype 3 exhibited but not limited to the relative higher platelet

count ($390.05 \pm 79.43 \times 10^9/L$), lower CRP ($20.23 \pm 11.99 \mu g/L$) and Creat ($1.42 \pm 1.08 \text{ mg/dl}$), compared with patients classified as other phenotypes. Besides that, rosuvastatin seemed to increase 90 day mortality for patients in phenotype 4 (HR 2.76[95% CI 0.09, 9.93], $P = 0.076$), with its adverse effect on the reduction of free of renal failure to day 14 (4.70 ± 4.99 vs 10.17 ± 4.69 , $P = 0.01$). Patients in phenotype 4 showed a relative severe illness baseline features particularly renal failure.

Conclusion: This secondary analysis of SAILS trial identified the specific population who can benefit from rosuvastatin using machine learning applied to clinical variables at the time of hospital presentation, which uncovered a novel value of rosuvastatin for the treatment of ARDS, with validation clinical trials to be warranted to assess these further.

Intensive Care Medicine Experimental 2020, **8(2)**: 000710

Introduction: The novel human coronavirus, severe acute respiratory syndrome coronavirus-2 (SARS-CoV-2), was declared a global pandemic by the World Health Organization on March 11, 2020. Hence, there is an urgency to find effective treatment. Of those patients afflicted in the United States, many have required treatment with ventilator secondary to acute respiratory distress syndrome (ARDS). Data are needed regarding the benefit of treatment and prevention of the cytokine storms in COVID-19 patients with Tocilizumab.

Objectives: There are over 5.8 million confirmed cases and 360,412 deaths have been identified worldwide as of May 28, 2020 due to SARS-CoV-2 (COVID-19). Our study showed improved survival outcome in COVID-19 ARDS patients treated with Tocilizumab.

Methods: Clinical outcomes data for patients admitted to Orange Regional Medical Center with confirmed COVID-19 from Mar 15, 2020 to Apr 20, 2020 were identified through electronic health record chart review. We conducted a retrospective case-control study in confirmed COVID 19 positive patients with ARDS requiring mechanical ventilation and compared outcome in terms of mortality and length of stay amongst those who received Tocilizumab as treatment modality opposed to those that did not.

Results: A total of 94 patients with COVID-19 ARDS were analyzed. 44 were in the study group and 50 in the control group. We tried to match both group as close as possible in terms of age, sex, BMI and HS score- calculated using inflammatory markers- ferritin, triglycerides, AST and fibrinogen. The median age was 55.5 years in the study group and 66 in the control group, difference was not statistically significant. Average HS score was 114 in the Tocilizumab group and 92 in the control group, difference was statistically significant with $P < 0.0001$. Also, the patients in the study group had elevated levels of IL-6, triglycerides, AST, ferritin which were statistically significant with $p < 0.0001$ when compared to the control group. Length of stay was longer,

average 17.9 days in the Tocilizumab. Survival rate was much lower at 48 % in the control group and 61.36 % in patients who received Tocilizumab with significant P value of < 0.00001 . The number needed to treat (NNT) was 7.48, if we treat 8 patients with Tocilizumab, 1 will not die.

Conclusion: Cytokine Release Syndrome (CRS) occurs in a large number of patients with severe COVID-19, which is also an important cause of death. IL-6 is the key molecule of CRS, so IL-6R antagonist Tocilizumab may be of value in improving outcomes. In our study Tocilizumab group seemed to have improved survival outcome.

Intensive Care Medicine Experimental 2020, **8(2)**: 000727

Introduction: The severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) can infect the endothelium leading to microvascular endothelialitis. The endothelial glycocalyx (eGC) plays an essential role in maintaining endothelial function.

Objectives: To investigate if injury to the eGC can be found in critical ill Covid-19 patients

Methods: Sublingual assessment of the eGC via sublingual dark field imaging was performed in 19 critically ill Covid-19 patients within 24h after intubation and in 10 controls. Blood samples

were analyzed for markers of endothelial and eGC injury. A 3D microfluidic flow assay was performed to examine eGC ex vivo in naïve and Heparanase-2 overexpressing endothelial cells (ECs).

Results: In Covid-19 patients, transmembrane proteins such as Syndecan-1 and sTie2 were increased in the circulation indicating pathological shedding. Hpa-1, a key regulator of eGC, and its enzymatic activity were unchanged. In contrast, its protective counterpart Hpa-2 was profoundly reduced (median (IQR) 18.7 (10.6-31.1) U/ml vs. 4.7 (2.6-5.6) U/ml, $p = 0.014$). Ex vivo stimulation of ECs with serum from Covid-19 patients was sufficient to lower Hpa-2 transcription and to induce glycocalyx damage that could be rescued by lentiviral Hpa-2 overexpression. Consistently, in vivo imaging of the eGC revealed a reduced thickness (increased perfused boundary region (PBR) 1.9 (1.8-1.9) μm vs. 2.1 (1.8-2.2) μm , $p = 0.009$) in Covid-19.

Conclusion: In critically ill patients with Covid-19, early endothelial injury involves the integrity of the glycocalyx. Acquired Hpa-2 deficiency might be a potentially causative factor. These observations may trigger novel therapeutic interventions aiming at protecting endothelial function.

Intensive Care Medicine Experimental 2020, **8(2)**: 000734

Introduction: Understanding the progression and optimum management of the COVID-19 as a “new disease” is of vital importance for healthcare workers worldwide to improve severe disease outcomes.

Objectives: The main purpose of the study is to investigate the progression of critically ill patients with confirmed COVID-19 infection in the ICU.

Methods: All consecutive patients who were admitted in the ICU of the Nicosia General Hospital, Cyprus due to severe COVID-19, between March 10th and May 1st, 2020 were reviewed. A confirmed case of COVID-19 was defined as a positive result on a reverse-transcriptase-polymerase-chain-reaction (RT-PCR) assay of a specimen collected either from nasopharyngeal swab or bronchial secretions. Data was collected regarding respiratory, cardiovascular, infectious, and other parameters.

Results: A total of 19 patients with confirmed COVID-19 were identified. Their mean age was 64, while 74% were men. Obesity (63%) and hypertension (53%) were the most common risk factors for ICU admission. Most patients were admitted with severe respiratory failure (68%) and all required mechanical ventilation. Patients were categorized in four groups of ventilation, based on H or L ventilation phenotype in association with co-morbidities. The first category were L phenotype patients that seemed to benefit from a few days of mechanical ventilation. These patients suffered from no of minor comorbidity. The second category L phenotype patients that seemed to suffer from ICU complications and had a prolonged weaning process. These patients had several comorbidities and/or older age. The third category were H phenotype patients that eventually changed to L phenotype. Among this group the patients exhibited radiological and ultrasonographic signs of atelectasis. Prone positioning seemed of great benefit in these patients. It may be argued that the transition from H to L phenotype may be due to the improvement of atelectasis rather than a change or improvement of lung inflammation. This group exhibited obesity with a high waist circumference partially explicatory of the high atelectasis rate found. Lastly the category “classic” ARDS patients or pure H phenotype. They had the worst outcome since they suffered from severe ARDS. 68% of patients required vasopressor support, and 42% developed AKI during their stay. Diarrhea was common with a median day of onset of 8 days. Lactate levels above 2 mmol/L in the first four days of admission were correlated with a negative outcome. Eight patients (42%) were successfully discharged from the ICU, 7 (39%) died and 4 patients remain in the ICU.

Conclusion: Obesity and male gender are significant risk factors for ICU admission. Ventilation phenotype on admission and during hospitalization may be predictive of outcome. Mechanical ventilation, lower PEEP values and early prone position may provide more favorable outcomes especially in L phenotype patients.

Correspondence: S. Rozencwajg

Intensive Care Medicine Experimental 2020, **8(2)**: 000751

Introduction: Acute pancreatitis (AP) is described as a common cause of acute respiratory distress syndrome (ARDS). Paradoxically, despite exponential increase in ECMO (ExtraCorporeal Membrane Oxygenation) use over the past decade¹, literature remains very poor concerning its use in these patients².

Objectives: Our objective was to describe the use of ECMO in this specific population.

Methods: French multicentric retrospective study. All adult patients on ECMO for an ARDS secondary to AP between 2010 and 2020 were included in the analysis. Demographic data, AP severity, respiratory complications and outcomes were collected. Results are expressed in median [interquartile range] and proportions.

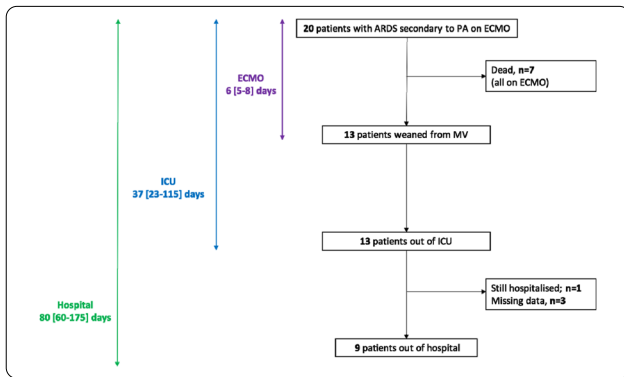

Results: Twenty-five patients with severe ARDS following PA requiring ECMO were identified, of which 5 were secondarily excluded (4 ECMO post-cardiac arrest, 1 for aspiration pneumonia unrelated to PA).

Patients were young (47 [38-60] years) and obese (body mass index 30 [26-34] kg/m²) men (90%) admitted for a severe AP (BISAP 2 score [1-2]), mainly of alcoholic (45%) and biliary (20%) origin. They presented a median sequential organ failure assessment (SOFA) score of 8 [4-13] at admission and a simplified acute physiology score (SAPS 2) of 50 [34-61].

Prior to ECMO initiation, ventilatory characteristics were as follows: tidal volume of 6.9 [5.7-8.6] mL/kg of ideal body weight, positive end-of-expiration pressure of 10 [8-12] cmH₂O and a plateau pressure of 30 [30-32] cmH₂O. Associated adjuvant therapies were neuromuscular blockades (100%), prone positioning (30%) and nitric oxide (30%). Before ECMO initiation, patients had a median pH of 7.26 [7.20-7.38] and a P/F ratio of 58 [52-82].

ECMO support was mainly venovenous (80%) with details presented in the **Table**. Thirteen patients (65%) underwent at least one surgical intervention under ECMO, mainly for digestive ischemia or abdominal compartment syndrome. Outcomes are listed in the **Figure**.

Main ECMO characteristics	
Variables	Patients (N=20)
Time from mechanical ventilation to ECMO, median [IQR], days	2 [0-10]
VV-ECMO / VA-ECMO / VAV-ECMO	16 (80) / 3 (15) / 1 (5)
Refractory hypoxaemia	14 (70)
Unable to achieve protective ventilation	3 (15)
Uncontrolled hypercapnia	2 (10)
Cardiogenic shock	1 (5)

Conclusion: ECMO appears to be an acceptable therapy for ARDS secondary to AP due to the young age and limited comorbidities of these patients. In particular, the need for abdominal surgery does not seem to change the risk-benefit balance and should not contraindicate ECMO in this population. A study comparing this cohort to AP in ARDS without ECMO will provide more answers and is currently underway.

Intensive Care Medicine Experimental 2020, **8(2)**: 000763

Introduction: Since the end of 2019 the world is enthralled by the novel COVID-19 pandemic, putting extreme pressure on Intensive Care Units. The general advice for patients with progressive respiratory failure due to COVID-19 disease was to start invasive mechanical ventilation (MV) early in the clinical course. This was based on the assumption that COVID-19 led to a moderate to severe ARDS requiring MV with PEEP and to prevent patient self-inflicted lung injury (P-SILI) [1]. In addition, non-invasive ventilation and High-Flow Nasal Cannula (HFNC) were discouraged because of the perceived risk of aerosol formation leading to disease transmission. However, it has become increasingly clear that patients with COVID-19 do not necessarily develop typical ARDS and the transmission risk of HFNC is considered comparable to conventional oxygen therapy [1-3]. HFNC is a validated therapy that can prevent intubation in patients with progressive hypoxemic respiratory failure and can also be used outside the ICU [4]. We hypothesize that implementation of HFNC in the pre-ICU setting can successfully reduce the need for MV and ICU-admission of COVID-19 patients.

Objectives: To investigate to what extent HFNC can prevent MV in patients with progressive hypoxemic respiratory failure due to COVID-19.

Methods: We performed a multicenter prospective cohort study between March 2020 and June 2020 on the regular pulmonary wards of an academic and teaching hospital in Rotterdam, the Netherlands. Patients on the regular wards with progressive hypoxemic respiratory failure due to COVID-19 while being treated with maximum oxygen (O₂) therapy (peripheral O₂ saturation < 92% or high work of breathing), started with HFNC. Maximum O₂ therapy before HFNC consisted

of 15L O₂/min flow via a non-rebreathing mask (NRM) in one center and 6L O₂/min flow via a nasal cannula in the other. Patients with contraindications for HFNC (such as hypercapnia, severe hypoxia) were excluded and intubated directly. Patients vital parameters (peripheral O₂ saturation, respiratory rate (RR)) and ROX-scores were monitored after one hour, followed by every two hours during HFNC. In case of an increasing oxygen demand or exhaustion, assessed by the corresponding ROX-scores, MV was initiated [5].

Results: HFNC was initiated in a total of 30 patients for progressive respiratory failure on conventional O₂ therapy (n = 25 nasal cannula; n = 5 NRM). Patients started HFNC after a median of 3 days (IQR: 1-4) after hospital admission, while having symptoms for a median of 11 days (IQR: 9-15). The median peripheral O₂ saturation and RR at start of HFNC was 94% (IQR: 93-96) and 28/min (IQR: 24-32) respectively. 14 out of 30 (47%) were eventually intubated after a median of 12 hours (IQR: 8-24) after starting HFNC. 2 out of 5 on an NRM (40%) were intubated versus 12 out of 25 (48%) on a nasal cannula. Median ROX-score at time of intubation was 4.82 (IQR: 4.60-4.98). Reasons for intubation were hypoxia (n = 1) and somnolence (n = 1) but mainly exhaustion (n = 12) defined as a RR ≥ 30/min with corresponding low ROX-scores. Patients stabilizing on HFNC continued therapy for a median of 5 days (IQR: 2-8) before switching to a nasal cannula.

Conclusion: Our study suggests that HFNC may prevent intubation in a relevant proportion of COVID-19 patients with isolated hypoxemic respiratory failure.

Intensive Care Medicine Experimental 2020, **8(2)**: 000796

Introduction: Lung and chest wall tissues absorb the dissipation of the energy during lung inflation through their viscoelastic properties. These can be represented by the Mount rheological model that consists of a Maxwell body (lung and chest wall viscoelastic elastance (E₂) and resistance (R₂) arranged in series) in parallel with the standard lung and chest wall elastance and resistance, according to the following equation: $P_{visc}(t) = R_2 V' (1 - \exp(-t/\tau_2))$ (1) where $P_{visc}(t)$ represents the viscoelastic elastic pressure dissipation into lung/chest wall during inflation time (t), V' the inflation flow and τ_2 the lung/chest wall viscoelastic time constant ($\tau_2 = R_2/E_2$).

Lung and chest wall viscoelastic properties have not previously been described during acute respiratory distress syndrome (ARDS) according to presence or absence of expiratory flow limitation (EFL).

Objectives: We aimed at assessing the relationship between EFL and viscoelastic dissipation characteristics of lung/chest wall in ARDS patients.

Methods: This is a secondary analysis of a previously reported study on ARDS patients meeting the Berlin definition criteria (1). Patients were intubated, sedated and paralyzed. Airway and esophageal pressures and flow signals were recorded in semi-recumbent position at PEEP 5, 10 and 15 cmH₂O. At PEEP 5, EFL was assessed by the atmospheric method as previously reported (2). Patients were classified as flow-limited (FL) or non-flow-limited (NFL). At each PEEP a 5-s end-inspiratory occlusion was performed at baseline ventilator settings. We used the single breath method (2) to estimate the viscoelastic elastance (E_{2,L} and E_{2,cw}) and resistance (R_{2,L} and R_{2,cw}) of lung and chest wall, respectively. Values are shown as median (1st-3rd quartiles) and compared between FL and NFL at PEEP 5 by using Wilcoxon rank test. The effect of EFL, PEEP and their interaction was further tested by linear mixed-effects model.

Results: Twenty-five ARDS patients were included. Eight were FL and 17 NFL. At PEEP 5, E_{2,L} and R_{2,L} were significantly higher in FL than in NFL patients, amounting to 12 (10-4) vs. 6 (5-8) cmH₂O/L (P = 0.03) and 7 (5-10) vs. 4 (2-6) cmH₂O/L/s (P = 0.04), respectively. Chest wall E_{2,cw} and R_{2,cw} were not different between FL and NFL patients. PEEP had no effect on viscoelastic constants but EFL had a significant effect on E_{2,L} and E_{2,cw} without interaction between PEEP and EFL. Over all PEEP levels, E_{2,L} was 11 (7-14) in FL and 5 (4-7) cmH₂O/L in NFL (P = 0.02) and E_{2,cw} was 2 (1-4) in FL and 3 (1-3) cmH₂O/L in NFL (P = 0.003).

Conclusion: In ARDS, lung viscoelastic constants are significantly higher in FL than in NFL patients. The mechanisms behind this finding should be explored.

Intensive Care Medicine Experimental 2020, **8(2)**: 000801

Introduction: Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) is an atypical Acute Respiratory Distress Syndrome (ARDS), characterized by an initial direct viral insult that could lead to a disproportionate inflammatory response that worsens lung function [1]. To date it is unknown if steroids may be a strategy in viral ARDS [2]. We tested the hypothesis that methylprednisolone reduces mortality at 28 days.

Objectives: Determine the effect of methylprednisolone on mortality at 28 days, on mechanical ventilation (MV) free days and major complications.

Methods: From February 22nd to March 22nd, 130 consecutive patients admitted in 6 ICUs of Ospedale Papa Giovanni XXIII (Bergamo) were retrospectively enrolled. Age, Charlson comorbidity index, SOFA score and PaO₂/FiO₂ ratio (P/F) at admission were collected. We compared 67 control patients (control group) with 63 receiving methylprednisolone (steroid group) at either low dose (1 mg/kg/day, n = 58) for 10 days or up to three high dose boluses (1000 mg, n = 5). Primary outcome was mortality at 28 days. Secondary outcomes were MV-free days and secondary infections. Baseline characteristics and MV-free days were compared in two groups using Mann Whitney test. The association with mortality and infection was evaluated with Fisher exact test.

Results: In our population median age was 62 (IQR 14), 107 (82%) were male, 115 (88%) required intubation.

In the steroid group all patients received methylprednisolone within the first 14 days after ICU admission, median therapy duration was 10 days (IQR 10). Steroid and control groups were similar in terms of age, Charlson comorbidity index, SOFA score and P/F. Methylprednisolone was associated with reduced mortality at 28 days (OR 0.35, 95% CI 0.17-0.77, p 0,009). No differences were observed in MV-free days, secondary infections and septic shock. The table summarizes baseline characteristics and main findings of the study.

	Steroid Group (63)	Control Group (67)	P
Age, median (IQR)	61 (12)	60 (11)	ns
Charlson comorbidity index, median3 (IQR)	2 (2)	2 (2)	ns
SOFA score, median (IQR)	6 (2)	6 (2)	ns
PaO ₂ /FiO ₂ , median (IQR)	110 (59)	109 (69)	ns
Secondary infections, n (%)	30 (52)	25 (40)	ns
Septic shock, n (%)	20 (32)	15 (26)	ns
MV-free days, median (IQR)	0 (15)	0 (8.5)	ns
Mortality at 28 days, n (%)	14 (22)	30 (45)	*

Conclusion: In our cohort of SARS CoV-2 patients, immunomodulation therapy with methylprednisolone was associated with reduced mortality at 28 days.

Intensive Care Medicine Experimental 2020, **8(2)**: 000821

Introduction: Patients with chronic obstructive pulmonary disease (COPD) have recurrent exacerbations that contribute to their clinical impairment (1). Computed tomography (CT) scanning can distinguish the underlying changes driven the airflow limitation, and many studies have showed the main pathological characteristics of emphysema, airway wall thickening and reduced lumen caliber (1-3).

CT has been used to quantify emphysema by detecting low attenuation areas (LAA%), and quantitative parameters of the parenchyma on inspiration and expiration allow indirect evaluation of small airway obstruction. While the quantification of emphysema by CT imaging has been well established and validated, the quantification of airway disease has proven to be more difficult to establish. The segmental and subsegmental bronchial wall area percent (WA%) have been found to be correlated with the forced expiratory volume in 1 s (FEV₁) (1-3).

Objectives: To estimate the association between radiological findings and the need for intensive care unit (ICU) or mortality in patients hospitalized by the emergency room with COPD exacerbation.

Methods: Prospective cohort study with adults attended in the emergency room of three reference hospitals in Medellín (Colombia), who consulted for acute exacerbation of COPD and required hospitalization between 2017 and 2020. Inspiratory and expiratory scans were performed. Morphometric assessment of the airways ([WA%] and airway inner luminal area [Ai]), as well as extent of emphysema (LAA%), were performed using 3D Slicer software. Data were collected from the segmental and subsegmental generations of the apical segment

of the right upper lobe (RB1) and the posterior-basal segmental and subsegmental bronchi of the right lower lobe (RB10). LAA thought to reflect emphysematous destruction of the lung parenchyma were defined using a Hounsfield Unit threshold of -50 (%LAA-950). The association between radiological measurements and inpatient death or admission to ICU was explored by locally weighted regression (LOWESS) and simple univariate logistic regression models.

Results: Among 1411 eligible patients, 326 (23%) were included. The main exclusions were pneumonia (30%), limiting to perform the CT (24%) and terminal illness (11%). The median age was 74 years (IQR 66 - 82) and 56% were women. Smoking history (86%) and exposure to biomass (61%) were the main risk factors. Hospital mortality rate was 2.5% and 40 (12.3%) patients required admission to ICU, with 43 (13.2%) patients with the outcome of interest. The means of WA% were: RB1 segmental 64.6 (58.8-70.7), subsegmental 70.3 (64.5-75.5), and RB10 segmental 63.3 (57.5-70.6), subsegmental 69.4 (62.8 -76.1). The mean for extent of emphysema (%LAA-950) was 14.7% (4.2-29.3). In univariate logistic regression analyzes, all radiological measurements showed no association with the outcome of death or need for ICU (Table 1).

Morphometric variable	Odds Ratio (95% CI)
Mean airway wall area percent (%) [WA]	
B1 Segmental	0.99 (0.96 - 1.02)
B10 Segmental	1.01 (0.98 - 1.04)
Mean airway inner luminal area (mm ²) [Ai]	
B1 Segmental	0.99 (0.98 - 1.02)
B10 Segmental	0.99 (0.98 - 1.01)
Volumetry	
%LAA-950	0.99 (0.97 - 1.02)
15th percentile	1.00 (0.97 - 1.01)

Conclusion: Morphometric assessment of the airways and the extent of emphysema did not differ between patients with and without the outcome of death or need for ICU.

Intensive Care Medicine Experimental 2020, **8(2)**: 000822

Introduction: COVID-19 may be associated with severe respiratory failure that, for patients requiring invasive ventilation carries an estimated mortality of 49% in the UK (1). A prominent feature of the disease is the development of thromboembolic complications that, despite thromboprophylaxis, occurs with an incidence of approximately 50% (2,3). We evaluated the presenting characteristics and outcomes of the patients admitted with COVID-19 in our ICU, particularly as regards to the development of thromboembolic complications.

Methods: Baseline characteristics, respiratory variables, coagulation and inflammatory parameters and ICU mortality were collected retrospectively on all patients admitted with either PCR-confirmed or clinically diagnosed COVID-19.

Results: Between March and May 2020 59 admissions with COVID-19 were recorded. Thirty-two patients (58%) required invasive ventilation and 27 patients (48%) received therapeutic anticoagulation. Thromboembolic complications occurred in 8 patients (14%) and 50% of those died. Of the patients that had ischaemic complications 5 (63%) were on prophylactic and 3 (38%) on therapeutic anticoagulation. Six patients developed haemorrhagic complications and 2 of those required blood transfusion. Mortality in the intubated patients was 47%. There was no difference in the mortality of patients that received therapeutic anticoagulation versus those that did not. Factors associated with mortality included CRP and respiratory variables, whereas D-dimer was associated with the development of thromboembolic complications. Maximum CRP in the first 72 hours of admission was significantly higher in the patients that died (mean (SD) 311 (80) vs 207 (86) mg/L, $p = 0.0002$); > 300 mg/L was associated with $> 70\%$ mortality. Minimum S/F ratio (median [IQR]) within the first 72 hours of admission in non-survivors vs survivors was 149 [114-165] vs 192 [157-269], $p = 0.0004$. Patients with lowest S/F < 150 and ≤ 100 had 60% and $> 80\%$ mortality respectively. Both D-dimer on admission and mean D-dimer during ICU stay were higher in the patients that experienced thromboembolic complications. However, there was no association between APTTR, anti-Xa, or Fibrinogen values with either mortality or the of thromboembolic complications (Figure).

Conclusion: Our analysis shows a lower incidence of thrombotic complications compared to other centres, likely because of our low threshold for anticoagulation. Therapeutic anticoagulation was not associated with improvement in outcomes and that was likely a result of patient selection, as those with clinically severe disease received therapeutic anticoagulation. Similar to other studies, D-dimer and CRP levels were associated with poor outcomes and may be used for prognostication and to guide anticoagulation treatment (4,5).

Intensive Care Medicine Experimental 2020, **8(2)**: 000825

Introduction: SARS-CoV-2 overwhelmed intensive care units capacity around the world. In this circumstances providing high complexity and resources consuming techniques as ECMO was a challenge.

Objectives: To describe characteristics and outcomes of patients receiving ECMO to support complications related with COVID-19 infection.

Methods: ECMO decision was based on ELSO recommendations for SARS-CoV-2 pandemic after discussion between ECMO team members (which consisted of cardiac surgeons, cardiologists and intensive care medicine specialists). Clinical records were analyzed to obtain relevant demographic, gas exchange and mechanical ventilation characteristics and outcomes. Descriptive statistics were performed.

Results: From February to May 2020 around 230 patients (> 95% invasive mechanical ventilation application) with SARS-CoV-2 diagnosis were admitted to the intensive care units of the two study centers and ECMO was used in 6 patients. Two H1N1 patients (with 0% mortality) were also subjected to ECMO during this time period but were excluded of this analysis. Five patients had ARDS as main diagnosis and reason for ECMO (veno-venous) while one had a diagnosis of miopericarditis and cardiogenic shock secondary to COVID-19 and veno-arterial ECMO was used. All patients were male, mean APACHE II was 15 ± 7 , age 51 ± 4 years, post intubation $\text{PaO}_2/\text{FiO}_2$ ratio was $152 \pm 57\text{mmHg}$ ($131 \pm 28\text{mmHg}$ when miopericarditis patient was excluded), PaCO_2 $55 \pm 12\text{mmHg}$, pH 7.32 ± 0.1 , tidal volume 442 ± 38 ml (always below 8ml/kg PBW) and PEEP 13.8 ± 1.6 cmH_2O and none of them had evidence of right ventricle failure. All veno-venous patients were in protective mechanical ventilation settings including prone position at the time of ECMO decision which occurred at day 13 ± 8 of admission and after 10 ± 7.16 mechanical ventilation days. In two patients ECMO was started after extubation failure and restart of mechanical ventilation. Variables at the time of ECMO start were $\text{PaO}_2/\text{FiO}_2$ ratio $89 \pm 14\text{mmHg}$, PaCO_2 $74 \pm 15\text{mmHg}$, pH 7.35 ± 0.07 , tidal volume 412 ± 30 and PEEP 12 ± 2.4 cmH_2O . In the veno-arterial patient ECMO was started in the admission day without data of respiratory failure. ECMO was used during 13 ± 7 days, survival was 66% and intensive care unit length of stay 56 ± 25 days (one patient remained in the ICU at the time of analysis). No differences in the analyzed variables were found between survivors and not survivors.

Conclusion: In this cohort of patients with severe COVID-19 infection ECMO showed encouraging results. Mortality was below the usual reported data. However length of stay was high. As long as material and human resources were available and well-coordinated, ECMO could be delivered in a safe way in times of SARS-CoV-2 pandemic.

Enhanced thromboprophylaxis dosing or therapeutic anticoagulation are not associated with a decrease in thrombo-embolic events in patients with COVID19: A single centre experience

A.M. Karimi¹; P.J. Masters²; E. Riddell¹; J. Ramzi¹; K. Patel²; M. Trivedi¹; R. Mahroof¹; A. Conway-Morris¹

²Acute medicine, Addenbrooke's Hospital, Cambridge, United Kingdom

Correspondence: A.M. Karimi

Intensive Care Medicine Experimental 2020, **8(2)**: 000876

Introduction: Multiple studies report that patients with COVID-19 have a high incidence of arterial and venous thromboses despite standard prophylaxis^{1,2,3}. Although this has led to recommendations for higher anticoagulant dosing⁴ in patients on ICU, it is unclear if this will reduce thrombotic complications.

Objectives: 1. To quantify the difference in thrombotic events between ICU and ward level patients.

2. To ascertain whether a higher prophylactic low molecular weight heparin (pLMWH) dose regime for ICU patients conferred protection from developing thromboses.

Methods: We collected data retrospectively on patients admitted to medical wards between 8th Apr 2020 to 22nd Apr 2020, who were PCR positive for SARS-CoV-2. Data collected included the use of prophylactic or therapeutic anticoagulation, clinically detected thrombotic complications or bleeding.

We also collected data on patients admitted to ICU from 15th Mar 2020 to 14th Jun 2020 with PCR confirmed COVID-19. These patients received either standard pLMWH, or, following introduction of new guidance, 'enhanced' pLMWH.

Results: 83 ward admissions were identified, of which 53 had standard pLMWH, 18 were already on therapeutic anticoagulation, and 12 received neither. 1 patient developed a venous thromboembolism (VTE) (1.2%). 2 patients, both on pre-admission therapeutic anticoagulation, had bleeding complications (2%).

73 ICU patients were identified; 13 VTE events (12 PE and 1 DVT) (18%). A further 20 filter-related line thromboses occurred, amongst 22 receiving CVVH. In total 29 patients (40%) experienced intra or extra-corporeal thrombotic events.

34 patients received standard pLMWH, whilst 39 received enhanced thromboprophylaxis or therapeutic anticoagulation initiated prior to development of any thrombotic event. Peak D-dimer was higher in patients developing thrombotic events or bleeding, (median 1410 vs 5374, $p < 0.0001$); none of the other measures were significantly different in either group (Table 1).

Table 1: Comparison of ICU patients receiving standard vs enhanced thromboprophylaxis

	Standard thromboprophylaxis (34)	Enhanced thromboprophylaxis (39)
Median age (range)	62 (55)	61 (60)
% (95% CI) female	10 [29% (17-46%)]	10 [26% (15-41%)]
Median (range) APACHE II score	12 (18)	14 (24)
Median (range) admission D-Dimer	384 (13033)	423 (36213)
Median (range) Peak D-Dimer	2566 (12944)	1491 (58383)
% (95% CI) ventilated	25 [74% (57-85%)]	33 [85% (70-93%)]
% (95% CI) developing pulmonary or deep vein thrombosis	6 [18% (8-34%)]	7 [18% (9-33%)]
% (95% CI) Bleeding complications	2 [6% (2-19%)]	5 [13% (6-27%)]

Conclusion: Thrombotic events were significantly more common amongst patients admitted to ICU than those who had ward level management only. Although the rate of these events was higher, we found no signal that increasing pLMWH doses was effective, and may have been associated with an increased risk of bleeding.

Baseline inequalities between our groups and relatively small numbers mean that these conclusions should be tested in larger data sets and trials of enhanced thromboprophylaxis are warranted.

Intensive Care Medicine Experimental 2020, **8(2)**: 000892

Introduction: On Feb 20,2020, the first patient with COVID-19 in Italy developed respiratory failure and was admitted to the ICU and the number of recorded cases increased rapidly throughout the country.

Objectives: Strong from Chinese experience and with 2 week-gap from Lombardy, we organized our hospital (AOUI of Verona, Italy) from 60 to 114 ICU beds.

We aimed to describe our COVID-19 critically ill patients.

Methods: Prospective observational study of all COVID-19-confirmed critically ill patients, treated at our ICUs between 6 March to 23 April, 2020.

Date of final follow-up was June 25, 2020.

Demographic and daily clinical data were collected, including data on clinical management, respiratory and other organ failure, management and outcome.

Results: Of the 122 pts included, the median age was 65 (56-71) yrs and 96 (78,7%) were male.

66 (54%) had cardiovascular disorders, 24 (20%) were obese, 17 (14%) had dyslipidemia, 20 (16%) had diabetes, 20 (16%) were current smokers, 16 (13%) had COPD.

34 (28%) patients were directly admitted from the ED, 60 (49%) from a medical ward and 27 (22%) were transferred from another hospital. The mean duration of symptoms before hospital admission was 7 days and 9 days before ICU admission.

The most common symptoms on admission to the hospital were shortness of breath (dyspnoea, 91 [74.2%]) and cough (60 [49.5%]).

At ICU admission, APACHE II and SOFA scores were 20 (13-28) and 8 (5-11), respectively.

Lymphocytopenia was present (0.5 [0.1-0.8] 10⁹/L); CRP was 137 (61-194) mg/L, PCT was 0.3 (0.2-0.8) ng/mL. Total CPK, LDH and D-Dimer were 131 (77-339) U/L, 421 (311-505) U/L and 1265 (570-2032), respectively; arterial lactate was 1.2 (0.9-1.6) mmol/L.

P/F at baseline was 81 (65-118); 117 pts (96%) received invasive mechanical ventilation and after tracheal intubation P/F was 115 (98-149), TV was 495 (450-500) mL, RR was 17 (15-20) apm, PEEP was 11 (10-12) cmH₂O, PPlat was 20 (18-22) cmH₂O, DP was 9 (8-10) cmH₂O and compliance was 47.25 mL/cmH₂O.

2 pts (1.6%) were treated with Sildenafil, 5 (4%) received iNO and 3 (2.5%) needed ECMO.

All received hydroxychloroquine, 112 (92%) lopinavir-ritonavir, 12(9.8%) remdesivir, 18(15%) tocilizumab. On D1 104 (86%) pts were under antibiotic therapy. 28 day ICU mortality was 18.9%. ICU LOS was 13 (2-40) for survs and 7 (1-35) for non survs.

Conclusion: Almost all our COVID-19 patients received a homogeneous management schema and invasive mechanical ventilation and ICU mortality was less than 20%.

Intensive Care Medicine Experimental 2020, **8(2)**: 000902

Introduction: Patients suffering from Severe Acute Respiratory Syndrome Coronavirus 2 (SARS-CoV-2) disease develop an atypical form of ARDS characterized by severe hypoxemia and preserved lung mechanics. Prone positioning (PP) is successfully used as a rescue therapy for severe hypoxemia in classic ARDS. Its effects are not yet clear in SARS-CoV-2.

Objectives: To describe the effects of PP on gas exchange and respiratory mechanics in a group of severely hypoxic patients with SARS-CoV-2.

Methods: From February 22th to March 22th, consecutive SARS-CoV-2 patients admitted to the ICUs of Papa Giovanni XXIII Hospital in Bergamo, were studied. PROSEVA study group criteria were used to identify modalities and clinical indications to PP2. Data about ventilation (positive end-expiratory pressure (PEEP), driving pressure (DP), compliance of respiratory system (CrS)) and gas exchange (PaO₂/FiO₂ (P/F ratio) and PCO₂) were collected at three time points: before (supine_pre), at the end (prone) and after 6 hours (supine_post) of each session. Data were analyzed using repeated measurements ANOVA followed by Dunnet post-hoc analysis.

Results: Among 115 SARS-CoV-2 patients admitted to the ICU receiving mechanical ventilation, 71 were pronated. 80% patients were male, mean age and BMI were 60 ± 10 and 30 ± 5, similarly to the rest of the population. At the beginning of mechanical ventilation P/F ratio and CrS were 123 ± 63 and 40 ± 11 ml/cmH₂O. Median time to the first prone session was 1 (0;3) day. 25 patients (35%) were pronated once while the remaining 46 needed more than a session. Table shows the results of the PP.

Cycle (patients)	First (n=71)			Second (n=46)			Third (n=23)		
	Supine_pre	Prone_post	Supine_post	Supine_pre	Prone_post	Supine_post	Supine_pre	Prone_post	Supine_post
P/F ratio	92±19	173±18*	137±8*	114±13	171±18*	138±5*	117±4*	171±6*	135±5*
PEEP (cmH ₂ O)	15±3	15±3	15±3	NS	15±3	15±3	NS	16±3	16±2
PCO ₂ (mmHg)	55±11	42±12	54±10	NS	56±13	54±8	NS	58±15	61±16
DP (cmH ₂ O)	11±3	12±3*	11±3	p=0.045	11±3	11±2	NS	11±3	10±3
CrS (ml/cmH ₂ O)	41±10	43±12	45±12*	p=0.018	44±16	42±9	NS	45±15	46±15

* comparison between prone versus supine_pre: p<0.05, and *supine_post versus supine_pre: p<0.05.
(NS=not Significant). Data are presented as mean ± standard deviation.

Major complications occurred in 16 cycles (11%): severe hypoxemia in 7, pneumothorax in 1, airway-related complications in 4, pulmonary embolism in 2 and cardiovascular instability in 2 cycles.

Conclusion: PP resulted in a significant increase in P/F ratio despite no effect on respiratory mechanics. These data suggest that PP could be used as rescue therapy for severe hypoxemia in SARS-CoV-2.

Intensive Care Medicine Experimental 2020, **8(2)**: 000925

Introduction: Identification of risk factors associated with mortality in coronavirus disease 2019 (COVID-19), could promote rapid and proper allocation of resources. (1)

Objectives: We sought to identify early detectable risk factors associated with 120-day mortality in subjects with COVID-19 admitted to the Intensive Care Unit (ICU).

Methods: We included all consecutive adult patients with COVID-19 admitted to the ICU at our institution between February 22 and March 22, 2020.

COVID-19 was defined according to at least one between clinical, radiological and/or laboratory criteria.

Variables were considered if clinically relevant, promptly available and were excluded if their accuracy was not verifiable (e.g. viral exposure and date of start symptoms, which were self-reported).

First, we used univariable logistic regressions to explore risk factors associated with 120-day mortality.

Secondly, variables with a p value at least inferior to 0.05 at univariable analyses were included in a multivariable logistic regression model; to avoid overfitting, we limited the number of regressors to 1 variable every 15 outcomes.

Finally, we computed a ROC curve of the multivariate analysis and its relative area under the curve (AUC) in order to assess the discriminative power of the model.

Results: In our cohort of 130 patients, 51 patients (39.2 %) died within 120 days after ICU admission.

Variable	Univariable analyses		Multivariable analysis	
	OR (95% CI)	p value	OR (95% CI)	p value
Age (year) *	1.14 (1.09 - 1.21)	< 0.001	1.13 (1.07 - 1.19)	< 0.001
BMI *	1.01 (0.94 - 1.08)	0.77	—	—
Male sex ^	1.01 (0.40 - 2.61)	0.99	—	—
COPD ^	10.3 (1.68 - 197)	< 0.05	5.54 (0.74 - 115)	0.14
RR admission > 24 bpm	0.91 (0.38 - 2.10)	0.83	—	—
CPAP/NIV to TI (days)*	0.96 (0.80 - 1.15)	0.68	—	—
ACE-I therapy ^	2.32 (0.8 - 7)	0.12	—	—
Blood group 0 ^	1.66 (0.69 - 3.94)	0.25	—	—
Blood group A ^	0.54 (0.22 - 1.25)	0.15	—	—
SOFA *	1.29 (1.10 - 1.54)	< 0.05	1.28 (1.06 - 1.57)	< 0.05

TABLE 1: ACE-I = Angiotensin Converting Enzyme Inhibitors, BMI = Body Mass Index, bpm = breath per minute, COPD = Chronic Obstructive Pulmonary Disease, CPAP = Continuous Positive Airway Pressure, NIV = Non Invasive Ventilation, RR = Respiratory Rate, SOFA = Sequential Organ Failure Assessment, TI = Tracheal Intubation * = per unit increase, ^ = true

We identified age, COPD and SOFA- score as independent predictors of mortality at 120 days (see Table 1).

In the multivariable model, both age and SOFA- score were associated with mortality and the AUC of the relative ROC curve was 0.84.

Conclusion: Facing the unpredicted trajectory of the still ongoing outbreak of COVID-19, we identified a “three early-detectable variables” model associated with 120-day mortality in critically ill COVID-19 patients.

If confirmed in other cohorts, our findings could promote the development of a mortality-predicting score, improving resource allocation in COVID-19 pandemic.

Intensive Care Medicine Experimental 2020, **8(2)**: 000965

Introduction: A substantial proportion of critically ill COVID-19 patients develop thromboembolic complications (ref 1-3). It is unclear what the optimal dose of thromboprophylaxis is for critically ill COVID-19 patients and whether higher doses are associated with lower mortality rates.

Objectives: To evaluate the association of initial dosing strategy of thromboprophylaxis in critically ill COVID-19 patients and the risk of death, thromboembolism, and bleeding.

Methods: This was an observational cohort study in a 600-bed emergency hospital in Stockholm, Sweden. All critically ill COVID-19 patients admitted to two ICUs in March and April 2020 were eligible. Exclusion criteria were short length of stay, ongoing anticoagulation therapy due to diagnosed thromboembolic disease, or no initial thromboprophylaxis in the ICU. Patients were categorized into three groups according to initial daily dose; low (2500-4500 IU tinzaparin or 2500-5000 IU dalteparin), medium (> 4500 IU but < 175 IU/kg of body weight tinzaparin or > 5000 IU but < 200 IU/kg of body weight dalteparin), and high dose thromboprophylaxis (≥ 175 IU/kg of body weight tinzaparin or ≥ 200 IU/kg of body weight dalteparin). The three study groups reflected a gradual increase in dose of thromboprophylaxis during the study period.

Results: A total of 152 patients were included, out of which 67 received low dose thromboprophylaxis, 48 medium dose thromboprophylaxis, and 37 high dose thromboprophylaxis. Demographic and clinical characteristics were similar in the three groups at baseline. Mortality was lower in patients treated with high (13.5%) vs medium (25.0%) and low dose thromboprophylaxis (38.8%), p = 0.02. The multivariable hazard ratio of death was 0.33 (95% confidence interval 0.13–0.87) with high vs low dose thromboprophylaxis when adjusted for sex, age, body mass index, Simplified Acute Physiology Score III and invasive respiratory support. There were fewer thromboembolic events in patients treated with high (2.7%) vs medium (18.8%) and low dose thromboprophylaxis (17.9%), p = 0.04, but no difference in the proportion of bleeding events, p = 0.16.

	Initial dosing strategy of thromboprophylaxis				P-value (d)
	Total (n=152)	Low dose (a) no=67	Medium dose (b) no=48	High dose (c) no=37	
Primary Outcome					
28-day mortality, No. (%)	43 (28.3)	26 (38.8)	12 (25.0)	5 (13.5)	0.02
Secondary Outcomes					
ICU-free days alive during 28 days from ICU-admission (days)	9 (0–21)	0 (0–20)	11 (0–19)	18 (0–26)	0.07
Thromboembolic events <28 days, No. (%)	22 (14.5)	12 (17.9)	9 (18.8)	1 (2.7)	0.04
Bleeding events <28 days, No. (%)	16 (10.5)	8 (11.9)	7 (14.6)	1 (2.7)	0.16

(a) tinzaparin, 2500–4500 IU OD; or dalteparin, 2500–5000 IU OD, (b) tinzaparin, >4500 IU OD to <175 IU/kg of body weight OD; or dalteparin, >5000 IU OD to <200 IU/kg of body weight OD, (c) tinzaparin, ≥175 IU/kg of body weight OD; or dalteparin, ≥200 IU/kg of body weight OD, (d) P-values for differences across exposure categories were obtained using Fisher's exact test for categorical and Kruskal-Wallis test for continuous data.

Conclusion: Among critically ill Covid-19 patients, high dose thromboprophylaxis was associated with a lower risk of death and a lower cumulative incidence of thromboembolic events compared with lower doses. There was no difference in the proportions of bleeding events between the groups.

National questionnaire of ECMO in Spanish Intensive Care Units

A. Delgado¹; P. Millán²; A. García De Lorenzo²; JM. Añon Elizalde²

¹Intensive Care, Ramón y Cajal University Hospital, Madrid, Spain; ²Intensive care medicine, La Paz University Hospital, Madrid, Spain

Correspondence: A. Delgado

Intensive Care Medicine Experimental 2020, **8(2)**: 000983

Introduction: The main objective is to analyse the organisation of ECMO in our country

Methods: A national questionnaire was performed (January 2019–2020) consisting in questions about pre-ECMO management, accessibility of the technique, characteristics of the ECMO team, quality, safety, training and membership of the EuroELSO.

Results: 86(29%) ICU units answered. In 57% (n = 49) ECMO was established. Only 8 regions of 17 have an ECMO retrieval team. In the management before ECMO: in 95 % (n = 81) prone position was trialled prior to ECMO. In 43% (n = 36) ECMO was considered if prone position was not successful in 12–24h. In 65 % (n = 55) ECMO was considered if Pa/ FiO₂ ≤100. In the hospitals with established ECMO, 63% (n = 41) do not have a specialised team. The Intensivist is the one that most frequently does the cannulation (40% (n = 15) and management (95% (n = 37)). V-V ECMO is the type most frequently used and ARDS is the most frequent indication. There is a large heterogeneity in the number of cases done per centre ranging from centres that have > 70 cases per year (n = 2) to centres that do > 10 cases (n = 23). Hypovolaemia and recirculation are the most frequent complications. 93% (n = 39) of the ICUs recognise that they do not do a monthly ECMO educational or simulation session. 81% (n = 35) do not belong to EuroELSO and 74 % (n = 31) do not participate in the ECMO registry.

Conclusion: There is a wide heterogeneity of the accessibility of ECMO in Spain. There is a high rate of trial of prone position prior to ECMO, as per current recommendations. A significant number of ICUs do not reach the minimal number of cases recommended by ELSO Criteria. There is ample heterogeneity in the teams and management. There is room for improvement in education, simulation, and membership of EuroELSO.

Intensive Care Medicine Experimental 2020, **8(2)**: 001040

Introduction: Dynamic hyperinflation may develop in patients with chronic obstructive pulmonary disease (COPD) and asthma due to dynamic airway collapse or due to airway narrowing by bronchospasm or bronchial wall edema. Dynamic hyperinflation during controlled mechanical ventilation may result in barotrauma and hemodynamic instability. To limit these risks, it is important to quantify pulmonary hyperinflation. Tuxen et al. (1,2) demonstrated that maintaining end-inspiratory lung volume (V_{ei}) below 1.4 L (or below 20 mL/kg when corrected for ideal body weight) prevents development of adverse effects related to pulmonary hyperinflation.

Objectives: To validate two clinically applicable bedside techniques for the measurement of V_{ei}.

Methods: V_{ei} was assessed using three techniques: i) Gold standard: the patient exhaled from end-inspiration in a calibrated glass tube with liquid level indicator. ii) Formula based on physiology: (Vt * Pplateau)/(Pplateau – PEEPtotal), with Vt the tidal volume, Pplateau the plateau pressure obtained after an inspiratory occlusion maneuver and PEEPtotal the positive end-expiratory pressure obtained after an expiratory occlusion maneuver. iii) Ventilator maneuver: measuring the expired volume using the flow sensor of the ventilator during passive exhalation from end-inspiration during pressure support ventilation. V_{ei} was determined using these three techniques in each patient with 5 minute interval. The gold standard was repeated after the three measurements to exclude changes in respiratory mechanics due to the study protocol.

Results: Seventeen patients were evaluated. V_{ei} according to the gold standard was 16.08 ± 1.17 mL/kg. V_{ei} according to the formula and ventilator maneuver had a low bias but large limits of agreement (0.64 ± 6.70 mL/kg and 0.46 ± 6.48 mL/kg, respectively) and were moderately correlated with the gold standard (r² = 0.47 with P = 0.0035 and r² = 0.56 with P = 0.0009, respectively). V_{ei} according to the gold standard did not change due to the study protocol: 0.21 ± 1.73 mL/kg as compared to the initial V_{ei} measurement.

Conclusion: In patients with airflow obstruction it is important to quantify pulmonary hyperinflation to limit risks associated with hyperinflation. We showed that using a formula to estimate V_{ei} and a ventilator maneuver to measure V_{ei} are too cumbersome to use at the bedside, due to low agreement and moderate correlations compared to the gold standard to measure V_{ei}.

Intensive Care Medicine Experimental 2020, **8(2)**:001043

Introduction: The human pathogen coronavirus CoVid-19 may cause life threatening pneumonia. 20% of those tested positive show severe signs of hypoxic respiratory failure, with 5% needing intensive care unit treatment, with a reported mortality between 30-60% (Grasselli, JAMA) While knowledge about the disease is increasing, no firm recommendations concerning treatment strategies have been made.

Objectives: The human pathogen coronavirus CoVid-19 may cause life threatening pneumonia. 20% of those tested positive show severe signs of hypoxic respiratory failure, with 5% needing intensive care unit treatment, with a reported mortality between 30-60% (Grasselli, JAMA) While knowledge about the disease is increasing, no firm recommendations concerning treatment strategies have been made.

Methods: From January 2020 to June 2020 data of all patients with respiratory failure who tested positively for SARS-COV-2, treated in the ICU of the Asklepios Klinik Langen, Germany, were sampled. We differentiated between those patients who required extracorporeal membrane oxygenation therapy (ECMO) and those who did not. Comorbidities, clinical examination and laboratory values were recorded. In case ECMO therapy had been necessary, we noted which type we used as well as the patients' outcome.

Results:

All patients n=27 Asklepios Klinik Langen, Germany	ECMO n=13	without n=14
Demographics		
male	10	10
female	3	4
BMI	28,7	26,2
Co-morbidities		
Hypertension, adiposity, pulmonary diseases, diabetes yes		yes
Presenting symptoms		
Median time to invasive ventilation (d)	4,2	3,2
Median time of invasive ventilation (h)	776	363,8
Tracheostomy	12	4
Median time to tracheostomy (d)	1	1
Thrombotic event	6	3
Pneumothorax	6	2
Presenting Laboratory Values		
White blood cell count (G/l)	10,7	9,7
Lymphocyte count (G/l)	9,7	13,9
C-reactive protein (mg/dl)	255	148,6
PCT (µg/l)	10,3	4,18
Ferritin (µ/l)	1932	1903
D-dimer (mg/l)	29,1	11,94
Troponin (µg/l)	277	26,3
Lactate (mmol/l)	2,5	1,1
Creatine kinase (U/l)	1195	217,78
SOFA score	5,1	1,2
SAPS II	35,6	28,1
SARS-Cov IgA	10	5,8
SARS- Cov IgG	12	6
Respiratory Paramters on intubation		
Bilateral infiltrates on chest x-ray/typical CT-scan	13	14
PaO2:FiO2	83	205,2
Median symptom onset to intubation (d)	4,2	3,2
Median time to admission	3,2	8,3
Outcome		
Median ICU stay (d)	32,5	11,9
Death	9	2
	9	2

Conclusion: Patients with ARDS caused by SARS-COV-2 treated with ECMO had a two times higher death rate compared to ARDS caused by other diseases (Combes, EOLIA). Especially patients of hospitals with lower care levels who underwent prolonged prone position with controlled ventilation and higher ventilation pressures had a more serious course of the disease and suffered from more complications compared to the patients who had immediate access to ECMO therapy if required.

Intensive Care Medicine Experimental 2020, **8(2)**: 001055

Introduction: Among patients with COVID-19, there is a high prevalence of cardiovascular disease, and it has been reported that 22% of critically ill patients experience myocardial injury from the infection.1 The British Society of Echocardiography and The European Association of Cardiovascular Imaging advise performing a focused TTE, on patients during the COVID -19 pandemic.2,3

In our critical care unit we performed a full standard TTE on COVID-19 + patients and we report the impact on the management of these patients.

Methods: This prospective study took place in the 36 bed critical care unit of the Mater Hospital. Critically ill COVID-19 + patients who had a TTE(s) were included. The studies were performed by an intensivist, or cardiac physiologist.

Results: Fifty-three COVID-19 + patients were admitted to critical care between 31/3/20 -17/6/20. Thirty-six TTE studies were performed on 22 patients. Indications; haemodynamic shock (11), assess RV (7), assess LV (12), ? endocarditis (6). Mean age; 60 ±11 years, male (n = 12) median critical care length of stay; 17 (12, 32) days, mean SOFA score 5 ± 2. Non- invasive ventilation (n = 2) and mechanical ventilation (n = 17). Thirteen patients received vasoactive medication, 4 patients required Extra Corporeal Membranous Oxygenation. Seven patients died.

Table 1. Baseline characteristics

	Total n= 22
CAD	n = 4 (18%)
Valvular heart disease	n = 3 (13%)
Congestive heart disease	n = 1 (4%)
Hypertension	n = 9 (40%)
Atrial fibrillation	n = 1 (4%)
COPD	n = 1 (4%)
Asthma	n = 4 (18%)
Diabetes	n = 6 (27%)
Chronic kidney disease	n = 4 (18%)
ACEi /ARB use	n = 7 (31%)

CAD: Coronary Artery Disease, COPD: Chronic Obstructive Pulmonary Disease, ACEi: angiotensin converting enzyme inhibitor, ARB: angiotensin receptor blocker.

Seven patients had 1 normal TTE. Seven patients had 19 TTE 's with echocardiographic abnormalities that did not immediately change management; including reduced LV EF, left ventricular hypertrophy,

regional wall motion abnormalities, diastolic dysfunction, cor pulmonale, tricuspid regurgitation and pericardial effusion. Eight patients had 10 TTE's which led directly to a change in management. These are summarized in Table 2.

Indication	TTE Findings	Management change	Outcome
Assess RV	RV severe dilatation, pressure overload LV	Cancellation discharge critical care	S
Haemodynamic shock	Severe LV hypertrophy normal LVEF	Noradrenaline	D
Haemodynamic shock	Large hemothorax tamponade effect	IR guided drainage	S
Assess LV	Normal LVEF Grade 2 diastolic dysfunction	ACEi + diuretic	S
Assess LV	Normal LVEF Grade 1 diastolic dysfunction	ACEi	S
Assess LV	Normal LVEF left ventricular hypertrophy	BP control GTN before extubation	S
Haemodynamic shock	Pericardial effusion, RV collapse	IR guided drainage	D
Haemodynamic shock	Pericardial effusion, RV collapse	IR guided drainage	D
Query endocarditis	No vegetations, evidence hypovolaemia	Fluid therapy	S
Assess RV	RV severe dilatation	Nitric oxide + sildenafil	S

RV: Right ventricle, LV: Left Ventricle, LVEF Left ventricular ejection fraction, IR: interventional radiology, BP: Blood pressure, GTN: Glyceryl trinitrate, D: Dead, S: Survived.

No Intensivist or cardiac physiologist involved in the study became infected with COVID-19.

Conclusion: Critically ill COVID-19 positive patients may develop cardiovascular pathologies in addition to myocardial injury. We recommend a standard TTE in such patients in order to diagnose and effect management changes as appropriate.

Intensive Care Medicine Experimental 2020, **8(2)**: 001070

Introduction: COVID-19 was declared a global pandemic by the World Health Organization (WHO) on March 11th 2020. The first case of COVID-19 identified in the Republic of Ireland was on February 29th 2020.

Objectives: Our aim was to collect data in order to examine clinical characteristics of COVID-19 patients admitted to Critical Care (ICU/

HDU) in an inner-city, university-affiliated, 570-bed, tertiary referral centre in Dublin, Ireland.

Methods: Prospective data collection took place from the arrival of the first COVID-19 positive patient to our ICU on March 8th 2020 until June 1st 2020.

Results: During the study period, 46 patients were admitted to Critical Care with symptoms of COVID-19. 45/46 (98%) were identified as COVID-19 positive by oro/nasopharyngeal specimens. 1 patient out of 46 (2%) was confirmed by bronchoalveolar lavage (BAL).

The median age was 59. 28/46 (61%) were male and 18/46 (39%) were female. In total, 28/46 (61%) patients required invasive mechanical ventilation, which lasted greater than 2 days for all.

The most common comorbidity was hypertension in 16/46 (35%) of patients, followed by both obstructive pulmonary disease and diabetes mellitus in 11/46 (24%) patients, chronic kidney disease (CKD) in 8/46 (17%) and ischemic heart disease in 7/46 (15%). 7/46 (15%) patients were healthcare workers and 4/46 (9%) were identified as positive contacts

The most predominant symptom was dyspnoea in 37/46 (80%) patients, followed by cough in 19/46 (41%), fever in 16/46 (35%), myalgia in 8/46 (17%), diarrhoea in 8/46 (17%) and altered consciousness in 1/46 (2%). 41/46 (89%) patients were lymphopaenic. 22/46 (47%) patients were prone for > 16 hours per day. 4/46 (9%) patients were placed on extracorporeal membrane oxygenation (ECMO). At the end of the study period, 5/46 (11%) patients remain in Critical Care.

Conclusion: The first patient tested positive for COVID-19 in Ireland in February 2020. It was essential to collect data on this novel virus as it presented to our Critical Care Unit. We identified the most prominent clinical characteristic in order to deliver effective treatment. In total, two thirds of patients presenting to Critical Care required invasive mechanical ventilation. Almost 70% survived their Critical Care admission, while 15% died. The clinical symptoms and co-morbidities of patients admitted to our ICU were comparable to that seen internationally at this time [1, 2].

Pandemic ICU Research as a Newly Qualified Doctor: An Experience from a District General Hospital

J. Caterson¹; MC. Frise¹

¹Intensive care unit, Royal Berkshire Hospital NHS Foundation Trust, Reading, United Kingdom

Correspondence: J. Caterson
Intensive Care Medicine Experimental 2020, **8(2)**: 001074

Introduction: Prior to the World Health Organisation declaring a pandemic in March 2020, research efforts into coronavirus disease 2019 (COVID-19) were rapidly gathering pace.[1] Simultaneously in the UK, final year medical students were graduating early,[2] having completed their core studies, to join the workforce as junior doctors. Locally, research training including a Good Clinical Practice course and close support from research clinicians was provided to some new doctors, offering a unique opportunity for involvement in pandemic research studies at the outset of their medical careers.

Objectives: To describe the challenges associated with recruiting to a pandemic study at a UK District General Hospital serving a population

of over 500,000,[3] and inform preparations for research during a possible 'second-wave' or future pandemics. A core focus was obstacles to recruitment.

Methods: Patient screening and recruitment was conducted in accordance with the GenOMICC study protocol.[4] Demographic data were anonymously collected for patients screened and deemed eligible. The Chi-Squared or Two-Tailed Fisher's Exact Test were used to compare enrolment into the study according to demographic characteristics. Statistical significance was taken as $p < 0.05$.

Results: Approval for recruitment was given on 19th April 2020 and the first patient recruited on 21st April. Over 6 weeks, 39 eligible patients were identified. 6 were approached directly and in 33 an opinion sought from relatives as the patients lacked capacity due to illness severity. 26 patients were enrolled, 5 declined, and 8 died during the process. 23 were recruited by the newly qualified doctor and 3 by research nurses.

There was no significant difference in enrolment according to sex ($p > 0.99$), age ($p = 0.15$), BMI ($p = 0.21$), or 60-day mortality ($p = 0.48$). There was a trend towards lower enrolment in Black, Asian and Minority Ethnic (BAME) groups compared with white patients ($p = 0.05$). The predominant reason for enrolment was a desire to improve understanding of COVID-19. Reasons for declining included fears of sharing genetic data and lack of acute benefit to the patient.

Conclusion: Newly qualified doctors can play a valuable role in the recruitment of patients to priority pandemic studies when other staff have been redeployed. Our analysis identifies several challenges to conducting observational pandemic research; notably timely set up to capture the population affected when the condition has a high early mortality, and communication when constrained by infection control requirements for a highly contagious airborne pathogen. The suggestion of lower recruitment from the BAME population – if real – would be of particular concern given the urgent need to determine the extent to which genetic factors contribute to apparently worse outcomes in these patients.[5]

Intensive Care Medicine Experimental 2020, **8(2)**: 001090

Introduction: Acute exacerbation of chronic obstructive pulmonary disease (eCOPD) can lead to hypercapnia and respiratory acidosis. It is a major determinant in health status. Non-invasive ventilation (NIV) is the gold standard therapy as it reduces work of breathing and improves gas exchange. However, for some patients NIV fails and intubation is needed which exposes them to mechanical invasive ventilation (MIV) complications and weaning difficulties. For those patients extracorporeal carbon dioxide removal (ECCO₂R) may be an option.

Methods: We conducted a single center retrospective analysis on successive eCOPD patients for whom NIV failed and didn't have limitation for MIV. For the first step (from January 2010 to February 2015) we observed blood gas measurements, respiratory rates and complication rates on 26 eCOPD patients treated with MIV after NIV failure. Then, for the second period (from February 2015 to February 2019) we observed the same parameters for 28eCOPD patients failing NIV for whom ECCO₂R was performed with the iLA active, iLA kit (Xenios Novalung, Heilbronn, Germany) device at a targeted blood flow of 1 L/min.

Variables are reported as mean \pm sd. Quantitative values are compared with t test (95% confidence interval) and qualitative values with Pearson's Chi-squared test with Yates' continuity correction. Population distribution was tested with the Shapiro-Wilk normality test.

Results: The two groups were comparable at baseline in demographics : gender, BMI, SAPS and age : respectively in the ECCO₂R and MIV group SAPS 48 \pm 15 and 50 \pm 14, age 66,1 \pm 11,4 years and 71,4 \pm 11 years. pH and PaCO₂ are showed in Figure 1. The respiratory rate 6 hours before ECCO₂R was 27,00 \pm 8,37 and 22,18 \pm 3,79 at decannulation ($p = 0,22$). In the MIV group, respiratory rate 6 hours before intubation was 25,88 \pm 3,83 and 21,25 \pm 5,44 at extubation ($p = 0,30$).

We were able to avoid MIV for 25 patients (89,3%) in the ECCO₂R group.

Complications for patients affected are listed in Table 1. The ECCO₂R duration was 5,7 \pm 4,2 days and in the MIV group ventilation lasted 28,2 \pm 42,5 days. In the MIV group, 5 patients had an extubation failure and 6 patients had autoextubated. ECCO₂R was stopped because of recovery for 20 patients, complication for 6 patients (with a mean duration of ECCO₂R of 5,7 days) and death for 2 patients. MIV was stopped because of recovery for 17 patients, tracheotomy for 2 patients and death for 7 patients.

Length of stay in the Intensive Care Unit for the ECCO₂R and the MIV group was 19 \pm 15,5 days and 31 \pm 42,2 days respectively ($p = 0,18$). Length of stay in the hospital for the ECCO₂R and the MIV group was 29,46 \pm 21,1 days and 50,58 \pm 52,4 days respectively ($p = 0,06$). Mortality at 28 days and 90 days was 8% and 14% respectively in the ECCO₂R group and 16% and 30% in the MIV group.

Conclusion: Our results show that ECCO₂R is feasible and brings significant improvement on pH and PaCO₂ with relatively low complication rate.

Evidence for a mortality benefice of ECCO₂R in eCOPD patients failing NIV therapy has yet to be proven in a larger randomized study.

Intensive Care Medicine Experimental 2020, **8(2)**: 001094

Introduction: The risk/benefit ratio of corticosteroids for patients with COVID-19-related acute respiratory failure has not been yet established.

Objectives: We compared the outcomes of patients receiving dexamethasone (DEXA) vs. methylprednisolone (METHYL), and the effects of rescue, short-term/high-dose pulses of glucocorticoids (BOLUS).

Methods: Consecutive patients admitted from March 1st to April 30th 2020 to the general ICU of a tertiary care hospital for COVID-19 were enrolled. As per Institutional protocol, from March 1st severe cases were given DEXA; as of April 10th the protocol was modified and

METHYL was suggested. On top of that, physicians were allowed to administer a 3-day course of 1000 mg/day of methylprednisolone in case of refractory hypoxemia within the first week of treatment.

Results: We enrolled 81 consecutive patients, 69 (85%) males, age 60 ± 10 years. At ICU admission SAPS II was 27 ± 7 and SOFA 4 [3; 6] points. 46 patients (56.8%) received DEXA, whereas 30 (37%) had METHYL; 5 patients did not receive corticosteroids. The groups were well-matched for age, comorbidities and severity at admission. No differences were found in the duration of mechanical ventilation (11 [7; 17] vs. 11 [8; 18] days, $p = 0.7021$), ICU mortality (37.0 vs 43.3%, $p = 0.578$), incidence of VAP (47.8 vs 53.3%, $p = 0.639$) or bacteremia (39.0 vs. 36.7%, $p = 0.829$). A significantly lower number of patients who had DEXA received a rescue BOLUS (34.8 vs. 66.7%, $p = 0.007$).

36 patients (44.4%) received a rescue BOLUS: they were more likely to be female (25.0 vs. 7.0%, $p = 0.021$) and obese (38.9 vs. 8.9%, $p = 0.002$). Table 1 shows the outcomes of patients who did vs. those who did not receive BOLUS.

	No BOLUS (N=45)	BOLUS (N=36)	P
Duration of mechanical ventilation (days)	9 [4; 16]	13 [8; 21]	0.0074
Duration of pressure support ventilation (days)	2 [1; 5]	4 [2; 9]	0.0349
ICU length of stay (days)	13 [9; 19]	18 [11; 26]	0.0287
Ventilator-free days (days)	12 [0; 22]	6 [0; 19]	0.0580
ICU mortality – n (%)	15 (33.3)	17 (47.2)	0.204
Patients who developed VAP – n (%)	17 (37.8)	23 (63.9)	0.020
Number of VAP per patient	2 [1; 2]	2 [1; 2]	0.6898
Patients who developed bacteremia – n (%)	14 (31.1)	17 (47.2)	0.138
Number of bacteremias per patient	1 [1; 2]	2 [1; 2]	0.2748

Conclusion: we were unable to find any difference between DEXA or METHYL on the explored outcomes; high-dose BOLUS of glucocorticoids seemed to be associated with a higher duration of mechanical ventilation and a higher incidence of complications. Further, prospective investigations are needed to confirm these results.

Intensive Care Medicine Experimental 2020, **8(2)**: 001098

Introduction: Barotrauma is a well-known complication of invasive mechanical ventilation and it has been anecdotally reported in critically ill patients with COVID-19.

Objectives: To analyse the incidence and factors associated with development of barotrauma in a cohort of COVID-19 patients.

Methods: Retrospective case series of consecutive patients with laboratory-confirmed COVID-19 admitted from March 1st to April 30th 2020 to the general ICU of a tertiary care hospital. Data regarding the use of CPAP before ICU admission, as well as the parameters of mechanical ventilation during the ICU stay were collected. Barotrauma

was defined as pneumothorax, pneumomediastinum or subcutaneous emphysema by means of clinical examination, lung ultrasound, chest XR or CT scan.

Results: 81 patients were enrolled in the study; age was 60 ± 10 years, 69 (85%) were male. 16 patients (20%) developed barotrauma. Table 1 shows the comparison of patients who did vs. those who did not develop barotrauma.

Variable	No barotrauma (n=65)	Barotrauma (n=16)	P
Age (years)	59 [53; 68]	68 [58; 73]	0.0496
COPD – n (%)	3 (4.7)	1 (6.3)	0.798
SAPS II score (points)	26.5±6.2	27.8±7.3	0.5024
SOFA score at ICU admission (points)	4±2	5±2	0.6070
Awake prone position – n (%)	32 (57.1)	5 (38.6)	0.224
Onset of symptoms to hospital admission (days)	7 [5; 10]	7 [5; 10]	0.8519
Hospital admission to CPAP (h)	5 [1; 45]	8 [2; 15]	0.4400
Beginning of CPAP to ICU admission (h)	53 [19; 96]	47 [28; 132]	0.7519
Duration of CPAP before ICU admission (days)	2 [1; 4]	3 [1; 5]	0.7046
Respiratory system compliance at ICU admission (ml/cmH2O)	51.9±13.3	49.4±13.3	0.5286
Plateau pressure at ICU admission (cmH2O)	24.3±3.1	24.8±3.4	0.5797
Number of prone-positioning cycles	3 [1; 6]	5 [4; 7]	0.0289
Duration of controlled mechanical ventilation (days)	6 [3; 10]	11 [9; 14]	0.0011
Duration of assisted mechanical ventilation (days)	3 [1; 5]	5 [1; 13]	0.0790
Incidence of VAP from S aureus – n (%)	20 (31.3)	6 (37.5)	0.633
ICU length of stay (days)	11 [6; 18]	13 [7; 17]	0.9766
ICU mortality – n (%)	23 (35.9)	10 (66.7)	0.030

3 patients already had barotrauma at ICU admission; in the remaining cases, barotrauma was diagnosed after 14 [10; 22] days of mechanical ventilation. At the diagnosis, 3 patients (19%) were spontaneously breathing, 5 (31%) were receiving pressure support ventilation and 8 (50%) controlled ventilation; in patients undergoing mechanical ventilation PEEP was 11.6 ± 2.6 cmH₂O and Plateau airway pressure was 28 ± 5 cmH₂O.

Conclusion: Barotrauma is a frequent, severe, late complication in mechanically ventilated COVID-19 patients. An older age and a longer course of controlled mechanical ventilation seem associated with the development of barotrauma.

Neutrophil-to-Lymphocyte Ratio as a prognostic marker in Covid 19

M. Portilla-Botelho¹; A. Bueno-Gonzalez²; M. Sanchez Casado²; J. Vejo³; J. Monserrat⁴; M. Alvarez-Mon⁵

¹Intensive care unit, Hospital General Universitario de Ciudad Real, Ciudad Real, Spain; ²Icu, Virgin Health Hospital, Toledo, Spain; ³Intensive care unit, Hospital Universitario La Paz, Madrid, Spain, Spain; ⁴Immunology department, University of Medicine of Alcalá de Henares, Alcalá de Henares, Spain; ⁵Immunology department, Hospital Príncipe de Asturias, Alcalá de Henares, Spain

Correspondence: M. Portilla-Botelho

Intensive Care Medicine Experimental 2020, **8(2)**: 001102

Introduction: The Neutrophil-to-Lymphocyte Ratio (NLR) is an expression of systemic inflammation in multiple immunologic, cardiovascular, and cancer diseases. An excessive inflammatory answer to SARS Cov2 can lead to acute respiratory distress that increases mortality

Objectives: We considered 1/- studying characteristics of patients with Covid19 admitted to Intensive Care Unit (ICU) due to SARS Cov2 severe pneumonia; and 2/- analysing if NLR and other inflammatory markers are associated with poor prognosis

Methods: We included Covid patients admitted to our ICU, with acute respiratory failure that required invasive mechanical ventilation (IMV). We analysed different inflammatory markers at the momento of ICU admission: NLR, plasmatic lymphocytes (L), fibrinogen, D dimer (DD), and C-Reactive Protein (CPR). Statistical analysis with STATA version 13.

Results: We analysed 63 patients, mean age of 62.3 years (SD 11.3), 63% were males. The most frequent risk factor was high blood pressure. Mean stay in ICU was 26.4 days (SD 19.4), and mean hospital stay was 59.4 days (SD 19.3). 71% of patients needen prone position, 13 patients (20%) suffered pulmonary barotrauma, and 29 patients (46%) died in ICU. All patients that survived in ICU were discharged to home.

In the study of prognostic factors, we found that patients who died, had a higher NLR (33.40 vs 15.75, $p < 0.001$), and more lymphopenia (772 vs 1540, $p = 0.004$). We did not find significant differences in DD or PCR values. Patients with barotrauma had a higher NLR than patients without it (43.51 vs 18.76, $p < 0.001$) and there were not differences in the other inflammatory markers studied. Patients with longer mechanical ventilation and longer ICU stay, did not present differences in NLR or L, but had higher DD (7509 vs 2364, $p = 0.002$). In multiple regression analysis, RNL and L at ICU admission, were independent risk factors of mortality (AUC ROC curve 0.75 IC: 0.62-0.87) and pulmonary barotrauma (AUC ROC curve 0.75 IC: 0.59-0.90). However these parameters did not correlate with ICU stay nor days of IMV.

Conclusion: Neutrophyl-to-lymphocyte ratio at ICU admission, is a simple low cost index that has important prognostic value in patients with severe SARS-Cov2 pneumonia.

Correspondence: M. Bento

Intensive Care Medicine Experimental 2020, **8(2)**: 001107

Introduction: Bronchoalveolar lavage (BAL) is the current gold-standard for the differential diagnosis of alveolar infiltrates in immunosuppressed patients. Its reported diagnostic yield has been between 30 to 67%, but its results have marginal repercussions on treatment options and prognosis. Performing BAL is not risk free and with the development of non-invasive techniques, the clinical relevance of BAL in establishing the etiology of acute respiratory failure (ARF) has recently been questioned.

Objectives: 1) To assess the diagnostic yield of BAL in establishing the etiology of ARF; 2) To compare the mortality rate between patients subjected to BAL or not; and 3) To evaluate the impact of BAL on time until diagnosis in hematologic patients admitted to the intensive care unit (ICU) with ARF.

Methods: Retrospective cohort study. Inclusion criteria: hematological patients admitted to a tertiary hospital's ICU due to ARF between January 2012 and June 2020 (8.5 years). Exclusion criteria: patients without infiltrates on chest radiography at admission. Primary endpoint was diagnostic yield of BAL, defined as the identification of microbiological agent or exclusion of other causes. Secondary endpoints were intra-ICU mortality rate, 30-day mortality rate, survival time and time until etiological diagnosis.

Results: A total of 79 hematological patients were included in the study, of which 34 (42.5%) were female, with a mean age of 59.01 ± 16.59 years. Twenty-one (26.3%) of the patients were subjected to BAL. Age, gender and need for mechanical ventilation were comparable between groups. Mean SOFA at admission, mean APACHE II and the number of neutropenic patients were significantly higher in the non-BAL group ($p < 0.05$).

BAL contributed to the etiological diagnosis in 47.37% of the clinical cases. Mortality rate was lower in the BAL group either evaluated as Intra-ICU mortality rate (38.1% for BAL vs. 71.9% for non-BAL, $p = 0.006$) or 30-day mortality (42.9% vs. 75.4%, $p = 0.013$). Survival time was longer in the BAL group (19.00 vs. 5.00 days, $p = 0.002$). On a multivariate analysis including APACHE II or OFA at admission and neutropenia, APACHE II was a significant confounding factor in the mortality rate difference between the 2 groups; yet, when analyzing survival time controlling for these same factors, BAL remained significantly associated with longer survival times ($p = 0.003$). We found no differences between the groups on the frequency of etiological diagnosis, time to diagnosis or duration of mechanical ventilation.

Conclusion: BAL is a useful diagnostic tool for acute respiratory failure in selected hematological patients in which diagnosis is not possible by non-invasive techniques.

A review of proning in non-intubated patients with Covid 19 who presented to a tertiary referral ICU

J. Kelliher¹

¹ICU, HSE Ireland, Dublin, Ireland

Correspondence: J. Kelliher

Intensive Care Medicine Experimental 2020, **8(2)**: 001134

Introduction: A review of proning in non-intubated patients with Covid 19 who presented to a tertiary referral ICU.

Objectives: This small retrospective study investigates 16 patients admitted to our ICU who were treated with awake proning.

The primary outcome studied was the difference in oxygen saturation before and 1 hour after self proning.

Secondary Outcomes include; decrease in the respiratory rate, increase in PF ratio, rates of subsequent intubation and the length of time proning was tolerated.

Methods: We conducted a retrospective chart review of consecutive patients admitted to our ICU between 31/03/20 to 25/04/20. Covid 19 diagnosis was confirmed by oropharyngeal and nasopharyngeal PCR. 52 patients with Covid 19 were admitted to our ICU during this time, 16 of whom self proned.

We document the changes in oxygen saturations, PF ratio and respiratory rate before and one hour after proning.

We also note the duration proning was tolerated in each session and how many proning sessions patients received.

Results: RESULTS

Oxygen saturations improved on average 3.6% on proning (range 1 to 6.8%; median 3.7%).

The average pre-proning O₂ saturation was 94% (on supplemental oxygen delivered by nasal prongs or Venturi mask).

Patients who required intubation had a poorer response to proning from the outset with an mean improvement in oxygen Saturations of only 2.2% (range 1- 3.7% median 2%) compared with 4.6% (range 2 to 7% median 4.5%) in the patients who did not require intubation.

The day of illness when proning was initiated was similar in both groups (8.8 v 8.0).

Overall, the PF ratio post proning improved by an average of 6.9kPa (ranging from 2.3 kPa to 23 kPa: median 4.5kpa). The PF ratio improved significantly more on self proning in those patients that did not require intubation (9.14kPa compared to an average improvement of only 5.4 kPa in those who required intubation)

PF ratios were lower from the outset in the patients who were subsequently intubated after trial self proning-average PF ratio 17.1 (range PF 14.6- 21.4: median 17) compared to PF ratio of 25.9 in patients who did not require intubation.

Proning was tolerated well with only one patient unable to continue for more than an hour.

The average hours proned per session was 2.7 hours; ranging from 1 hour to 8hours per session.

The number of sessions ranged from 1 to 13 sessions.

The Respiratory Rates after proning did not significantly change with proning 25.4 to 24.4 average. 7 patients out of the 16 patients were ultimately intubated (43%).

All patients survived to ICU discharge.

Conclusion: CONCLUSIONS

This study adds to a body of observational evidence that awake prone position improves oxygenation in the non-intubated patient with respiratory failure and that it is well tolerated in short sessions.[i]Limitations include small sample size and its retrospective nature.

Intensive Care Medicine Experimental 2020, **8**(2): 001149

Introduction: The coronavirus disease 2019 (Covid-19) pandemic, mainly affects the respiratory system and the evolution into acute respiratory distress syndrome (ARDS) is the main cause of admission in ICU. It is known now that the Covid-19-induced ARDS presents some unusual characteristics compared to common ARDS. Although the practice of prone positioning (PP) is part of the actual recommendations in Covid-19 severe ARDS management (based on common ARDS trials), there is, to our knowledge, no studies which assessed the efficacy of prone positioning on blood oxygenation and mortality in this context.

Methods: We performed a monocentric analysis of prospectively collected data in the medical ICU of Bichat-Claude-Bernard Hospital (France) between January and June 2020. Covid-19 confirmed patients, admitted for ARDS, who required intubation and prone positioning (practiced for a PaO₂/FiO₂ (P/F) ratio < 150 mmHg after positive end-expiratory pressure (PEEP) optimization) were included. P/F ratio before and after the first PP were collected, and response was defined as [(P/F after PP – P/F before PP)/ P/F before PP] X 100. A response was considered significant if ≥ 20%. We analyzed predictors of significant response and day 60 (d60) mortality.

Results: 42 patients were included. 31 patients were dead at d60 (mortality rate: 64.5%). No difference in baseline characteristics were found between survivors and decedents (Table 1). Compliance (mean 28.9 vs 29 ml/cmH₂O) at the time of prone position did not differentiate survivors from decedents (Table 1).

In the overall population, the response was high, with a mean rate of 94.4% and was correlated with a better outcome at d60 (mean 145% vs 76%, p = 0.038, Wilcoxon test, Figure 1). Significant response to first PP was observed in 73.8%. 10/11 (90.9%) in d60 survivors responded to first PP vs 21/31 (67.7%) in d60 decedents (p = 0.23, Fischer test, Table 1).

Higher response remained associated with a lower d60 mortality after adjustment on age, extra-respiratory components of SOFA at day 1 and first Covid-19 viral load recovered from the respiratory tract (adjusted OR (per % of response) [CI] = 0.992 [0.98;1], p = 0.0618)

Significant response was not associated to age, body mass index, severity at admission, first Covid-19 viral load, time from intubation to PP or compliance.

Table 1: Baseline characteristics of the population, and endpoints.

Characteristics	Alive at day-60 (n=11)	Dead at day-60 (n=31)	P value
Age, year, median [IQR]	56 [51 ; 69]	63 [51 ; 69]	0.5351
Simplified Acute Physiology Score II, median [IQR]	37 [27 ; 46]	32 [25 ; 50]	0.7967
Sepsis-related Organ Failure Assessment score at day 1, median [IQR]	1 [0 ; 4]	2 [1 ; 5]	0.1735
Body Mass Index, median [IQR]	33 [26 ; 34]	28 [24 ; 32]	0.1752
Delay from intubation to PP, hour, median [IQR]	64.5 [25 ; 136]	46 [18 ; 100]	0.6783
PaO ₂ /FiO ₂ ratio before PP, median [IQR]	102 [78 ; 110.1]	101.3 [83 ; 121]	0.5576
Admission nCov19 viral load ¹ , log (10) copy, median [IQR]	6 [5 ; 9]	8 [6 ; 8]	0.1430
Static compliance of the respiratory system, before PP, mL/cmH ₂ O, median [IQR]	25 [23.1 ; 34]	28.6 [21.4 ; 34.2]	0.9668
Response to PP ² , percentage, median [IQR]	149 [52 ; 232]	62 [11 ; 119]	0.0381
Significant response to PP ³ , n (%)	10 (90.9)	21 (67.7)	0.2342

Abbreviations: PaO₂: partial pressure of oxygen in arterial blood, FiO₂: fraction of oxygen in air, PP: prone positioning, nCov19: novel Coronavirus 2019, SD: standard deviation, IQR: interquartile range

¹ Obtained by polymerase chained reaction on respiratory tract swab

² Defined as: [(P/F after PP – P/F before PP)/ P/F before PP] X 100, in percentage

³ Defined as response ≥ 20%

Conclusion: In our study, patients with severe Covid-19 induced ARDS mainly responded to the first PP, although mortality rate was high. Using a 20% increase threshold, no difference was found regarding response rate to first PP between patients alive and dead at day 60. However, the response was significantly better in the d60 survivors. This suggests that the threshold used to define our endpoint may be too low to use it as a predictive factor. These results tend to highlight that response to first PP is correlated with survival.

Correspondence: N. Van Veenendaal
Intensive Care Medicine Experimental 2020, **8(2)**: 001160

Introduction: Coronavirus disease 2019 (COVID-19) is associated with hypercoagulable states and high incidences of thromboembolic complications. Conventional coagulation tests show trends of coagulopathy, but currently no test reliably identifies COVID-19 patients at increased risk of developing thromboembolic complications. Rotational thromboelastometry (ROTEM®) is a point-of-care device that evaluates viscoelastic changes during coagulation and may provide valuable information to identify patients at risk of developing thromboembolic complications.

Objectives: The aim of this study was to evaluate ROTEM® profiles of COVID-19 patients in identifying thromboembolic complications.

Methods: All patients diagnosed with COVID-19 admitted to the ICU in April 2020 were enrolled in this single-center, retrospective observational study. Blood samples were collected for ROTEM® thromboelastometry. Coagulation patterns were analyzed using extrinsic, intrinsic and fibrinogen rotational thromboelastometry activators (respectively EXTEM, INTEM and FIBTEM). ROTEM® patterns were analyzed for all COVID-19 patients and were compared between patients

with and without thromboembolic complications. Hypercoagulability was defined as a reduction in clot formation time (CFT) and a maximum clot firmness (MCF) above the upper limit of the normal reference values.

Patients who were clinically suspected to have a thromboembolic complication underwent additional imaging. The decision for imaging was based on clinical features and was at the discretion of the attending intensivist.

Additionally, ROTEM® parameters were compared with conventional coagulation parameters including, partial thromboplastin time (PT), activated partial thromboplastin time (APTT), fibrinogen, and platelet count.

Results: ROTEM® patterns of forty-seven COVID-19 patients were analyzed. Ten patients (21.3%) developed thromboembolic complications during ICU admission, all being pulmonary embolisms confirmed by CT-scan. MCF in EXTEM was lower in patients with and without thromboembolic complications (75.0 vs. 77.9 mm, $p = 0.047$). COVID-19 patients with thromboembolic complications had an increased CFT compared to patients without complications in EXTEM (54.1 vs. 42.9 s, $p = 0.001$) and INTEM (53.3 vs. 43.5 s, $p = 0.03$). EXTEM clot firmness at 5 minutes (A5) was significantly decreased in patients with thromboembolic complications compared to patients without complications (58.5 vs. 64.3 mm, $p = 0.009$).

The conventional coagulation tests showed no significant differences between patients with and without thromboembolic complications.

Univariate linear analysis identified nine variables for multiple regression analysis. None of the ROTEM® variables were associated with thromboembolic complications in the multiple linear regression model. ROTEM® variables could not predict the risk of developing thromboembolic complications ($R^2 = 0.266$; $F(9,37) = 1,489$; $p 0.188$).

Conclusion: ROTEM® patterns of COVID-19 patients showed no clinical significant differences between patients with and without thromboembolic complications. Hence, our study does not support the use of ROTEM® in identifying COVID-19 patients at risk for developing thromboembolic complications.

The mobile ECMO team to retrieve refractory ARDS patients - justify the results the efforts ?

J.K.M. Fichte¹; M. Schoeffner¹; S. Ullrich¹; A. Starl¹; A. Ernst¹; H.B. Hopf¹

¹Anesthesia and perioperative medicine, Asklepios Klinik Langen, Langen (Hessen), Germany

Correspondence: J.K.M. Fichte
Intensive Care Medicine Experimental 2020, **8(2)**: 001165

Introduction: Mortality rates of patients with ARDS still are around 45% (Combes, NEJM). Since the resources for delivering an ECMO therapy are available only in a minority of hospitals, mobile ECMO teams have been established by ECMO centres to retrieve ARDS patients from primary or secondary care hospitals after implanting an ECMO system on site and consecutively transporting the patient in an ECMO centre. However, data on survival rates of those patients compared to patients who were implanted in the ECMO centre are scarce. Accordingly we retrospectively examined the data of our patients in which the ECMO system has been implanted in the submitting hospital with emphasis on survival rates compared to those primarily admitted to our ECMO centre.

Methods: We examined the data of all patients retrieved by our ECMO team in primary and secondary hospitals who had called our ECMO-support hotline. All patients had been initially admitted in hospitals in the Rhine-Main region from January 2017 till June 2020. We restricted our evaluation to patients with ARDS

We divided the patients in two groups - ECMO implantation in the requesting hospital or in our hospital. We retrospectively noted the following variables: type of cannula, CPR before or during ECMO implantation, the frequency of palliative treatment, mortality rate. We compared the data of the ECMO patients implanted at the requesting hospital with those of the patients who were implanted at our hospital. Primary outcome variable was hospital mortality rate. Secondary

outcome variables: SAPS II score, sofa-score, incidence of acute renal failure, time to weaning off the ventilator, duration of ICU stay.

Results: From 2017–2020 we treated 234 patients with ECMO on our intensive care unit. 170 patients have been admitted directly to our hospital. 66 patients have been retrieved from external clinics with a majority of patients who suffered from severe acute respiratory distress syndrome (ARDS) of different origins.

Remarkably is the extremely higher survival rate with ECMO treatment in patients initiated already at an external clinic. 36% compared to 55% of deceased patients in the in hospital patients group.

Table 1 : All patients with external ECMO- implantation by the mobile ECLS/ECMO-team of the Asklepios Klinik Langen

ECMO mobile patients (n) 2017-2020	survived	deceased	palliative care	CPR
2017-2020	42 (64%)	24 (36%)	21 (88%)	9 (14%)
ARDS (n) 2017-2020	46	30 (65%)	16 (35%)	15 (94%)
				4 (9%)

Table 2: All patients of the Asklepios Klinik Langen with in house ECMO implantation

In hospital patients (n) 2017-2020	survived	deceased	palliative care	CPR
2017-2020	170	73 (43%)	93 (55%)	73 (79%)
ARDS (n) 2017-2020	27	16 (59%)	11 (41%)	8 (73%)
				9 (33%)

Conclusion: Our results suggest, that ECMO treatment, if required is more helpful to improve mortality the sooner the better. Especially patients with ARDS obviously seem to benefit from immediate treatment changes to ECMO therapy which gets along with shorter ventilation times, lower ventilation pressures, less sedation of the patients and spontaneously breathing patients. Patients initially admitted to external hospitals have been presented for ECMO therapy only after having exploited all other possible treatment options. Presumably ECMO should become more than only a rescue treatment, but a more and earlier considered option to improve mortality in serious medical conditions.

Shuttlescope[®], a novel laryngoscope. One-handed endotracheal intubation makes a difference by allowing continuous suction

JM. Alonso Babarro¹; HN. Bui²; P. Boyer²; A. Boyer²; J. Medrano³

¹Intensive care unit, The Prince Charles Hospital, Brisbane, Australia; ²Service de médecine intensive réanimation, CHU Pellegrin, Bordeaux, France; ³Bioaraba, Basque Country University, UPV/EHU, Vitoria-Gasteiz, Spain

Correspondence: J. Medrano

Intensive Care Medicine Experimental 2020, **8(2)**: 000035

Introduction: Despite the fact that videolaryngoscopy has largely improved laryngoscopy, endotracheal intubation (ETI) is still a two-handed procedure. While the first hand holds the videolaryngoscope, the second hand is required to introduce the endotracheal tube (ETT). Shuttlescope[®] is a novel laryngoscope that allows performing both laryngoscopy and delivering of the ETT with the same hand, leaving an extra hand free. This may improve safety by allowing continuous oral suction in difficult scenarios.

Objectives: Our hypothesis was that Shuttlescope[®] videolaryngoscope allows similar efficiency in ETI than conventional laryngoscope while improving safety by allowing simultaneous suction. Main objective was to compare efficacy and safety of endotracheal intubation with Shuttlescope[®] and Macintosh laryngoscope by intensivists in a simulated difficult scenario.

Methods: We conduct a randomized cross-over trial to assess efficacy and safety of Shuttlescope[®] videolaryngoscope compared to Macintosh laryngoscope in a manikin model (AirSim, TrueCorp[®]). A difficult scenario which required continuous suction was designed, with a modified yaunkauer suction tip capable to determine suction time. All operators were intensivists from the service de Médecine Intensive Réanimation (Bordeaux, France) who received a rigorous 15 min standardized training on the new device and technique, which they didn't experience before. Three attempts with each device were compared

for each operator. The primary endpoint was a combination of time to intubation and success rate. Secondary endpoints were cumulative suction time and capability to aspirate continuously. Mean times and proportions were compared with the T-Student and chi-square test, respectively.

Results: In total, 20 operators participate to the study. After randomisation, 10 intensivists started ETI with the Shuttlescope[®] and 10 started with Macintosh, providing a total of 60 intubations with each device. Mean time for ETI with Macintosh laryngoscope compared to Shuttlescope[®] was 14 s [6-37] and 11 s [6-28], $p < 0.001$, respectively. Success rate was 100% of ETT in the trachea with both devices ($p = N.S$). Mean suction time was 2 sg [1-10] with Macintosh and 3.6 sg [2-10], with Shuttlescope[®] ($p < 0.001$). Finally, only 5% of ETI done with Macintosh could be performed with a continuous suction compared to 90% with Shuttlescope[®] ($p < 0.001$).

Conclusion: Shuttlescope[®] is a novel device that allows safe and easy ETI while leaving the right hand of the operator free during the procedure. It allows effective suction which may confer a relevant advantage in situations with a high risk of aspiration.

Intensive Care Medicine Experimental 2020, **8(2)**: 000243

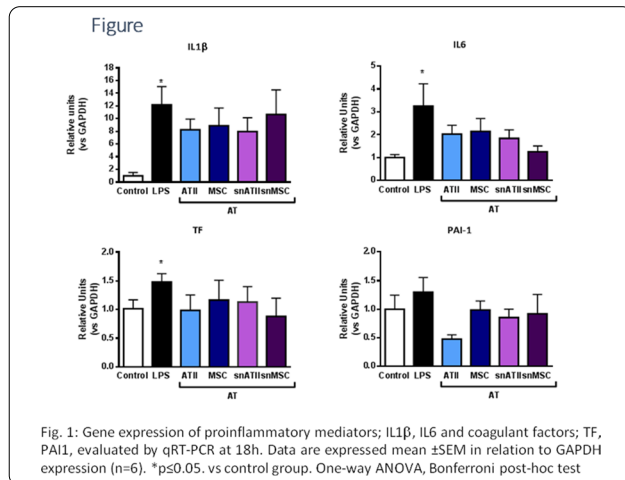

Introduction: The lungs of patients with acute respiratory distress syndrome (ARDS) are characterized by an acute inflammation and an increased procoagulant activity. Recent evidence suggests the beneficial effects of cell therapies and nebulized anticoagulants for ARDS (1,2). Considering the different mechanism through which cell therapies and antithrombin act in ARDS, we propose a combined administration of these therapies to potentiate their therapeutic properties and face the different pathways and processes involved in the pathophysiology of ARDS.

Objectives: Determine the therapeutic benefit of a combined cell therapy (alveolar type II cells (ATII), mesenchymal stem cells (MSC), supernatant (SN) ATII, SN MSC) with antithrombin in vitro in a coculture of ATII and alveolar macrophages injured with lipopolysaccharide (LPS).

Methods: Cocultured ATII and alveolar macrophages isolated from rat lungs were injured with LPS (10 ng/ml). Two hours after the injury a combined cell therapy (ATII, MSC, SN ATII, SN MSC) with antithrombin (0.1 IU/ml) was administered. The effect of the administered treatments was assessed by the analysis of proinflammatory mediators and coagulants factors via qRT-PCR at 18 h. Data are expressed as

mean±SEM. Statistical analysis was performed using One-Way-ANOVA and Newman-Keuls post-hoc test (statistical significance $p \leq 0.05$).

Results: Proinflammatory mediators and coagulant factors were significantly increased after LPS administration (Figure). After administering the different treatments the expression of IL1 β , IL6, TF and PAI-1 was not as high as in the LPS group.

Conclusion: The results indicate that combined cell therapy with antithrombin are able to attenuate inflammation and coagulation in vitro in a coculture of ATII and macrophages. Further studies need to be performed to elucidate the effect of both treatments in the different processes involved in lung injury.

Intensive Care Medicine Experimental 2020, **8(2)**: 000311

Introduction: This talk will share trials and tribulations of creating National randomized controlled study during Corona pandemic. This is a study designed to assess the therapeutic value of intravenous tocilizumab administered as single 8mg/Kg dose compared to placebo in patients affected by SARS-CoV2 infection with a pulmonary manifestation causing hypoxia

Objectives: Aim of the study is to test the hypothesis that an anti-IL6 treatment can be effective in calming the virus-induced cytokine storm, blocking deterioration of lung function or even promoting a rapid improvement of clinical conditions, preventing naso-tracheal intubation and/or death. In addition, lessons learned from institutional and national ethics committee submissions, safety board review and

revisions, creating digital data capture, and data monitoring will be shared.

Methods: When COVID 19 pandemic started in China we approached government offices for support and strategy. A protocol was developed and implementation plans were established. When ethical approval was granted in one medical institution digital electronic data capture platform was created, tested and launched. We recruited all Intensive care and infectious disease units, to join the national study. After national Ministry of health approval was granted each hospital needed institutional approval. Within 1 week, 6 other centers received approval, received study drug and started recruiting patients. Nurses trained medical centers on data capture and protocol adherence. Zoom and whatsapp platforms were utilized for training. Close Data monitoring was performed at base hospital.

Results: At present 20 patients have been recruited and by time of presentation many more will be added. We will demonstrate change from baseline in cytokines IL-1 β , IL-6, IL-8 and TNF- α [Outcome data -mortality, length of Hospital and ICU stay, ventilation days, and ventilation methods. In addition, technologies used to organize and manage multi-center- multi-disciplinary communications in a randomized placebo controlled drug study during Corona epidemic will be shared and discussed.

Conclusion: Sharing lessons learned in creating, organizing and managing a multi-center multi-disciplinary national randomized controlled trial is vital for applying in order to duplicate during the next pandemic.

Intensive Care Medicine Experimental 2020, **8(2)**: 000497

Introduction: Alterations of the microbiota can cause a dysregulation of the immune system locally and systemically, facilitating the clinical progression in different pathologies with inflammation as ALI.

Objectives: To assess changes in lung and intestinal microbiome in a murine model of acute lung injury (ALI) and subsequent treatment with an anti-IL-33 antibody.

Methods: Experimental model in which 36 male BALB/c mice were included (CEEA: JME-16-0025). ALI was induced at Day 1 by the intranasal administration of lipopolysaccharide (LPS) at a dose of 8mg/kg. Treatment with Anti-IL-33 (3.6 μ g/day) or placebo (saline) was administered, intraperitoneally, at days 2, 3 and 4. On day 5, body weight gain was registered and bronchoalveolar lavage (BAL), lung, feces and blood samples were collected. The studied groups were: 1) Control group without ALI including those treated with placebo or anti-IL-33 (CTL-PCB, n = 6 and CTL-Anti-IL33, n = 6), 2) Experimental group with ALI and placebo (ALI-PCB, n = 12) and 3) Experimental group with ALI and anti-IL-33 (ALI-Anti-IL-33, n = 12). Microbiome was assessed by the analysis of 16SrRNA in BAL and feces and bioinformatic analysis was performed. Cell count, total protein and IL-33 levels were measured in BAL fluid. IL-33 levels were also measured in blood samples. ALI was assessed by histology and wet-to-dry lung weight ratio (W/D). The data was expressed as mean (standard deviation) or as median (interquartile range). Significance was set to $p < 0.05$. The comparison

of the microbiome between samples was carried out by correspondence analysis with the QIIME and UNIFRAC programs.

Results: Intestinal microbiota showed a greater richness but not evenness (α diversity) in comparison with lung microbiota ($p < 0.000$) in all groups. Differences between the microbial communities (beta-diversity) in gut CTL, ALI-PCB and ALI-Anti-IL-33 groups were observed (Bray Curtis, Permanova 0.027, Permdisp > 0.05 , ANOSIM 0.0797, $p = 0.062$). Clear differences in microbial communities were observed in the three groups when comparing gut vs lung (Unweighted Unifrac, Permanova = 0.001, Permdisp > 0.05 , ANOSIM 0.5025, $p = 0.001$). ALI-PCB group compared with the CTL group presented a decreased in the body weight gain [-11.5 (6.2) vs 2.8 (1.8), $p < 0.001$], an increase in the W/D [0.16 (0.02) vs 0.10 (0.00), $p < 0.001$] and higher neutrophil percentage [69.4 (67.4-71.1) vs 2.7 (2.0-3.1), $p < 0.001$], protein levels [596.2 (462.8-760.8) vs 112.0 (81.5-194.9), $p < 0.001$] and IL-33 levels [26.1 (25.2-29.6) vs 15.1(11.1-20.1), $p = 0.004$] in BAL. It also showed higher rates of proteinaceous debris [1.1 (0.7) vs 0.0 (0.0), $p = 0.01$] and polymorphonuclear (PMN) cells in alveolar and interstitial space [1.7 (0.4) vs 0.0 (0.0), $p < 0.001$; 1.1 (0.4) vs 0.0 (0.0), $p = 0.002$]. Differences between gut and lung communities were lower in ALI groups than in CTL groups, showing a greater similarity in the lung-gut microbial communities in this group ($p < 0.001$).

Treatment with Anti-IL-33 compared with placebo reduced the W/D [0.13(0.02) vs 0.16(0.02), $p = 0.02$], the BALF neutrophil percentage [63.1(52.6-68.1) vs 69.4(67.4-71.1); $p = 0.03$], the interstitial PMN [0.4(0.5) vs 1.1(0.4), $p = 0.01$] and proteinaceous debris [0.3(0.4) vs 1.1(0.7), $p = 0.02$]. Anti-IL-33 treatment did not reverse the observed changes in the microbiome of both echosystems.

Conclusion: ALI modifies the respiratory microbiome, resembling lung microbiota to intestinal. Anti-IL-33 could partially restore the ALI-induced histopathological and biochemical but not the microbiome changes. Treatment directed to restore microbiome in ALI could be a new therapeutic target independent to anti-inflammatory approach.

Introduction: It is questioned whether spontaneous breathing (SB) should be used in early Acute Respiratory Distress Syndrome (ARDS). Recent papers have reported concerns regarding SB, for the potential of triggering the so-called patient self-induced lung injury (1). Despite a clear improvement in ventilatory strategies, we still lack knowledge that could make SB fully protective. Assessment of potential parenchymal injury must take into account stress and strain as the real physical quantities acting on the lung structures. Moreover, the lack of information regarding regional lung mechanics and deformation at the acinar level is likely the main determinant of these unresolved issues.

Objectives: Aim of the present study was to investigate regional Lung Strain and Stress during continuous positive airway pressure (CPAP) ventilation, in an animal model of mild ARDS during SB.

Methods: Mild experimental ARDS (PaO₂/FiO₂ ratio of 250 mmHg) was induced in anesthetized pigs (n = 5) breathing at three positive end-expiratory pressure (PEEP) levels during CPAP: 12, 6 and 0 cmH₂O. Computed tomography (CT) of the lung was performed at Functional Residual Capacity (FRC) and then during uninterrupted CPAP breathing at the three PEEP levels. Airway pressure and flow together with gastric and esophageal pressures were acquired simultaneously to CT execution. One lung slice above the diaphragm dome was continuously exposed and successively analysed. By analysing representative breaths at each PEEP level, regional Strain and Stress (transpulmonary

pressure, PTP) were computed in three regions of interest (ROI) of the lung: nondependent, middle and dependent.

The obtained data were successively analysed for statistical significance by applying ANOVA test for repeated measurements with $\alpha = 0.05$ (SigmaPlot, Systat Soft.,USA).

Results: When decreasing PEEP from 12 to 0 cmH₂O, regional lung Strain decreased from 0.78 \pm 0.17 to 0.37 \pm 0.10 ($p < 0.001$) respectively. Regional lung Stress was significantly higher at PEEP 12 (4.30 \pm 0.90 cmH₂O) than PEEP 6 (3.83 \pm 0.70 cmH₂O), but the highest PTP values were recorded at PEEP 0 (5.00 \pm 1.1 cmH₂O) ($p < 0.001$). Stress significantly increased in all the studied ROIs passing from PEEP 0 to 6 and from 0 to 12 cmH₂O. Both stress and strain were significantly higher in dependent ROIs than in middle and non-dependent.

Conclusion: This study shows that high regional Stress and Strain occur during spontaneous breathing in dependent ROIs and at the two extremes of the PEEP spectrum: high regional Stress is present during CPAP at the lowest extreme (PEEP 0) whereas high regional strain at the highest one (PEEP 12). Titrating PEEP to reach the best compromise between preventing both lung regional strain and stress can enable a fully protective CPAP ventilation during SB.

Introduction: Lung tissues absorb the dissipation of the energy during lung inflation through their viscoelastic properties. These can be represented by the Mount rheological model that consists of a Maxwell body (lung viscoelastic elastance (E2) and resistance (R2) arranged in series) in parallel with the standard lung elastance and resistance, according to the following equation: $P_{visc}(t) = R2 V' (1 - \exp(-t/\tau2))$ (1) where $P_{visc}(t)$ represents the viscoelastic elastic pressure dissipation into the lungs during inflation time (ti), V' the inflation flow and $\tau2$ the lung viscoelastic time constant ($\tau2 = R2/E2$).

Objectives: In present study we aimed at assessing the effect of supine versus prone position on global and regional E2,L and R2,L at different positive end-expiratory pressure (PEEP). We also analyzed the relationship of regional E2,L and R2,L to lung collapse and overdistension.

Methods: This is a secondary analysis of a previous study in 6 pigs in whom ARDS was induced by surfactant depletion (1). Overall Trans-Pulmonary pressure (PL) was measured as Paw minus esophageal pressure. Regional dorsal and ventral PL were obtained by subtracting Paw from dorsal and ventral pleural pressure, respectively. Pleural pressure was measured directly into the anterior and posterior 6th intercostal space. Lung ventilation was measured with electrical impedance tomography (EIT). Animals were ventilated in volume controlled mode at constant flow inflation, FiO₂ 100% and tidal volume (VT) 6 ml/kg. After ARDS induction the lungs were recruited and then PEEP was reduced from 20 to 5 cmH₂O by steps of 5 cmH₂O. E2,L and R2,L were obtained by fitting the global and regional PL during a 5s end-inspiratory hold to equation 1 as initially proposed (2). The effect of PEEP and position was analyzed by a linear mixed-effects model. The lung collapse and overdistension was measured by EIT as the change in impedance pixel-by-pixel during the decremental PEEP

trial. Correlation was assessed by Spearman Rho coefficient. Values are median (1st-3rd quartiles).

Results: The fitting of data to equation 1 was successful in every instance.

Position	Supine				Prone			
	20	15	10	5	20	15	10	5
PEEP	8 (6-9)	4 (3-6)	5 (4-7)	10 (9-12)	12 (8-18)	6 (4-6)	6 (5-10)	6 (5-12)
Es.L. (cmH ₂ O/L)	8 (6-9)	5 (4-6)	5 (5-6)	9 (9-15)	12 (9-15)	5 (4-8)	6 (5-10)	10 (6-21)
Dorsal Es.L. (cmH ₂ O/L)	8 (6-9)	5 (3-6)	6 (6-7)	10 (9-14)	13 (11-16)	5 (3-7)	9 (4-13)	9 (5-18)
Ventral Es.L. (cmH ₂ O/L)	37 (11-45)	5 (4-6)	12 (8-20)	41 (27-54)	15 (9-50)	8 (6-11)	8 (5-12)	13 (6-19)
R _s .L. (cmH ₂ O/L)	18 (16-20)	9 (6-11)	8 (6-9)	29 (24-37)	29 (15-63)	9 (4-13)	24 (5-58)	19 (13-23)
Ventral R _s .L. (cmH ₂ O/L)	20 (9-25)	14 (9-16)	12 (7-30)	28 (17-33)	16 (11-32)	7 (6-12)	12 (11-98)	18 (16-21)

Conclusion: Prone position does not significantly change the lung viscoelastic properties in an ARDS porcine model of surfactant depletion.

Intensive Care Medicine Experimental 2020, **8(2)**: 000226

Introduction: It has been proposed that SARS CoV2 patients requiring invasive mechanical ventilation represent a particular type of ARDS with a different ventilatory profile, being managed with lower pressures, as well as having a distinguished physiopathology element involving blunted hypoxic pulmonary vasoconstriction. Therefore, we might expect a specific hemodynamic profile of these patients, with less prevalence of right ventricular (RV) failure.

Objectives: To describe the hemodynamic profile, measured by conventional monitoring as well as echocardiography, of the patients with ARDS caused by SARS CoV2 admitted to the ICU and treated with protective mechanical ventilation.

Methods: From April to May 2020, we performed a single-centre, prospective, observational study, which included consecutive patients with a diagnosis of ARDS caused by SARS CoV2 who required treatment with invasive mechanical ventilation and who had no previous cardiac nor respiratory chronic condition. The patients were managed with a protective ventilatory strategy. Hemodynamic parameters, as well as echocardiographic biventricular function and respiratory mechanics were measured.

Two transthoracic echocardiograms, separated by an interval of 30 minutes, were performed during the first 72 hours after initiation of mechanical ventilation. The first one with parameters set by the attending physician following our approach of reaching a SaO₂ > 90% with a low PEEP high FiO₂ strategy. The second echocardiogram was performed after either increasing the PEEP 2-4 cmH₂O if a FiO₂ > 60% were necessary to reach the SaO₂ goal or increasing the FiO₂ to 100% if the SaO₂ goal were reached with a lower FiO₂. A third echocardiogram was performed 72h hours later with the ventilatory adjustments considered by the physician in charge of the patient. Arterial blood gas analysis was performed previously to each echocardiogram.

Results: We included 8 patients. Respiratory and hemodynamic variables are shown in Table 1. All patients showed hemodynamic stability with a median of MAP > 75 mmHg, both at baseline and 72h later and low dose norepinephrine was used in one of them. We observed that in both groups, and particularly in the PEEP group, ventilatory changes did not have a negative effect on hemodynamics except by

a trend to a decrease in the pulmonary acceleration time. All patients had preserved both left and right ventricular ejection fraction. None of the patients developed RV failure. A slight increase in PEEP tended to worsen pulmonary compliance but this was not followed by a hemodynamic worsening.

Table 1

	PEEP change N=3			FiO ₂ change N= 5		
	ECO1	ECO2	ECO3	ECO1	ECO2	ECO3

PVA T(msec)	123 [118-128]	109 [107-111]	90 [87-93]	115 [111-125]	118 [114-128]	121 [100-128]
LVOT VTI (cm)	19 [14.4-24]	18.7 [17.8-19.6]	22.7 [21.8-27.6]	20.1 [18.5-21.5]	17.7 [15.8-20.4]	25.5 [20.6-28.6]
TAPSE (mm)	32 [30-32]	26 [22-29]	24 [22-26]	25 [19-29]	24 [19-27]	24 [21-26]
RVD	44 [38-46]	43 [40-47]	38 [31-39]	38 [37-42]	38 [36-40]	38 [31-41]
RVD/LVD	0.88 [0.80-1.0]	0.87 [0.90-1.0]	0.76 [0.67-0.91]	0.86 [0.82-0.86]	0.8 [0.75-0.83]	0.88 [0.70-0.88]

MAP - Mean Arterial Pressure, HR - Heart Rate, CVP - Central Venous Pressure, PPV - Pulse Pressure Variation
 FiO₂ - Fraction of inspired oxygen, PaO₂ - Partial Pressure of Oxygen, PaCO₂ - Partial Pressure of Carbon Dioxide, Hb - Hemoglobin
 SaO₂ - Oxygen Saturation, LVOT VTI - Left Ventricular Outflow Tract Velocity Time Integral
 RVOT VTI - Right Ventricular Outflow Tract Velocity Time Integral, PVA T - Pulmonary Velocity Acceleration Time
 TAPSE - Tricuspid Annular Plane Systolic Excursion, RVD - Right Ventricular Diameter

Conclusion: Despite the low oxygenation levels, this cohort of patients with SARS CoV2 shows hemodynamic stability and presents normal RV function. An increase in PEEP tends to worsen pulmonary mechanics but without an enormous impact in hemodynamics. This hemodynamic profile could be related with a blunted hypoxic pulmonary vasoconstriction and could be relevant at the time of choosing the best management strategy for this kind of patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 000395

Introduction: In February 2020, Italy reported the first cases of novel coronavirus disease (COVID-19) requiring admission to ICU for acute respiratory failure (ARF)[1]. Lung ultrasound (LUS) is useful in ARF for lung assessment and monitoring[2]: performed bedside avoiding transport to radiology, it is easily repeatable and it doesn't involve further healthcare providers, thus limiting potential exposure to COVID-19 contamination[3].

Objectives: To describe LUS patterns at admission to ICU in patients with COVID-19.

Methods: Retrospective observational study; analysis of the LUS performed within the first 24 hours from admission to ICU. We computed the LUS score, from 0 (normal aeration) to 3 (complete loss of aeration), in 6 standard regions per hemithorax and registered lung features (subpleural/lobar consolidations, pleural irregularities, sliding, artefacts distribution, pleural effusion)[2].

Results: We present the first 13 patients admitted to our ICU (77% males, median age 64 [56-73] year-old, median BMI 28 [26-29] kg/m²). They were all examined under pressure-controlled ventilation (median PEEP 14 [11-15]cmH₂O, FiO₂ > 50% in 85% of patients). In all patients, we observed bilateral distribution of pathological findings, with at least one area with B-pattern (score > 1 - 100%) and pleural

irregularities (100%). We frequently observed subpleural consolidation (85%) and lobar consolidation (77%); lung sliding was frequently reduced in anterior fields (92%). The median LUS score was 18 [14-19]. Small pleural effusion was visualized in 3 patients (23.1% - median interpleural distance 0.8 cm). 23.1% of patient had a bacterial overinfections, confirmed with positive BAL; they all had lobar consolidations.

Conclusion: LUS features of COVID-19 include bilateral loss of aeration with diffuse B-pattern, pleural irregularities and frequent subpleural consolidations. Lobar consolidations may suggest bacterial overinfection.

Intensive Care Medicine 2020, **8(2)**: 000457

Introduction: Coronavirus disease 2019 (COVID-19) is a potentially severe acute respiratory infection which presents most commonly as a pneumonia, complicated by hypoxaemic respiratory failure in up to 41.8% of patients(1). Pandemic COVID-19 has placed unprecedented pressures on critical care services. Safe delivery of respiratory support on a large scale has proved a major challenge. High flow oxygen therapy (HFOT) and continuous positive airway pressure (CPAP) devices are recommended by interim guidance but significant controversy remains over their use for COVID-19-associated hypoxaemic respiratory failure(2,3).

Objectives: We describe the real-world use of HFOT and CPAP in a single centre during the COVID-19 epidemic. We ask: 1. What respiratory parameters predict failure of respiratory devices in COVID-19? 2. Can the ROX index be used to monitor HFOT for COVID-19? 3. Does HFOT compare to CPAP for management of hypoxaemic respiratory failure in COVID-19?

Methods: Data were collected retrospectively for all patients admitted to a single hospital with confirmed or probable COVID-19 between 27/03-06/04/20. Confirmed COVID-19 was defined by laboratory PCR testing of respiratory samples. Probable COVID-19 was defined as high clinical suspicion with negative COVID-19 testing. Outcomes were defined as severe (death or intubation) and non-severe (no intubation) at 30 days. Digital notes review captured demographic, clinical and respiratory parameters. Qualitative data were compared with the Fisher exact test. Quantitative data were compared with the Student's t-test.

Results: Of 239 adults with confirmed (221, 92.4%) or probable COVID-19 (18, 7.6%), 149 patients received HFOT and/or CPAP. 45 (30.3%) and 104 (69.7%) patients had severe and non-severe outcomes respectively. 60 patients received HFOT and/or CPAP in 78 episodes of device use (Table 1). Mean PaO₂/FiO₂ (PF) ratios for patients initiating CPAP were lower than for those initiating HFOT (Table 1). In patients receiving HFOT, ROX index at all time points was significantly lower in those with severe versus non-severe outcomes (Figure 1). The mean ROX index at 0 to 12 hours was less than 4.88 in the severe outcome group, and above 4.88 in the non-severe group. For all patients receiving respiratory support devices, PF ratio was significantly lower in those with severe versus non-severe outcomes (Figure 2).

Table 1. Summary data for patients receiving HFOT and/or CPAP

	HFOT		CPAP	
	Severe	Non-severe	Severe	Non-severe
Total (n, % all device use)	30 (38%)	17 (22%)	24 (31%)	7 (9%)
PF ratio at admission(mean, range)	154.5(45.5 – 367.9)	206.5(71.3 – 341.5)	125.5(45.5 – 283.6)	140.7(72.7 – 317.9)
PF ratio before device(mean, range)	89.5(45.5 – 269)	122.3(59.2 – 250)	76.5(45.5 – 195.0)	105.2(74.9 – 150.0)
ROX index at 12 hours HFOT (mean, range)	4.83 (2.2 – 7.6)	7.69 (4.7 – 10.8)	-	-
First device (n, % all device use)	19 (24%)	16 (21%)	16 (21%)	4 (5%)
Only device (n, % all device use)	16 (21%)	13 (17%)	10 (22%)	3 (4%)
Time to intubation(days, range)	3.2 (0 – 9)	-	4.5 (0 – 12)	-

Figure 1. ROX indices for patients receiving HFOT

Figure 2. PF ratios for patients receiving HFOT or CPAP

Conclusion: Data from our single site retrospective cohort study suggest ROX index parameters may predict failure of HFOT, and PF ratio may predict failure of HFOT and CPAP in COVID-19 consistent with non-COVID-19 literature(4). In our study, clinicians favoured CPAP for individuals presenting with more severe hypoxaemic respiratory

failure making comparisons between HFOT and CPAP challenging. However HFOT was associated with successful outcomes in certain patients. ROX index may be useful in selecting this sub-group and warrants prospective study.

Intensive Care Medicine Experimental 2020, **8(2)**: 000470

Introduction: Mechanical ventilation (MV) is vital for the management of patients with acute respiratory distress syndrome (ARDS). In recent years there has been important technological development. Along with technological advances and a better understanding of respiratory pathophysiology, it has been determined that MV can have deleterious effects on these kinds of patients.

Objectives: to estimate respiratory work by means of the pressure-time product (PTP) and the Campbell's diagram (WOB), to estimate different parameters related to ventilator induced lung injury (VILI) according to classical and rheological theories: driving pressure (DP), stress index (SI) and mechanical power (PM)

Methods: Data were collected from adult patients connected to MV with ARDS criteria as proposed in the Berlin definition. The Fluxmed[®] respiratory mechanics monitor was used after insertion of an esophageal pressure probe and placement of a flow sensor (Image 1). Parameters related to VILI were collected: DP, SI and MP was calculated according to the formula proposed by Gattinoni. PTP and WOB were also calculated with the FluxReview[®] software (Picture 2). Data were collected for 5 minutes after esophageal probe insertion, in volume controlled mode and under the effects of a neuromuscular blocking agent. The variables are presented as an average (95% CI). Hypothesis contrast for mean difference was performed with Mann-Whitney test.

Results: 8 patients with the following baseline characteristics were included. Age 69.4 (61.6-77.2) years, sex 87.5% men, weight 71.6 (60.3-83) kg, height 166.8 (158.1-175.4) cm, APACHE 26 (9.2-42.8), SAPSII 53.3 (42-64.5), SOFA 6.9 (3.4-10.4). Patients were ventilated with Vt 7.6 (6.6-8.7) ml/kg, PEEP 9.8 (7.9-11.6) cmH₂O, FiO₂ 0.63, FR 22 (18.7-25.3) rpm. PaO₂/FiO₂ was 140.5 (88-193) mmHg. PTP of the respiratory system was 9.5 (7.8-11.2) cmH₂O x sec., with an elastic component of 49.6 % (37.6-61.5) % and a resistive component of 43 % (33.4-52.5) %. The elastic WOB was 4.3 (3.2-5.5) cmH₂O x l, expiratory resistive WOB was 2.8 (1.8-3.8) cmH₂O x l, inspiratory resistive WOB was -3.4 (-4.5-2.2) cmH₂O x l. DP was 13.6 (10-17.2) cmH₂O, MP 10.2 (7-13.4) J/min and SI 0.95 (0.8-1.1). Mortality was 62.5% and duration of MV was 16.6 (5.5-27.8) days. A statistically significant difference was observed in the

level of PEEP among survivors and non-survivors: 3 cmH₂O (0.2 -6) p < 0.05. Differences were also observed in MP 5.9 J/min (1.5-10.3) and PTP 2.7 cmH₂O x sec. (0.5-5.4) but without reaching statistical significance (p = 0.053).

Conclusion: Advanced monitoring and knowledge of the different theories that explain VILI may allow us to optimize MV programming and reduce the damage associated with it.

Impact of prone ventilation in mechanically ventilated & rescue self positioned awake ARDS patients with Covid-19

S. Hartigan¹; C. Joyce¹; R. Turner¹; B. Marsh¹

¹Intensive care unit, The Mater Misericordiae University Hospital, Dublin, Ireland

Correspondence: S. Hartigan

Intensive Care Medicine Experimental 2020, **8(2)**: 001001

Introduction: SARS-CoV2 is a novel pathogen which, in humans, can lead to respiratory failure and acute respiratory distress syndrome (ARDS)(1). Prone ventilation has been shown to improve mortality in patients with severe ARDS(2). From early case reports in SARS-CoV2 infected patients and previous literature on ARDS, we hypothesised that prone ventilation may play a role improving oxygenation(2)(3).

Prone positioning for patients receiving non-invasive ventilation has been demonstrated to improve oxygenation in a case series(4). Given potential issues with resource allocation and simplicity of this measure, patients requiring NIV were encouraged to self prone(5). We used SpO₂:FiO₂ (SPF) ratio as a surrogate for PaO₂:FiO₂ (PF) ratios these have been shown to have a linear relationship with PF ratios previously(6).

Objectives: 1. To assess the impact of prone ventilation on P:F ratios for invasively ventilated patients with SARS-CoV2 infection with severe ARDS.

2. To assess impact on SpO₂:FiO₂ ratio, intubation rates and patient compliance with prone positioning for conscious patients with SARS-CoV2 infection receiving NIV

Methods: Retrospective observational cohort study of patients with severe ARDS secondary to SARS-CoV2, admitted to the ICU receiving mechanical ventilation in the prone position for at least twelve consecutive hours. Prone Ventilation occurred as per local protocol, aiming for 18 hours prone per day. All patients receiving mandatory mechanical ventilation received lung protective ventilation as per ARDSNET protocol 6ml/kg PBW, with titrated PEEP. For proning patients received a bolus of non-depolarising muscle relaxant and a weight based atracurium infusion for the duration of prone ventilation.

In the self prone group we assessed patients who had non invasive ventilatory support who had any proning event.

Results: 17 patients with SARS-CoV2 infection at MMUH received prone position invasive mechanical ventilation (3 during venovenous extra corporeal life support). This was associated with a mean improvement in P:F ratio of 16 kPa during the first episode of prone ventilation. This improvement declined with subsequent episodes. Patients received a mean of 4.2 episodes of prone ventilation. The rate of improvement in PF ratio was greatest in the first 6 hours of proning and declined from hour 6-17.

11 patients undertook awake prone positioning whilst receiving NIV. The average number of awake proning events was 5.4 events per patient. The mean SpO₂ / FiO₂ ratio prior to the first self prone event was 179 There was an average best increase in SpFiO₂ ratio of 33.6. In the awake proning group only 18% of patients required mechanical ventilation.

Conclusion: In our cohort of patients who received prone ventilation for severe ARDS secondary to SARS-CoV2 there was an improvement in their PF ratios, the greatest benefit was seen in the first 6 hours of the prone period. This is consistent with data previously seen in other causes of ARDS. Although not all patients demonstrated a significant improvement in SPF ratio on self proning, we note that this intervention may have avoided intubation for some patients where patient adherence to the protocol was high.

Intensive Care Medicine Experimental 2020, **8(2)**: 001030

Introduction: Coronavirus Disease 2019 (COVID-19) presented as a challenge to Intensive Care Units (ICU). An effort is still being made to clarify the main features and the impact of invasive mechanical ventilation (IMV) in outcomes.

Objectives: To describe the characteristics of an ICU COVID-19 population and to analyze the evolution of the decision on the ideal ventilation moment and the impact on mortality between invasively ventilated and non-invasively ventilated patients.

Methods: Retrospective cohort study of Polymerase Chain Reaction confirmed SARS-COV-2 adult patients admitted to an ICU in the interior north of Portugal between March 23 and May 23, 2020. Data collection on clinical characteristics and management decisions was performed. Patients were grouped according to the oxygen or ventilation support mode: group 1 – IMV; group 2 - non-invasive ventilation, high flow nasal canula and facial mask oxygen. Variables were analyzed using the SPSS statistical software and the significance level used was 0.05.

Results: During the study period were admitted 20 patients, 60% were women, the median age was 67.5 years [44; 87].

Seventeen patients (85%) were admitted for respiratory failure, 35% of whom with PaO₂/FiO₂ ratio below 100mmHg, 2 patients (10%) for septic shock in context of gastroenteritis and 1 patient with acute coronary syndrome and mild respiratory symptoms.

The median SAPS II at admission was 34 [15; 50], the mortality rates in the ICU and at 30 days were 25% and 35%, respectively.

When analyzing the ventilation support, 60% required IMV and 55% were prone. When comparing groups, group 1 mortality was clinically significant higher ($p = 0.055$) and had a significant longer ICU stay ($p = 0.006$). In terms of laboratorial features on admission there were no differences between groups. Regarding COVID 19 and ICU complication, group 1 had more superinfections ($p = 0.019$), but without impact in mortality. Otherwise, we found no differences in renal, cardiac or thromboembolic complications.

Within group 1, the median PaO₂/FiO₂ ratio was initially higher, mainly in the first month. As time went by and experience accumulated, a tendency to tolerate lower ratios before invasive ventilation and an inverted ratio between the number of ventilated and non-ventilated patients can be seen.

Conclusion: Patients who received IMV had a higher rate of infection and a significantly longer stay in ICU with impact on mortality.

Initially patients were invasively ventilated earlier in accordance with studies and expert opinion, however with experience, non-invasive strategies were preferred without impact in the outcomes. The decision not to ventilate was well tolerated and allowed patients to overcome infection without the need to be ventilated, even under traditional “mandatory” ventilation ratios. Outcomes like neurological dysfunction were not evaluated but we raise the hypothesis that non-ventilation probably spares that dysfunction, as well as decreases secondary lung infection.

The main limitation of this study is the small sample. Further large-scale studies would be interesting analyzing the mortality and prevalence of post-ICU impairment in ventilated and non-ventilated patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 001110

Introduction: On 11 March 2020, the WHO characterised COVID-19 as a pandemic. At that point, in the UK, there were only 364 patients with proven coronavirus infection and only seven deaths. We could, however, glimpse the possible future from the horrors that struck Italy and China. We therefore began plans to upskill and re-organise our workforce, both medical and nursing staff.

Objectives: Due to resource limitations, non-respiratory doctors and nurses would have to learn how to manage patients with COVID-19 related respiratory failure. Consequently, we wanted to ensure that staff were as well prepared and confident in their new roles as possible.

Methods: We developed ‘Respiratory Failure Escalation Guidelines’ and a twice daily, two-hour teaching session delivered by a team of experienced doctors and nurses from Acute and Respiratory Medicine and Intensive Care (ITU). These started with a lecture on the basics of respiratory failure and its management - including the use of High Flow Oxygen Therapy (HFOT), Continuous Positive Airway Pressure (CPAP) and Non-Invasive Ventilation (NIV) - followed by a demonstration of our hospital’s respiratory support devices with time for hands-on experience. We advertised the training to all members of the multidisciplinary team, from all specialties, working within the hospital.

Results: Between 17 March and 15 May 2020, we had 435 confirmed attendees (as per registers collected during teaching times). The below pie charts demonstrate the broad professional backgrounds (Fig. 1) and specialties (Fig. 2) of the attendees.

We received post-course feedback from 64 attendees, across different departments and professions, which was overwhelmingly positive (Fig. 3). Many requested further teaching on the subject, even suggesting annual training, and around 72% of respondents attended our associated courses, suggesting there was a genuine desire for this type of education.

Fig. 3: Feedback

Conclusion: During the first wave of the pandemic, 78 patients with COVID-19 requiring enhanced respiratory support were managed on wards previously unfamiliar with this treatment modality. The educational sessions were essential in building the confidence of our staff in managing COVID-19 related respiratory failure throughout the hospital and were extremely well received. In response to their requests for further teaching, and in order to facilitate ongoing learning and revision, we developed complementary material including respiratory support device set-up videos, online presentations and e-assessment modules accessible to all staff through the Trust's intranet.

The key lessons we learned from the development and delivery of these training sessions were as follows:

Truly multidisciplinary training is both possible and effective. The skill mix and varied backgrounds of the participants appeared to have no negative effects on the sessions.

We did not have the time available to deliver the longer sessions normally used in nurse-training. Instead, we adopted an approach more typical of medical education. This style was, nevertheless, warmly received by all participants and showed that shorter sessions may be effective for future nurse-training in our Trust.

As the programme developed, the importance of providing resources in a variety of formats became increasingly clear. Our complimentary resources, developed by the same team of educators, was easily accessible to all staff to review whenever they wished.

Intensive Care Medicine Experimental 2020, **8(2)**: 001150

Introduction: ARDS ventilator management is one of the most difficult tasks in the ICU. Monitoring lung mechanics and oxygenation

parameters is one of the keys in this entity, and provide useful information about the evolution as well as prognosis.

Methods: Retrospective, descriptive study of patients admitted in ICU from 2017 to 2019, with H1N1 influenza diagnosis, ARDS and MV. Clinical, epidemiological and result-related variables were analyzed, between them: MV and sedative timing, needs of vasoactives, renal failure, prone position, PaO₂-FiO₂, A-aO₂ gradient, OI, OSI, PaO₂, PaCO₂, ICU mortality and UCI length of stay, as well as SOFA, APACHE II. Quantitative variables are expressed as mean and standard deviation, while qualitative variables are expressed as ratios and absolute value.

Results: A total number of 17 patients were included. 52.9% were men, with a mean age of 53.93 ± years. APACHE and SOFA scores at the ICU admission were 5.65 ± 3.06 and 13.88 ± 3.53 respectively. Prone position was needed in 58.8% of the patients. Length of mechanical ventilation was 17.7 ± 9.47 days; sedatives were needed an average of 17.47 ± 9.47 days. 58.8% of the patients developed renal injury, 29.4% among them needed RRT.

When the sample was divided into two groups, survivors and non-survivors, statistically significant differences (p < 0.05) were observed in oxygenation parameters: PaO₂-FiO₂, A-aO₂ gradient, OI, and OSI. There were no significant differences (p 0.07) in PaO₂ and pCO₂. The best cut-points were: PaO₂-FiO₂ 202.5 (S 83.3%; E 72.7%); A-aO₂ gradient was 193.18 (S 66.7%; E 72.7%), OI 9.21 (S 66.7%; E 72.7%), and OSI 8.66 (S 83.3%, E 72.7%).

The length of stay in the ICU was 21.71 ± 11.53 days. ICU observed mortality was 35.29%.

Conclusion: An increase in mortality risk was observed in those patients who kept PaO₂-FiO₂ values < 202 and OI > 9.21.

Oxygenation parameters monitoring in ARSD patients provide prognosis value and allow for the assessment in the day-to-day patient situation.

Protecting Prone Patients: Collateral Complications of COVID-19

R. Carrington¹; V. Jenkins¹; M. Phull¹

¹Intensive care, Queen's Hospital, London, United Kingdom

Correspondence: R. Carrington

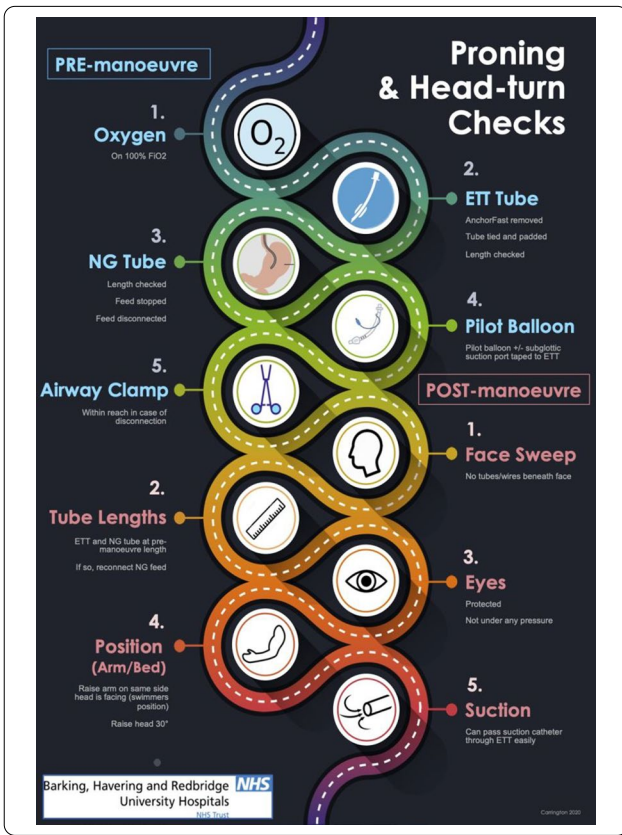

Intensive Care Medicine Experimental 2020, **8(2)**: 000447

Introduction: Covid-19 has resulted in a proning pandemic. Intensive care units (ICUs) across the world have proned more patients in March and April 2020 than they would expect to in a year. The prone position is thought to improve the condition of patients with COVID-19 by increasing recruitment in dorsocaudal regions of the lung, reducing alveolar shunt and increasing tidal volume(1). Putting patients in the prone position, along with the necessary frequent head-turns, has well-recognised risks and complications(2). The increased need for this labour-intensive procedure, combined with overstretched staff with varied levels of ICU experience, has led to a surge in the number of proning-related complications.

Objectives:

- To identify the number of patients with COVID-19 admitted in ICU at Queen's Hospital on 23rd April 2020 that had been proned during their admission
- To determine the number of complications that occurred secondary to proning and head-turns
- To design and implement a simple, efficient and effective method of reducing common complications

Methods: Retrospective data collection from all patients admitted in Queen's Hospital COVID-19 ICU on 23rd April 2020. The number of patients that had been proned during their admission, the duration of each prone period and any complications that occurred were recorded. Directed by the most common complications, and by the Faculty of Intensive Care Medicine guidelines(3), we designed a graphic highlighting five simple checks to be carried out before each proning/head-turn, and five simple checks to be carried out afterwards (Fig. 1).

Results: 31 patients with COVID-19 were admitted in ICU at Queen’s Hospital on 23rd April 2020. 22 (71%) were prone during their admission. 17 (77%) of these patients experienced at least one complication secondary to being prone. There was a total of 52 prone periods, with an average duration of 27.8 hours. The occurrence of different types of complications are shown in Table 1.

Table 1. Complications secondary to prone and head-turns

Complications	Number of patients	Percentage of prone patients
Nasogastric tube removal	12	55%
Facial pressure sores	8	36%
Endotracheal tube removal to level needing replacing	2	9%
Central venous access removal	1	5%
Retro-orbital haematoma	1	5%

Conclusion: There has been a high rate of complications secondary to prone during this period of the COVID-19 pandemic. Our results show that 77% of patients who were prone experienced at least one complication. The consequences of these ranged from the need to replace an NG tube to potentially permanent loss of sight. Going forward, we have implemented our prone checks graphic by displaying it across the ICU, attaching it to dedicated prone equipment packs and explaining it to members of the prone team. We continue to monitor its effect and strive to improve ways of protecting our patients from these complications.

Correspondence: A. Estella

Intensive Care Medicine Experimental 2020, **8(2)**: 000597

Introduction: Percutaneous dilational tracheostomy is usually performed blindly, entry into the trachea can be visualized using bronchoscopy. With SARS COV 2 pandemic, measures to perform the procedure safely for protecting healthcare personnel from undue risk of exposure and infection must be taken. To delay the procedure has been recommended due to a significant risk of viral transmission because it is an aerosol-generating procedure.

Objectives: The aim of the present study are: to describe the clinical experience in the realization of tracheostomy guided by bronchoscopy in critically ill patients with SARS COV 2 infection and to analyze the complications related to the procedure.

Methods: Retrospective study in a 17 bed medical-surgical ICU during two months: march and april 2020. We included patients with confirmed SARS COV 2 respiratory infection. Variables analyzed were clinical characteristics and outcome, day of tracheostomy during ICU admission, duration of procedure, complications related with the tracheostomy. Statistical analysis: Data were analyzed by SPSS 18 and quantitative variables were expressed as a mean ± standard deviation.
Results: Twenty consecutive patients with confirmed SARS COV 2 infection were admitted in ICU. Mean age was 61,7 ±8,25. 65% male and 35% female. Apache II at admission was 10,3 ± 4,21 and SOFA score 3,45 ± 1,87. Mechanical ventilation was required in 80% of patients. In nine patients, 45%, tracheostomy was performed, all the procedure were performed guided by videobronchoscopy to avoid the use of laryngoscopy and to distance itself from the oral cavity and airways during the procedure during withdrawing orotraqueal tube. Mean duration of procedure was 5 minutes and 19 seconds.

No major complications related with the procedure were described, in two patients first attempt of needleinsertion failed and with the bronchoscope the positioning of the needle were directly visualized before entry into the trachea and a guidewire was introduced (figure 1). Four patients developed hypoxemia during the procedure, they had no clinical significance and were transient.

Conclusion:

- Video bronchoscopy visualization during tracheostomy minimizing risk for healthcare practitioners in SARS COV 2 infected patients.
- Bronchoscopy facilitates optimal visualization of the wall of the trachea, to locate the correct needle entrance during percutaneous dilational tracheostomy improving safety of the procedure.

Correspondence: E. Sancho

Intensive Care Medicine Experimental 2020, **8(2)**: 000630

Introduction: During COVID 19 pandemic, many considerations have been discussed about tracheostomy in ICU patients, in terms of efficacy, timing, and health care professionals safety. Tracheostomy is an aerosol generating procedure and therefore some recommendations have been proposed: skilled intervening staff, surgical technique, full personal protective equipment (PPE) use and negative pressure environment if possible. However in our medical ICU we were not able to apply some of these recommendations.

Objectives: To describe and analyse patient and staff safety of bedside percutaneous tracheostomy in COVID-19 patients in a medical ICU

Methods: We recorded data of consecutive patients diagnosed with ARDS secondary to COVID 19 who required extended mechanical ventilation and tracheostomy during their ICU stay. We registered demographic data, mechanical ventilation parameters, information about the procedure and we finally prospectively evaluated SARS-CoV-2 transmission to health care professionals.

Results: We included 35 COVID-19 mechanically ventilated patients; tracheostomy was performed in 11 patients (31%). Negative pressure environment was unavailable. Percutaneous technique with single dilator was applied at bedside in ICU. Previous ultrasound assessment was implemented and bronchoscopy was used as a standard of care during the procedure. The mean duration of the procedure was 38 minutes [35.1- 40.9]. Nine out of 11 tracheostomies (81.8%) were performed by critical care resident doctors (4th-5th year of training). Only 4 patients (36.36%) had negative SARS-CoV-2 PCR at the moment of the procedure. PPE including fluid-resistant gown, ocular protection (goggles or face shield), gloves and FFP3 mask, was used in all cases. Median of mechanical ventilation days up to tracheostomy was 21 [20-24]. Any technique complication was detected. SARS-CoV-2 PCR and serology (IgM/IgG) were negative in all staff participants after a proper window period.

Conclusion: Despite not following all the expert opinion recommendations regarding tracheostomy in COVID-19 patients, no safety events occurred to our patients and no SARS-CoV-2 transmission to healthcare providers was detected.

The Impact of Surgical vs. Percutaneous Tracheostomy – An Audit of Tracheostomy Insertion in Intensive Care

T. Ross¹; M. Komorowski¹

¹Intensive Care, Charing Cross Hospital, London, United Kingdom

Correspondence: T. Ross

Intensive Care Medicine Experimental 2020, **8(2)**: 000632

Introduction: Up to a third of patients in intensive care requiring prolonged mechanical ventilation receive a tracheostomy. In the United Kingdom, this equates to around 15,000 tracheostomies annually. Tracheostomy insertion aims to facilitate ventilator wean through reducing dead space and improving secretion clearance. They can be performed either surgically or percutaneously. Tracheostomy timing has been an area of controversy in the literature, with some groups advocating that early insertion can lead to reduced sedative use, faster ventilator wean, shorter hospitalisation and reduced mortality.

Objectives: In 2013, a large randomised controlled trial, TracMan, was carried out assessing the impact of early versus late tracheostomy insertion on outcomes. This audit aimed to compare outcomes following tracheostomy insertion in our tertiary intensive care to those of the TracMan study.

Methods: All ventilated patients undergoing tracheostomy (either surgically or percutaneously) in 2019 were included (n = 53). Patients undergoing emergency tracheostomy, intra-operative tracheostomy during elective head and neck surgery and with a pre-existing tracheostomy were excluded. Data was collected from electronic health records retrospectively.

Results: In contrast to the TracMan study where 89% of tracheostomies were performed percutaneously, we performed only 17% this way. This introduced quite a significant time delay between decision to insertion of tracheostomy. Often patients were clinically deteriorating prior to going to theatre for a surgical tracheostomy, resulting in even further delays. "Short neck" was cited as the most common reason for referral for a surgical tracheostomy. More complications were seen in the cohort receiving surgical tracheostomies, however this group contained higher risk patients. Early tracheostomy also reduced the risk of complications. Contrary to the TracMan population, our patients achieved ventilator wean faster when tracheostomy was performed earlier, which we felt was related to differing definitions of this term. Similar, early tracheostomy reduced length of stay on intensive care and shortened time on sedation. Mortality was also higher in the group receiving late tracheostomy.

Conclusion: Overall, duration from decision to insertion of tracheostomy was shorter when a percutaneous approach was chosen. If a percutaneous approach is feasible, this should therefore be preferable over a surgical approach, as it expedited tracheostomy insertion, reduced length of stay and appeared to be associated with fewer complications. Similarly, identifying patients for early tracheostomy insertion should be advocated, given the improved outcomes seen in our unit.

Regional Experiences of Endotracheal Intubation During The COVID-19 Pandemic in The United Kingdom

B. Shuker¹; E. Smith²; P. Checketts³; Q. Khan⁴

¹Department of Anaesthesia, Warwick Hospital, Warwick, United Kingdom; ²Department of anaesthesia, University Hospital Coventry & Warwickshire, Coventry, United Kingdom; ³Department of anaesthesia, The Shrewsbury and Telford Hospital NHS Trust, Shrewsbury, United Kingdom; ⁴Department of anaesthesia, University Hospitals Birmingham (Heartlands Hospital), Birmingham, United Kingdom

Correspondence: B. Shuker

Intensive Care Medicine Experimental 2020, **8(2)**: 000686

Introduction: In the United Kingdom (UK), consensus guidelines for airway management were published early in the COVID-19 pandemic making recommendations to support clinicians during this potentially challenging intervention (1). Adaptions to existing guidance for airway management in critically ill adults from the Difficult Airway Society (2) included: use of personal protective equipment (PPE), preferential use of the best skilled airway manager to maximise chance of first-pass

success, avoidance of aerosol-generating procedures (such as non-invasive ventilation, high flow nasal oxygenation), and use of reliable well practiced techniques (including videolaryngoscopy where appropriate).

Objectives: Areas of the West Midlands were some of the worst affected by the COVID-19 pandemic in the UK (3). We aimed to gain insight into the experiences of clinicians involved with airway management during the COVID-19 pandemic in this region.

Methods: An online survey was distributed to multiple centres within the West Midlands region of the UK. Clinicians who had experience of endotracheal intubation in patients with confirmed, suspected, or unknown COVID-19 status were asked to reflect upon their experience of one patient intubation.

Results: 127 clinicians from 16 hospitals including 3 large university hospitals responded to the online survey, most were consultant grade (56.7%). Clinicians self-reported an average approximate number of pandemic intubations of 7.35 (range 1-30).

When asked to reflect on a single intubation, clinicians reflected on intubations in ICU (42.5%), emergency departments (20.5%), wards (8.7%), and theatre (28.3%). Appropriate PPE was available in 96.1%. The most senior clinician available intubated in 65.4%.

Clinicians reported first pass success in 93.7% of responses. Most intubators reported use of videolaryngoscopy (74.8%), however 26% reported not using this equipment regularly and 5.5% did not feel confident with their equipment. Despite a high success rate, difficulties were reported in 15.1%. The most common was desaturation. Other common difficulties included equipment or environment unfamiliarity, lack of skilled support.

When asked what advice they would give to colleagues, frequently occurring themes included: ensuring familiarity with equipment, use of a checklist, use of videolaryngoscopy, and availability of a second intubator. Desire for simulation and equipment familiarisation was highlighted in multiple responses, and in one example a clinician attributed their success to a simulation session performed in the week prior.

Conclusion: Experiences from clinicians in this region highlight the specific challenges encountered involved in airway management of patients with COVID-19, in particular highlighting the importance of advance preparation for intubation when faced with unfamiliar circumstances. Simulation sessions, use of checklists and standard operating procedures for emergency intubation may contribute to maintaining preparedness for intubation in this challenging patient group.

Introduction: Community-acquired pneumonia COVID 19 has been a recent and frequent cause of admission to intensive care units worldwide. Its rapid expansion and high number of cases mean that there are many open questions regarding its management, treatment and prognostic. The performance of a tracheostomy in the affected patients is one of these questions.

Methods: A retrospective, observational study was carried out with all the patients admitted to the Intensive Care Unit at a University Hospital with the diagnosis of COVID-19 pneumonia. All patients who require mechanical ventilation support and tracheostomy during the pandemic were included.

Results: 37 patients were analysed. 70.3% of the sample were men (26/37). Average age 59.4 ± 9.4 . APACHE II 14.8 ± 4.67 . The average days of mechanical ventilation prior to performing a tracheostomy was 11 ± 2.66 . Three of them were completed during the first week. Percutaneous tracheostomy was performed in 86.5% (32/37) of the cases; 31/37 in the course of the second week and 3 of them after the first two weeks. The average days from tracheostomy to decannulation was 17.7 ± 10.6 . 17 patients have been decannulated (46%). 16 of these 17 patients have been discharged from the hospital. The characteristics of surviving and non-surviving patients are shown in the Table 1.

	Survivors	Non survivors	p
N	26	11	
Age	59	60,5	0,68
Sex (M)	65%	81,8%	0,28
APACHE II	14,2	16	0,4
Cardiovascular history	57,7%	45%	0,57
Respiratory history	7,6%	18,1%	0,34
Other medical history	34,6%	18,1%	0,28
Prone	77%	100%	0,09
Neuromuscular blockers	88,4%	100%	0,33
Days to traqueostomy	11	11	1
Percutaneous procedure	88,4%	81,8%	0,47

Conclusion: We present the results of 37 patients who required a tracheostomy as a part of the management of COVID 19 pneumonia. We describe the performance and the prognostic of the technique

Comparison of complication rates of surgical vs. percutaneous approach to tracheostomy insertion in a specialist burns critical care unit

A. Gandhi¹; L. Christie¹

¹Magill department of anaesthesia, Chelsea and Westminster Hospital, London, United Kingdom

Correspondence: A. Gandhi

Intensive Care Medicine Experimental 2020, **8(2)**: 000834

Introduction: Critically ill burns patients frequently require a tracheostomy, but pose particular challenges including airway and/or neck swelling, face and neck grafting and high oxygen and ventilation requirements. Grade 2 evidence exists for percutaneous dilation technique (PDT) over surgical technique (ST) in the burns setting[1]. ST is associated with lower costs when performed at the bedside or in association with another surgical procedure [2].

Objectives: We sought to compare the rate and severity of complications between PDT and ST in critically ill burns patients, within a regional burns critical care unit.

Methods: Retrospective data was collected over 33 months (May 2017 to February 2020) from all admissions to a regional burns critical care unit. Basic demographic data was collected in addition to data regarding technique, staff performing tracheostomy and tracheostomy

complications during hospital stay. Complications were classed as severe or not severe based on the necessity for significant ventilator changes, transfusion or tracheostomy change/bronchoscopy. Averages were expressed as medians with interquartile ranges. Mann Whitney-U analysis was used for non-parametric continuous data and X2 Fisher's exact test for categorical data using SPSS (IBM corp). A p-value < 0.05 was considered significant.

Results: From 71 admissions, 49 required ventilation and 13 patients required a tracheostomy. Of these 13 tracheostomy patients, the median burn surface area was 23% (IQR 37%), 46% (n = 6/13) had inhalational injuries of grade 2 or worse and 92% (n = 12/13) had burns involving their neck. ST was employed in 70% of cases. Demographic data showed overall homogeneity between the PDT and ST groups. However the ST group had a greater proportion of males, severe inhalational injuries and burns involving the neck was although not significant. The average time between intubation and tracheostomy formation was comparable between groups. Decannulation time also did not differ significantly. The majority of tracheostomies were performed in the theatre setting (n = 12/13) to coincide with debridement or skin grafting. PDT was performed predominantly by senior trainee anaesthetists (75%) and in the theatre setting with surgical presence. All STs were performed by consultant surgeons, using an open approach.

At least one pre-procedural concerns was highlighted in 69% of all cases, including ventilatory concerns (3) (e.g. pneumonia, frequent desaturation), oedema at desired tracheostomy site (2), neck burns (2), distorted anatomy (1) and presence of graft at tracheostomy site (1). Similar rates of pre-procedural concerns were highlighted for ST and PDT cases (6/9 vs 3/4 respectively)

Early complication rate was greater with ST, with the majority being considered severe such as dislodgement, stomal leak, significant bleeding, surgical emphysema and occlusion due to malposition. PDT demonstrated a lower complication rate but all were severe.

	PDT (n=4)	ST (n=9)	p-value
Age (years)	38(23)	55.5 (16.75)	0.266
Weight (kg)	74.5 (28.3)	89 (16.4)	0.559
Male Sex	1 (25%)	6 (67%)	0.266
Inhalational injuries grade ≥2	1 (25%)	5 (56%)	0.559
Burns to neck	3 (75%)	9 (100%)	0.308
Burns Surface Area (%)	26 (17.5)	23 (47)	1.00
Time to tracheostomy formation (days)	9.5 (6.75)	8 (3.0)	1.00
Time to de-cannulation (days)	20 (5)	18.5 (13.75)	1.00
Complications	2 (50%)	8 (88.9%)	0.41
Severe	2 (50%)	6 (66.7%)	0.203
Not severe	0 (0%)	2 (22.2%)	0.510

Conclusion: Tracheostomies in critically ill burns patients are associated with a high risk of severe early complications[3]. We observed a higher rate of early complications (loss of airway and bleeding) in ST vs PDT. Although this data appears to favour PDT, the ST group had more pre-procedural concerns (e.g. more neck burns, distorted neck anatomy, oedema and inhalational injury) and therefore represent a higher risk group. We believe a national database is required to capture tracheostomy technique and complications to enable recommendations in this high risk specialised cohort.

Intensive Care Medicine Experimental 2020, **8(2)**: 000047

Introduction: The National Tracheostomy Safety Project (NTSP) produces resources to improve multidisciplinary management of tracheostomies [1]. However, tracheostomy tube emergencies on the Intensive Care Unit (ICU) differ significantly to the rest of the hospital. We therefore created new algorithms specific to ICU with emphasis on the use of capnography.

Methods: The algorithms were designed using 'Plan, Do, Study, Act' (PDSA) cycles to sit alongside existing NTSP bedhead tracheostomy or laryngectomy signs and use a stepwise approach suitable for any member of the multidisciplinary team to use in an emergency. We use the headings: 'Tracheostomy: with patent upper airway' and 'Laryngectomy: Neck-ONLY breather' to emphasise that while both patients are 'neck breathers' only the laryngectomy patient is an obligate neck breather [2]. Using a multidisciplinary bedside training programme, using the 'tea trolley' method to provide 10-15 minute teaching sessions for each staff member [3], we familiarised staff with the algorithms and enabled them to employ them in a low fidelity simulation tool.

Results: We trained 67 staff members including all grades of nurses and doctors. 100% of participants preferred our algorithms to the NTSP algorithm, judging them to be clearer and easier to follow in an emergency. 100% of participants recommended this training programme to other ICUs.

Conclusion: In ICU the patient with a tracheostomy is often ventilator-dependent, capnography-monitored and displacement is more common than obstruction. This necessitates a different pathway to that on the wards (where obstruction is more common). Our ICU-specific algorithms were preferred and easier to follow. Conversely the NTSP algorithms, while an excellent teaching resource, can become overwhelming in an emergency due to excessive detail.

001067**Percutaneous tracheostomy in COVID-19 patients: assessing patient benefits and clinician risks**A. Williamson¹; M. Roberts¹; J. Phillips¹; R. Saha¹¹Critical care, Princess Alexandra Hospital, Harlow, United Kingdom**Correspondence:** A. Williamson*Intensive Care Medicine Experimental* 2020, **8(2)**: 001067

Introduction: Many patients with COVID-19 require long-term mechanical ventilation. Early tracheostomy may offer a route to weaning ventilation, decreased sedation, and reduced cardiovascular support for intensive care patients. However, at the peak of the COVID-19 pandemic, advice in the UK was to wait for 14 days and/or a negative COVID-19 test due to perceived risks to the operator [1,2].

Objectives: To determine the impact of early percutaneous tracheostomies (< 10 days after intubation) on sedation and vasopressor requirements. In addition, we examine whether modifications to reduce viral exposure avoided COVID-19 transmission to the treating team.

Methods: We conducted a retrospective analysis of all mechanically ventilated COVID-19 patients receiving tracheostomies at a single-centre general intensive care unit in the UK from 19 March to 29 June 2020 (n = 31). This involved a modified percutaneous technique to minimise aerosol generation. We compare patient sedation and cardiovascular support over a five-day follow-up period, as well as 30-day discharge and mortality, with an indicative control group of five clinically similar patients who did not receive a tracheostomy as they were transferred to different hospitals for exogenous reasons of ICU bed capacity. The treating team were also screened for COVID-19 antibodies > 2 weeks after the procedures.

Results: Compared to baseline preceding tracheostomy, patients showed a decrease in both sedative and cardiovascular support requirements with no similar improvements in the control group. Median sedative requirements decreased from an average of over 10 mg/hr of both morphine and midazolam or equivalent to less than 5 mg/hr of both five days after tracheostomy, whilst median sedation remained above 10mg/hr of both for the controls. Median noradrenaline decreased from 5 to 0 mcg/min over the same period, whilst the control group increased from 2.66 to 8 mcg/min. After 30 days, 15 tracheostomy patients (48.3%) had been discharged from hospital, two (6.5%) were receiving ongoing care on step-down wards, and 14 were deceased (45.1%). Of the indicative control group, after 30 days since meeting the criteria for tracheostomy two (40%) had been discharged and three (60%) were deceased. Of the 31 procedures only two involved complications (6.4%); both featured transient desaturation and hypoxia but neither resulted in lasting sequelae. In addition, we find that all clinicians involved with tracheostomies received negative COVID-19 antibody tests.

Conclusion: In a small sample size, we demonstrate the potential for early tracheostomy as a strategy for reducing sedative and vasopressor requirements. This may improve outcomes for mechanically ventilated patients in a pandemic setting without compromising the safety of the treating team.

The authors acknowledge Aisling Corcoran, Becca Parrott, and Cheryl Pit-tuck for helpful data assistance.

001085**Early vs late tracheostomy in SARS-COV-2 patients. Does it really make a difference?**J. Gonzalez Londoño¹; C. Vera Ching²; M. Buxó³; P. Ortiz Ballujera²; JM. Sirvent Calvera²¹Intensive care medicine, Hospital de Santa Caterina, Salt, Spain; ²Intensive care medicine, Hospital Universitari de Girona Dr Josep Trueta, Girona, Spain; ³Statistical and methodological support unit, Fundació Privada Institut d'Investigació Biomèdica de Girona Doctor Josep Trueta, Salt, Spain**Correspondence:** J. Gonzalez Londoño*Intensive Care Medicine Experimental* 2020, **8(2)**: 001085

Introduction: The most serious form of COVID 19 infection manifested itself with a high number of patients with severe and long-standing ARDS, many of whom required a tracheostomy during the course of their illness. Currently, there is no consensus on the best time to perform tracheostomies. According to current recommendations, in the SARS-COV-2 pandemic situation, it is recommended to perform a tracheostomy after 10 to 14 days of mechanical ventilation (MV) to minimize exposure to the viral load that exists in earlier stages and for a better selection of patients.

Objectives: The objective of this study is to compare the results of patients with ARDS secondary to SARS-COV-2 that required a tracheostomy because of prolonged mechanical ventilation in two Intensive Care Units (ICU) in Spain

Methods: We carried out a retrospective observational study in the period between March and June 2020, in which SARS-COV-2 patients that developed ARDS and required a tracheostomy were divided in two groups. We considered early-tracheostomy patients as the ones who had a tracheostomy during the first 14 days of MV and late-tracheostomy after the 14th day. Data are presented as the mean \pm standard deviation (SD), the median with the 25 -75 percentiles and the frequencies with percentages, as appropriate. Continuous variables were analyzed with Student's t-test or the Mann-Whitney test, and categorical variables were analyzed with the chi-square test or Fisher's exact test. A level of statistical significance was set for values of $p < 0.05$

Results: 57 patients were included, of whom 73.7% were men, the mean age was 60.4 years old (± 13.2). APACHE II at admission was 21.5 (± 8.1) and SOFA 8.9 (± 8.1). 29.6% of the patients were obese, 43.9% had a history of HT and 22.8% were diagnosed with diabetes. At admission 29.8% had severe ARDS and 56.1% moderate ARDS. The CURB-65 and PORT-PSI mean were 2.07 (± 0.8) and 4.09 (± 0.8) respectively. In 42% of patients, an early tracheostomy was performed (12.1 (± 1.7) days) and 58% late (17.4 (± 2.7) days).

The duration of MV in the early TQT group was 23.5 days (20.2-33)) and in the late 30 days (25-41) ($p 0.049$); no significant differences were found in the days of ICU stay or in mortality.

Conclusion: In our series, patients with early-tracheostomy required fewer days of MV; however, we did not find significant differences in the days of ICU stay or mortality. These findings are similar to other studies in non SARS-COV-2 patients.

001172**Suction assisted containment of respiratory droplets during airway management with the SALAD technique**C. Della Vella¹; R. Barrix²; C. Root³; J. Horowitz⁴; J. Ducanto⁵¹Catholic University of the Sacred Heart, Agostino Gemelli Hospital, Rome, Italy; ²Ems, Emergency Medical Services, Madison, United States of America; ³Emergency medicine, Department of Emergency Medicine, Albuquerque, United States of America; ⁴Emergency medicine, NYU Langone Health, New York, United States of America; ⁵Anesthesia, Medical College of Wisconsin, Milwaukee, United States of America**Correspondence:** C. Della Vella*Intensive Care Medicine Experimental* 2020, **8(2)**: 001172

Introduction: The COVID-19 pandemic has generated significant discussion of different means to reduce the risk of transmission to the clinician tasked with intubating an infected patient. Appropriate personal protective provides a barrier and video laryngoscopy increase

the distance between the clinician and the respiratory tract, however additional proposed methods such as translucent plastic boxes have been shown to be less than helpful. We present a simulation to examine the implications of the deliberate use of suction during the airway management of a patient with a respiratory infectious disease, and to examine a technique that may serve to reduce respiratory droplet emissions and potentially increase the safety of the procedure for the clinician.

Methods: The right mainstem bronchus of the 7-Sigma mannequin was coupled with two medication nebulizer systems filled with diet tonic water, which fluoresces on contact with ultraviolet (UV) light. The nebulizers are then connected to two separate medical flowmeters set to 15 L per minute flow. The left mainstem bronchus and esophagus of the mannequin are occluded to enhance the nebulizer gas flow through the mannequin to the oropharynx. The fresh gas flow through the nebulizer units produces a fine mist/aerosol, which is visible in the room air when illuminated by UV light. Two separate 60-watt UV lights, which are placed immediately to the sides and behind the endoscopist—to minimize the exposure of UV light to the endoscopist's eyes—are utilized to illuminate the aerosol mist.

When the clinician introduces the suction catheter into the oropharynx, the stream of aerosolized ceases to be visible as it is fully diverted into the stream of the suction. Utilizing the Suction Assisted Laryngoscopy and Airway Decontamination (SALAD) technique, the intubation can continue while leaving the suction catheter in place in the hypopharynx.

Results: This simulation shows the potential for a medical suction system to decontaminate the air space directly above the mouth of a mannequin emitting a nebulizer aerosol that is visible on UV light; and furthermore, it demonstrates the “intraoral” and “hypopharyngeal” decontamination of the nebulizer aerosol during simulated tracheal intubation. Battery-powered suction systems, such as those used on code carts and by prehospital providers, typically draw approximately 25 to 30 L per minute of gas through the suction system. This airflow is equivalent to 1 cubic foot per minute. Though this volume is small, and it is dubious at best to predict whether this procedure would improve clinical safety of airway management in the presence of a respiratory infectious disease especially if the patient were to forcefully cough. Indeed, this implies that proper PPE, adequate paralysis and formal protocols are mandatory to maintain caregiver safety during an airway management procedure.

Conclusion:

The concept here is to reduce the potential inoculum that the caregiver's PPE is exposed to during the procedure, such that the filtering capability of their respiratory protection mask is not overwhelmed. Proactive use of the suction should prove to reduce the exposure of the physician PPE to a large inoculum of infectious respiratory particles if it accompanies the intubation attempt. Keeping the suction alongside the laryngoscope but above the esophagus and larynx could further help to reduce the airborne infectious respiratory particles in a patient under full induction and paralysis during intubation. Further focused studies are warranted.

Real time assessment of diaphragmatic muscle motion with Tissue Doppler Imaging; data from a single-center observational study in ICU patients

A. Kefalidou¹; E. Doumakis¹; S. Savvidou¹; I. Iordanidou¹; E. Soilemezi¹; M. Tsagourias¹; D. Matamis¹

¹Icu, Papageorgiou General Hospital, Thessaloniki, Greece

Correspondence: E. Soilemezi

Intensive Care Medicine Experimental 2020, **8(2)**: 000205

Introduction: Diaphragmatic Tissue Doppler Imaging (TDI) allows real time assessment of the diaphragmatic tissue motion velocity. TDI of diaphragmatic tissue motion has been studied very little so far in adults, and no information exists regarding its reference values nor its clinical significance in ICU patients.

Objectives: To determine whether TDI-derived parameters can differentiate patients who succeed from patients who fail a spontaneous breathing trial.

Methods: In consecutive ICU patients undergoing a T-tube trial, the following TDI-derived parameters were measured: Peak Contraction Velocity (PCV), defined as the maximal diaphragmatic velocity during contraction, measured in cm/sec; Peak Relaxation Velocity (PRV), defined as the maximal diaphragmatic velocity during relaxation, measured in cm/sec; TDI-derived Maximal Relaxation Rate (TDI-MRR), defined as the slope of the initial steepest part of the diaphragmatic motion velocity curve during relaxation, measured in cm/sec². Measurements are presented as medians with 25th-75th interquartile ranges (IQR). Areas under the receiver operating characteristic (AUROC) with 95% Confidence Intervals (95%CI) have been calculated.

Results: A total of 116 patients were included (67 succeed and 49 failed weaning). Baseline patient characteristics: 87 (75.2%) males, aged 66.2 ± 12.5 years old, median 6 days under mechanical ventilation, reason for ICU admission: respiratory failure 18.9%, multiple trauma 13.8%, sepsis 13.8%, coma 5.2%. Groups did not differ in their baseline characteristics, but in TDI-derived measurements: PCV was 1.36 (IQR 1.06-1.79) vs. 2.02 (IQR 1.28-2.89) cm/sec, $p = 0.001$; PRV 1.36 (IQR 0.96-1.78) vs. 2.70 (IQR 1.41-4.86) cm/sec, $p < 0.001$; and TDI-MRR 10.31 (IQR 5.66-13.74) vs. 21.75 (IQR 11.83-38) cm/sec², $p < 0.001$, for weaning success and weaning failure patients respectively. AUROC for PCV, PRV and TDI-MRR were 0.712 (95% CI 0.607-0.816, $p < 0.001$), 0.772 (95% CI 0.677-0.867, $p < 0.001$) and 0.804 (95% CI 0.716-0.893, $p < 0.001$), respectively.

Conclusion: The results of this study suggest that TDI-derived measurements may serve as good markers for predicting success in a spontaneous breathing trial in ICU patients.

Effects of End-Expiratory Lung Volume (EELV) versus PaO₂ Guided PEEP Determination on Respiratory Mechanics and Oxygenation in Moderate to Severe ARDS: A Randomised Controlled Trial

K. Rollas¹; P. Hanci¹; A. Topeli¹

¹Department of internal medicine division of intensive care medicine, Hacettepe University Faculty of Medicine, Ankara, Turkey

Correspondence: K. Rollas

Intensive Care Medicine Experimental 2020, **8(2)**: 000287

Introduction: There is no ideal method for determination of PEEP in ARDS patients. We compared the effects of an EELV-guided versus PaO₂ guided PEEP determination on respiratory mechanics and oxygenation during the first 48 hours in moderate to severe ARDS.

Methods: Twenty-two patients with moderate to severe ARDS admitted to an academic MICU were randomly assigned to PaO₂-guided (n = 11) or to an EELV-guided PEEP determination (n = 11) group. Incremental PEEP trial was performed by increasing PEEP by 3 cmH₂O

steps from 8 to 20 cmH₂O and in each step EELV and lung mechanics were measured in both groups. EELV was measured with a modified nitrogen multiple breath wash-out/wash-in technique. In the PaO₂-guided group, optimal PEEP was accepted as the minimum PEEP level associated with PaO₂ ≥ 60 mmHg and FiO₂ ≤ 0.60. In the EELV-guided group, optimal PEEP was accepted as the PEEP that caused a > 10% increase in EELV. Oxygenation and respiratory mechanics were measured under the determined PEEP at 4, 12, 24, and 48th hours. Results are presented as median [25-75th percentile]. Friedman and Spearman's rho tests were used where appropriate. P value < 0.05 is accepted as statistically significant.

Results: As seen in the Table after the incremental PEEP trial, over the 48 hours of the study, PaO₂ and PaO₂/FiO₂ increased in the EELV-guided group as compared to PaO₂-guided group. EELV, static compliance (Cs), driving pressure, and strain remained similar in the two groups. In all patients, the median value of EELV change (ΔEELV) during incremental PEEP trial was 25%. As seen in the Table in patients with ΔEELV > 25% (n = 11) PaO₂, PaO₂/FiO₂ and Cs increased over time in 48 hours, whereas they did not change in those with ΔEELV ≤ 25% (n = 11). There was a negative correlation between EELV and driving pressure measured at 48th hour of the study period (r = -0.77, p < 0.001).

Table: Gas Exchange and respiratory mechanics in PaO₂ guided versus EELV guided groups, and between groups with ΔEELV >25% and ≤25% over 48 hours

	4th hour	12th hour	24th hour	48th hour	p value*
PaO₂, mmHg					
PaO ₂ guided	63 [59-71]	60 [53-69]	61 [55-90]	68 [62-84]	0.09
EELV guided	66 [61-74]	68 [62-81]	66 [61-75]	70 [62-88]	0.04
ΔEELV > 25%	67 [59-73]	68 [53-80]	62 [60-90]	76 [68-91]	0.03

* Friedman tests were conducted to test whether there is a significant change in the variables within each group.

Conclusion: Compared to PaO₂-guided PEEP determination, EELV-guided PEEP determination resulted in greater improvement in oxygenation over time. Patients who had > 25% improvement in EELV during a PEEP trial had greater improvement in oxygenation and compliance over 48 hours. Measurement of EELV might not only help to determine optimal PEEP but also imply lung recruitability in patients with moderate to severe ARDS.

Intensive Care Medicine Experimental 2020, **8(2)**: 000318

Introduction: Existing clinical practice guidelines support the use of neuromuscular blocking agents (NMBA) in acute respiratory distress syndrome (ARDS). However a recent large randomized clinical trial (RCT) has questioned this practice. Therefore, we updated a previous systematic review to determine the efficacy and safety of NMBAs in ARDS.

Methods: We searched MEDLINE, EMBASE (October 2012 to July 2019), the Cochrane (Central) database, and clinical trial registries (clinicaltrials.gov, ISRCTN Register, and WHO ICTRP) for RCTs comparing the effects of NMBA as a continuous infusion versus placebo or no NMBA infusion on patient-important outcomes for adults with ARDS. Two independent reviewers assessed methodologic quality of the primary studies and abstracted data.

Results: Seven RCTs, including four new RCTs, met eligibility criteria for this review. These trials enrolled 1,598 patients with moderate to severe ARDS at centres in the United States, France, and China. All trials assessed short-term continuous infusions of cisatracurium or vecuronium. The pooled estimate for mortality outcomes showed significant statistical heterogeneity, which was only explained by a subgroup analysis by depth of sedation in the control arm. A continuous NMBA infusion did not improve mortality when compared to a light sedation strategy with no NMBA infusion (relative risk [RR] 0.99; 95% CI 0.86 - 1.15; moderate certainty; P = 0.93). On the other hand, continuous NMBA infusion reduced mortality when compared to deep sedation with as needed NMBA boluses (RR 0.71; 95% CI 0.57 - 0.89; low certainty; P = 0.003). Continuous NMBA infusion reduced the rate of barotrauma (RR 0.55; 95% CI 0.35 - 0.85, moderate certainty; P = 0.008)

across eligible trials, but the effect on ventilator-free days, duration of mechanical ventilation, and ICU-acquired weakness was uncertain.

Conclusion: Inconsistency in study methods and findings precluded the pooling of all trials for mortality. Earliest trials suggested a mortality reduction with a continuous NMBA infusion; however, when compared to the current practice of ARDS management with lighter sedation, use of continuous NMBA infusion did not reduce the risk of death. In both situations, a continuous NMBA infusion may reduce the risk of barotrauma, but the effects on other patient-important outcomes remain unclear.

Comparison of survival outcomes between patients ventilated on anaesthetic machines and conventional ventilators during the Coronavirus pandemic: A retrospective case series

P. Jain¹; J. Dixon¹; V. Shukla¹

¹Intensive care unit St Helier hospital, Epsom and St Helier University Hospitals, London, United Kingdom

Correspondence: P. Jain

Intensive Care Medicine Experimental 2020, **8(2)**: 000329

Introduction: The coronavirus disease 2019 (COVID-19) pandemic has led to rapid exhaustion of intensive care facilities across the UK and the world. The use of anaesthetic machines for long term ventilation as an off label use received regulatory clearance in this setting. We compare the survival outcomes of COVID-19 patients between 2 groups - those ventilated on anaesthetic machines and on those on standard ventilators. This was a retrospective observational case series conducted at Epsom and St Helier university hospitals in London.

Methods: 63 patients admitted to our intensive care unit with confirmed SARS-CoV2 (severe acute respiratory syndrome coronavirus-2) infection between 07 March and 27 April were included in this case series. These patients were either ventilated on anaesthetic machines or conventional ventilators depending on the availability of these machines. All the patients were treated with similar management protocols. The mortality rates, APACHE 2 scores and the length of ventilator days of the deceased patients were compared between the two groups.

Results: The mean±standard deviation (SD) APACHE2 score in the anaesthetic machine group was 14.21 ± 4.05 and in the ventilator group was 19.72 ± 5.66; p-value 0.0002. The mean±SD number of ventilator days was 6.87 ± 4.3 and 8.36 ± 6.68 in the anaesthetic machine and ventilator groups respectively (p-value 0.41). The mortality rate in the anaesthetic machine group was 80% and in the ventilator group was 66.66%; p value 0.82.

Conclusion: There was no difference in outcomes between the patients ventilated on conventional ventilators versus those with anaesthetic machines. However, the results could be different if the APACHE scores were similar.

Anaesthetic machines were not intended for long term ventilation and their use in the times of such pandemics seem justified and essential when the availability of the conventional ventilators is limited. This is important because having a back up stock / inventory of conventional ventilators anticipating the occasional pandemic may not be viable financially for most healthcare organisations.

Intensive Care Medicine Experimental 2020, **8(2)**: 000410

Introduction: In ARDS patients, controlled mechanical ventilation - either volumetric or pressometric - is commonly employed. Several studies investigated the effects of inspiratory flow on clinical parameters.1 Yet, a systematic approach to this issue is still lacking, and so are its clinical consequences.

Objectives: To appraise the effects of four different inspiratory flow waveforms on gas exchange, pulmonary mechanics and hemodynamics during volume-controlled mechanical ventilation.

Methods: Within 72 hours from the diagnosis of ARDS, patients were enrolled. Supine position, myorelaxation and esophageal pressure monitoring were inclusion criteria. Volume-controlled ventilation with Hamilton S1 (Hamilton Medical, Bonaduz, CH) was instituted as it follows: Tidal Volume 6-8 ml/kgIBW, Plateau Pressure ≤25 cm H₂O, PEEP as described by the high-PEEP/low-FiO₂ branch of the LOV study.2 Patients were randomized to receive: square (SQ), decelerated (DE), sinusoidal (SIN), and trunk decelerated (TDE) waveform. After 20 min of clinical stabilization following each waveform change, data were collected and analyzed.

Results: Twenty-six patients were enrolled and randomized. Gas exchange, pulmonary mechanics and hemodynamic data are clustered on the basis of inspiratory waveform (Table 1). Significant difference was observed in peak inspiratory flow (Figure 1) between DE and TDE (p < 0.001), SQ (p < 0.001) and SIN (p = 0.001); among TDE and SIN (p < 0.001); between SQ and SIN (p < 0.001). Nevertheless, variations in terms of gas exchange, pulmonary mechanics and hemodynamics resulted shy of statistical relevance.

Table 1. Grouped gas exchange, pulmonary mechanics and hemodynamics

	DE	TED	SQ	SIN	p
Peak Inspiratory Flow (ml/sec)	707.9±121.1	475.5±74.1	423.1±88.7	598.1±105.1	<0.01

Impact of a stepwise increase in PEEP (PEEP-trial) on haemodynamics, static compliance, functional residual capacity and tidal volume: a study in patients with PiCCO-monitoring

Intensive Care Medicine Experimental 2020, **8(2)**: 000476

Introduction: Advanced respirator technologies provide automated stepwise PEEP-increases in parallel with the measurement of functional residual capacity (FRC) and static pulmonary compliance (C_{stat}). While this PEEP-trial (PT) may help facilitate optimal PEEP-setting, it also carries the risk of haemodynamic instability due to the reduced venous return. We hypothesized that a standard PT with stepwise increases in PEEP of a total of 8 cmH₂O might result in substantial haemodynamic changes. Since heart lung interactions have been suggested to diagnose volume responsiveness, the PT could be used as a combined approach to optimize ventilation and haemodynamics.

Methods: In 50 mechanically ventilated patients (Carescape R860; GE; pressure-controlled ventilation; PF-ratio of 249 + -83) and PiCCO-monitoring, an automated five step PEEP-trial was performed. PEEP was increased from values of 4 cmH₂O below, to 4 cmH₂O above the present PEEP-level. PiCCO-data, ventilator settings, FRC and C_{stat} were measured at baseline and after each increase.

Results: Mean values for most haemodynamic parameters including heart rate, MAP, CVP, global end-diastolic volume index GEDVI, stroke volume index SVI, stroke volume variation SVV, extravascular lung water index EVLWI and cardiac power index CPI were not significantly different at the end compared to the start of the PT. Mean cardiac index CI decreased significantly as the heart rate decreased with increasing PEEP. PEEP (5,1 \pm 1,7 vs. 12,8 \pm 2,4 cmH₂O; $p < 0.001$) and FRC (1493 \pm 588 vs. 1940 \pm 778 ml; $p < 0.001$) were significantly higher after the PT, while all other respiratory data including tidal volume and C_{stat} were not different after the PT. Individual maximum values during the PT were significantly higher for tidal volume (461 \pm 151 vs. 526 \pm 126 mL; $p < 0.001$) and C_{stat} (38 \pm 21 vs. 48 \pm 23 mL/cmH₂O; $p < 0.001$) compared to baseline.

Conclusion: 1.) The PT did not impair haemodynamics. While the PT is haemodynamically safe, its use to detect volume deficiency appears to be low. 2.) Adjustment of PEEP in response to PT data substantially improves FRC, C_{stat} and tidal volume.

Intensive Care Medicine Experimental 2020, **8(2)**: 000493

Introduction: A tracheostomy (TSY) is a well-recognised means to provide a safe interface for weaning off prolonged mechanical ventilation, especially in those with severe respiratory failure. Aerosol generating procedures (AGPs) are associated with significant cross infection risks to healthcare workers with deaths reported, including those of ENT surgeons. No national consensus exists on the role or timing of TSY in COVID-19 pts. Initially TSYs were requested ad-hoc based on clinical need. However, with the dynamic and rapidly evolving pandemic it became clear an agreed pathway was required with clarity on indications and timing of the procedure. We present a tertiary centre experience of creating a novel TSY pathway for long stay COVID-19 patients.

Methods: Regular multidisciplinary team (MDT) discussions between intensivists, ENT surgeons and operating room staff provided a forum to address and discuss all relevant issues, concerns and risks (both to patients as well as staff) of undertaking a TSY in COVID-19 pts. An agreed step-wise approach was instituted with potential for review. Consecutive COVID-19 positive pts admitted to ICU at a tertiary referral centre over 8 weeks were included. Contemporaneous electronic case notes and results were retrospectively reviewed.

Results: The step-wise plan agreed was as follows

1. Avoid TSY before 14 days
2. TSY only in patients with favourable prognosis
3. Need for TSY agreed by 2 ICU Consultants
4. Aim percutaneous TSY as first option if possible
5. Surgical TSY following MDT discussion
6. All procedures to be undertaken under full PPE

MDT meetings took place at set times, 3 times a week. The order of patients for surgical TSY was also agreed.

During this time 72 COVID pts were admitted to ICU with 59/72 (82%) intubated and mechanically ventilated; their characteristics are shown in Table 1.

The median time from admission to intubation was 1 (range 0-34) day and from intubation to TSY 16 (2-34) days. TSY was performed in 27/59 (46%) of patients; with a surgical approach 24/27 (89%) being commonest. Median time from decision for TSY and the procedure was 4 (0-26) days. Median time from TSY to spontaneous breathing trial was 4 (2-19) days and to decannulation was 12 (6-24) days. There were no TSY related complications. 13 patients were successfully primarily extubated at a median time of 10 (3-17) days after endotracheal intubation.

Importantly, no healthcare worker cross infection from TSY has been recorded.

Characteristics	Total n=72
<i>Patient characteristics</i>	
Age (years) – mean (standard deviation)	57.9 (\pm 12.7)
Male sex – n (%)	53 (74%)
BMI – mean (standard deviation)	29.1 (\pm 6.2)
<i>Comorbidity – n (%)</i>	
Cardiac	20 (28%)
Respiratory	12 (17%)
Renal	5 (7%)
Neurological	6 (8%)
Diabetes	10 (14%)

Conclusion: Engagement of key stakeholders is essential to create a streamlined TSY pathway for COVID-19 pts. Clarity and agreement between multiple specialties has helped provide an effective service without an increased infection risk to staff.

Intensive Care Medicine Experimental 2020, **8(2)**: 000513

Introduction: Specific respiratory features, ventilatory management, and outcomes of patients with acute respiratory distress syndrome (ARDS) caused by coronavirus disease 2019 (COVID-19) have not been well established yet.

Objectives: The aim of this observational study was to describe characteristics of confirmed ARDS COVID-19 patients that received invasive mechanical ventilation (MV) and other adjunctive therapies.

Methods: From March 12th to April 8th 2020, this prospective, multicenter, observational, cohort study enrolled patients with COVID-19 ARDS admitted to the ICU, in 28 hospitals, with a 28-day follow up. Patient medical data were collected into an anonymized online data acquisition system (CoVid19.ubikare.io). Inclusion criteria: > 18 y/o, intubated and mechanically ventilated, confirmed SARS-CoV-2 infection using PCR-based tests, and ARDS, as defined by the Berlin criteria. Recorded data included demographics, ventilator parameters, adjunctive therapies, disease chronology (initiation of MV, ventilator-free-days, ICU-length-of-stay), discharge from ICU and 28-day mortality. Patients were stratified by severity of ARDS. Descriptive variables were expressed as percentage, mean and standard deviation (SD), or median and interquartile range (IQR), as appropriate. To compare variables, Student t-test or Mann-Whitney test and one-way ANOVA or Kruskal-Wallis test for numerical variables, and Chi squared test or Fisher exact test for categorical variables were used. Time to event curves were plotted using the Kaplan-Meier method and analyzed with log-rank test and univariable Cox regression analysis.

Results: A total of 504 patients were included: 96 (19.0%) with mild, 235 (46.6%) with moderate, and 173 (34.3%) with severe ARDS. Median (IQR) values were: PaO₂/FiO₂ 127 (88-182) mmHg, VT 6.9 (6.3-7.8) ml/kg PBW, PEEP 12 (10-14) cmH₂O, Crs 35 (28-45) ml/cmH₂O, Pplat 24 (20-28) cmH₂O, and driving pressure 12 (9-14) cmH₂O. Recruitment maneuvers (RM) were used in 414 (82%) without differences between groups. Prone position was used in 385 (76%) patients, and neuromuscular blocking agents (NMBA) were used in 340 (66%) patients. Degree of ARDS severity was associated with significant differences in the use of prone position (p = 0.001) and NMBA (p = 0.008). There was a higher likelihood of discontinuation of MV (p = 0.006), ICU discharge (p = 0.010) and 28-day survival (p = 0.004) with decreasing severity of ARDS. All-cause 28-day mortality was 18% (94 patients). The risk of 28-day mortality was higher in severe ARDS compared to moderate ARDS [hazard ratio (RR) 0.47 (95%CI: 0.30-0.76), p = 0.002].

Conclusion: On average, in this large series, COVID-19 ARDS patients were managed with standard practice of lung-protective mechanical ventilation frequently associated to RM and prone position. General clinical features, ventilatory management, and 28-day outcome did

not differ from other causes of ARDS. The degree of ARDS severity was a significant prognostic factor.

Intensive Care Medicine Experimental 2020, **8(2)**: 000534

Introduction: A new coronavirus (SARS-CoV-2) emerged from China in December 2019, causing an severe acute respiratory distress syndrome (ARDS) that rapidly spread to become a pandemic.

Objectives: To describe patients admitted to a medical Intensive Care Unit (ICU) in a second-level university Hospital due to severe ARDS related to COVID-19 infection.

Methods: Retrospective and descriptive analysis between March and April 2020 of critically ill patients with COVID-19-related severe acute respiratory distress syndrome admitted to a medical ICU. The following parameters were analyzed: demographic values (gender, age, severity scores, comorbidities), hemodynamic instability, renal failure, respiratory failure (ventilatory mode, FiO₂ level, PEEP, prone ventilation, continuous neuromuscular blockade (NMB), endotracheal tube exchange, tracheostomy, days spent under mechanical ventilation), laboratory parameters (lactate dehydrogenase (LDH), low white blood cell (WBC) count, C-reactive protein (CRP), D-dimer, serum ferritin), length of ICU stay and outcomes.

Results: 22 patients (19 male, 3 female) were admitted, mean age: 67 ± 6,1 (< 60 years old:4, 60-70 years old: 13 (59%), > 70 years old: 7). APACHE II score: 26 ± 7, SOFA : 7,5 ± 1,9. Comorbidities: chronic airflow limitation (CAL): 4, obesity (BMI > 30): 5 (22,7%), hypertension: 13 (59%), diabetes: 4. Inotropic support: 6 (27,3%), renal failure (continuous renal replacement therapy(CRRT)): 3 (13,7%), respiratory support: 22 (100%), ventilatory mode: pressure 14 (64%), volumen 8, FiO₂ (max): < 0.6: 5, between 0.6-0.8: 12 (54,5%), > 0.8: 5. PEEP (max): < 9 cmH₂O:3, between 9-12: 13 (60%), > 12: 6. Prone ventilation: 18 (81%): within the first 24 hours:8, after 24 hours: 10. Continuous NMB: 14 (64%). Reintubation: 4 (18%), endotracheal tube exchange (obstruction):7 (32%), tracheostomy:5 (22,7%), 4 surgical tracheostomy (3 difficult airway, 1 coagulopathy), 1 percutaneous. Time spent under mechanical ventilation: 18 ± 8,5 days. Laboratory parameters: 14 LDH, 10 low WBC count, 19 (86%) CPR, 18 (81%) D-dimer, 19 (86%) serum ferritin. Length of ICU stay: 19,8 ± 8 days. Outcome: 18 (81,8%) discharged (alive), 3 deaths, 1 still in ICU.

Conclusion: According to our series, the type of patient admitted with COVID-19 related severe acute respiratory distress syndrome (ARDS) was a male between 60-70 years old, with hypertension and/or obesity, under mechanical ventilation (pressure mode:64%) and FiO₂ (within the first 24 hours): 0.6-0.8 (54,5%), PEEP 9-12 cmH₂O (60%), in prone positioning (81%) and continuous NMB infusion (64%), requiring tracheostomy (22,7%) and a 81,8% of survival rate.

Intensive Care Medicine Experimental 2020, **8(2)**: 000594

Introduction: Ventilator associated pneumonia (VAP) is the commonest complication of mechanical ventilation and is a major cause of morbidity and mortality. VAP incidence varies based on definitions, but has been estimated to affect between 8-28% of patients(1). The SARS-CoV-2 pandemic has resulted in a large increase in the numbers of patients being mechanically ventilated. We examine the incidence and cause of VAP in COVID positive and negative individuals during the first wave of SARS-CoV-2 in a UK tertiary care intensivist unit.

Objectives: To determine the incidence of suspected VAP in patients with COVID-19.

Methods: We performed a retrospective chart review of all patients admitted to Addenbrooke's hospital requiring mechanical ventilation with confirmed SARS-CoV-2 for 7weeks up to and including the 1/5/2020. Patients were defined as having a suspected VAP based on worsening oxygenation or increased sputum combined with systemic inflammation (pyrexia and/or raised neutrophil count) and radiological features (new or progressive chest x-ray infiltrates), confirmed VAP required positive quantitative microbiological culture or molecular detection of a pathogenic organism.

Results: 64 COVID-19 positive patients required invasive ventilation, receiving a median 15 (IQR 10-22) days of ventilation and a total of 1017 ventilator days. 53 (83%) developed a suspected VAP, with 26 cases confirmed by microbiology. The incidence density of suspected VAP amongst all COVID-19 positive intubated patients was 52 cases per 1000 ventilator-days. ICU Mortality was 56% in this cohort, amongst those who did not develop suspected or confirmed VAP it was 29%. The organisms detected are shown in table 1 below.

Organism	Frequency
Gram-Positive	
<i>Staphylococcus aureus</i>	3
Gram-Negative	
<i>Escherichia Coli</i>	3
<i>Enterobater sp.</i>	4
<i>Hemophilus influenzae</i>	3
<i>Klesiella sp.</i>	9
<i>Proteus sp.</i>	1
<i>Pseudomonas aeruginosa</i>	7
<i>Serratia liquifaciens</i>	1
Fungi	
<i>Aspergillus fumigatus</i>	1

Conclusion: VAP rates appear to be high amongst patients with COVID19, reflecting both their prolonged need for ventilation(1) and critical-illness induced immunosuppression(2). The rate reported here may reflect the diagnostic modalities used, as early on endotracheal aspirate (which over-estimates true incidence) (3) was used until we developed a safe system for bronchoscopic sampling. Gram-negative organisms predominate. The extent to which VAP mediates the high

mortality seen remains uncertain but calls for antibiotic stewardship, vigilance, and detailed work in this area.

Intensive Care Medicine Experimental 2020, **8(2)**: 000605

Introduction: An atypical behavior of ARDS caused by COVID-19 has been suggested, since several patients with profound hypoxemia had close to normal respiratory system compliance (Cr_s). However, data confirming this assumption are scarce, and there is still controversy on the most appropriate oxygenation and ventilation strategies for these patients.

Objectives: We performed a secondary analysis of an observational study to compare clinical features, ventilatory management and clinical outcomes in COVID-19 ARDS patients on mechanical ventilation (MV) with normal and low Cr_s.

Methods: From March 12th to April 8th 2020, a prospective, multi-center, observational, cohort study that enrolled patients with COVID-19 ARDS admitted to the ICU in 28 hospitals was performed, using a specifically designed online anonymized data acquisition system (CoVid19.ubikare.io). Inclusion criteria: > 18 y/o, intubated and MV, confirmed SARS-CoV-2 infection from a respiratory tract sample using PCR-based tests, and ARDS, as defined by the Berlin criteria. Recorded data: demographics, ventilator parameters, adjunctive therapies, disease chronology (initiation of MV, ventilator-free-days, ICU-length-of-stay), discharge from ICU and 28-days in-hospital mortality. Patients were stratified as having normal Cr_s (≥ 50 ml/cmH₂O) or low Cr_s (< 50 ml/cmH₂O) according to baseline values. Descriptive variables were expressed as percentage, mean and standard deviation (SD), or median and interquartile range (IQR), as appropriate for each variable. To compare variables across groups, Student t-test or Mann-Whitney test and one-way ANOVA or Kruskal-Wallis test for numerical variables, and Chi squared test or Fisher exact test for categorical variables were used. Time to event curves were plotted using the Kaplan-Meier method and analyzed with log-rank test and univariable Cox regression analysis.

Results: A total number of 504 patients were included. From the 286 patients (56%) with Cr_s data, median baseline was 35 [28-48], 216 (75.5%) were classified as having low Cr_s and 70 (24.5%) as having normal Cr_s. Time from symptoms onset to MV showed no differences between groups [11 (ICR: 8-15)]. There were no significant differences in PaO₂/FiO₂ between patients with normal or low Cr_s and the ventilation strategy (VT and PEEP) did not vary. Although the distribution of patients with normal or low Cr_s showed significant differences in driving pressure, both at baseline [9 (IQR: 6-10) vs 12 (IQR: 10-16) cmH₂O, p < 0.001] and at maximum values [12 (IQR: 9-15) vs 16 (IQR: 12- 18) cmH₂O, p < 0.001], these differences were not associated with ARDS severity. No differences were observed in the use of recruitment maneuvers and prone positioning. The probability of discontinuation from MV and the probability of ICU discharge did not increase with normal Cr_s. The risk of 28-day mortality was not impacted by Cr_s.

Conclusion: We found a median baseline Crs similar to non-COVID-19 ARDS patients, and 75% of patients had low Crs right after initiation of MV. No differences were found in ventilation management and outcomes.

Intensive Care Medicine Experimental 2020, **8(2)**: 000621

Introduction: Corona Virus Disease 2019 (COVID-19) is a life-threatening viral infection caused by a new strand of the coronaviridae family[1], that was declared a pandemic by WHO on March 11th. The most severe form of the disease is characterized by severe hypoxemic respiratory failure with a need for ventilatory support. Despite fulfilling the Berlin ARDS Criteria, these patients have severe hypoxemia with a near-normal lung compliance, differing from traditional ARDS patients[2]. This presented a new challenge for Intensivists, who had to develop new ventilatory strategies.

Objectives: Study the ventilatory dynamics of COVID-19 patients and their impact on critical care outcomes.
Methods: Retrospective observational cohort study of all patients with a laboratory confirmation of SARS-CoV-2 infection, admitted to the Intensive Care Unit (ICU) of a tertiary Hospital in Northern Portugal, from March 15th to May 10th.

Results: During the study period, 264 COVID-19 patients were admitted to our hospital and 36 required ICU admission. Median age was 62 years [58,25 -65,75] and the majority were male (63.9%). Median ICU stay was 16 days [7.0-23.5]. 86.1% of patients required invasive mechanical ventilation, with a median duration of 17 days [8-24]. One patient required veno-arterial extracorporeal oxygenation. Mean pO₂/FiO₂ ratio at admission was 174.1 ±67.4. pO₂/FiO₂ ratio at admission and variation during the first 48h of stay were not associated with ICU length of stay (p = 0.063 and p = 0.820, respectively) or duration of invasive mechanical ventilation (p = 0.103 and p = 0.916, respectively).

At admission, median Positive End-Expiratory Pressure (PEEP) levels were 9cmH2O [8-10] and patients were ventilated with an average 7.6 ± 1.1 ml/kg of tidal volume. During the total length of ICU stay, median PEEP levels were 8.5cm H2O [7.7 -9.7] and patients were ventilated with 7.6 ±0.9ml/kg of tidal volume. Average driving Pressure levels at admission and during ICU stay were 14.6 ±4.8 and 12.8 ± 3.9, respectively.

Neuromuscular block perfusion was used in 64.5% of patients and 54.8% of patients required at least one period of prone position (mean duration of 3.6 ±2.7 days). Due to prolonged weaning, 33.3% of patients were tracheostomized.

During the ICU stay 9 (25%) patients died. Non-survivors had significantly lower pO₂/FiO₂ ratio (168.3 VS 176.0, p = 0.001), higher driving pressures (15.40 vs 11.7, p = 0.018) and lower tidal volumes (6.95 vs 7.85; p = 0.022) during ICU stay. No other ventilatory variable was associated with ICU mortality. At the time of analysis, 1 patient remained in the ICU and only 9 (25%) patients were discharged from the hospital.

Conclusion: COVID-19 patients require lengthy periods of invasive mechanical ventilation, with higher tidal volume strategies than normal ARDS patients and high rates of tracheostomy as part of the

ventilatory weaning strategy. The retrospective nature and low sample size are the study main limitations.

Pneumoniae in patient with Covid-19: Strategies to Decrease Patient's Self-Inflicted Lung injury

JÁ. Benitez Lozano¹; JM. Serrano Simón²
¹Intensive care medicine, Hospital Quirónsalud Málaga, Málaga, Spain;
²Intensive care medicine, Reina Sofia University Hospital, Córdoba, Spain

Intensive Care Medicine Experimental 2020, **8(2)**: 000640

Introduction: Spontaneous breathing in hypoxemic respiratory failure can lead to Patient self-inflicted lung injury (P-SILI) due to various factors related to intense inspiratory effort with high transpulmonary pressures (1,2).

Objectives: To evaluate respiratory mechanics, Effort (PTP/min), Work of breathing (WOB), and delta muscle pressure (Dpmus) in patients with COVID-19 pneumonia during mechanical ventilation (MV), with three ventilatory strategies during spontaneous ventilation, as well as in passive mode.

Methods: We have studied eleven patients with COVID-19 pneumonia mechanically ventilated during volume-controlled ventilation (CMV), pressure support ventilation (PSV) with inspiratory pressure 10/PEEP 10 cmH₂O, airway pressure release ventilation (APRV) 20/0 cmH₂O with expiratory time for 75% peak flow expiratory (Pef) and double CPAP (CPAPd) 20/10 cmH₂O. Respiratory signals: Flow, airway pressure and volume were recording from the Medibus protocol of the Evita Dräger ventilator, at 125 htz, using personal software. The three components of the equation of motion for the respiratory system: elastance (Ers), Resistances (Rrs) and total PEEP (PEEPt) were obtained in the passive mode using multiple linear regression. In support pressure, we use the inspiratory, expiratory occlusion manoeuvres for Ers, and the measurement of the time constant (t), as the time required to empty the lung 2/3 of its tidal volume to obtain Rrs. In this way, the signals of Pressure Muscular, alveolar and total pressure were obtained. Parameters related to the respiratory drive, effort, work of breathing, and breathing pattern were calculated in each ventilatory mode, cycle by cycle. The clinical and demographic characteristics were collected. Data were analyzed for descriptive methods and expressed as mean±SD, coefficient of variation (CV) and medians (IRQ).

Results: N 11 cases. Sex M 7 (63%). Age (y): 63 ± 9.81. Died 4. Apachell Score 18.92 (17.25-20.75). BMI 28.58 ± 2.43. MV, days 12 (5.25-21.7). P/F 194.8 ± 49.64 mmHg; FiO₂ 0.48 ± 0.08 mmHg. PCO₂ 53.09 ± 15.59 mmHg. ECMO-vv 1.

Intensive Care Medicine Experimental 2020, **8(2)**: 000691

Introduction: COVID-19 is a pandemic associated with acute respiratory failure [1]. Management of critically ill COVID-19 patients with severe hypoxemia is associated with high mortality [2].

Objectives: To reduce ICU length-of-stay (LOS), mechanical ventilation (MV) and mortality implementing a standardized “care map”.

Methods: A retrospective analysis was conducted on consecutive COVID-19 patients admitted in ICU for severe pneumonia in our Center in Lugano. A standardized multidisciplinary approach was implemented to improve patients monitoring using a) uniform patient selection for ICU admission, b) a low-PEEP strategy and c) an enlarged pharmacologic venous thromboembolism (VTE) management.

1. Dyspnea, mental confusion or SpO₂ less than 85% were criteria for ICU admission.
2. Ventilation approach employed low PEEP values (about 10 cmH₂O in presence of lung compliance > 40 mL/cmH₂O) and FiO₂ as needed. In presence of lower lung compliance (< 40 mL/cmH₂O) PEEP value was increased to about 14 cmH₂O.
3. Enlarged prophylactic anticoagulation (Enoxaparine 60 mg bid SC if weight > 80 Kg, Enoxaparine 40 mg bid SC if weight < 80 Kg, Unfractionated Heparin in case of AKI) with daily ultrasound Color-Doppler lower limbs and plasmatic D-dimer level monitoring was performed; in case of suspected or confirmed thromboembolism, treatment was switched to therapeutic anticoagulation (Enoxaparine 1 mg/Kg bid SC – Unfractionated Heparin in case of AKI at 14 UI/Kg/day in perfusion, adapted according to anti-Xa values).

Results: From March 16th to April 12th 2020, 48 patients were presented to be evaluated for ICU admission. Twenty-two of them were not admitted, they have been carefully monitored and presented a 100% of overall survival at 30 days.

Forty-one patients were admitted to ICU: 26 from the Internal Medicine Department, 10 from Emergency Department and 5 transferred from other hospitals. Mean SAPS was 45 (SD 18.4), mean NEMS was 30 (SD 10.4). Thirty-four (82.9%) patients needed MV; low PEEP values based on BMI (PEEP 11 ± 3.8 (10-12) cmH₂O if BMI < 30 kg/m²; PEEP 15 ± 3.26 (12-18) cmH₂O if BMI > 30 kg/m²) was employed. Six patients (14.6%) presented major VTE phenomena. According to VTE prophylaxis strategy, 15 (36.5%) patients were treated through prophylaxis, 26 (63.4%) were managed by full therapeutic anticoagulation. No patient presented bleeding complication, nor clinical sign requiring anticoagulation removal.

Median duration of MV was 7 days; the median LOS was 9 days. After 4 weeks, 25 patients (61%) were discharged from ICU, 4 (9.7%) were still under MV, 2 were transferred to another hospital; ICU mortality rate was 24.3%. P/F ratio had daily improvement during first 72 hours (p < 0.0001).

Conclusion: Our multidisciplinary program allowed to reduce MV days, ICU LOS and mortality in COVID-19 critical care patients; a standardized “multimodal approach” could be the base for further specific patients’ management in this emergency clinical scenario.

Predictive models of postextubation respiratory failure and reintubation

C. Macharete¹; C. Subira¹; C. Alegre¹; O. Rubio¹; S. Cano¹; L. Ventura¹; I. Catalan¹; G. Rognoni¹; M. Batlle¹; R. Fernandez¹

¹Intensive care unit, Althaia, Xarxa Assistencial Universitària de Manresa, Manresa, Spain

Correspondence: C. Macharete

Intensive Care Medicine Experimental 2020, **8(2)**: 000759

Introduction: Postextubation respiratory failure is associated with bad prognosis, leading to reintubation within 72 hours in up to 50% of cases. A model to identify which patients are at high risk of failure can be useful to improve outcome.

Objectives: To design a model to identify those patients with high risk of postextubation failure

Methods: Post-hoc analysis of a randomized clinical trial (reference). Variables associated with postextubation respiratory failure and reintubation were tested by multiple logistic analyses. Then, using logit methodology, we designed models to predict postextubation respiratory failure and reintubation. We calculated the area under the curve (AUC) for each model.

Results: We analyzed 950 patients extubated after a successful SBT, 199 (21%) of them developed respiratory failure, and 104 (11%) needed reintubation. The variables related with postextubation respiratory failure were respiratory rate (RR) > 25x’ at the end of SBT (OR 1.73, p = 0.02), duration of MV > 4 days (OR 1.75, p = 0.001), SatO₂/FiO₂ < 240 (OR 1.89, p = 0.002), and neoplastic disease (OR 1.62, p = 0.02). Reintubation was only associated with duration of MV > 4 days (OR 1.86, p = 0.005) and RR > 25 at the end of SBT (OR 1.99, p = 0.002). The AUCs were low in both models (0.63 for respiratory failure and 0.60 for reintubation).

The model classified patients in 3 groups of risk for respiratory failure. The actual rate of respiratory failure in patients classified as low risk was 13%, 22% at middle risk and 34% at high risk of failure patients.

The model also classified patients in 3 groups of risk for reintubation. The reintubation rate was 7% in patients in low risk, 14% in patients in middle risk, and 24% in patients in high risk of reintubation.

Conclusion: RR > 25 bpm, length of MV > 4 days, SatO₂/FiO₂ < 240 and neoplastic disease were related with higher postextubation respiratory failure. Only the length of MV > 4 days and RR > 25 were related with reintubation. Despite low AUC, both models for respiratory failure and reintubation identified 3 groups of patients with very different risks.

Intensive Care Medicine Experimental 2020, **8(2)**: 000773

Introduction: Respiratory failure requiring mechanical ventilation due to COVID 19 pneumonia has been the principal cause of admission to Intensive Care during the months of March, April, May and June in Europe.

Objectives: We present a sample with the factors that we have associated with mortality in patients on mechanical ventilation.

Methods: A retrospective, observational study was performed with all the patients admitted to the Intensive Medicine Service at a University Hospital with the diagnosis of Community-acquired pneumonia due to COVID 19.

Variables analysed age, sex, APACHE II, mechanical ventilation, length of stay, laboratory values, prone, neuromuscular blocking drugs, tracheostomy and mortality during their stay in intensive care.

Results: 90 patients were analysed. 40% (36/90) have been discharged. The sample has a mortality rate of 34.4% (31/90) and 25.1% (23/90) have been transferred.

Excluding the transferred patients, analysing the 67 patients who received complete treatment in our hospital: Length of stay 14.1 ± 10 , average age 60 years, APACHE II 14.3 ± 5.2 . 67.2% males. Average worst creatinine result 1.48 ± 1.26 mg/dl, Average worst ferritin value 2310 ± 3322 mg/l, Mean value of worst total bilirubin value 2 ± 2.2 mg/dl. 100% of the patients required mechanical ventilation. 65.7% prone position, 74.6% neuromuscular blockers and 98.5% vasoactive drugs. Tracheostomy was performed in 45.3% of the patients. The table shows the values in the group of survivors and non-survivors.

	Survivors	Non survivors	P
Age	56,9	63,4	0,006
Sex (Male)	55%	80%	0,026
APACHE II	12,6	16	0,03
Length of stay	16,5	11,5	0,042
Creatinine Max.	1	1,96	0,003
Bilirrubine Max.	1,71	2,4	0,2
Ferritine Max.	1836	2990	0,2
D Dimer	17,2	19,9	0,67
CV disease	38,8%	51%	0,21
Pulmonar disease	19,4%	19,3%	0,6
Dyslipidemia	27,7%	48%	0,069
Traqueostomy	51%	37,4%	0,2
Prone	52,7%	80%	0,015
Neuromuscular Bloq.	58%	93%	0,001

Conclusion: In our sample the need of prone position, neuromuscular blocking drugs in relation to distress severity have been related to increased mortality. Furthermore, acute renal failure, age and sex (male) are statistically significantly related factors.

Intensive Care Medicine Experimental 2020, **8(2)**: 000806

Introduction: Covid-19 pneumonia can lead to a severe respiratory failure requiring invasive ventilation. Inverse-ratio APRV is a ventilation mode in which Tidal Volume (VT) is delivered during a short decrease in pressure. The expiration phase is interrupted before the expiratory flow reaches zero (1). This refers to the concept of Time Controlled Adaptive Ventilation (TCAV) (2).

Inverse-ratio Airway Pressure Release Ventilation (APRV) was proposed as a ventilation mode for ARDS in a monocentric randomized study showing a reduction in ventilation time in the APRV group (3). We report our experience of switching patients from conventional

ventilation (volume control or pressure support) to APRV in two French ICUs during the Covid-19 pandemic.

Methods: Seventeen consecutive patients who have completed a 6-hour APRV trial in April 2020 were studied (we excluded 3 patients on VV-ECMO and 3 who were unable to be maintained on APRV).

Initial APRV settings were: P-high 28 cmH₂O, T-high 3.5 seconds, P-low 5 cmH₂O and T-low 0.5 seconds. T-low was then immediately adjusted to obtain a sufficient tidal volume and the expiratory flow curve was observed to ensure an interruption of the release phase at around 50 to 75% of the peak expiratory flow. P-low was seldom set to 0 cmH₂O due to concerns of alveolar pressure reaching the set P-low (in case of inappropriately long T-low) and was frequently set to 5 cmH₂O as it was by Zhou et al (3). Within the first hour of APRV, blood gases were measured to detect an eventual increase in PaCO₂ and if necessary, increase the respiratory rate (by decreasing T-high).

Results: The mean (\pm SD) PaO₂:FiO₂ ratio increased from 126 (\pm 28) to 178 (\pm 53) after 6 hours of APRV ($p < 0.001$). In 12/17 patients, the PF ratio increase was of more than 20%. Two patients presented a decrease of the PaO₂:FiO₂ ratio after 6 hours of APRV. Median (interquartile range) ventilation time before the APRV trial was of 14 (8-19) days. At baseline, 12 of the 17 patients were on Volume Assist Control and 5 patients were on Pressure Support. After 6 hours of APRV, the mean Tidal Volume was of 6.5 (\pm 1.7) ml. There was no significant hemodynamic impairment appearing during APRV and an eventual increase in PaCO₂ during the first hour of APRV was managed by increasing respiratory rate (i.e. shortening Thigh) and/or increasing tidal volume (i.e. increasing T-low).

Conclusion: To conclude, in our severe ARDS covid19 patients, the use of inverse ratio APRV was well tolerated and associated with a marked improvement in oxygenation parameters. This could be explained by the high recruitability potential in some cases of Covid-19 associated ARDS (4,5).

Automatic Tube Compensation for spontaneous breathing trial-A systematic review and a network meta-analysisP. Cardinal-Fernández¹; J. Bougnaud²; L. Argaud²; M. Cour²; C. Guérin²¹Intensive care unit, HM University Sanchinarro Hospital, Madrid, Spain;²Intensive réanimation, groupement hospitalier centre, Hôpital Edouard Herriot, Lyon, Université de Lyon, Lyon, France**Correspondence:** P. Cardinal-Fernández*Intensive Care Medicine Experimental* 2020, **8(2)**: 000818

Introduction: Spontaneous Breathing Trial (SBT) is an established test for evaluating the capability of the patient to breathe without ventilator assistance before a scheduled extubation. Among the different techniques used to perform SBT, Automatic Tube Compensation (ATC) calculates the pressure drop across the endotracheal tube and provides with a breathing assistance that counteracts it. In that way ATC acts as a within-cycle closed loop.

Objectives: To conduct a system review (SR) with a network meta-analysis (NMA) that compares the effect of ATC with other techniques for SBT in terms of test tolerance and extubation success.

Methods: This NMA of published studies was conducted following the Preferred Reporting Items for Systematic Reviews and Meta-Analyses (PRISMA) guidelines. Studies were identified using MEDLINE, Web of Science, Cochrane Register of Controlled Trials, LILACS and citation review. The inclusion criteria used the PICO approach. Patients are adults, intubated in the ICU; Intervention is ATC; Control is either the patient (before/after) or another non-ATC intervention; Outcome is either physiologic or patient-centered depending on the category the study falls into. Two authors, independently and blinded each to otherselected studies for inclusion (JB and PCF). Were excluded animal studies, other languages than English, Spanish or French, not in full text format (eg. abstract or letter were excluded) and reviews.

Data analysis. Publication bias was analyzed with a funnel plot for the endpoint extubation success. Relative risk (RR) with random-effects models were used to pool the effect of each SBT technique. Statistical significance was set at $P < 0.05$ with a two-tailed test. Data were analyzed using "netmeta" library from R package.

Results: Four of the 108 studies included the ATC as a SBT representing 769 patients and 4 interventions (ATC100% + Continuous Positive Airway Pressure (CPAP) $< 7.5\text{cmH}_2\text{O}$ [$n = 319$], CPAP $< 7.5\text{cmH}_2\text{O}$ [$n = 120$], Pressure Support (PS) $5\text{cmH}_2\text{O}$ + CPAP $< 7.5\text{cmH}_2\text{O}$ [$n = 30$] and T-tube [$n = 300$]). In terms of successful SBT, the probability of being the best (in decremental order) were: ATC100% + CPAP $< 7.5\text{cmH}_2\text{O}$ (reference group), CPAP $< 7.5\text{cmH}_2\text{O}$, PS5 cmH_2O + CPAP $< 7.5\text{cmH}_2\text{O}$ and T-tube. For extubation success the decremental order from the best to the worst was: ATC100% + CPAP $< 7.5\text{cmH}_2\text{O}$, PS5 cmH_2O + CPAP $< 7.5\text{cmH}_2\text{O}$, T-tube and CPAP $< 7.5\text{cmH}_2\text{O}$. No publication bias was identified.

Conclusion: ATC100% associated to CPAP $< 7.5\text{cmH}_2\text{O}$ may be the best technique in terms of SBT and extubation success.

Association of peak inspiratory muscle pressure and work of breathing estimated by proportional assist ventilation during spontaneous breathing trial with duration of mechanical ventilation in patients who failed SBT: An interim reportA. Ishizuka¹; Y. Norisue¹¹Intensive care medicine, Tokyo Bay Urayasu Ichikawa Medical Center, Urayasu, Japan**Correspondence:** A. Ishizuka*Intensive Care Medicine Experimental* 2020, **8(2)**: 000927

Introduction: Ventilator-induced diaphragmatic dysfunction is known to be one of the main causes of prolonged mechanical ventilation. We hypothesized that patients who failed spontaneous breathing (SBT) due to respiratory muscle weakness are more likely to need longer duration of mechanical ventilator support than patients who failed SBT not because of inspiratory muscle weakness but because of abnormal respiratory mechanics which potentially improves rapidly. Proportional assist ventilation with load adjustable gain factors (PAV+) is the ventilator mode that calculates the pressure generated by patient (Pmus) and patient's work of breathing (WOBpt) during spontaneous breathing.

Objectives: We investigated whether Pmus and WOBpt estimated by PAV+ during SBT can predict duration of mechanical ventilation in patients who failed SBT.

Methods: This study was a prospective observational study in a single center in Japan. All patients over 18 years old who were mechanically ventilated and failed SBT using a mode of PAV+ with a support rate 20% were included. We recorded the average of WOBpt, peak inspiratory pressure (Ppeak), compliance and resistance measured by PAV+ during SBT. We also calculated the peak Pmus from Ppeak. The primary outcome of this study was duration of mechanical ventilation. We defined prolonged mechanical ventilation group as patients who failed at least three weaning attempts or require > 7 days of weaning after the first SBT.

Results: A total of 20 mechanically ventilated patients who failed SBT were included. All patients weaned from mechanical ventilator eventually. 3 patients were categorized into prolonged mechanical ventilation group. The medians of WOB, Pmus, compliance and resistance measured by PAV+ were 0.600(0.580-0.780), 24.00(20.60-24.60), 48.00(41.00-56.00), 5.900(5.000-8.200) in prolonged mechanical ventilation group and 0.700(0.560-0.800), 21.60(11.72-25.60), 50.00(35.00-64.00), 5.900(5.000-8.200) in non-prolonged mechanical ventilation group respectively without significant differences in all variables.

Conclusion: There are no significant differences in Peak Pmus and WOBpt estimated by PAV+ during failed SBT between prolonged mechanical ventilation group and non-mechanical ventilation group in this interim analysis with the small sample size. Larger sample size is needed to further investigate our hypothesis.

Linear approach of respiratory mechanics during VCMV and PCMV modes of mechanical ventilationN. Karampela¹; C. Bostantzoglou¹; G. Marinakis¹; T. Tsoutsouras¹; M. Patrani¹; M. Paraschos¹; M. Vassiliou¹¹Icu, Korgialeneio-Mpenakeio Red Cross Hospital, Athens, Greece**Correspondence:** M. Paraschos*Intensive Care Medicine Experimental* 2020, **8(2)**: 001087

Introduction: Volume control (VCMV) and Pressure control mechanical ventilation (PCMV) are the main modes of respiratory mechanical support. Linear regression analysis (LRA) and Fourier analysis (FA) are methods used for the linear evaluation of Respiratory system (RS) mechanics, independently of the mode of ventilation and without intervening with the ventilators settings.

Objectives: The present study attempts a comparison of RS mechanics on linear basis between two different modes of mechanical ventilation (MV): VCMV and PCMV.

Methods: The Airway Pressure (Paw) and Flow (V') signals were digitally acquired from 25 intubated and mechanically ventilated patients in the Red Cross Hospital ICU. Data were recorded under VCMV and PCMV with stable ventilatory settings (frequency, VT and PEEP). The off-line analysis, included the tidal volume (VT) calculation by numerical integration of V' and the application of LRA and FA with the aid of a specifically developed software. The calculated mechanical parameters were: RS Elastance (Ers), RS Resistance (Rrs), End Expiratory Pressure (EEP). The Error of the applied models (RMSD) according to both techniques were also evaluated. Comparisons for every index between the four applied instances were evaluated with the aid of Analysis of Variance ($p = 0.05$).

Results: All calculated indices are presented in the following table as mean values± standard deviations.

Ventilation Mode	Ers	Ers	Rrs	Rrs	EEP	EEP	RMSD	RMSD
	(LRA)	(FA)	(LRA)	(FA)	(LRA)	(FA)	(LRA)	(FA)
	(hPa/L)	(hPa/L)	(hPa/l/s)	(hPa/l/s)	(hPa)	(hPa)	(hPa)	(hPa)
CMV	31.6±	31.4±	12.9±	15.4±	6.4±	6.4±	1.25±	1.64±
	13.68	14.16	4.67	7.00	3.67	3.67	0.97	1.63
PCV	31.4±	31.7±	13.0±	15.0±	6.4±	6.2±	1.22±	1.56±
	12.82	14.16	4.04	5.89	3.78	3.88	0.95	1.53

Applied comparisons revealed not significant differences for every mechanical index in all studied cases ($p > 0.05$). Nevertheless, FA showed a tendency for higher Rrs values especially in patients with underlying obstructive disorder, which is in accordance with previous findings of ours. The same issue is true for the Error of the applied linear modeling.

Conclusion: Respiratory mechanics are equivalently evaluated with the aid of two different linear methods (LRA and FA) under two different modes of MV (VCMV and PCMV). Our results reinforce the applicability of both calculating techniques and also suggest that both modes of MV have almost identical mechanical effect on respiration. Further research in homogenous conditions concerning the underlying respiratory disorder (COPD, ALI, ARDS e.t.c.) would further clarify the issue.

Intensive Care Medicine Experimental 2020, **8(2)**: 000262

Introduction: Approximately 60% of ventilated patients are affected by weakness of the diaphragm at the time of the first spontaneous breathing trial [1, 2]. A possible non-invasive intervention to preserve diaphragmatic function is magnetic stimulation of the phrenic nerve [3]. Since safety instructions state a minimum distance to magnetically sensitive objects of at least 1 m and prohibit the use near life-sustaining equipment, it is currently unknown if such stimulation would be safe in an intensive care unit (ICU) environment.

Objectives: This investigation aimed to (1) measure distances between patients and life-sustaining medical equipment in a typical ICU surrounding and (2) measure the magnetic fields generated by stimulation coils (located at the patient’s neck) at the patient and surrounding medical equipment with regard to safety in a pilot study.

Methods: A typical ICU patient room was simulated and equipped at the Berliner Simulations- und Trainingszentrum at Charité – Universitätsmedizin Berlin (full data set) and at the Inselspital Bern (distances to devices measured only). A resuscitation manikin was used to simulate the patient position in bed. Stimulations were performed using the PowerMag Research 100 Stimulator® (MAG & More GmbH, Munich, Germany) with a butterfly coil (PMD70-pCool) generating a single, biphasic stimulus at maximum intensity. Magnetic field intensity B in Tesla [T] was measured at various distances vertical to the center of the coil (table 1) and raw data analyzed. Furthermore, possible heating of the metal bed rails and ECG electrodes was investigated using 85% intensity, a frequency of 20 Hertz [Hz] and 2-3 sequences with a length of 5-10 s and 0 mm safety distance.

Table 1. Measurements of the magnetic field intensity at different distances with a single stimulus at 100% power. Direction means position of the sensor to the stimulation coil.

#	Power [%]	Stimulus	Distance [mm]	Direction
1	100	Single	0	center of the stimulation coil
2	100	Single	20	vertical to center of the stimulation coil
3	100	Single	30	vertical to center of the stimulation coil
4	100	Single	70	vertical to center of the stimulation coil
5	100	Single	300	vertical to center of the stimulation coil
6	100	Single	400	vertical to center of the stimulation coil
7	100	Single	150	horizontal to stimulation coil

Results: Distances were 1.2 m and 0.8 m to the ventilator, 1 m and 1 m to the perfusors and 0.7 m and 1 m to the touch panel or vital sign monitor in Berlin and Bern, respectively.

The magnetic field intensity declined with rising distance to the coil (figure 1). It illustrates the results of our measurements at different distances to the coil during stimulation. At 40 cm distance, only general signal noise could be observed.

The heating test resulted in heating of the bed rail to 70 ° C and a safety stop of the coil at the temperature of 40 °C. The ECG electrodes did not heat up. The ECG signal at the monitor showed artefacts during stimulation as known from surgical equipment. Direct stimulation of the perfusor did not lead to any obvious malfunction.

Magnetic field intensity was measured at six points vertical to the center of the stimulation coil and once horizontal to the center of the stimulation coil. Stimulation was done with 100% power. Magnetic field intensity B is measured in Tesla [T].

Conclusion: In standard ICU environment, the distance of magnetically-sensitive objects to the coil can be lower than 1 m. The magnetic fields in this experiment declined with distance from the stimulator. The measurements are providing relevant information for the risk-benefit assessment of magnetic coils to stimulate the phrenic nerve in an ICU environment. With only 40% intensity necessary to generate sufficient tidal volume [3], field intensity should be even lower in clinical practice.

Individualization of tidal volume based on lung compliance in flow controlled ventilation - a step towards personalized medicine in artificial ventilation

P. Spraidner¹; J. Abram¹; G. Putzer¹; J. Martini¹

¹Department of anaesthesiology and intensive care medicine, Medizinische Universität Innsbruck, Innsbruck, Austria

Correspondence: P. Spraidner

Intensive Care Medicine Experimental 2020, **8(2)**: 000279

Introduction: Flow-controlled ventilation (FCV) guarantees a constant gas flow during in- and expiration. Coupled with direct intratracheal pressure measurement, it allows for a precise determination of dynamic lung compliance and ventilation can be adjusted accordingly.

Objectives: Aim of this study was to investigate correlation of observed tidal volume and lung compliance in individualized FCV, based on dynamic compliance measurements, compared to state-of-the-art pressure-controlled ventilation (PCV) in lung healthy- and lung injured animals.

Methods: Anaesthetized pigs were ventilated with either FCV or PCV over a period of 10 hours in lung healthy animals (FCV n = 6, PCV n = 6), and 2 hours after oleic acid induced acute respiratory distress syndrome (ARDS) (FCV n = 8, PCV n = 8). FCV was individualized with compliance guided positive end-expiratory (PEEP) and peak pressure settings. PCV was performed with a PEEP of 5 cmH₂O and a peak pressure set to achieve a tidal volume of 6-8 ml/kg in lung healthy animals and a tidal volume of 6 ml/kg and compliance guided PEEP titration in lung injured animals as a lung protective low tidal volume strategy. Tidal volume and pressure measurement were recorded directly from the respirator; compliance was calculated subsequently. As a surrogate parameter of lung stiffness compliance was then correlated to applied tidal volume.

Results: Overall, applied tidal volume showed a significant correlation to lung compliance ($r = 0.704$, $p < 0.001$) in individualized FCV. Lung healthy animals showed a slightly lower correlation ($r = 0.375$, $p = 0.0014$) compared to ARDS animals ($r = 0.734$, $p < 0.001$). Obviously, in PCV there was no correlation since tidal volume was set to 6-8 ml/kg in lung healthy and 6 ml/kg in lung injured animals.

Conclusion: Compliance guided pressure settings in FCV showed a significant correlation of applied tidal volume to lung compliance as a surrogate parameter of lung stiffness. Thus, we hypothesize individualized FCV to be a more lung protective ventilation strategy as applied tidal volumes are based on individualized lung mechanics measurements. "One size does not fit all", even if best standard of care low tidal volume ventilation is performed.

Intensive Care Medicine Experimental 2020, **8(2)**: 000450

Introduction: Extracorporeal CO₂ Removal (ECCO₂R) allows ultraprotective ventilation avoiding hypercapnia and thus can be used in ARDS patients with the aim of reducing the ventilation load to the lungs [1], but only a few studies investigated the effects of a decrease in respiratory rate during ECCO₂R.

Objectives: The aims of our study were: to investigate the effects of decreased respiratory rate during ECCO₂R on respiratory mechanics, oxygenation, hemodynamics and the development of atelectasis.

Methods: Six female pigs were sedated and paralyzed; volume controlled ventilation was set with TV 10 ml/Kg, PEEP 5 cmH₂O and respiratory rate (RR) 24 bpm. Animals underwent surgical cannulation of the right iliac and jugular veins, then were placed on v-v ECLS (iliac-jugular) with extracorporeal blood flow maintained at 1.5 L/min. RR was reduced in three 8-hours steps to 18, 12 and 6 breaths/min while keeping same TV and PEEP, inspiratory time was adapted to maintain I:E = 1:2. Gas flow was adjusted to maintain PaCO₂ 30-40 mmHg. At Baseline and at the end of each step respiratory, hemodynamic, ECLS and gas exchange parameters were collected, and end-expiratory chest CT scan was performed.

Results: All animals completed the study protocol. During progressive decrease of RR the VCO₂ of the membrane lung progressively increased to maintain a stable PaCO₂. The mechanical power progressively diminished, while plateau pressure, compliance and PaO₂/FiO₂ ratio worsened. Mean pulmonary artery pressure rose. Quantitative analysis of CT scan showed increase in the non-aerated lung compartment but no change in total lung weight. (See Table).

Total Lung Weight, g	661±119	647±125	631±96	695±107	p=0.260
Non-Aerated Lung, %	1.7[1.1-5.2]	2.4[1.5-4.2]	4.5[2.5-9.3]	9.5[7.4-16.5]#	p<0.050

*Post-Hoc Holm-Sidak p<0.05 vs RR24 #Post-Hoc Dunnett's on Ranks p<0.05 vs RR24

When dependent and non-dependent lung regions are analyzed separately, it can be noted that the increase in non-aerated compartment is larger in the dependent regions of the lung (see Figure below : Two-way RM Anova: region p = 0.022, RR p = 0.007, interaction p < 0.001; Post-Hoc: # p < 0.05 NDEP vs DEP § DEP p < 0.05 vs RR24).

Conclusion: In healthy lungs decreased respiratory rate during ECCO₂R allows a reduction of the ventilatory load to the lung at the expense of worsening oxygenation and compliance. Atelectasis progressively develop mainly in the dependent lung.

Intensive Care Medicine Experimental 2020, **8(2)**: 000590

Introduction: Transmission of infectious diseases through patient-derived aerosols (bioaerosols) may increase the prevalence of a disease in the general population[1]. In the critical care setting, aerosol therapy is often used concurrently with mechanical ventilation in the treatment of patients with respiratory issues[2]. If these patients are infectious, the breaking of the circuit, and subsequent potential release of patient-derived bioaerosols during nebuliser refill has the potential to impact the health of caregivers near the patient. Unlike conventional nebulisers, the Aerogen Solo nebuliser is designed to not require breaking of the ventilator circuit when refilling.

Objectives: To assess the potential for release of patient-derived bioaerosols into the local environment during drug refill of a vibrating mesh nebuliser (VMN) during mechanical ventilation.

Methods: A mechanical ventilator (Bellavista, IMT Medical, Switzerland), with a dual limb circuit (RT200, Fisher & Paykel, New Zealand) incorporating a heat moisture exchange filter (HMEF) (Intersurgical, UK) at the patient side of the wye, was set to simulate an adult ventilation pattern (Vt 500 mL, 15BPM, & I:E Ratio 1:1). A VMN (Aerogen Solo, Aerogen, Ireland) was placed between the HMEF and the endotracheal tube (ETT) (8.0mm, Flexicare, UK). An experimental breath actuated aerosol generator was placed at the end of the ETT to generate simulated exhaled patient-derived bioaerosol, using saline (0.9%, Braun, Germany). Aerosol concentrations of particles sized between 0.5 and 20 µm per cm³ were recorded using two Aerodynamic Particle Sizers (APS, Model 3321, TSI Inc., US) positioned at 30 cm and 90 cm from the nebuliser. Test runs were 10 minutes in duration. An initial two-minute period without simulated bioaerosol being generated established ambient aerosol concentrations. Testing (in triplicate) was completed with the VMN in the circuit with the silicon medication cup cap opened or closed for the 10-minute test period.

Results: Results are illustrated in Figure 1.

Figure 1: Particle concentration across all tests

Conclusion: There was no increase in particle concentration noted over the 10-minute test period. Results on average ranged from 6–10 particles per cm³ across all tests at both distances and were in line with ambient levels, also recorded at 6–10 particles per cm³. Variations in ambient levels are due to localised conditions during testing. The results of this study confirm that there is no release of patient-derived bioaerosol through the VMN with the silicon plug opened or closed during mechanical ventilation.

Transvenous-stimulated diaphragm contractions combined with mechanical ventilation reduce systemic inflammation in healthy pigs

E. Rohrs¹; T. Bassi¹; K. Fernandez¹; M. Ornowska¹; M. Nicholas¹; S. Reynolds¹
¹Physiology, Simon Fraser University, Burnaby, Canada

Intensive Care Medicine Experimental 2020, **8(2)**: 000644

Introduction: Mechanical ventilation damages the alveolar epithelium through increased and cyclical stretch due to non-physiological distribution of tidal volume.¹ This, combined with shear stress from repeated opening and closing of alveoli in atelectatic regions, triggers the release of proinflammatory cytokines such as IL-1 β , IL-6 and IL-8.² Excessive cyclic stretch induces cell membrane leakage, causing a spillover of intracellular contents.³ In addition, injured cells release alarmins that elicit a local pro-inflammatory response.⁴ If the injury to lung epithelium progresses such that the compartmentalization of the alveoli is lost, these cytokines translocate into the circulation and have the potential to cause secondary organ injury that leads to multi-system organ failure, which contributes to morbidity and mortality.⁵ This is known as biotrauma. Contracting the diaphragm during mechanical ventilation may reduce atelectrauma that leads to biotrauma.

Objectives: We studied diaphragm contractions elicited by transvenous phrenic nerve stimulation (TTDN) delivered in synchrony with the inspiratory phase of ventilation as a method to reduce lung injury and biotrauma in a sedated, preclinical, ICU model with non-injured lungs.

Methods: Human-sized pigs were sedated and ventilated under mock ICU conditions for 50 hours. They were ventilated with protective volume control, and one group received temporary transvenous diaphragmatic neurostimulation during inspiration on every second breath (MV + TTDN group) while the other did not (MV group). IL-1 β , IL-6 and IL-8 were measured in BAL fluid and serum.

Results: BAL fluid concentrations were not significantly different for IL-1 β (14324 pg/ml MV group vs. 9287 pg/ml MV + TTDN group, $p = 0.27$), IL-6 (210.7 pg/ml MV group vs. 186.2 pg/ml MV + TTDN group, $p = 0.67$), or IL-8 (15814 pg/ml MV group vs. 15401 pg/ml MV + TTDN group, $p = 0.99$). Serum concentrations were significantly lower in the MV + TTDN group for IL-1 β (434.6 pg/ml MV group vs. 104.1 pg/ml MV + TTDN group, $p = 0.02$), IL-6 (182.1 pg/ml MV group vs. 30.7 pg/ml MV + TTDN group, $p = 0.03$), and IL-8 (35.0 pg/ml MV group vs. 13.2 pg/ml MV + TTDN group, $p = 0.04$).

Conclusion: BAL washings were taken both at the start and the end of the experiment and the initial wash may have initiated an inflammatory process that was independent of ventilation, confounding the BAL cytokine results. Transvenous phrenic-nerve-stimulated diaphragm contraction combined with protective mechanical ventilation on every second breath reduced biotrauma in healthy porcine lungs that were ventilated for 50 hours.

Intensive Care Medicine Experimental 2020, **8(2)**: 000721

Introduction: The OxVent [1] is a low-cost volume control mechanical ventilator designed to be rapidly produced at scale to meet a large and sudden increase in ventilators' need, like during the COVID-19 pandemic. It is based on a pneumatic core component driven by compressed air flow controlled by a solenoid valve. Near-patient spirometry measures delivered tidal volume and solenoid actuation is adjusted by a closed feedback loop. Expiration occurs through a commodity mechanical PEEP valve. The device has been characterised on the bench to meet the UK rapidly manufactured ventilator system requirements [2].

Objectives: Determine the performance of the OxVent in uninjured and lung-lavaged pigs.

Methods: Variations in PEEP and tidal volume were set on the OxVent in a protocolised manner both before and after surfactant depletion with saline lung lavage in 4 anaesthetised and paralysed pigs (30 (1) kg; mean (SD)). Set tidal volumes (VTset) ranged from 170 to 340 mL (6 to 11 mL/kg). Respiratory rate (RRset) was set at either 16 or 28 min⁻¹ to maintain minute ventilation around 170 mL/min/kg. PEEP was varied between 5, 10 and 20 cmH₂O (PEEPset). Airway flow and pressure waveforms were measured independently (Datex-Ohmeda Capnomac Ultima) and analysed to determine actual tidal volume (VTact) and PEEP (PEEPact). End-expiratory lung volume (EELV) was measured using a sulphur hexafluoride washout technique.

Results: Lung lavage decreased respiratory system compliance from 22 (5) to 15 (5) mL/cmH₂O ($P < 0.001$), EELV from 570 (158) to 272 (97) mL ($P = 0.04$), and PaO₂/FiO₂ ratio from 438 (39) mmHg to 298 (133) mmHg ($P = 0.11$), all measured at PEEP 5 cmH₂O. Airway resistance was 7.8 (2.8) cmH₂O/L/s.

VTact correlated with VTset ($R2 = 0.71$, gradient of regression line 1.02), mean bias was -1 [-11 to 9] mL (mean [95% confidence interval]) with 95% limits of agreement -90 [-107 to -73] mL and 88 [71 to 105] mL. PEEPact was 3.9 (1.2), 8.1 (1.9) and 13.7 (14.8) cmH_2O for PEEPset of 5, 10 and 20 cmH_2O respectively. Airway pressure did not drop to PEEPact immediately during expiration, but remained 2.7 [2.5 to 2.9] and 1.1 [1.0 to 1.2] cmH_2O above PEEPset respectively at 50% and 75% of the expiratory period. End-expiratory flow was 50 (17) and 88 (15) mL/s respectively at PEEPset 5 and 20 cmH_2O .

The presence of lung injury did not alter any outcome measure.

Conclusion: The OxVent delivered tidal volumes and PEEP similar to those set over a wide range in uninjured pigs and those with a saline-lavage lung injury model. The commodity PEEP valve was unable to maintain PEEP at the set value and our tests identified an expiratory flow limitation, which was not apparent on bench-top testing. This flow limitation was PEEP-dependent, suggesting that the valve was the culprit. The system has since been redesigned following profiling of the valve. Rapidly developed safety critical devices for pandemic use should still be thoroughly tested *in vivo* over a range of typical usage scenarios to mitigate all possible risks to patients.

The Effect of Closed Loop Ventilation on Mechanical Power – results from a pilot study of Adaptive Support Ventilation

L.A. Buiteman-Kruizinga¹; H.E. Mkadmi²; M.J. Schultz²; P.L. Tangkau¹; P.L.J. Van Der Heiden¹

Intensive Care Medicine Experimental 2020, **8(2)**: 000785

Introduction: ‘Mechanical Power of ventilation’ (MP) is a summary variable that includes tidal volume (VT), respiratory rate (RR), flow and driving pressure (ΔP), all the components that play a role in VILI [1]. MP has been shown to be associated with important patient-centered outcomes [2]. The complex interplay between its components makes it difficult to set a ventilator so that the least amount of energy per time (MP) is transferred from the ventilator to the respiratory system in an individual patient. Adaptive Support Ventilation (ASV) is a closed-loop mode that provides pressure-controlled or pressure-support ventilation depending on patient’s activity. With ASV, all components that can cause VILI are under control of the ventilator.

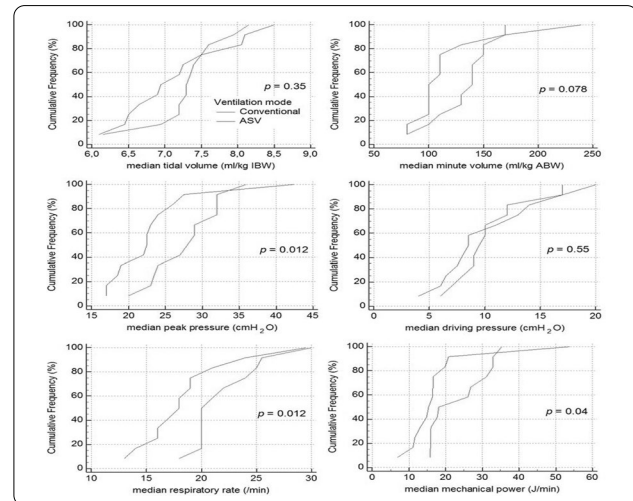

Objectives: The aim of this study is to compare MP under ASV and under conventional ventilation.

Methods: We calculated and compared MP in 12 patients under standard ventilation in which VT, peak- and driving pressure, and RR were set by experienced caregivers, with MP in 12 patients under ASV. Patients were sedated and without spontaneous breathing activity. MP was calculated three times per day over the first 4 days of ventilation, using the following equation [3]: $0.098 * VT * RR * (P_{\text{peak}} - \frac{1}{2} * \Delta P)$ A linear mixed model regression was used to assess the effect of time (as random factor) on MP. The regression was adjusted for ventilation mode and gender as fixed factors, and the APACHE IV score as a covariate. A p-value < 0.05 was considered significant. This pilot study was performed on the ICU in the Reinier de Graaf hospital in Delft, the Netherlands, from march till august 2019.

Results: Median MP was 15.1 [6.1–32.0] J/min with ASV versus 22.9 [4.9–49.1] J/min with conventional ventilation (mean difference 6.2 J/min). MP with ASV was lower at all time points data were collected.

Linear mixed model regression analysis showed that the factor ventilation mode was statistically significant (95%–confidence interval 1.45 to 11.62, $P = 0.013$). With ASV, VT was not different from that with pressure controlled ventilation, but Ppeak and RR were significantly lower ($P = 0.012$) (Figure 1).

Conclusion: Findings of this pilot study suggest that concerning the MP transferred from the ventilator to the respiratory system, ASV is superior to standard ventilation. This effect is not achieved by simple limitation of VT alone, but by a reduction in applied pressure and RR.

Intensive Care Medicine Experimental 2020, **8(2)**: 000881

Introduction: Expiratory Flow Limitation (EFL) is an inability to exceed a certain flow regardless of the pressure exerted, which accounts for 60% of extubation failure. However, a spontaneous breathing trial (SBT) method that suits for this specific condition is uncertain.

Objectives: We aimed to evaluate an effect of 30-minute T-piece and 30-minute pressure support ventilation (PSV) on a success rate of extubation in patients with EFL.

Methods: We conducted a non-inferiority randomized controlled trial comparing 30-minute T-piece SBT and 30-minute SBT with PSV (PS 6 cmH₂O and PEEP 5 cmH₂O) in mechanically ventilated patients with EFL who were considered as readiness to wean. The primary outcome was successful extubation (72-hour ventilator free after extubation). Secondary outcomes were a reintubation rate, time to reintubation, and a success rate of SBT.

Results: A total of 40 ventilated patients with EFL were recruited. The majority of them were male (62.5%) with the median age of 72[IQR 21] years. The most common cause of acute respiratory failure was the intrapulmonary cause (87%). The eligible patients were randomized into 2 groups: 21 patients in the T-piece group and 19 patients in the PSV group. The success rates of extubation were not significantly different between 2 groups: 85.71% in the T-piece group and 84.21% in the PSV group, $p = 0.62$. There were no significant differences in the reintubation rate (9.52% in the T-piece group VS 5.26% in the PSV group, $p = 0.54$), time to reintubation (41 hours in the T-piece group VS 6.5 hours in the PSV group, $p = 0.221$) and the SBT success rate (95.24% in the T-piece group VS 89.47% in the PSV group, $p = 0.462$).

Conclusion: Among the patients with EFL, the 30-minute T-piece SBT was non-inferior to the 30-minute SBT with PSV in terms of the successful extubation, successful SBT, reintubation rate and time to reintubation.

Intensive Care Medicine Experimental 2020, **8(2)**: 001100

Introduction: Patients with severe coronavirus disease 2019 (COVID-19) often need admission to an intensive care unit (ICU) for invasive ventilation [1]. This new disease often challenged the caregiver to initiate ventilation in a lung protective manner. The ‘mechanical power of ventilation’ (MP), a summary variable that includes all components that play a role in worsening of lung injury, is associated with outcome in patients with ARDS from another cause. Fully-automated ventilation has been shown to reduce MP in patients not having COVID-19 [2]. Whether fully-automated ventilation affects MP in COVID-19 patients is uncertain.

Objectives: The aim of this study is to compare MP under INTELLiVENT-ASV, a fully-automated mode of ventilation, versus conventional ventilation in COVID-19 patients.

Methods: Observational crossover study performed in the ICU in the Reinier de Graaf Hospital in Delft, The Netherlands, during the first

months of the outbreak from march till May 2020. Ventilation variables and parameters, necessary to calculate MP, were collected in 31 invasively ventilated COVID-19 patients—2 hours during pressure controlled ventilation (conventional ventilation) and 2 hours during INTELLiVENT-ASV (fully-automated ventilation). During conventional ventilation, tidal volume (VT) peak and driving pressure (Ppeak and ΔP), and respiratory rate (RR) were set by the caregivers strictly following the local guideline for invasive ventilation. During fully-automated ventilation, these settings were under control of the ventilator, and a target etCO₂ and SpO₂ was set as targeted with conventional ventilation. MP was calculated using the following equation [3]: $0.098 * VT * RR * (P_{peak} - \frac{1}{2} * \Delta P)$

Mean MP during conventional ventilation and fully-automated were compared using paired T-test; a p-value < 0.05 was considered statistically significant.

Results: Mean MP under conventional ventilation was 31.5 J/min (SD 13.9) and 22.4 J/min (SD 9.2) under fully-automated ventilation (mean difference 9.1 J/min; 95%-confidence interval 6.1 to 12.2, $P = < 0.0001$). Individual data are shown in the figure.

Conclusion: INTELLiVENT-ASV is superior to conventional ventilation with respect to the amount of energy transferred from the ventilator to a patient’s respiratory system in invasively ventilated COVID-19 patients.

Why recording ideal body weight matters

S. Nasser¹

¹Intensive Care Department, Surrey and Sussex Healthcare NHS Trust, Redhill, United Kingdom

Correspondence: S. Nasser

Intensive Care Medicine Experimental 2020, **8(2)**: 000032

Introduction: ARDSNet demonstrated 22% increased mortality in patients ventilated at 11.8 ml/kg rather than 6.2 ml/kg, with the promotion of lung inflammation as a possible mechanism for its deleterious effects [1]. Lung protective ventilation however, depends on the

correct assessment of the patient's Ideal Body Weight (IBW). Measurement and accurate recording of IBW is, therefore, of fundamental importance in the Intensive Care Unit (ICU), to enable implementation of lung protection strategies.

Objectives: Assessment of recording of patient weight in a UK District General Hospital ICU, with analysis of implications in discrepancies between recorded weight and IBW as measured by ulna-length, on lung-protective ventilation strategies.

Methods: Collection of recorded weights for 49 patients admitted to ICU between 06/11/2019–27/11/2019 and comparison to IBW using ulna-length measurement to calculate IBW.

Results: IBW was not the recorded weight in any patients (22 female; 27 male), with only actual body weight (ABW) recorded, derived from visual estimation, measured weight, or from pre-admission notes. The recorded weight was, on average, 1.3 times higher than IBW as derived from ulna-length measurement. Had 8 ml/kg tidal volumes been used on patients at the recorded weight, the mean equivalent tidal volume delivered would have been 10.5 ml/kg of IBW (median 9.92 ml/kg), giving an average higher tidal volume of 147 ml. For the 16 obese patients in the sample (BMI > 30) the corresponding values were 13.04 ml/kg of IBW and 296 ml.

Conclusion: In the UK, 28.7% of the population are obese (BMI > 30) with 3.6% morbidly obese (BMI > 40) [2], constituting around 20% of ICU admissions [3]. Obese individuals are more prone to Acute Respiratory Distress Syndrome [4] due to de-recruitment and atelectasis as well as a decreased Functional Residual Capacity [5], and thus have been posited as a population requiring more aggressive implementation of ventilation protection strategies. Yet this is precisely the population most prone to erroneous recording of their IBW, and thus, overventilation, due to failure to proactively record IBW rather than ABW. Whether through ulna-length derived values or through direct measurement of patient height, recording of IBW with a standardised method should be a high priority for any patients admitted to ICU.

Intensive Care Medicine Experimental 2020, **8(2)**: 000105

Introduction: Bronchoalveolar lavage (BAL) is a useful tool for the diagnostic evaluation and often performed under mechanical ventilation. The concerns about performing BAL in hypoxemic patients are shunt caused by administered fluid and/or loss of lung aeration during procedure, resulting in impairment of oxygenation. In mechanically ventilated patients positive end-expiratory pressure (PEEP) could maintain lung volume during BAL, however, the impact of BAL on regional ventilation and aeration has not been fully investigated. Electrical impedance tomography (EIT) can evaluate lung volume, regional

ventilation non-invasively in a real-time at the bedside. Fluid instillation in the lung decreases impedance value.

Objectives: The objective of this study was to examine the change in lung impedance throughout the BAL procedure in acute respiratory distress syndrome (ARDS) patients.

Methods: The moderate ARDS patients with bilateral ground-glass opacity were included. All patients were ventilated with pressure-controlled ventilation with PEEP of 5 to 10 cmH₂O. We monitored end-expiratory lung impedance (EELI), which is impedance value at the end of expiration and corresponds to end-expiratory lung volume. The measurements were performed at four time points, (1) before BAL, (2) during fiberoptic examination, (3) after instillation of fluid for lavage, (4) 15 min after completion of BAL. The value of EELI at before BAL was defined as baseline, and changes in EELI from at before BAL were calculated at each time point and expressed as a percentage of tidal impedance change at before BAL. The change in EELI was analyzed by one-way ANOVA with repeated measures and Turkey test as post-hoc analysis. PaO₂/FIO₂ ratio before and after BAL was compared by paired t test.

Results: Five patients were included. The entire procedure was finished within 20 min in all cases. Mean collected volume of fluid was 45% of administered fluid. EELI significantly changed during the entire course of the procedure (P = 0.024). EELI at after instillation of fluid for lavage was significantly decreased from at before BAL (mean values: -53 ± 16%, P = 0.030). However, EELI was recovered gradually after removal of bronchoscopy towards the level of at baseline, showing no significant difference at 15 min after completion of BAL (mean values: -43 ± 16%, P = 0.103) compared to at before BAL. Mean difference in PaO₂/FIO₂ ratio between before and after BAL was -4 ± 20 (95% confidence interval, -60 to 52) and no significant difference was detected.

Conclusion: Lung impedance value significantly decreased during BAL, probably due to saline instillation, collapse in the lung during the procedure etc. However, it recovered promptly resulting in maintenance of oxygenation.

Intensive Care Medicine Experimental 2020, **8(2)**: 000325

Introduction: Pulmonary dysfunction in trauma patients may be induced by a variety of causes. In addition to the trauma-related etiologies, mechanical ventilation itself may contribute to the deterioration of respiratory function through ventilator induced lung injury or the impairment of respiratory muscle function. Ventilator-induced diaphragmatic dysfunction (VIDD) is an entity induced by the inactivity during invasive mechanical ventilation, associated with a profound loss of diaphragm muscle mass.

Methods: In order to assess the incidence of VIDD in polytrauma patients we performed an observational, retrospective, longitudinal study which included 24 polytraumatized patients, who were mechanically ventilated for at least 48 h and underwent two chest CT scans for clinical reasons during their ICU stay. Diaphragmatic thickness was measured by two independent radiologists on coronal and axial images, at the level of celiac plexus. Statistical analysis was performed using MedCalc 14.1, applying T-test and correlation tests.

Results: Mean age in the study group was 59 years old, APACHE II score had a mean value of 19 and the Injury severity score 35. The mean duration between chest CT scans was 7 days. The thickness of the diaphragm was significantly decreased on both the left and right sides (left side: -0.82 mm axial p = 0.034; -0.79 mm coronal p = 0.05; right side: -0.94 mm axial p = 0.016; -0.91 coronal p = 0.013). In addition, we obtained a positive correlation between

the number of days of mechanical ventilation and the difference between the two measurements of the diaphragm thickness on both sides ($r = 0.5$; $p = 0.02$). There was no statistically significant correlation between the body mass indexes on admission, use of vitamin C or N-acetyl cysteine and the differences of diaphragmatic thickness.

Conclusion: Considering prioritization of life-threatening injuries in the trauma care, secondary dysfunctions such as VIDD are often overlooked. This study provides evidence of early impairment of diaphragm after mechanical ventilation in polytraumatized patients. Moreover, we obtained that a prolonged period of mechanical ventilation is proportional with the loss of diaphragmatic thickness.

Intensive Care Medicine Experimental 2020, **8(2)**: 000360

Introduction: We hypothesized that the lack of benefit of low vs. high positive end-expiratory pressure (PEEP) in patients with acute respiratory distress syndrome may partly come from a difference in the dynamic behavior of the active expiratory valve in ICU ventilators.

Objectives: Our goal was to compare the resistance of the expiratory valve across current ICU ventilators on the bench.

Methods: Seven current ICU ventilators (C5, C6, Carescape, PB980, ServoU, V500 and V680) were attached to an ASL 5000 lung model set in passive condition with compliance 20 ml/cmH₂O and resistance 5 cmH₂O/L/s. Ventilators were set in volume-controlled mode with a tidal volume of 0.8 L and respiratory rate of 10 breaths/min. Flow and pressure were measured just before the exhalation valve. PEEP was set at 5, 10 and 15 cmH₂O. Flow and pressure signals were acquired at 200 Hz (Biopac 150). On three consecutive breaths the instantaneous expiratory resistance was computed as the pressure drop to atmosphere divided by the flow. The valve opening delay was measured as the maximal slope of pressure-flow relationship from zero flow to peak flow. Finally, the time spent with PEEP above or below the set value, ie the pressure-time product (PTP) was computed. The median value of instantaneous expiratory resistance was taken as the primary end-point. Median (1st–3rd quartiles) were compared by two-factor ANOVA. P-value was set to $P < 0.0007$ to take into account the number of comparisons done.

Results: The median instantaneous expiratory resistance was significantly different between ventilators and PEEP with a significant interaction between them. Therefore, ventilators were compared at each PEEP. Between C5, C6, Carescape, PB980, ServoU, V500 and V680, the median expiratory resistance was 3.9 (3.5–4.7), 3.0 (3.0–3.1), 20.9 (15.8–24.9), 27.4 (26.5–43.2), 13.8 (13.6–13.9), 4.4 (4.0–4.6) and 34.3 (33.7–33.8) cmH₂O/L/s, respectively, at PEEP5 ($P < 0.0007$ with all pairwise differences $P > 0.0007$). Over all PEEP, the corresponding opening delay was 0.080 (0.077–0.082), 0.082 (0.080–0.085), Carescape 0.110 (0.105–0.110), 0.100 (0.085–0.105), 0.072(0.062–0.072), 0.145 (0.115–0.150) and 0.075 (0.070–0.080), respectively. Over all PEEP PTP was 2.8 (2.1–7.4), 6.8 (6.7–7.3), 2.4 (2.1–2.4), 3.5 (2.7–3.6), 1.8 (1.8–2.1), 2.8 (2.7–2.9), and 5.7 (5.4–5.9) cmH₂O.

Conclusion: We found on the bench that the resistance of active expiratory valve significantly differ between seven current ICU ventilators.

Intensive Care Medicine Experimental 2020, **8(2)**: 000361

Introduction: COVID-19 pandemics has set the healthcare system to a shortage of ventilators. Among the strategies to overcome this burden one is to divide the same ventilator to more than one patient.

Objectives: We aimed at assessing tidal volume (VT) delivery and air recirculation during expiration when one ventilator is divided to 2 patients. We designed the study to mimic nonsymmetrical impairment in respiratory mechanics.

Methods: We performed a bench study in a research lab taking part of a University medical ICU. Four ventilators (V500, Servo-I, MonnalT60 and Elisee350) were attached to A and B test-lungs (QuickLung) through a dedicated flow-splitter (Michelin, France). A 50 mL/cmH₂O Compliance (C) and 5 cmH₂O/L/s Resistance (Rp) were set in both (C1 condition), C50Rp20 in A/C20Rp20 in B (C2), C20Rp20 in A/C10Rp20 in B (C3), and C50Rp20 in A/C20Rp5 in B (C4). Each ventilator was set in volume-controlled (VCV) and pressure-controlled (PCV) mode targeting 0.8L as delivered global volume. VT was measured from a pneumotachograph placed immediately before each lung. Values are median (1st–3rd quartiles) and compared between ventilators by Kruskal-Wallis test in each condition.

Results: In VCV VT was greater in A than in B by a factor of 1.83 (1.22–2.07), 2.14 (1.68–2.15), and 1.65 (1.27–1.67) for C2, C3 and C4 conditions, setting A to risk of overdistension. In PCV targeted VT was maintained in each lung for A in C2 (0.388L (0.321–0.540)) and C4 (0.445L (0.416–0.454)), but not in C3 (0.180L (0.169–0.368)). The corresponding VT in B were 0.230L (0.147–0.342), 0.320L (0.185–0.338), and 0.09L (0.08–0.18), respectively. Recirculated air was substantial in VCV, 53 mL in C4, setting risk to cross-infection, but negligible in PCV.

Conclusion: Dedicating one ventilator to two or three patients is feasible. For safety reasons, due to dependence of VT to C and risk of cross-contamination, the ventilator should be set in PCV in order to maintain adequate in VT at least in one patient when C and/or Rp changes abruptly and monitoring of VT should be done carefully.

Intensive Care Medicine Experimental 2020, **8(2)**: 000543

Introduction: Esophageal pressure monitoring could help clinicians to better tailor ARDS-patients ventilatory setting, to reduce the risk of VILI; however, it has been mainly used in clinical research and not in daily clinical practice, mostly because of technical difficulties and the inability to obtain easy and accurate measurements. Recently, an automatic monitoring system (Optivent, Sidam Srl, Modena, Italy), able to directly measure both airway pressure and esophageal pressure, has been released.

Objectives: Aim of this study was to compare measurements of respiratory mechanics in ARDS patients by using a dedicated manual device, assumed as gold standard, with those obtained by two other systems: Optivent and a bedside equipment. We focused on end-expiratory esophageal pressure, end-expiratory transpulmonary pressure and lung stress.

Methods: Forty mechanically ventilated sedated and paralyzed ARDS patients admitted in the intensive care unit (ICU) from February to September 2019, were enrolled. Patients were ventilated with a tidal volume between 6–8 ml/kg of predicted body weight and a respiratory rate to maintain an arterial pH between 7.30 and 7.45. Esophageal pressure was measured by using a radiopaque catheter equipped with a balloon (Nutrivent, Sidam Srl., Modena, Italy). Measurements of the airway pressure and esophageal pressure during end-inspiratory and end-expiratory pauses were performed at three levels of PEEP, randomly applied: clinical level, 50% higher and 50% lower.

- **Optivent system:** Optivent is an automatic self-calibrating system composed by a touchscreen monitor directly connected to the patient with a real time airway and esophageal pressure measurements;
- **Bedside system:** This hybrid system is composed by the ventilator and the patient's hemodynamic monitor. Airway pressure was measured by the mechanical ventilator and esophageal pressure by a pressure transducer (TruWave/VAMP Plus, Edwards Lifesciences, Unterschleissheim) connected to a hemodynamic monitor.
- **Dedicated system:** The airway and esophageal pressure were measured by pressure transducers and recorded on a personal computer using a specific software for subsequent analysis (Coligo, Elekton, Milan, Italy).

Results: End-expiratory esophageal pressure measured by the dedicated system, the bedside system and Optivent were 10.0 ± 4.2 , 10 ± 4 and 9.9 ± 4.0 cmH₂O, respectively. End-expiratory transpulmonary pressures, respectively computed with data acquired by the dedicated system, bedside system and Optivent, were -1.6 ± 4.6 , -1.4 ± 4.5 and -1.2 ± 4.3 cmH₂O. Lung Stress values, respectively computed with data acquired by dedicated system, bedside system and Optivent, were 14.0 ± 5.8 , 15.0 ± 6.6 , and 15.0 ± 6.1 cmH₂O. Both Optivent and the bedside system exhibited a high correlation with the dedicated system for all the three investigated variables. The respective bias and limits of agreement between the dedicated system and Optivent and between the dedicated system and the bedside system were as follows: end-expiratory esophageal pressure, 0.25 cmH₂O, (-0.4 to 0.9) and -0.1 cmH₂O (-1.9 to 1.7); end-expiratory transpulmonary pressure, -0.6 cmH₂O (-1.7 to 0.4) and -0.4 cmH₂O, (-2.2 to 1.5); lung stress -0.9 cmH₂O (-3.00 to 1.10) and -1.50 cmH₂O (-4.4 to 1.4).

Conclusion: Both Optivent and the bedside system present clinical acceptability in measuring esophageal pressure and its derived variables. The possibility to apply one of these systems could make the measurement of esophageal pressure easier, with a consequent wider application in clinical practice.

Intensive Care Medicine Experimental 2020, **8(2)**: 000655

Introduction: In northern France during March of 2020, a surge in patients presenting with infection and acute respiratory failure (ARF) from the novel 2019 coronavirus prompted urgent action. The surge created a heavy burden on French hospital facilities and finances. This paper contains an assessment of the health and cost benefits obtained by the construction of a temporary intermediate care unit (IMCU) with an advanced remote monitoring system. Facilities that include an IMCU in combination with ICUs have demonstrated significantly lower mortality rates in large multinational studies. [1] Improved health outcomes were an expected result. Furthermore, the addition

of real time patient remote monitoring in the form of telemedicine in ICUs has been proven to reduce both mortality and length of stay (LOS) within critical care. [2] Over a three-day period, a team built a temporary IMCU with an advanced monitoring system in Avicenne Hospital, Bobigny France.

Methods: Mimicking modern ICU and emergency department telemonitoring systems, the network in the IMCU consisted of a 10-bed facility connected to a central workstation. The central workstation allowed a staff-worker who remained isolated from the infected patients to monitor respiratory data and pulse oximetry.

The system would display real time data along with patient alarms through connection to a dedicated USB port on a portable life-support ventilator, (TrilogyEvo, Philips Respironics, USA). The workstation had dedicated software to review all patient data and it included a mathematical algorithm determining the degree of patient-ventilator asynchrony. [3] This station contained an early warning system (EWS) to alert the clinical staff in the IMCU when it was appropriate to intervene.

Results: As a result, 40 patients were treated during the month of April in the Avicenne IMCU. Twenty-four patients (60%) treated at the IMCU had ARF but were considered ineligible for ICU due to frailties such as age (≥ 80) or high-risk comorbidities. The expected mortality of this critical population with ARF is near 49% [4, 5]. 4 patients in this cohort (17%) died, thus exceeding survival expectations. 12 patients (30%) were admitted into the IMCU due to a progression from mild to severe Covid-19 related hypoxemia. Within this cohort, 4 patients (33%) progressed to the ICU. 4 patients (10%) were admitted into the IMCU following discharge from the ICU, and 1 patient (25%) was readmitted to the ICU.

The incidence of alerts prompting intervention were HR (<50 or >120) = 3.1 ± 7.5 alarm/hour, SpO₂ (<90) = 8.1 ± 10.0 alarm/hr and leak (>40 L/min) = 6.7 ± 12.9 alarm/hr. (Total = 17.9 alerts/hour). 280 ICU bed days were spared in the month of April 2020 due to the construction of this ICU. According to the cost data collected from 7 European countries, the average daily cost in ICU is approximately 1850€, resulting in a computed savings of 518 k€ [6].

Conclusion: The construction of a temporary IMCU, using advanced telemonitoring with an EWS, successfully improved patient outcomes and reduced the financial burden on the hospital system. The frequency of interventional care recorded within this unit was once per 3.5 minutes on average. Without alerts, this level of care would require continuous, rotating bedside contact by staff. Consequently, the directed interventions from the central workstation may have reduced exposure times.

A tidal volume calculator to improve lung protective ventilation in COVID-19 related Acute Respiratory Distress Syndrome (ARDS)

J. Blair¹; A. Baldwin²; S. Hester¹; T. Ali²

¹Intensive care, The Shrewsbury and Telford Hospital NHS Trust, Shrewsbury, United Kingdom; ²Intensive care, Stoke Mandeville Hospital, Stoke Mandeville, United Kingdom

Correspondence: J. Blair

Intensive Care Medicine Experimental 2020, **8(2)**: 000687

Introduction: Routine use of lower tidal volumes (TVs) for the mechanical ventilation of patients with ARDS results in decreased mortality and increases the number of days without ventilator use [1]. Severe COVID-19 pneumonia has been associated with the development of ARDS as characterised by the Berlin definition [2]. A multi-centre preliminary audit was undertaken to identify whether ventilated COVID-19 related ARDS patients were receiving optimal TVs, as recommended by the Faculty of Intensive Care Medicine (FICM) and Intensive Care Society (ICS) ARDS management guidelines [3].

Objectives: As a result of the audit, three main areas for improvement were identified.

1. To achieve accurate calculations for ideal body weight (IBW) and target TV
2. To improve documentation of IBW and target TV
3. To achieve TVs no greater than 6 ml/kg

Methods: A ‘tidal volume calculator’ tool was developed using Microsoft Excel, which was simple, colour coded and kept on all Intensive Care Unit (ICU) computer desktops. This tool was designed to use height to calculate IBW and, if the patient’s height was unavailable, could also be utilised to calculate height from ulna length. IBW was subsequently used to calculate a target TV. Staff received training on how to apply the tool.

Two snapshot audits were carried out in April and May 2020 at two ICUs. The first was conducted prior to the tool’s introduction with the second two weeks after its implementation. All patients receiving mechanical ventilation, except those spontaneously breathing, were included. Data was extracted from patient notes, charts and ventilator settings.

Results: The initial audit included 14 patients. Six patients did not have an IBW documented. Three patients had documented IBWs that were 12 kg, 15 kg and 23 kg greater than the weight calculated using the tool, leading to increased tidal volume targets. Only three patients were achieving TVs of 4–6 ml/kg. Eleven patients were achieving a TV greater than 6 ml/kg, with two of these achieving a TV of greater than 8 ml/kg.

The follow-up audit included ten patients. This revealed that all patients had an IBW clearly documented. Moreover, nine patients were achieving TVs within 4–6 ml/kg, with only one patient found to be achieving a TV greater than 6 ml/kg.

Conclusion: This audit cycle revealed that initially adherence to lung protective ventilation and documentation of IBW was poor. In some instances, documented IBW was vastly different to the calculated IBW, suggesting that in these situations actual body weight may have been used.

In a time when clinicians were being redeployed to support ICU, this simple tool was shown to support staff by clearly calculating and displaying IBW and target TV for reference. This directly led to improved adherence to lung protective ventilation and optimisation of patient care.

Limitations include that no consideration was made for overall patient outcome, and only a snapshot of achieved TVs from ventilators were recorded; daily/weekly trends were not studied.

End tidal CO2 in out of hospital intubated critically ill patients: Is it a reliable surrogate for plasma CO2 concentration?

S. Naeem¹; S. Bloomfield²; J. Leung³; R. Lyon⁴

¹Accident and Emergency, East Kent Hospitals University Foundation Trust, Maidstone, United Kingdom; ²Accident & emergency, East Kent Hospitals University Foundation Trust, Maidstone, United Kingdom; ³Accident & emergency, East Kent Hospitals University Foundation Trust, Ashford, United Kingdom; ⁴Hems, Air Ambulance Kent Surrey Sussex, Redhill, United Kingdom

Correspondence: S. Naeem

Intensive Care Medicine Experimental 2020, **8(2)**: 000896

Introduction: End tidal CO2 (ETCO2) monitoring is a standard for all intubated patients in the pre-hospital environment. ETCO2 is used as surrogate marker for determining plasma CO2 concentration (pCO2) in intubated patients as pCO2 measurement is not readily available in the resource limited pre-hospital environment. Maintenance of normocapnia (4.4–5 kPa) is crucial for neuroprotection in critically ill patients.

Objectives: The objective was to determine whether ETCO2 can serve as a reliable surrogate marker for pCO2.

Methods: Data was retrospectively collected from the Air Ambulance Kent, Surrey and Sussex hospital database for critically ill non-trauma patients conveyed to the William Harvey Hospital between September 2017 and March 2019. The latest pre-hospital ETCO2 value was paired with pCO2 values from initial blood gas results. Patient demographics, pre-hospital haemodynamic instability (use of vasopressor), other blood gas parameters and mortality within the same admission were also recorded. The paired data sets were analysed using the Mann-Whitney test.

Results: 18 data sets that met the inclusion criteria were generated. Median ETCO2 and pCO2 was 4.4 kPa (IQR 3.9-4.8 kPa) and 7.3 kPa (6.5-9.4 kPa) respectively. Median difference between ETCO2 & pCO2 was significant 3.0 kPa (p<0.001, CI 2.6-3.6 kPa). Median ETCO2, pCO2 and difference was 4.4 kPa (IQR 4.0- 4.5 kPa), 7.2 kPa (IQR 6.5-8.0 kPa) and 3.3 kPa (IQR 2.1-3.6 kPa) respectively in patients who survived. Median ETCO2, pCO2 and difference was 4.3 kPa (IQR 4.0-4.5 kPa), 8.3 kPa (IQR 7.0-11.3 kPa) and 3.0 kPa (IQR 2.9-4.5 kPa) respectively in patients who died. Median difference was not significantly associated with mortality (p = 0.69). The median difference between the pCO2 and ETCO2 in cardiovascularly stable vs unstable patients was 3.0 kPa and 3.4 kPa and was not statistically significant (p = 0.59).

Table 1: Comparison of ETCO2 and PCO2 values

Measurement	n	Median [IQR]	Difference (*)	P-value
			Median (95% CI)	
ETCO2	18	4.4 [3.9, 4.8]	0	
PCO2	18	7.3 [6.5, 9.4]	3.0 (2.6, 3.6)	<0.001

(*) Differences calculated as PCO2 – ETCO2

Measurement	Stable		Unstable		P-value
	n	Median [IQR]	n	Median [IQR]	
ETCO2	7	4.5 [4.0, 5.5]	11	4.3 [3.5, 4.4]	0.13
PCO2	7	7.3 [6.5, 8.8]	12	7.6 [6.6, 10.7]	0.93
CO2 difference (*)	7	3.0 [2.5, 3.3]	11	3.4 [2.1, 4.5]	0.59

(*) Differences calculated as PCO2 – ETCO2

Conclusion: ETCO₂ is an unreliable surrogate marker of pCO₂ and consistently underestimates the true pCO₂ value by 3.0 kPa [C.I 2.6-3.6 kPa]. The use of vasopressor does not appear to significantly impact the ETCO₂ and pCO₂ difference. Hence ETCO₂ should not be used to determine normocapnia in the pre-hospital environment.

Intensive Care Medicine Experimental 2020, **8(2)**: 000942

Introduction: Lung protective ventilation (LPV) is an essential strategy in the management of patients mechanically ventilated due to severe respiratory failure, including those with COVID-19. When utilised, LPV has been proven to reduce absolute mortality by 8.8% and significantly increase ventilator free days (1). Despite this, a recent study of 459 ICUS's from across 50 countries found that only 65% of patients received adequate LPV and 35% actually received potentially harmful volumes [2]. To manage the increased numbers of mechanically ventilated patients during the COVID-19 pandemic, a ventilation team was created to support the management and adherence to LPV targets.

Objectives: To evaluate the impact of a multi-faceted approach to ventilatory management on adherence to LPV targets.

Methods: A new supportive ventilation team was created, utilising existing members of the physiotherapy service with training taking place in March 2020, with a focus on promoting compliance with LPV. After an initial training period, this team implemented a multi-faceted approach to ventilatory management. This included measurement of patient height on admission and calculation of ideal body weight, documented LPV targets in each bed space on whiteboards and twice daily physiotherapy led ventilation ward rounds to review and amend ventilator settings as required. Hourly tidal volume data was collected for all patients mechanically ventilated over a 2 month period during the COVID-19 pandemic (April–May 2020) and compared to a 2 month baseline period (January–February 2020). Primary outcome was compliance with target tidal volumes of < 8 ml/kg, with secondary outcome was PEEP/FiO₂ compliance. Data was analysed using Chi Square test.

Results: A total of 62,656 hours of mechanical ventilation were included for analysis, with the results presented in table. 1. The introduction of the ventilation team was associated with a significant increase in compliance with target tidal volumes of < 8 ml/kg (76% vs 69%, p<0.0001) and a significant reduction in occurrence of volumes >10 ml/kg (4% vs 10%, p<0.0001). No significant differences were observed with regards to PEEP/FiO₂ compliance.

	Baseline (Pre COVID)	Ventilation Team (COVID)	P
n	25237	38529	
< 8mls / kg (hours)	17290 (69%)	28086 (76%)	<0.0001
> 10mls / kg (hours)	2590 (10%)	1424 (4%)	<0.0001

Figure 1 – Percentage hours at each lung volume

Conclusion: The implementation of a specialist ventilation team was associated with a significant improvement in compliance with LPV targets for tidal volumes. This also led to a significant reduction in the percentage of ventilation hours in which patients may receive potentially harmful tidal volumes.

Central venous pressure swing outperforms diaphragm ultrasound as a measure of inspiratory effort during pressure support ventilation in covid-19 patients

S. Lassola¹; S. Miori¹; A. Sanna¹; A. Cucino¹; S. Magnoni¹; M. Umbrello²

²Anestesia e rianimazione, Ospedale San Paolo – Polo Universitario, ASST Santi Paolo e Carlo, Milano, Italy

Correspondence: S. Magnoni

Intensive Care Medicine Experimental 2020, **8(2)**: 000968

Introduction: An increasing number of patients required prolonged mechanical ventilation during the recent COVID-19 pandemic. The associated shortage of ICU beds and monitoring devices magnified the need of simple tools to properly titrate the level of ventilator assistances. Observation of breathing pattern with utilization of accessory muscles, rapid or shallow breathing, or the inspection of ventilator waveforms are not useful to assess breathing efforts in a quantitative way. Thus, appropriate bedside monitoring of inspiratory effort is strongly required.

Objectives: We investigated whether bedside-available indices such as the ultrasonographic changes in diaphragm thickening ratio (TR) and the tidal swing in central venous pressure (Δ CVP) are reliable

estimates of respiratory effort, as assessed by the tidal swing in esophageal pressure (ΔP_{es}).

Methods: Fourteen critically-ill patients were enrolled (age 64 ± 7 years, BMI 29 ± 4 kg/m²), after 6 [3; 9] days from onset of assisted ventilation. A three-level pressure support trial was performed, at 10 (PS10), 5 (PS5) and 0 cmH₂O (PS0). In each step, the esophageal and central venous pressure tidal swing were recorded, as well as diaphragm ultrasound.

Results: The reduction of pressure support was associated with an increased respiratory rate and a reduced tidal volume, while minute ventilation was unchanged. ΔP_{es} significantly increased with reducing support (5 [3; 8] vs. 8 [14; 13] vs. 12 [6; 16] cmH₂O, $p < 0.0001$), as did the diaphragm TR (9.2 ± 6.1 vs. 17.6 ± 7.2 vs. $28.0 \pm 10.0\%$, $p < 0.0001$) and the ΔCVP (4 [3; 7] vs. 8 [5; 9] vs. 10 [7; 11] cmH₂O, $p < 0.0001$). ΔCVP was significantly associated with ΔP_{es} ($R^2 = 0.810$, $p < 0.001$), as was diaphragm TR, albeit with a lower coefficient of determination ($R^2 = 0.399$, $p < 0.001$). In a multivariable, linear, fixed-effects regression, only ΔCVP was significantly associated with ΔP_{es} (coefficient: 1.45 ± 0.16 , $p < 0.001$), while diaphragm TR was not (coefficient: -0.07 ± 0.05 , $p = 0.184$).

Conclusion: In patients with COVID-19-associated respiratory failure undergoing assisted mechanical ventilation, ΔCVP is a better estimate of inspiratory effort than diaphragm ultrasound.

Noninvasive ventilation (NIV) in an intermediate care unit

H. van Nieuw Amerongen¹; J.J. Spijkstra¹; L. Heunks¹

¹Intensive care volwassenen, Amsterdam UMC, Amsterdam, Netherlands

Correspondence: H. van Nieuw Amerongen

Intensive Care Medicine Experimental 2020, **8(2)**: 000089

Introduction: In the past decades noninvasive ventilation (NIV) has obtained an important role in the treatment of patients with acute respiratory failure (ARF). Most NIV studies have been conducted in an intensive care unit (ICU) setting. There are studies which have shown that NIV can be performed safely and effectively outside the ICU. The outcome of patients failing NIV in an intermediate care unit remains to be established. The aim of the current study was to investigate the safety and feasibility of providing acute NIV in a heterogeneous group of patients with ARF in an intermediate care unit.

Methods: This study was a retrospective analysis of patients admitted to the intermediate care unit of Amsterdam UMC, location VUmc between January 2010 and January 2016. Patients with acute respiratory failure were included as well as those whose respiratory status slowly deteriorated, whatever underlying disease. Patients with CPAP at home or obstructive sleep apnea syndrome (OSAS) were excluded. Patients were subdivided into two categories: Hypercapnic failure and non-hypercapnic failure before the start of NIV. In both groups we analyzed admission source and their outcome (discharge destination).

Results:

RESULTS.

	Total group of patients	Hypercapnia group	Non hypercapnia Group
n (%)	241 (100)	75 (31)	152 (63)
Demographic characteristics			
Male sex (%)	150 (62)	43 (57)	100 (66)
Age (SD)	66 (16)	69 (14)	64 (16)
Location prior to admission			
General ward (%)	53 (22)	28 (37)	28 (18)
Intensive Care Unit (%)	110 (46)	22 (29)	81 (53)
Post Anaesthesia Care Unit (%)	32 (13)	9 (12)	19 (13)
Emergency Department (%)	39 (16)	14 (19)	20 (13)
Other (%)	7 (3)	2 (3)	4 (3)
Discharge location			
General ward (%)	109 (45)	25 (33)	76 (50)
Intensive Care Unit (%)	85 (35)	28 (37)	54 (36)
Died (%)	33 (14)	19 (25)	13 (9)
Other destinations (%)	14 (6)	3 (4)	9 (6)

NIV at intermediate care (n=241):

No arterial blood gas before start NIV (n=14)

Hypercapnia (n=75):

Endotracheal intubation (n=23): 4 patients died and 19 survived

No endotracheal intubation (n=52): 23 patients died and 29 survived

Non hypercapnia (n=152):

Endotracheal intubation (n=43): 10 patients died and 33 survived

No endotracheal intubation (n=109): 19 patients died and 90 survived

The admission diagnosis was heterogeneous: 36% of all the patients who received NIV was admitted to the intermediate care unit primarily for respiratory failure. The duration of NIV treatment ranged from 1 hour to more than 40 hours. Overall 61 of the 241 patients treated with NIV died within 28 days of the start of NIV on the intermediate care. They died either in the intermediate care unit (33 patients), or in the ICU after the transfer from intermediate care unit (12 patients), or elsewhere (16 patients). Patients dying in the intermediate care unit had do-not-intubate orders.

Conclusion: We found that it is feasible to treat patients with NIV in an intermediate care unit, both for hypercapnic and non-hypercapnic indications. There is a need for more studies to confirm the safety of providing NIV in an intermediate care setting.

Can a peak C-Reactive Protein in viral pneumonias patients during COVID-19 pandemic predict CPAP failure leading to invasive ventilation in Intensive Care? (Retrospective analysis)T. Wray¹; M. Mazalkov²¹Intensive Care, Peterborough City Hospital, Peterborough, United Kingdom;²Anaesthetics, Peterborough City Hospital, Peterborough, United Kingdom**Correspondence:** T. Wray*Intensive Care Medicine Experimental* 2020, **8(2)**: 000375

Introduction: C-reactive protein (CRP) is an acute inflammatory protein known to increase in those with COVID-19 pneumonia caused by the novel SARS-CoV-2 virus. Several studies have correlated an increased in pneumonia severity in those with higher CRP levels. Patients with severe/critical COVID-19 infections often require additional support with oxygenation and ventilation in the intensive care unit (ICU) in the form of Continuous Positive Airway Pressure (CPAP) or invasive mechanical ventilation (IMV).

Some critical care societies had advised during the initial phases of the 2020 pandemic for an “earlier” intubation in those with hypoxia resistant to standard oxygen therapy. Intubation and mechanical ventilation comes with its own risks, from the difficulty of intubating the critically ill patient to other ventilator associated complications in those who may have improved on CPAP alone. With CPAP there are concerns over viral aerosolization transmission to healthcare staff and insufficient hospital oxygen supply if it is extensively used during pandemic. A proportion of those started on CPAP will deteriorate and require intubation, but as yet there seems to be little evidence if CRP can help predict those who might deteriorate.

Objectives: To see if the initial peak CRP in patients started on CPAP can predict those who will go on to need invasive mechanical ventilation.

Methods: We included patients accepted to the Intensive Care Unit (ICU) during February to May 2020 who presented with viral pneumonia (either a laboratory confirmed SARS-CoV-2 viral PCR test or strong clinical suspicions of a COVID-19 infection) causing hypoxia refractory to standard ward oxygen supplementation. Patients in ICU were either immediately intubated and mechanically ventilated (primary IMV), or started on CPAP. No high flow nasal oxygenation was used at this hospital. Some of these patients improved on CPAP only and were successfully stepped down from ICU to the wards. Others on CPAP deteriorated and were subsequently intubated (CPAP failure). Excluded from the study were; patients on CPAP who died in ICU, patients who had a limit on respiratory therapeutic level of care to CPAP only, or were on still on CPAP in ICU at time of data collection. All patients included had their CRP (mg/L) measured at hospital admission and 1st peak level.

The results are presented as full sets of numbers for respective groups. Statistical analysis was performed using Kruskal-Wallis test.

Results: A total of 40 patients with viral pneumonia were identified. Of those in the CPAP group, 3 were excluded from analysis. This meant there were 70.3% (n=26/37) in the CPAP arm and 29.7% (n=11/37, mean age 67) who underwent primary IMV. Of those who started on CPAP 62.0% (n=16/26, mean age 56.4) were successfully discharged with only CPAP, while 38.5% (n=10/26, mean age 55) failed CPAP and underwent secondary intubation.

Patients for whom CPAP was successful had a mean peak CRP of 240 (110, 145, 153, 162, 173, 228, 230, 244, 245, 254, 268, 287, 304, 324, 350 and 359). Those who failed CPAP and underwent secondary intubation had a mean peak of 353 (204, 283, 298, 323, 329, 338, 345, 346, 526 and 538). For the primary intubation group the mean peak CRP was 342 (192, 212, 237, 314, 345, 345, 349, 349, 377, 493 and 547).

The difference in the peak CRPs was found to be statistically significant between the CPAP only group when compared to the CPAP failure group (p = 0.0098). The difference between the CPAP only group and primary IMV was also significant (p = 0.023).

Time difference between the date of peak CRP and date of intubation from failure of CPAP ranged between 4 days prior to 6 days post intubation. Only in half of the cases (n=5/10) did the CRP peak before intubation.

Time taken from starting CPAP to CPAP failure on ICU was between 1-8 days (median 3.5).

The 1 month mortality was higher in the primary intubation group at 45.5% (n=5/11). There were 2/16 deaths (12.5%) in the CPAP only group and 3/10 (33.3%) who died in the failed CPAP group.

Conclusion: Whilst a small study, these results seem to indicate that patients with a higher peak CRP on CPAP with COVID-19 pneumonia are more likely to fail CPAP support and require intubation than those with lower values. However at present we cannot advocate the use of peak CRP as a predictor for CPAP failure with current data showing that CRP peaked in half cases *after* intubation. The authors feel that a larger population is needed to see if the peak CRP (or CRP at time of ICU admission) could be used to prognosticate CPAP failure in COVID-19 pneumonias.

CPAP versus standard oxygen in acute respiratory failure sustained by SARS-CoV-2M. Giovini¹; C. San Nicola¹; M. Bergonzi¹; M. Barbera¹; E. Antonucci¹¹Intermediate care unit, Ospedale “Guglielmo da Saliceto”, Piacenza, Italy**Correspondence:** E. Antonucci*Intensive Care Medicine Experimental* 2020, **8(2)**: 000419

Introduction: Severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) outbreak was declared pandemic on March 2020, due to increasing number of cases around the world. Patients with SARS-CoV-2 can develop coronavirus disease 2019 (COVID-19), which has resulted in high rates of intensive care unit (ICU) admission. Alternatives to endotracheal intubation (ETI) such as continuous Positive Airway Pressure (C-PAP) were adopted to supply the lack of ICU beds during this extraordinary pandemic. C-PAP can be used such as a “bridge” to ETI in intermediate care units (IMCU) or in general wards.

Objectives: We hypothesized that C-PAP can reduce ETI and mortality rates when compared to standard oxygen (SO) in COVID-19 patients with moderate-to-severe acute respiratory failure (ARF).

Methods: We performed a retrospective analysis, reviewing all COVID-19 patients with moderate-to-severe ARF and admitted to our IMCU from March 1st to March 31st 2020. The inclusion criteria were age \geq 18 years old; diagnosis of COVID-19 by a nasopharyngeal swab; moderate-to-severe ARF at IMCU admission (PaO₂/FiO₂ ratio < 200 mmHg during oxygen therapy at a flow rate >10 L/min for at least 15 minutes); oxygenation with SO or helmet CPAP (stand-alone system) for 2 consecutive hours at least. Exclusion criteria were: not confirmed diagnosis of COVID-19 infection; do-not-intubate order. We analyzed two groups (C-PAP and SO) matched for age, SAPS2 score, SOFA score and PaO₂/FiO₂ at IMCU admission. We also collected demographic characteristics and we investigated rates of ETI and hospital mortality.

Results: We reviewed 93 patients and 42/93 respected the inclusion criteria (21 in SO group; 21 in C-PAP group). The two groups were well matched (PaO₂/FiO₂ ratio at admission: 86 \pm 20 (C-PAP), 92 \pm 17 (SO) p = 0.3; SAPS 2 score: 29 \pm 2 (C-PAP), 35 \pm 7 (SO) p = 0.2; SOFA score: 3 \pm 2 (C-PAP), 3 \pm 2 (SO) p = 0.4; age: 62 \pm 3 (C-PAP), 64 \pm 10 (SO) p = 0.2). Demographic characteristics are shown in Table 1. Patients in C-PAP group were more frequently intubated (14/21) than patients in SO group (8/21) although in not statistically significant way (OR 3.25, 95% CI 0.92 to 11.51, p = 0.07). We also found no significant difference in rate of hospital mortality [C-PAP 8/21, SO 6/21, OR= 1.54, 95% CI 0.42 to 5.61, p = 0.51] between the two groups (see Figure 1).

	C-PAP n. of patients (%)	SO n. of patients (%)
Obesity	3/21 (14%)	6/21 (29%)
Malignancy	2/21 (9%)	2/21 (9%)
COPD/asthma	2/21 (9%)	1/21 (5%)
Diabetes	5/21 (24%)	3/21 (14%)
Cardiovascular disease	3/21 (14%)	5/21 (24%)
Hypertension	8/21 (28%)	11/21 (52%)

Table 1. Demographic characteristic

Figure 1. ETI and mortality rates

Conclusion: C-PAP did not reduce ETI and mortality rates when compared to SO in COVID-19 patients with ARF.

A trial of non invasive ventilation in severe COVID-19

T. Grundy¹; R. Bandopadhyay¹; S. Yoon¹; R. Breeze¹

¹Intensive care unit, University Hospital Lewisham, London, United Kingdom

Correspondence: S. Yoon

Intensive Care Medicine Experimental 2020, **8(2)**: 000503

Introduction: While the optimal mode of respiratory support in severe COVID-19 disease has been the subject of ongoing debate, non-invasive ventilation (NIV) has been included in management guidelines from WHO (1), NHS England (2) and the Surviving Sepsis Campaign (3). NIV is an effective treatment for mild-moderate acute respiratory failure with evidence of mortality reduction when compared to mechanically ventilated or spontaneously breathing patients (4). There is the risk of nosocomial transmission via viral aerosolisation (5-6), however NIV may offer benefits over an early invasive ventilation strategy in terms of resource allocation and preventing morbidity from intubation and mechanical ventilation (IMV), especially in health-care settings with limited invasive ventilation capacity. There are a number of evolving safety considerations alongside this.

Objectives: To characterise and describe initial outcomes of patients receiving a trial of NIV in a small, single centre intensive care unit in London. We aim to assess whether NIV is a safe therapy in pandemic surge planning, and understand its impact on the need for IMV in anticipation of future waves of COVID-19 infection.

Methods: Data was collected retrospectively on 44 patients admitted with severe respiratory failure during the first wave of the COVID-19 pandemic between March and April 2020, all of whom received NIV as part of their initial critical care management. Data was collected on age, gender, BMI, requirement for IMV, and survival. We collected data on critical care staff infection rates during the same period as part of hospital wide audit.

Results: Of the 44 patients, 35 (79.5%) were male and 9 (20.5%) were female. Median age of the group was 56 (IQR 52–64), and median BMI was 29 (IQR 27–34). Overall 40.9% of patients died. 23 (52.3%) of patients went on to require IMV, on average after 56 hours of NIV. 60.9% of those who required IMV subsequently died, whereas 19% of those who only received NIV for respiratory support died. Key characteristics for both sub-groups were similar. Median APACHE II score and Clinical Frailty Score (CFS) for those who required IMV was 16 (IQR 13-17) and 2 respectively and 15 (IQR 12-19) and 2 for patients who remained on NIV only. Prior to commencing NIV, baseline median SpO₂ was 91% and FiO₂ requirement was 80% in both groups. Importantly, there was marked improvement in PaO₂, FiO₂, and SpO₂ 2-4 hours after starting NIV, with PaO₂ increased to 9.67 kPa, FiO₂ requirement reduced to 60% and SpO₂ increased to 95%. There was greater improvement in PaO₂ 2-4 hours after starting NIV in the NIV only sub-group when compared to those who required IMV (10.45 kPa NIV, 8.98 kPa IMV). Average length of time to discharge home from critical care admission was reduced from 17.2 days in the IMV sub-group to 15.9 days in the NIV only sub-group. We did not note any increase in staff sickness rates in comparison with other departments, including emergency medicine, general medicine and anaesthetics.

Conclusion: Our data suggests there are benefits of administering a trial of NIV for respiratory failure in COVID-19. We demonstrate that in a significant proportion of cases it prevented or delayed IMV despite similar clinical severity at time of admission, and we also observed rapid improvements in work of breathing and oxygen requirements after initiation of NIV. This could ensure that invasive ventilators are kept free for those requiring emergent IMV. Survival was similar to national outcomes (7). NIV is not without its complications and therefore frequent review of these patients for escalation of their care is important. Particular consideration needs to be given to staff safety, including adequate supply of appropriate protective equipment, hospital ventilation and airflow dynamics, and an adequate supply of oxygen and consumables needs to be ensured.

Intensive Care Medicine Experimental 2020, **8(2)**: 000610

Introduction: Performing diagnostic fiberoptic bronchoscopy in critically ill patients may produce arterial blood gas and hemodynamic changes. The use of High-flow nasal oxygen therapy (HFOT) could decrease these complications.

Objectives: To compare the incidence of complications in the two studied oxygen therapy modalities during fiberoptic bronchoscopy.

Methods: Forty critically ill patients without invasive mechanical ventilation were consecutively collected. Their responsible physician decided to perform diagnostic fiberoptic bronchoscopy suspecting lung infection. Twenty patients received HFOT (Flow 60L/min and FiO₂ 40%) and 20 received conventional oxygen therapy (nasal cannula at 5 Lt/min). The fiberoptic bronchoscopy was performed at bed side. Variables were collected before, during and 2 hours after performing the bronchoscopy. All the patients were sedated with Dexmedetomidine Hydrochloride. Delta of oxygen saturation was defined as the difference between the initial saturation and the lowest saturation during bronchial fibroscopy measured by pulse oximetry. The data was compared with the Mann-Whitney test. Data are presented in median and interquartile range.

RESULTS. The main results are shown in the table below.

VARIABLES	HIGH FLOW OXYGEN THERAPY (n=20)	CONVENTIONAL OXYGEN (n=20)	P
Age (years)	51 [28,72]	44 [30,70]	0.86
Days of hospitalization	5 [2,10]	4 [2,5]	0.11
SAPS III (admission)	44 [36,60]	49 [40,59]	0.68
PAM (before study, mmHg)	83 [76,94]	94 [84,104]	0.4
Sat O ₂ (before study, %)	96 [92,98]	95 [92,99]	0.85
FR (before study)	18 [15,20]	18 [14,26]	0.59
PAM (during study, mmHg)	76 [70,97]	89 [71,97]	0.5
Sat O ₂ (during study, %)	94 [89,96]	90 [85,94]	0.43
FR (during study)	19 [17,22]	19 [17,26]	0.28
Delta Sat O ₂ (during study, %)	2 [1,3]	5 [2,10]	0.01
PAM (two hours after study, mmHg)	82 [72,87]	81 [76,91]	0.6
Sat O ₂ (two hours after, %)	92 [87,96]	94 [91,96]	0.38
FR (two hours after)	18 [15,20]	19 [16,22]	0.37

Conclusion: The use of high-flow oxygen therapy is related to a lower decrease in saturation compared to conventional oxygen therapy.

Intensive Care Medicine Experimental 2020, **8(2)**: 000651

Introduction: Barotrauma, including both pneumothorax and pneumomediastinum, is a well-known complication of prolonged non-invasive ventilation (NIV) [1]. Vigorous respiratory efforts lead to increased transpulmonary pressure and to patient self induced lung injury [2]. In Coronavirus Disease 2019 (Covid-19), correct timing to declare failure of NIV and proceed to intubation and invasive ventilation is unknown. We tested the hypothesis that in Covid-19 prolonged NIV is associated with barotrauma.

Objectives: To describe incidence of barotrauma in Covid-19 and its onset time from hospital admission.

To evaluate association between barotrauma and duration of NIV in Covid-19.

Methods: We retrospectively enrolled 104 consecutive Covid-19 patients, admitted to our ICU from February 22nd to March 22nd, requiring intubation after failure of NIV. Age, sex and SOFA score were collected at ICU admission. Diagnosis of barotrauma was confirmed by radiological evidence (ultrasound/chest x-ray, chest CT) during the first 2 weeks from ICU admission. Different time intervals (from hospital admission to intubation (T1) and from beginning of NIV to intubation (T2)) were compared between patients with barotrauma and controls, using the Mann-Whitney test. We then identified a subgroup of barotrauma patients, defined "early", characterized by occurrence of barotrauma before or within the first 24 hours after intubation. We compared this group with controls with the Mann-Whitney test.

Results: Mean age was 61±10, 84 (80.7%) were male and median SOFA score was 6 (range 4-8). Barotrauma occurred in 15 patients (14%), at a median time of 8 days (IQR 6-12) from hospital admission. No differences were found either in T1 (median days 3, IQR 2-5.5 vs 5, IQR 2-9, p ns), or in T2 (median days 2, IQR 1-4 vs 3, IQR 2-6, p ns)

between controls and patients with barotrauma. However 6 patients had an early barotrauma; in this subgroup, T2 was longer in patients who developed early barotrauma compared to controls (Table).

Time intervals	Controls (n=89)	Early Barotrauma (n=6)
T1, days (median, IQR)	3.0 (2.0-5.5)	6.5 (2.5-13.2)
T2, days (median, IQR)	2.0 (1.0-4.0)	6.0 (1.7-9.2)*

*p<0.05 between early barotrauma and controls

Conclusion: In Covid-19 barotrauma had an incidence similar to other forms of acute respiratory failure. However, early barotrauma was associated with prolonged use of NIV.

Intensive Care Medicine Experimental 2020, **8(2)**: 000678

Introduction: The decision to use non-invasive ventilation (NIV) to treat acute respiratory diseases in the ICU avoids intubation and reduces invasive mechanical ventilation risks [1].

Objectives: To investigate the patients who started NIV in our ICU and study their failure and mortality rates.

Methods: Retrospective single-centre study of all patients admitted during a five-year period who received NIV, except for chronic therapeutic purposes. Data of demographics, mortality scores, cause for NIV and NIV failure (defined as intubation need) of 167 patients were recorded and processed with SPSS 23. NIV failure was studied, excluding patients on a weaning strategy.

Results: The average age was 70 years, with a mean SOFA score on admission of 8.7 compared with 6.6 at discharge. The mean ICU stay was 10 days with NIV duration of 53 hours. The patients admitted were mainly medical, with only 10.8% admitted due to emergency surgery. Half the patients had previous respiratory diseases, accounting COPD with 44.3%, 46.7% had cardiovascular pathology and 36.5% had respiratory illnesses. The number of patients who started NIV due to COPD and acute cardiogenic pulmonary oedema was similar (16.8%), while 11.4% had pneumonia. 13.6% were on mechanical ventilation weaning. Considering all patients, 36.5% had NIV failure rate and 32.3% of mortality rate.

Patients who survived were younger (69.2 vs 72.7 years), had better scores on admission (SAPS II 51 vs 64; APACHE II 26.9 vs 31.6; SOFA 7.7 vs 10.7), had less need for haemodynamic support (27 vs 54%) and less time gap between admission and NIV start (45 vs 70 hours). These patients had more respiratory and cardiovascular diseases than those who died and there were fewer patients in need for NIV due to pneumonia (9.7 vs 14.8%). About 28% of patients that lived had NIV failure compared with those that did not (54%).

A significant difference was observed in those who failed NIV trial with those who did not with in between admission and discharged SOFA score (on admission 7.27 vs 10.34; on discharge 5.56 vs 8.34), aminergic support (42 vs 58%), ICU stay (6 vs 15 days) and mortality rate (21 vs 48%). Average SAPS II score of those who survived and did not fail NIV trial was 47 compared with 59 in intubated patients. Failed NIV survivors had higher pH levels (7.28 vs 6.7), while the opposite happened within those who succeeded NIV trial (7.07 vs 7.28).

Conclusion: Patients who had the best outcomes had more comorbidities, opposing to the higher percentage of pneumonia in between those who died. Despite studies showing a SAPS II score > 34 to be independently related to NIV failure [2], our patients who succeeded had an average score of 47. Although indications for NIV trial in patients with a pH >7.25 [3, 4], there was no significant pH difference. NIV is a useful treatment and more studies are needed to identify early factors associated with higher mortality.

Intensive Care Medicine Experimental 2020, **8(2)**: 000846

Introduction: Noninvasive ventilation (NIV) is considered as the standard treatment for moderate to severe exacerbations of Chronic Obstructive Pulmonary Disease (COPD). However, the way to withdraw NIV after stabilization is not well established.

Objectives: We performed a National Survey to disclose this issue in clinical practice.

Methods: A national survey was launched to Spanish hospitals having general or respiratory ICU through the intensive (SEMICYUC) and pulmonology (SEPAR) national societies. The survey was carried out between January and March 2019.

One response per Unit was analyzed (that of the NIV expert or the head of the service in his absence). Characteristics of the center, specialty and withdrawal strategies are collected: time of beginning of disconnection, direct or progressive withdrawal, type of progression, with or without analytic control (arterial or venous), among others.

Data analysis was conducted using SPSS Version 21.0. The data are presented as n (%); p value < 0.05 were considered statistically significant doing contingency tables and using the Chi-Square or the Fisher test.

Results: We received a total of 179 responses, leaving us with 141 after the elimination of double responses. The final analysis was performed on 129 answers after eliminating 12 answers from third level hospitals that do not admit this pathology (AECOPD).

Responses from 129 units were analyzed, 84(60%) by intensivists and 57(40%) by pulmonologists. The 54.6% were tertiary hospitals.

96.6% of physicians (n 128) perform blood gases to decide to initiate disconnections. The use of an arterial sample is more common among pulmonologists than among intensivists (94.7% vs 66.2%, p<0.05).

Only in 26 units (20.3%) is direct withdrawal attempted and it is more frequent among intensivists (28.2% vs 10.5% p<0.05).

When they make a progressive withdrawal, 42.2% extend the disconnections, 6.9% decrease the support and 51% combine both. Night-time NIV is indicated in 88.4% of cases.

The majority of the respondents required hemodynamic stability (82%), respiratory rate <30 b/min (98%) and blood gas analysis (97%), for making decisions. Venous blood gas samples were used in 21%

of the cases. Pulmonologists conducted progressive withdrawal and used arterial blood gases significantly more often than intensivists.

Conclusion: To our knowledge, this is the first descriptive study of NIV withdrawal in patients with AECOPD.

The criteria for initiating withdrawal are fairly homogeneous, although some different strategies may be evident depending on the specialty. Pulmonologist usually do withdrawal progressively and use arterial blood gases more often than intensivists.

Unilateral diaphragm paralysis: the evolving role of diaphragm pacing (DP)

R. Onders¹; H. R.²; M. Elmo¹

¹Surgery, University Hospitals Cleveland Medical Center, Cleveland, United States of America; ²Pulmonary, University Hospitals Cleveland Medical Center, Cleveland, United States of America

Correspondence: R. Onders

Intensive Care Medicine Experimental 2020, **8(2)**: 001005

Introduction: Unilateral diaphragm dysfunction (UDD) is an underdiagnosed condition. Of the benign causes, the most common is the idiopathic type. Other causes include complications of cardiac surgery, trauma, metabolic derangements, as well as some infections. It has been postulated that the functional diaphragm increases in strength and compensates for the dysfunctional side thus the asymptomatic state in the majority of patients. However, in a smaller group this dysfunction may lead to dyspnea, sleep-disordered breathing, exercise intolerance, fatigue and even respiratory failure.

Objectives: We report the outcome of symptomatic UDD patients implanted with DP to treat the isolated dysfunction

Methods: This is an IRB approved retrospective analysis of a prospective, non-randomized interventional experience at a single institution. Patients underwent laparoscopic diaphragm mapping and electrode implantation. Post implantation patients were evaluated radiographically with either chest radiography or fluoroscopic sniff test, reported symptoms and diaphragm electromyography (dEMG) using the implanted DP electrodes. Success was considered when there was improvement or recovery in 2 of the 3 data points

Results: In the diaphragm dysfunction database, 62 patients with UDD were identified. Etiologies of the paralysis codified into 7 groups: idiopathic (n = 27), chest/thoracic procedure (n = 13), neck/shoulder surgery/injection (n = 8), trauma (n = 4), infection (n = 3), chemo/radiation (n = 3), Parsonage Turner's syndrome (N = 3), and post liver transplant (n = 1). The average age was 60 ± 10 years. All patients had significant respiratory symptoms and abnormal chest radiographs. Symptom duration was greater than 6 months in 49 patients (79%). Fifty-nine (95%) had fluoroscopic evaluation of the diaphragm with 51% showing paradoxical motion; the others showed no movement. Post implantation, 44 (70.9%) of patients reported improvement in symptom, 46 (74%) had improvement in dEMG and 23 (37%) had

improved radiologic testing. Thirty nine patients (62.9%) had recovery of 2 data points. Recovery rate was at 63.2% and 40% in patients with symptom duration greater than 6 and 18 months respectively. Additionally, there was a significant improvement in those with paradoxical motion 78% compared to those without paradoxical movement (59%).

Conclusion: DP can play a significant role in patients with symptomatic UDD. It could be offered as a treatment modality in UDD where the diaphragm can be electrically stimulated prior to proceeding with plication procedures

Outcomes of CPAP usage for COVID-19 pneumonitis

T. Disney¹; G. Dempsey¹; E. O'callaghan¹

¹Critical care unit, Aintree University Hospital, Liverpool, United Kingdom

Correspondence: T. Disney

Intensive Care Medicine Experimental 2020, **8(2)**: 001021

Introduction: The outcome for COVID-19 patients undergoing a trial of continuous positive airway pressure (CPAP) prior to invasive ventilation is unclear. There may be a role for avoiding invasive ventilation at the risk of worsening outcomes for those failing such a trial, however there is a lack of definitive evidence.

Objectives: To identify prognostic factors which may indicate a successful CPAP trial for COVID-19 patients and determine the effect of CPAP on mortality for those invasively ventilated after a CPAP trial.

Methods: A prospective cohort study of adult patients admitted to the ICU with COVID-19 pneumonitis in respiratory failure. Primary outcome: failure of CPAP trial resulting in invasive ventilation. Secondary outcome: mortality in patients requiring invasive ventilation after a CPAP trial.

Results: 45 patients underwent a trial of CPAP during the study period. 33 (73%) patients failed the trial and required invasive ventilation. There was no significant difference in age, Clinical Frailty Score, Extended Medical Research Council Dyspnoea Score (eMRCD), APACHE and SOFA scores (see Table 1). All patients over 70 years failed their CPAP trial. Patients undergoing a successful trial had shorter duration of ICU and hospital stay (see Table 2). 14 (42%) patients died after they failed a CPAP trial. 12/22 (55%) patients undergoing invasive ventilation without CPAP died.

		CPAP	Failed CPAP & subsequently intubated
Age (Years)	Mean	54.6	56.4
	Median	53.0	58.5
Clinical Frailty Score	Mean	1.5	1.5
	Median	1.0	1.0
eMRCD	Mean	1.4	1.3
	Median	1.0	1.0
APACHE	Mean	11.4	12.6
	Median	10.0	12.0
SOFA	Mean	2.2	2.9
	Median	2.0	2.5

Table 1. Comparison of attributes on admission between patients receiving successful CPAP and those failing CPAP and requiring invasive ventilation.

		CPAP	Failed CPAP & subsequently intubated
ICU Length of Stay (Days)	Mean	2.8	21.9
	Median	2.0	22.5
Hospital Length of Stay (Days)	Mean	15.1	34.1
	Median	13.0	32.5

Table 2. Comparison of ICU and hospital length of stay between patients receiving successful CPAP and those failing CPAP and requiring invasive ventilation.

Conclusion: Mortality for patients undergoing a CPAP trial does not appear to be increased. All patients over 70 years failed CPAP. Successful CPAP trial results in reduced ICU and hospital stay.

Intensive Care Medicine Experimental 2020, **8(2)**: 001174

Introduction: Prone positioning increases oxygenation by recruiting dorsal lung regions and drain airway secretions, improves gas exchange and survival in ARDS. We described efficacy of prone positioning in awake non-intubated spontaneously breathing COVID-19 positive patients with hypoxemic acute respiratory failure.

Methods: We studied 26 awake non-intubated spontaneously breathing patients with hypoxemic respiratory failure treated with prone positioning. Patients were kept in prone positioning for two hours in each session and four such sessions were given to patients in 24 hours. SPO₂, PaO₂, RR and hemodynamics were measured before prone positioning (PRE), 60 minutes of prone positioning (PRONE) and after one hour of the completion of session (POST).

Results: 26 patients (12 males and 14 females) non-intubated spontaneously breathing with SPO₂ <94% on 0.4 FiO₂ were treated with prone positioning. One patient required intubation and was shifted to ICU, rest 25 patients were discharged from HDU. Mean hours of prone positioning was 19.4 ± 2.06 hr. There was significant improvement in oxygenation (increase in PaO₂ from 53.15 ± 6.0 mmHg to 64.23 ± 6.96 mmHg in PRE and POST sessions respectively, likewise there was increase in SPO₂). No complications were noted with various sessions.

Conclusion: Prone positioning was feasible and improved oxygenation in awake non-intubated, spontaneously breathing COVID-19 patients with hypoxemic acute respiratory failure.

Prognostic factors in critically ill patients with hematologic malignancies admitted to Intensive Care Units

T. Isidoro Duarte¹; P. Faria¹; A. Martins¹; N. Germano¹

¹Intensive Care Medicine Department, Centro Hospitalar Universitário de Lisboa Central, Lisboa, Portugal

Correspondence: T. Isidoro Duarte

Intensive Care Medicine Experimental 2020, **8(2)**: 000340

Introduction: Survival of patients with hematologic malignancies (HM) admitted to Intensive Care Units (ICU) have been changing over the years. Nevertheless, still exists some reluctance in intensive care providers to admit and treat patients with these diseases. The ability to identify key prognostic variables of outcome within the first days may help to recognize those who are most likely to benefit from ICU therapy.

Methods: We studied a retrospective cohort of 56 adult patients with HM admitted to a non-hematologic ICU between January 2015 and September 2019. Patient’s baseline characteristics, organ failure scores and outcome were analyzed in order to identify clinically useful prognostic factors.

Results: Median age was 56 years. The most common hematologic diseases were acute myelogenous leukemia (17; 30%), malignant

lymphoma (16; 29%), acute lymphoblastic leukemia (6; 11,4%) and multiple myeloma (5; 8,6%). Primary reason for ICU admission were septic shock (30; 54%), respiratory failure (11; 20,3%), acute kidney injury AKIN ≥ 2 (5; 9%) and gastrointestinal complications mainly due to upper gastrointestinal bleeding (3; 5,7%). Median time in-hospital before ICU admission was 10 days and the median duration of ICU stay was 6 days. Median ICU and in-hospital mortality were 57 and 68,5%, respectively. Median SAPS II score was 56 with an estimated mortality of 59,6%. Median SOFA score 48 and 24 hours before ICU admission was higher in non-survivors group (6 vs 4 and 9 vs 7, respectively). Mortality was higher in patients with acute leukemia, septic shock and need for mechanical ventilation and vasopressor support during ICU admission.

Conclusion: Higher mortality in patients with HM admitted to the ICU was associated with more severe illness and respiratory or hemodynamic instability. Organ failure scores done before admission may suggest delay on ICU admission and worst outcome.

Intensive Care Medicine Experimental 2020, **8(2)**: 000432

Introduction: Patients affected by hematologic malignancies admitted to an Intensive Care Unit (ICU) have been a subject of debate for many years. Reported survival rates are low, especially in those patients who develop several organ failures.

Objectives: To determine the factors associated with ICU mortality in patients with hematologic malignancies.

Methods: Study period: January 2015 to December 2019. It has been collected demographic variables, severity scores, hematological characteristics, organ dysfunctions, microbiological data, length of stay and ICU and hospital mortality. Statistical analysis includes qualitative variables, presented as proportions and 95% confidence interval (CI); quantitative variables have been presented as medians and 95% CI. Shapiro-Wilk test has been used for the assessment of normality. The univariate analysis was performed using the simple linear regression test. ICU mortality was determined in the multivariate analysis using the logistic regression test.

Results: n = 84. Males 0.61 (95%CI: 0.5 to 0.7). Age: 57.5 years (95%CI: 52.5 to 61.5). Hematologic therapies: hematopoietic stem cell transplant 0.38 (95%CI: 0.28 to 0.48); intra-ICU chemotherapy 0.14 (95%CI: 0.08 to 0.23). Severity scores and biomarkers on admission: APACHE II 27 (95%CI: 25 to 28); SOFA 8 (95%CI: 7 to 9); procalcitonin 4 (95%CI: 0.9 to 19.5). Acute respiratory failure (ARF) was the main reason for admission 0.5 (95%CI: 0.4 to 0.6), followed by sepsis 0.34 (95%CI: 0.24 to 0.44). The proportion of patients with positive blood cultures on admission was 0.21 (95%CI: 0.13 to 0.31), all of them of unknown focus. Pathogen most frequently isolated: *Escherichia coli* 0.33 (95%CI: 0.14 to 0.59). Organ dysfunctions developed in ICU: ARF 0.85 (95%CI: 0.76 to 0.91); shock 0.64 (95%CI: 0.54 to 0.74); renal failure 0.64 (95%CI: 0.54 to 0.74); coma 0.14 (95%CI: 0.08 to 0.23). Life support measures: high flow nasal cannula 0.3 (95%CI: 0.21 to 0.41); non-invasive ventilation 0.47 (95%CI: 0.36 to 0.57); invasive ventilation 0.7 (95%CI: 0.65 to

0.83); continuous renal replacement therapy (CRRT) 0.34 (95%CI: 0.24 to 0.44). The ICU stay was 9 days (95%CI: 6.9 to 14) and the hospital stay was 18 days (95%CI: 15 to 23). The ICU mortality was 0.46 (95%CI: 0.36 to 0.57) and the hospital mortality was 0.59 (95%CI: 0.48 to 0.69). Variables significantly associated with mortality: APACHE II (OR 1.1; 95%CI: 1.04 to 1.19); SOFA (OR 1.21; 95%CI: 1.04 to 1.4); shock (OR 3.7; 95%CI: 1.4 to 9.8); ARF (OR 12; 95%CI: 1.5 to 100); invasive ventilation (OR 30.4; 95%CI: 3.8 to 241.1); CRRT (OR 3; 95%CI: 1.16 to 7.7). Regarding multivariate analysis, the variable which independently explains mortality is invasive ventilation (OR 22.7; 95%CI: 2.8 to 184.9).

Conclusion: The main determinant of mortality in patients admitted to the ICU due to hematologic malignancies is the acute respiratory failure and the need of invasive ventilation.

Intensive Care Medicine Experimental 2020, **8(2)**: 000474

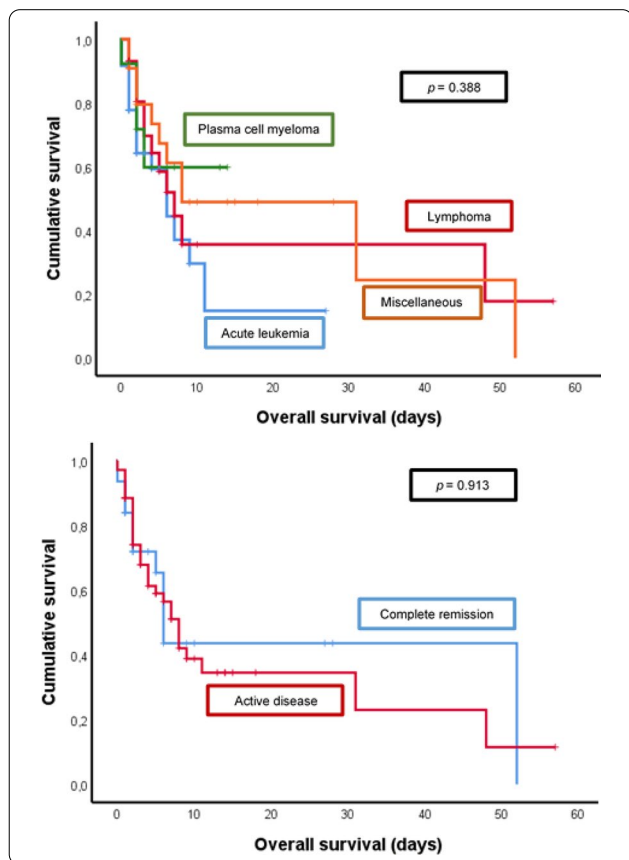

Introduction: ICU admission and organ support in patients with hematologic malignancies with systemic organ failure is still debatable, given the high associated mortality and absence of reliable outcome predictors (1,2).

Objectives: Identification of prognostic factors in patients with hematologic malignancy and multisystemic organ failure admitted to an ICU. Mortality and functional outcome 3-months and 1-year after ICU discharge were the primary and secondary outcomes, respectively.

Methods: Retrospective, single centre study from a tertiary care, university hospital. Clinical and laboratory data from patients with hematologic malignancies admitted to ICU, from June 2014 to June 2019, were extracted from electronic registries. Functional assessment was performed through clinical registries plus phone contact and scored according to Eastern Cooperative Oncology Group (ECOG) scale. Statistical analysis was performed through IBM® SPSS® Statistics 25.

Results: We included 100 patients (112 ICU admissions), mostly male (60%) with a median age of 60 years old [inter-quartile range (IQR): 45-65], median SAPS II of 56 (IQR: 19-129) and median admission SOFA of 9 (IQR: 2-22). Acute leukemia (34.8%), non-Hodgkin lymphoma (25.9%) and multiple myeloma (13.4%) were the most prevalent diagnosis. Most of the patients had active disease (70%) and were under treatment, half of them on first line. 25% had been submitted to allogeneic stem cell transplant. Septic shock (40%) and respiratory failure (38.4%) were the most frequent causes for ICU admission. During their ICU stay, 80% had respiratory failure (50% received invasive mechanical ventilation) and 68.8% had cardiovascular failure; half of the patients had 3 or more organ failures. We observed a 54% ICU, 38% hospital, 28% 3 months and 26% 1 year survival rates. Main cause of death was refractory shock (37%). Each additional organ failure was associated with lower survival probability by univariate analysis, except for neurologic failure; age was not a predictor of early death; by multivariate analysis, only respiratory failure and mechanical

ventilation were associated with lower survival (HR 11.59, 95% CI 1.56 – 86.45, $p = 0.02$ and HR 3.05, 95% CI 1.41 – 6.57, $p = 0.01$, respectively). Type of hematologic malignancy and disease status at ICU admission were not predictors of ICU survival (Fig. 1 and 2, respectively). One month after ICU discharge, lower ECOG scores were associated with higher survival ($p < 0.001$). One year after ICU discharge, 74% of the survivors had ECOG score 0 or 1 and 68.4% were in complete remission.

Conclusion: Patients with hematologic malignancy and multiorgan failure are at increased risk of death, however timely ICU care can still be associated with 40% survival. Mechanical ventilation, but not hematologic diagnosis nor age, was associated with lower survival probability. Importantly, patients surviving ICU admission attain good functional state at 1-year.

Acute kidney injury in critically ill oncohaematological patients: single centre experience

S. Judickas¹; R. Stasiūnaitis²; J. Sipylaite¹

¹Institute of Clinical Medicine, Clinic of Anaesthesiology and Intensive Care, Faculty of Medicine of Vilnius University, Vilnius, Lithuania; ²Faculty of medicine, Vilnius University, Vilnius, Lithuania

Correspondence: S. Judickas

Intensive Care Medicine Experimental 2020, **8(2)**: 000518

Introduction: Organ dysfunction is one of the main reasons for admission to intensive care unit (ICU) and it is associated with higher mortality. Acute renal injury (AKI) might occur not only because of general reasons but it is also associated with haematological malignancy itself, treatment and complications.

Objectives: The aim of our study was to analyse AKI in critically ill oncohaematological patients.

Methods: We retrospectively analysed data of oncohaematological patients who were admitted to the 3rd ICU in Vilnius university hospital Santaros clinics from 13 07 2017 to 27 12 2019. Inclusion criteria were: oncohaematological malignancy, age > 18 years, arterial or central line inserted, signed informed consent form. AKI was diagnosed according to KDIGO and RIFLE scoring systems. Baseline creatinine level was calculated at least 6 months before admission to ICU. Levels of creatinine were taken and recorded on admission to the hospital and ICU. Decision to admit patient to ICU and/or start renal replacement therapy was made by ICU doctor in charge. All of the continuous renal replacement therapies were performed with Prismaflex machine using citrate anticoagulation and CVVHDF mode. The effluent dose was prescribed by attending ICU doctor. SOFA score was calculated on admission to ICU. Statistical analysis was performed with R statistical package. A p-value of less than 0,05 was considered to be statistically significant.

Results: 117 patients (67 males and 50 females with the average age of 59,86 ± 15,26) were included into the study. The baseline creatinine was 91,07 μmol/L ± 59,34, creatinine on admission to hospital was 118,96 ± 91,86, on admission to ICU 130,37 ± 94,61. Incidence of acute renal injury on admission to hospital according to KDIGO and RIFLE score were 35 (29,91%) and 15 (12,82%) on the admission to ICU 48 (41,03%), 19 (16,24%). Patients with KDIGO stage ³1 had lower arterial pH (7,41 vs 7,46, p value < 0,05), lower BE (-4,0 vs -0,2, p value < 0,05), higher lactate (1,3 vs 2,0, p-value < 0,001) on admission to ICU. Patients with AKI according to RIFLE on admission to ICU had higher creatinine on admission to hospital (151 vs 75, p-value < 0,001). CVVHDF was used for 30 (25,42%) patients. Higher proportion of patients who received CVVHDF had renal injury according to RIFLE not only in ICU (52,63% vs 20,20%, p value < 0,05), but also on a ward (46,66% vs 22,33%, p value < 0,05). Patients who received CVVHDF had lower arterial pH (7,37 vs 7,45, p value < 0,05), lower BE (-5,9 vs -0,3, p value < 0,001), higher lactate (2,1 vs 1,4 p value < 0,05), higher creatinine on admission to hospital (108 vs 82,5 p value < 0,05), higher creatinine on admission to ICU (174,5 vs 86, p value < 0,05). Patients who received CVVHDF had higher ICU mortality and worse overall survival (83,33% vs 38,64%, p value < 0,0001, 96,67 vs 64,77, p value < 0,001).

Conclusion: Acute renal injury is common in critically ill oncohaematological patients. Higher incidence is seen if diagnosed with KDIGO scoring system. Patients with AKI and those who received renal replacement therapy had more derangements on arterial blood gases. Patients who received CVVHDF had signs of acute renal injury already on a ward they also had higher ICU mortality and lower overall survival.

High dose vitamin C therapy for oncohaematological patients with septic shock

S. Judickas¹; R. Pelanis²; J. Sipylaite¹

¹Institute of Clinical Medicine, Clinic of Anaesthesiology and Intensive Care, Faculty of Medicine of Vilnius University, Vilnius, Lithuania; ²Faculty of medicine, Vilnius University, Vilnius, Lithuania

Correspondence: S. Judickas

Intensive Care Medicine Experimental 2020, **8(2)**: 000519

Introduction: Patients with septic shock have a very high mortality rate despite of aggressive treatment in intensive care unit (ICU). Prognosis of oncohaematological patients is even worse. High dose vitamin C therapy received a lot of attention over the last years as a supplementary therapy which could lead to improvement during septic shock.

Objectives: The aim of our study was to evaluate the impact of high dose vitamin C therapy during septic shock in oncohaematological patients.

Methods: We retrospectively analysed data of oncohaematological patients with septic shock who were admitted to the 3rd Intensive care unit from 13 07 2017 to 19 02 2019 in Vilnius university hospital Santaros clinics. Inclusion criteria were: oncohaematological malignancy, age > 18 years, septic shock, arterial or central line inserted, signed informed consent form. Sepsis and septic shock were defined as per SEPSIS-3 definition. When noradrenaline dose reached 0,1 mcg/kg/min. patients received vitamin C 1500 mg every six hours i/v together with hydrocortisone 50 mg every six hours i/v, thiamine 200 mg i/v once per day supplementary to the standard treatment of septic shock according to local practice. Control group consisted of oncohaematological patients with septic shock who didn't receive high dose vitamin C therapy. High dose vitamin C therapy was stopped when patients became haemodynamically stable. Statistical analysis was performed with R statistical package. A p-value less than 0.05 was considered to be statistically significant.

Results: 71 patients with haematological malignancies were admitted to ICU. 36 patients were diagnosed with sepsis and 33 of them had septic shock. 23 patients received high dose Vitamin C therapy. 9 patients were excluded from the analysis due to the violation of dosage of vitamin C. Final analysis included 14 patients who received high dose vitamin C therapy. Control group consisted of 10 patients. Patients in high dose vitamin C group were older (65,57 vs 53,95, $p < 0.0027$), they had a higher SOFA score on day1, day2 and day3 in intensive care unit (accordingly 8,64 vs 6,2*, 10,62 vs 7,12**, 10,09 vs 5,92***, p value *- 0.0534, ** - 0.0051, *** - 0.002597). Arterial pH, BE, lactate did not differ between groups on arrival to intensive care unit (accordingly 7.46 vs 7.43 ($p = 0.44$), BE -2,99 vs 0,53 ($p = 0.48$), lactate 1,9 vs 1,2 ($p = 0.09$)). Intensive care unit survival of patients treated with high dose vitamin C therapy was 21,43% (3/14) compared with 47,37% (9/19) in standard treatment group (p value 0.1258). There was no difference in terms of intravenous fluids (per hour), time spent in intensive care unit, length of vasopressor therapy and renal replacement therapy between the groups (149.15 ml vs 131,1 ml, 69,5 h vs 71 h, 62 h vs 10 h and 50% (7/7) vs 26,32% (5/19)).

Conclusion: High dose vitamin C therapy didn't improve survival of oncohaematological patients with septic shock. Patients with high dose vitamin C had higher SOFA scores on the first, second and third days in intensive care unit.

Lymphocyte subpopulations in critical SARS-CoV2 infection

L. P. Moulart¹; P. Henin¹; V. Huberlant¹; J. B. Mesland¹

¹Icu, Jolimont Hospital, La Louvière, Belgium

Correspondence: J.B. Mesland

Intensive Care Medicine Experimental 2020, **8(2)**: 000553

Introduction: Since the beginning of the new SARS-CoV2 pandemic, numerous biological and clinical findings have been described through the literature. Lymphopenia is one of them and is found in nearly all severe cases (1). Little is known about the lymphocyte subset in this pathology, despite interesting data that could help to better understand SARS-CoV2 infection.

Objectives: To review the lymphocyte subpopulations in SARS-CoV2 infected patients admitted in our ICU.

Methods: Observational, retrospective and descriptive study. We reviewed all our SARS-CoV2 patients admitted in our ICU between march 2020 and may 2020 and selected patients who had lymphocytes subset requested at admission. Epidemiological data, hemoglobin, leucocyte count, leucocyte population, and lymphocyte subpopulation (studied by flow cytometry) were collected.

Results: Of 46 patients admitted in our ICU (22 beds), 10 had lymphocyte subset requested. Mean age (+/- SD) was 56,18 years (+/- 11). All of these 10 patients were critical SARS-CoV2 pneumonia, requiring

mechanical ventilation within their stay. 5/10 patients required VV-ECMO. All patients were HIV negative.

8/10 patients had low CD4+ T-lymphocyte count (317/mm³ +/-94), with proportionally more profound alteration in CD8+ T-lymphocyte count (82/mm³ +/-30). The T-Lymphocyte Helper/Suppressor ratio was elevated in most of the patients (7/10), with mean value of 4,3 (+/-2). No patient had a ratio less than 1. There was an increase in proportion of circulating B lymphocytes (24% +/-10%), with normal absolute value (148/mm³ +/-53). All patients had normal NK cells value (75/mm³ +/-31).

Opportunistic infections are classically described in patients having specific risk factor (malignancies, solid organ transplant, specific drugs) or HIV patients having CD4+ count lower than 200/mm³ (2) which was the case in only 2/10 patients (lowest value of 126/mm³).

Conclusion: Lymphocytes are playing an important role in the maintenance of immune system function. Subsets are uniformly affected with low CD4+ and CD8+ T-lymphocyte, higher ratio, and increased proportion of circulating B lymphocytes. These findings are correlated to the severity of the disease (2), but underlying consequence of it is unknown. Potential treatment aimed to restore a better immune function as used in cancer immunotherapy or tested in sepsis might be a promising tool to correct those alterations(3).

Intensive Care Medicine Experimental 2020, **8(2)**: 000716

Introduction: Cytokine release syndrome (CRS) is a clinical syndrome derived from the massive release of cytokines after immunotherapy, which can range in severity from a flu-like illness to multiorgan dysfunction syndrome.

Objectives: To describe the clinical profile of CRS and to identify risk factors for developing CRS and for CRS severity after Chimeric Antigen Receptor (CAR) T-cell therapy.

Methods: Retrospective study that included those patients treated with CAR T-cell therapy in the Advanced Therapies in Hematology Unit (UTAH) at Vall d'Hebron University Hospital (Barcelona) from August 2018 to December 2019. The UTAH is a 12-bed, monitored unit, staffed by Hematologists, with the support of a multidisciplinary team including ICU, Neurology, Pediatrics, Infectious Diseases, Microbiology, Immunology and Pharmacy specialists. Patients were admitted before

CART-cell infusion for lymphodepletive chemotherapy and were followed up during at least 10 days after CAR T-cell infusion, per protocol. CRS and immune effector cell-associated neurotoxicity syndrome (ICANs) were defined and graded according to ASTCT Consensus (Biol Blood Marrow Transplant 2019; 25: 625-38). We considered CRS onset in the first 72 hours after CAR T-cell infusion as early CRS (eCRS), and severe CRS (sCRS) as CRS grade >1. Chi-Square, Fisher's test, T test, U Mann-Whitney and logistic regression were employed as appropriate. Quantitative variables are reported as median (IQR) and categorical as frequency (%).

Results: Forty-one patients, 31 (76%) male with a median age of 57 (47-66) years, were treated with anti-CD19 CAR T-cells for refractory non Hodgkin lymphoma (38, 93%) and acute lymphoblastic leukemia (3, 7%). Costimulatory domains for CAR T-cells were 4-1BB and CD28 in 39 (95%) and 2 (5%) patients, respectively. Thirty (73%) developed CRS: 13 (32%) grade 1, 16 (39%) grade 2, and 1 (2%) grade 3. All of them had fever, with a median peak temperature of 38.4°C (38-39), 13 (32%) developed hypotension that required fluid bolus and 11 (27%) hypoxemia requiring supplemental oxygen (6 liters per minute or less in 10 and 30 lpm administered with high-flow nasal cannula in 1 patient). Time from CAR T-cell infusion to CRS was 4 (2-6) days. Ten (33%) patients developed eCRS. Duration of CRS was 5 (3-8) days. Tocilizumab was used in 8 (20%) patients and was associated with resolution of CRS in all treated cases; one patient (2%) needed a second dose to control CRS. Moreover, 8 (20%) patients developed ICANs, at a median of 7 (5-9) days after CAR T cell infusion; 1 (2%) grade 1, 6 (15%) grade 2 and 1 (2%) grade 3. Seven of these 8 patients developed ICANs after CRS onset. Patients with ICANs grade 2 and 3 were treated with corticosteroids with complete resolution in all patients. Baseline biomarkers were not predictors of CRS (Table 1). Patients with sCRS had earlier CRS onset, higher temperature, higher CRP at day 1 of CRS, higher CRP peak, LDH peak and interleukin 6 peak levels (Table 2). After multivariate analysis, peak temperature (OR 44.6, 95% IC 1.6-1243, $p = 0.025$) and early CRS (OR 39.7, 95% IC 1.2-1279, $p = 0.038$) were associated with severity. Most patients were successfully managed in the UTAH, with only 2 requiring admission to the ICU. No fatal events were observed due to CAR T-cell related toxicity.

Table 1. Baseline biomarkers in patients with and without CRS

Variable	All (n=41)	No CRS (n=11)	CRS (n=30)	p value
CRP (mg/dL)	3 (1.1-8.7)	1.6 (1.1-7.8)	3.1 (1.5-11.4)	0.311
LDH (UI/L)	594 (399-1084)	441 (332-659)	650 (416-1405)	0.499
Ferritin (ng/mL)	741 (396-1578)	1426 (387-1542)	702 (406-1695)	0.547

Table 2. Characteristics of CRS depending on severity

Variable	CRS (n=30)	Grade 1 CRS (n=13)	Severe CRS (n=17)	p value
Day 1 of CRS				
CRP (mg/dL)	3 (1.7-8.7)	1.8 (1.7-3)	5.4 (3-18.4)	0.029
Peak value				
CRP (mg/dL)	12.3 (6.7-25)	8.9 (6.6-9.8)	19.8 (13.6-42.4)	0.016
LDH (UI/L)	809 (474-2003)	553 (474-1092)	1485 (613-3095)	0.035
IL-6 (pg/mL)	68.7 (31.6-269.3)	46.5 (20-63.7)	214.5 (72.3-317.8)	0.001
Temp (°C)	38.8 (38.2-39.1)	38.4 (38.1-38.5)	39.1 (38.8-39.3)	<0.001
Early CRS	10 (33)	1 (8)	9 (53)	0.017

Conclusion: Most patients treated with CAR T-cell therapy presented some adverse event, including CRS and/or ICANs. Resolution was fast in most cases, with no fatal events in our cohort. These results were achieved with a proactive multidisciplinary approach, leading to an early detection and appropriate therapy. Peak temperature and early onset of CRS may be useful to identify those patients with higher CRS severity.

Intensive Care Medicine Experimental 2020, **8(2)**: 000731

Introduction: Over the last two decades, the number of cancer patients requiring ICU care has dramatically increased with 15% of ICU beds occupied by cancer patients. Thus, in the following years intensive care medicine will become a key component in the management of these patients.

Objectives: Our aim was to describe the cohort of patients with solid organ cancer admitted to a tertiary hospital ICU and analyze factors associated with survival.

Methods: Seven-year (2010-2017) retrospective study, including adult patients with solid organ cancer who required ICU admission. Chi-Square, Fisher's test, T test, U Mann-Whitney and Cox's regression (including all significant variables in the univariate analysis) were employed as appropriate. Quantitative variables are reported as median (IQR) and categorical as frequency (%).

Results: Two hundred patients were included, 107 (54%) were male with a median age of 60 (50-68) years. Lung cancer was present in 53 (27%), followed by colon 27 (14%), breast 16 (8%) and ovary 15 (7%). One hundred and six (53%) had metastatic disease. Most of the patients (181; 91%) were on ECOG 0-2 and Charlson Index was 9 (5-11). Respiratory failure was the reason for ICU admission in 72 (36%) patients, shock in 41 (21%), respiratory failure and shock in 33 (17%), urgent surgery in 36 (18%) and central nervous system involvement in 12 (6%). Neutropenia was present in 27 (14%). SOFA score at day 1 was 6 (4-9). Eighty-four (42%) had a lower SOFA score at day 3 and 60 (30%) at day 5. One hundred and twenty-five (62%) required vasopressors (VP), 89 (45%) invasive mechanical ventilation (IMV), 72 (36%) nasal high flow (NHF) and 18 (9%) renal replacement therapy (RRT). Of those patients treated with NHF, 24 (33%) were intubated, while 35 (49%) were not intubated after improvement in their condition and 7 (10%) because of a do not intubate order. ICU mortality affected to 50 (25%) and in-hospital mortality to 86 (43%). Differences between hospital survivors and non-survivors are detailed in Table 1. Patients requiring RRT (HR 2.7, 95% IC (1.1-6.8) $p = 0.036$) and those who did not decrease their SOFA score at day 5 (HR 2.3 IC 95% (1.1-4.9) had higher in-hospital mortality after multivariate analysis.

Variable	Survivors (n=114)	Non-survivors (n=86)	p value
Age (years)	59 (50-68)	61 (48-69)	0.420
Male	53 (49%)	38 (44%)	0.537
Lung cancer	22 (20%)	30 (35%)	0.021
Charlson	9 (5-10)	7 (5-10)	0.478
Metastasis	57 (56%)	49 (60%)	0.767
Neutropenia	14 (13%)	13 (15%)	0.648
NHF	35 (32%)	37 (43%)	0.117
IMV	31 (29%)	57 (67%)	<0.001
VP	61 (57%)	61 (73%)	0.021
RRT	5 (4%)	13 (15%)	0.012
SOFA day 1	5 (2-7)	7 (3-11)	0.001
No decrease in SOFA			
Day 3	21 (27%)	25 (49%)	0.01
Day 5	10 (18%)	23 (64%)	<0.001

Conclusion: Hospital mortality of oncologic patients that require ICU admission remains high. Mortality may be more dependant on organ failure development and need for organ support suggesting that these patients may benefit of an earlier ICU admission. Persistent organ failure is associated with worse outcomes and, therefore, this information could be useful in the bedside clinical decision making process during an ICU trial, although clinical global assessment must prevail.

Intensive Care Medicine Experimental 2020, **8(2)**: 000954

Introduction: Chimeric antigen receptor-modified T (CAR-T) cells are a revolutionary treatment for patients with advanced blood cancers. A proportion of these patients will develop significant toxicities, requiring critical care management. Our hospital was one of 7 in the UK approved for the treatment of relapsed/refractory high-grade lymphoma and refractory acute lymphoblastic leukaemia (ALL).

Objectives: To describe our experience with lymphoma and ALL patients, who received CAR-T CD19 cells and were admitted to the intensive care unit (ICU).

Methods: From January 2019 until May 2020, patients with diffuse large B cell lymphoma (DLBCL), transformed follicular lymphoma, primary mediastinal B-cell lymphoma (PMBCL) or ALL, who were infused with CAR-T CD19 cells and developed \geq grade 2 Cytokine Release Syndrome (CRS) and Immune Effector Cell Associated Neurotoxicity Syndrome (ICANS) were analysed.

Results: Sixty-one patients underwent CAR-T therapy during the study period, with 21 (34%) requiring admission to ICU. The mean age at presentation to ICU was 57 years and 76% of the admissions were males. All patients were receiving broad spectrum antibiotics and 19% of treatments were broadened in ICU and an antifungal was added.

CRS/sepsis (n=12, 57%) was the most common documented reason for admission to ICU, with a proven infection documented in only 2 patients. The reasons for admission are shown in figure 1. Median duration of ICU stay was 4 (range 1-21) days. Grade 2 CRS was documented in 12 patients (57%) for a median duration of 2 (range 0-6) days. Grade 3 CRS was seen in 6 patients (29%) for 1-3 days. No patient progressed to grade 4 CRS during their ICU stay. Six patients had grade 1 ICANS each for a median duration of 4 (2-6) days, whereas another 6 had grade 3 ICANS for 2 days (1-4).

During their ICU stay, 9 patients (48%) required vasopressors for a median duration of 2 (1-3) days. Three patients (14%) needed mechanical ventilation with a median duration of 5 (4-9) days and 2 patients needed renal replacement therapy for a median duration of 4 (1-7) days. IL-1, IL-6 antagonists and steroid administration are shown in figure 2. Three patients (14%) died in ICU, all in multi-organ failure. Two deaths were attributed to invasive pulmonary aspergillosis and the third to disease progression. Further 7 patients that were discharged alive from ICU, died before hospital discharge from disease progression.

Conclusion: A significant number of patients receiving CAR-T therapy will need admission to ICU, requiring various level of organ support. Differentiation between CRS and neutropenic sepsis was difficult, and all patients stayed on antibiotics for the duration of their ICU stay. The observed ICU mortality (14%) was in accordance to the one reported in international literature and no deaths were attributed to treatment toxicity. Close collaboration between haematology and ICU is warranted for the optimal management of CAR-T patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 001105

Introduction: Since the beginning of the COVID-19 pandemic, rapid evidence was suggesting a pro-coagulant state (1).

There are currently insufficient data to recommend for or against the use of thrombolytics or increasing anticoagulant doses for VTE prophylaxis in hospitalised COVID-19 patients outside the setting of a clinical trial (2). Currently, the guidance adopted by the national institute of health recommends anticoagulation treatment risk to be assessed on individual patient basis and therapeutic anticoagulation to commence in the event when it's clinically indicated (2), namely when patients develop thrombo-embolic manifestations.

Objectives: We have undertaken a retrospective data analysis of the patients admitted to our hospital between Mid February to mid April 2020 with COVID-19 illness to ITU and to the general wards. We have established the number need to treat for both patients groups based on a single outcome (death), in an effort to establish a possible benefit from starting anticoagulation earlier to ward patients as ITU patients.

Methods: Drug history was identified through hospital records for confirmed patients with COVID-19 disease to identify patients who have been on anticoagulation prior to hospital admission for an independent reason. For both groups (ward patients and ITU patients) the outcome was established as Death or improvement at the time of data collection. Total number of cases explored for ITU is 51 patients, compared to 156 patients on the ward.

Results: For ITU patients the NNT(number needed to treat) to prevent adverse outcome (death) =2, with an absolute risk reduction of 52.17% and a CI (confidence interval) for NNT =1.5-2.6.

For ward patients the NNT =4, with an absolute risk reduction of 23.4% and a CI of 2.2-162.0.

Conclusion: The above mentioned results does not support changing the current practice to starting therapeutic anticoagulation on ward patients "empirically". The risk assessment therefore is to be conducted on individual basis and assessed for each patient individually.

000005**Lean body mass as a prognostic factor in post-cardiac arrest patients treated by targeted temperature management: a retrospective cohort study**H. H. Kim¹; E. L. Sung¹¹Emergency Medicine, Ajou University Hospital, Suwon, Republic of Korea**Correspondence:** H. H. Kim*Intensive Care Medicine Experimental* 2020, **8(2)**: 000005

Introduction: Post-cardiac arrest patients with return of spontaneous circulation have a very low survival rate and poor prognosis despite aggressive treatments. Prediction these patients' prognosis is important for planning the treatment of the patients and providing information to their families. Several studies have reported body mass index (BMI) as a prognostic factor in post-cardiac arrest patients, which is called "obesity paradox". In this study, researchers aimed to investigate the relationship of LBM with the prognosis of post-cardiac arrest patients.

Methods: This retrospective cohort study included adult patients of out-of-hospital cardiac arrest between January 2015 and August 2018. The enrolled patients were divided into 2 groups based on clinical outcomes (cerebral performance category score, 1 to 2 and 3 to 5) and compare the characteristics of these two groups. Association of LBM with good neurologic outcomes (CPC score 1 to 2) was analyzed by dividing patients into quartile segment by their LBM. Predictive value of optimal cutoff points of LBM in post-cardiac arrest patients was evaluated.

Results: A total 169 patients were analyzed (CPC score 1 to 2, n=55; CPC score 3 to 5, n=114). Patients' age, frequency of witnessed cardiac arrest, initial shock rhythm, post-hospital flow time, estimated cardiac arrest, and LBM were different in the two groups ($p < 0.05$). LBM was associated with the prognosis of post cardiac arrest patients in the 4th quartile segment. Cutoff point of lean body mass for prediction of cardiac arrest outcomes was 48.34 (sensitivity = 0.600, specificity = 0.763, accuracy = 0.710) and the predictive value was 0.68 (95% confidence interval, 0.60 to 0.75).

Conclusion: High LBM is related to good neurological prognosis of patients after cardiac arrest. The increase in muscle mass due to exercise is interpreted as showing positive effects on hypoxic injury in cardiac arrest and reperfusion injury after return of spontaneous circulation.

Introduction: Various randomized clinical trials reported no differences in outcome when mechanical chest compressions (CC) were used in cardiac arrest patients [1-3]; however, in these trials mechanical CC were systematically applied soon after ALS arrival to evaluate its effectiveness compared to manual CC. The evidence regarding the impact of mechanical CC on mortality in patients with refractory out-of-hospital cardiac arrest (OHCA) and prolonged resuscitation efforts, when mechanical CC are initiated later, is scarce.

Methods: This is a post hoc, propensity score (PS) analysis of OHCA patients who received or did not received mechanical CC during resuscitation manoeuvres in the TTH48 trial. A predefined set of covariates (recruiting centre, age, height, weight, gender, location of OHCA, witnessed OHCA, initial cardiac rhythm, bystander cardiopulmonary resuscitation, automatic external defibrillator used, time from OHCA to basic life support, time from OHCA to advanced life support, resuscitation drugs used, intubation on scene) were explored and used for developing a PS for the receipt of mechanical CC using multiple binary logistic regression. The PS was then applied as an adjustment factor, together with the receipt of mechanical CC, in a Cox proportional hazard model to estimate the impact on 6-months mortality.

Results: Out of 351 patients included in the analysis, 25.6% received mechanical CC. No major differences in baseline characteristics were observed between groups, except for prolonged time to ROSC (26 [20;38] vs 20 [15;25] min, $p < 0.01$) and more frequent use of resuscitation drug (adrenaline: 80 vs 57%, $p < 0.01$; amiodarone: 53 vs 37%, $p < 0.01$) in the mechanical CC group. The Cox proportional hazard models did not show a significant impact of the probability to receive mechanical CC and the receipt of mechanical CC on 6-months mortality (1.676 [0.580-4.842], $p = 0.34$ and 1.683 [0.925-3.061], $p = 0.09$, respectively). We computed another PS including time from OHCA to ROSC to the same covariates used previously; in this case, the predicted probability to receive mechanical CC was significantly associated with 6 months mortality (3.713 [1.437-9.599], $p < 0.01$).

Conclusion: When time to ROSC was included in the PS, the likelihood to receive mechanical CC during cardiac arrest significantly correlated with 6-months mortality while receipt of mechanical chest compressions did not. The same association was not observed when time to ROSC wasn't accounted in the PS. The longer duration of resuscitation

efforts observed in patients that received mechanical CC could explain the results. Notably, mechanical CC, per se, was never associated with mortality.

Intensive Care Medicine Experimental 2020, **8(2)**: 000380

Introduction: The occurrence of in-hospital cardiopulmonary arrest (CPA) is associated with worse outcomes. Identifying the most at-risk patients is crucial to ensure greater vigilance and a more “offensive” posture in these cases.

Objectives: Characterization of patients admitted by NSTEMI with progression in Cardiac Arrest (CPA). Creation of intra-hospital CPA predictor score in this population and comparison with 2 recently published SAFER and CHADS2 scores in international publications.

Methods: Multicenter study conducted over a period of 7 years and 9 months. Patients without diagnosis of NSTEMI, with CPA as a symptom of hospital admission or without information on the occurrence of in-hospital CRP were excluded from the study.

Results: A total of 10430 patients were admitted, 95 of whom had in-hospital CPA. Patients with CPA were older, with more hypotensive profile and Killip class > 1. Electrocardiographic changes (LBB (left bundle block), RBB (right bundle block) and ST depression) were also more frequent in this group, as well as the use of IAB, Invasive Mechanical Ventilation and temporary PM.

By logistic regression 6 CPA predictor variables were identified: 1) admission SAP ≤ 125 mmHg (1 point), 2) Killip class > 1 at admission (1 point), 3) LBB at admission EkG (2 points), 4) RBB on admission EkG (1 point), 5) ST depression on admission EkG (1 point), 6) CHB (complete heart block) / VT / cardiogenic shock within the first 24 hours after admission (2 points). This allowed the creation of 3 risk groups according to the score obtained: low risk (0-2 points), medium risk (3-4 points) and high risk (5-7 points).

ROC curves were created comparing the new score with the SAFER and CHADS2 score. The new score was found to have a higher predictive power than the 2 previously reported scores (AUC: 0.723; 95% CI 0.714-0.731; p-value <0.05).

Conclusion: Our study allowed us to create a new score that is easy to apply on a daily basis. Internal and external validation is crucial to assessing its true impact.

Intensive Care Medicine Experimental 2020, **8(2)**: 000414

Introduction: The quality of chest compressions is very important in improving prognosis in patients following cardiac arrest. High quality chest compressions leads to increased cardiac output and maintains perfusion of systemic organs. Thus, resuscitation team members should evaluate the degree of systemic organ perfusion to improve the quality of chest compressions during cardiopulmonary resuscitation (CPR).

End tidal carbon dioxide (EtCO₂) is one of the most useful physiological markers to evaluate the degree of systemic organ perfusion during CPR. EtCO₂ is an indicator of cardiac output and reflects pulmonary perfusion, but EtCO₂ measurement requires intubation, which is not easily and rapidly performed.

In contrast, cerebral tissue oxygen saturation can be rapidly assessed during CPR, and serves as a possible indicator of return of spontaneous circulation (ROSC). Cerebral tissue oxygen saturation can be easily assessed by placing oximeter probes on the patients’ forehead. Increase in cardiac output and pulmonary perfusion improves systemic oxygenation and elevates regional cerebral tissue oxygen saturation. Studies that elucidate the relationship between cerebral tissue oxygen saturation and EtCO₂ during CPR are warranted.

Objectives: We investigated the relationship between cerebral tissue oxygen saturation and EtCO₂ to determine if cerebral tissue oxygen saturation can evaluate the quality of chest compression during CPR.

Methods: This is an observational study conducted from April to September 2019. Patients arrived in a state of cardiac arrest at the emergency department of Yamagata University Hospital in Japan. Cerebral tissue oxygen saturation was measured by near infrared spectroscopy (NIRO-200NX, Hamamatsu photonics, Japan) during CPR.

We assessed cerebral tissue oxygen saturation using two approaches. The first is TOI, which represents the ratio of oxygenated haemoglobin to total haemoglobin and the second is SnO₂, which is the ratio between the change in oxygenated haemoglobin and change in total haemoglobin. We also measured EtCO₂ following intubation. We compared cerebral tissue oxygen saturation with EtCO₂ every minute in cases in which both parameters were measured.

Results: Seven cases were included, and the median age was 81 years old. Three of the seven cases achieved ROSC, but none survived for one month. The median values for EtCO₂, TOI, and SnO₂ were 14.0 mmHg (inter quartile range (IQR): 10.0-18.0), 37.7% (IQR: 32.4-42.7) and 38.2% (IQR: 17.8-59.5), respectively. The correlation coefficient between TOI and EtCO₂ was 0.681 (95% confidence interval (95%CI) 0.559-0.774, p<0.001), and between SnO₂ and EtCO₂ was 0.459 (95%CI 0.288-0.601, p<0.001), respectively.

Conclusion: This study showed a strong correlation between tissue oxygen saturation and EtCO₂. This suggests that cerebral tissue oxygen saturation may reflect the degree of cardiac output that results from chest compressions during CPR.

Intensive Care Medicine Experimental 2020, **8(2)**: 000482

Introduction: Activation of a systemic inflammatory response after cardiac arrest (CA) due to whole-body ischemia/reperfusion injury complicates recovery and may lead to organ dysfunction. Neutrophilic granulocytes are rapidly reacting inflammatory cells that play a role in ischemia/reperfusion injury. Myeloperoxidase (MPO) and resistin are released from activated neutrophils. MPO is involved in the generation of reactive oxygen species upon neutrophil activation. Resistin has a

dual role in inflammation, it increases the production of several pro-inflammatory cytokines but inhibits neutrophil migration.

Objectives: We tested the association of MPO and resistin levels with 6-month neurological outcome in ICU-treated out-of-hospital cardiac arrest (OHCA) patients.

Methods: We analyzed blood samples taken upon ICU admission and at 48 hours from 108 OHCA patients with shockable rhythm included in the COMACARE study. We defined 6-month cerebral performance category (CPC) 1-2 as good and CPC 3-5 as poor outcome. We calculated area under receiver operating characteristic curve (AUC) to determine association of biomarker levels with poor outcome. We tested the relationship between return of spontaneous circulation (ROSC) delay and admission biomarker levels with linear regression.

Results: At ICU admission, median (interquartile range, IQR) concentration of MPO was 97 (46-170) ng/mL in good and 98 (52-197) ng/mL in poor outcome groups, and of resistin 39 (25-57) ng/mL in good and 43 (29-64) ng/mL in poor outcome groups. At admission the AUC for the association of MPO levels with poor outcome was 0.52 (95% CI 0.41 - 0.64) and for resistin 0.57 (95% CI 0.46 - 0.69). At 48 h the median (IQR) concentration of MPO was 92 (50-163) ng/mL in good and 104 (50-138) ng/mL in poor outcome groups, and of resistin 83 (57-146) ng/mL in good and 86 (53-172) ng/mL in poor outcome groups. At 48 h the AUC values were 0.47 (95% CI 0.36 - 0.58) (MPO) and 0.52 (95% CI 0.40 - 0.64) (resistin). The linear regression analysis showed that MPO levels at the time of admission were associated with ROSC delay (B 4.8, 95% CI 0.75 - 8.9, p-value 0.02). The same was observed for admission levels of resistin (B 0.77, 95% CI 0.09 - 1.45, p-value 0.03).

Conclusion: Duration of ischemia is associated with ICU admission levels of MPO and resistin, suggesting neutrophil involvement in the systemic inflammatory response after CA. The markers showed no ability to predict long term neurological outcome.

Intensive Care Medicine Experimental 2020, **8(2)**: 000485

Introduction: Cardiac arrest (CA) leads to activation of the inflammatory system due to whole body ischemia-reperfusion injury. Osteopontin (OPN), an extracellular matrix protein produced by many tissues and Proprotein convertase subtilisin/kexin 9 (PCSK9), a regulator of cholesterol homeostasis, play a role in the low-grade inflammation leading to coronary artery disease (CAD).

Objectives: Since CAD is the most important cause for CA, we tested if the release of OPN and PCSK9 is increased in the acute inflammation after out-of-hospital cardiac arrest (OHCA) and hypothesized, that they have prognostic value.

Methods: We studied blood samples of 112 patients with OHCA and shockable rhythm included in the COMACARE study. Biomarker levels were measured at the time of ICU admission and at 24, 48 and 72 hours. We used 6-month cerebral performance category (CPC) as the main outcome and defined CPC 1-2 as good and CPC 3-5 as poor outcome. We evaluated the association of admission biomarker levels with outcome using area under receiver operating characteristic curve

(AUC) analysis. We assessed temporal differences in biomarker levels with linear modeling with restricted maximum likelihood estimation (REML).

Results: Median (interquartile range IQR) concentration of OPN was 53 (41-79) ng/mL at admission, 160 (100-190) ng/mL at 24 h, 240 (170-360) ng/mL at 48 h and 240 (190-320) ng/mL at 72 h. For PCSK9 the concentrations were 160 (100-210) ng/mL at admission, 110 (74-160) ng/mL at 24 h, 160 (92-220) ng/mL at 48 h and 240 (170-330) ng/mL at 72 h. The predictive value of OPN at admission was weak (AUC 0.548, 95% confidence interval, CI 0.43-0.66) and similar results were observed for PCSK9 (AUC 0.551, 95% CI 0.44-0.67). With linear modeling we observed an effect of sample collection timepoint (F 98, P < 0.01) and poor outcome (F 6.8, P = 0.01) on OPN concentration. Sample collection timepoint had an effect (F 78, P < 0.01) on PCSK9 concentration but poor outcome did not show a statistically significant effect. The interaction of sample collection timepoint and poor outcome did not show a statistically significant effect on the concentrations of OPN or PCSK9.

Conclusion: Cardiac arrest is followed by changes in OPN and PCSK9 concentrations and the temporal course of OPN response differs between 6-month neurological outcome groups. The biomarkers did not have clinically relevant predictive value at ICU admission.

Intensive Care Medicine Experimental 2020, **8(2)**: 000510

Introduction: The Hampshire & Isle of Wight Air Ambulance (HIO-WAA) works alongside the ambulance service to provide a Prehospital Critical Care (PHCC) team to the south central region of England. It responds between the hours of 0700 - 0200 to both medical emergencies and major trauma, either by road or by helicopter. In November 2018, HIO-WAA adopted a new database (ARCnet) to support its commitment to a robust clinical governance frame

Objectives: This report reviews cases of medical (i.e. non-traumatic) out-of-hospital cardiac arrests (OOHCA) attended by the HIO-WAA team from the inception of the database to the end of December 2019 (13 months).

Methods: The ARCnet database was interrogated for all cardiac arrests from the beginning of November 2018 to the end of December 2019. Cases were included where HIO-WAA attended the scene and the patient had received chest compressions at any point. Likely or confirmed traumatic cardiac arrests were excluded. Retrospective review of the patient record forms (PRFs) were then carried out and key data collected.

Results: A total of 192 cases of non-traumatic cardiac arrest were identified over the study period. The median age was 61 (IQR 50-71; range). Over two thirds of patients were male (133 [69.3%] vs 58 [30.2%]).

Most missions were in the more populated urban and suburban main-land areas in the south of the region (Southampton, Portsmouth and the M27 corridor), with another cluster around Basingstoke. Overall, 106 patients (55.2%) were conveyed to hospital with HIO-WAA.

The majority of patients conveyed were taken to hospital by road (99 [94.3%]). Six patients (5.7%) were taken to their destination hospital by air, of which 5 were from the Isle of Wight (IOW) and one from Winchester to University Hospital Southampton (UHS). All patients transported by air had established return of spontaneous circulation (ROSC) prior to transfer and were either fully conscious and self-ventilating (2 patients) or sedated and ventilated (4 patients). In one case the mode of transport was not recorded and could not be established from the patient record. A doctor and paramedic crew attended 107 missions (55.7%) and 85 (44.3%) were attended by a paramedic only crew. Initial 999 calls occurred between the hours of 20:00-08:00 for 22 missions (11.5%).

The initial rhythm in most patients was non-shockable (i.e. asystole or pulseless electrical activity [PEA]). A quarter of patients had ROSC prior

to the arrival of HIOWAA. Of the remainder, a quarter subsequently achieved ROSC while treated by HIOWAA.

Cardiac arrest was witnessed in 126 patients (65.6%), unwitnessed in 58 (30.2%) and not recorded or unknown for 8 patients (4.2%). Of witnessed arrests, 102 patients (81%) received documented bystander CPR of which 67 (53.2%) had ROSC on arrival in ED. Unwitnessed arrests received bystander CPR in 41 patients (70.7%), did not receive bystander CPR in 10 (17.2%) and was not recorded in 7 (12.1%). Of the 10 patients that were neither witnessed nor received bystander CPR, two (20%) had ROSC on arrival in the ED.

A number of interventions were performed in both groups. In survivors, prehospital emergency anaesthesia (PHEA) was carried out in 24 patients (29.3%), vasopressors post-ROSC in 34 (41.5%) and ongoing intravenous sedation in 31 (37.8%). In non-survivors, life was declared extinct on scene in 81 patients (73.6%)

Conclusion: Our data is consistent with known determinants of outcome following cardiac arrest (witnessed cardiac arrest, bystander CPR and shockable rhythm all associated with higher chance of ROSC). Increasing age was associated with a lower chance of survival. In successful resuscitation, key interventions performed by the PHCC team not available to standard ambulance crews related primarily to post-resuscitation care following ROSC. In unsuccessful resuscitation, the PHCC team was also able to support decision-making and aid prognostication with the aid of ultrasound, which allowed termination of futile treatment without admission to hospital in the majority of cases without ROSC.

Intensive Care Medicine Experimental 2020, **8(2)**: 000528

Introduction: Prolonged depletion of oxygen and glucose during cardiac arrest may result in cytotoxic cerebral oedema. In cytotoxic oedema, water diffusion within the brain becomes restricted. Diffusion Tensor Imaging (DTI) allows quantification of diffusion restriction through Fractional Anisotropy (FA, the directionality of diffusion) and Mean Diffusivity (MD, the amount of diffusion). White matter FA appeared a promising outcome predictor after prolonged postanoxic coma [1, 2]. We now investigate predictive values of FA and MD in both grey and white matter, 2-4 days after cardiac arrest.

Objectives: To study differences in diffusion restriction of the brain using FA and MD, between comatose patients after cardiac arrest with good and poor neurological recovery, and estimate predictive values.

Methods: In an ongoing prospective cohort study, 33 comatose patients after cardiac arrest underwent 3T brain MRI 3±1 days after return of spontaneous circulation. From the DTI sequence, we calculated FA and MD of the whole brain, grey matter (GM) and skeletonised white matter (WM). MD and FA are likely influenced by free water, e.g. cerebrospinal fluid and vasogenic oedema. Other than in previous studies, we corrected MD and FA for the influence of free water [3]. As predictive marker, we calculated the percentage of brain volume with severe oedema, defined as MD<500*10⁻⁶. We compared FA and MD between patients with good (Cerebral Performance Category (CPC) 1-2) and poor (CPC3-5) outcome at 6 months and estimated predictive value based on a preliminary logistic regression model.

Results: Patients with poor outcome (n=16) showed significantly lower whole brain mean FA and MD (FA: 0.31, MD: 544*10⁻⁶) than patients with good outcome (FA: 0.34, MD: 589*10⁻⁶, p = 0.01, p =

0.01). MD within the GM showed the highest between-group difference (poor: 532*10⁻⁶, good: 585*10⁻⁶, p = 0.03). Patients with poor outcome had a significantly larger proportion of the brain with severe cytotoxic oedema (poor: 20%, good: 5%, p = 0.01). In a preliminary prediction model, we could predict poor outcome at 100% specificity with 75% sensitivity (95%CI: 46-93%, figure 1)

Conclusion: MD and FA of grey and white matter differ between patients with good and poor outcome, and hold potential to add to prediction of neurological recovery of comatose patients after cardiac arrest. The study is ongoing and updated results will be presented.

The use of neuron specific enolase to predict long term neurological outcome in OOHCA survivors

M. Nunn¹; M. Cadd¹; R. Grey¹; C. Maher²; J. Worthy¹; O. Boyd¹

¹Intensive care unit, Brighton & Sussex University Hospitals NHS Trust, Brighton, United Kingdom; ²Brighton & sussex medical school, Brighton & Sussex Medical School, Brighton, United Kingdom

Intensive Care Medicine Experimental 2020, **8(2)**: 000552

Introduction: There are approximately 60,000 out-of-hospital cardiac arrests (OOHCA) in the UK each year. Less than 10% of these patients survive to discharge (1) and hypoxic-ischaemic brain injury (HIBI) is common (2). HIBI can cause a range of sequelae from mild cognitive impairment to brain death.

Prognostication for HIBI post OOHCA remains difficult. The European Resuscitation Council (ERC) suggests a multimodal approach to prognostication including electroencephalogram (EEG), brain imaging and Neuron Specific Enolase (NSE) (2).

Objectives: To ascertain if there is a relationship between NSE, long-term neurological outcome and quality of life in OOHCA survivors.

Methods: This study was carried out at a tertiary centre with 31 critical care beds and was approved by the local research committee. The critical care electronic database was retrospectively analysed for OOHCA patients who survived to ICU discharge between May 2017 and November 2018. Patient demographics, NSE values, EEG and imaging reports were obtained for each patient.

Follow up telephone contact was made with each patient at least 14 months following ICU discharge. Verbal consent was obtained to collect anonymised information. A single investigator, who was blinded to NSE values, conducted all patient interviews. Neurological outcome was stratified using in-house standardised questions and the validated Cerebral Performance Category (CPC) (3). Patients were asked to subjectively assess their QoL on a locally devised numerical scale (Figure 1).

Results: Thirty-two patients (36.0%) survived to hospital discharge, four patients had subsequently died and two were not contactable; these patients were excluded from analysis. Eighty four percent of patients were male, the median age was 65 and 66% had known cardiovascular disease. Twenty patients (77%) had an NSE level. Data were analysed using Mann Whitney U test.

There were 3 patients with a poor neurological outcome (defined as $CPC \geq 3$) therefore it is a small patient group for analysis. However, there was no significant relationship between NSE and neurological outcome (good outcome defined as $CPC 1$ or 2 , poor outcome as $CPC \geq 3$) $p = 0.0963$.

Conclusion: The 72-hour NSE result in survivors showed no relationship with neurological outcome post-OOHCA at 14 months. It is noteworthy that the patient with the highest NSE had the worst outcome. Previous in-house research has shown an NSE of $>64.5 \mu\text{g/L}$ (100% specificity, 78% sensitivity) correlates with poor neurological outcome (4). One study suggests the NSE ratio at 48 and 24 hours can be used as a reliable prediction of outcome, which should be further investigated in our patient group (8). Larger scale follow-up studies should therefore be conducted to further assess the use of NSE in prognostication of long-term neurological outcomes for OOHCA patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 000593

Introduction: Recent studies [1] suggested a potential role of P25/30 SSEP in prediction of neurological outcome after OHCA. However it is not clear whether any particular patterns of 20-30msec SSEP complex could potentially improve the already established predictive value of N20.

Objectives: The main objective of this study is the integrated analysis of the 20-30 msec SSEP complex in order to identify all possible patterns and their potential prognostic value.

Methods: Single-centre, prospective, observational study. Adult comatose survivors of OHCA with Targeted Temperature Management [TTM] [normothermia], neuroprotection and organ support on ICU. SSEP recorded 24-36 h post return of spontaneous circulation. Analysis of the 20-30msec SSEP complex was performed by 2 independent interpreters: 1. The amplitude of both N20 and P25/30 was measured bilaterally from an agreed baseline. An amplitude threshold of 0.5microvolt [mcV] determined the presence or absence of each SSEP component. 2. The Peak To Peak Amplitude (PTPA) of the 20-30msec complex (peak of N20 to peak of P25) was also measured bilaterally. The largest PTPA was used to test potential correlations with patients' neurological outcome. Short term neurological outcome assessed at hospital discharge used the cerebral performance category [CPC] score: favourable outcome 1-2, unfavourable outcome 3-5.

Results: Data from the first 52 patients: 37 male, 15 female, median age 59.5 years. OHCA rhythm: 31 VF, 21 asystole. Cause of OHCA: 38 cardiac, 13 non-cardiac, 1 unknown. Median anoxic time 25 min. Median Temperature [T] in the first 24 h 36.0C. Median time of SSEP recording 25 h. Median T during SSEP recording 36.1oC. The preliminary clinical and neurophysiological analysis has done for the first 48 patients. 23 patients had favourable and 25 had unfavourable neurological outcomes. Among the 23 patients with a favourable outcome, both N20 and P25/30 SSEP were present in all. Among patients with an unfavourable outcome, both N20 and P25/30 were absent in 22, and N20 was absent but P25/30 was present in 3.

Use of 0.5 mcV as a threshold for the N20-P25/30 presence provided an objective method to minimise inter-interpretor variability and limit the effect of background noise in the analysis of the SSEP.

Median N20 amplitudes were consistently lower than P25/30 median amplitudes in patients with both favourable [N20: 1.325mcV, P25/30:

2.6mcV] and unfavourable outcomes [N20: 0.275mcV, P25/30: 0.35mcV].

The highest PTPA was ≥ 1.20 mcV in all patients with a favourable outcome [range 1.2-15.7mcV, median 3.825mcV], whereas in patients with an unfavourable outcome the highest PTPA was ≤ 1.3 mcV [range 0.1-1.3mcV, median 0.5mcV]. In the latter group, the PTPA was ≤ 1.0 mcV in all except 1 patient [1.3mcV]. PTPA values between 1.1 and 1.3mcV could be correlated with both outcomes. We are further investigating whether separate measurement of N20 or P25/30 amplitude could be used in this patient cohort as a distinctive feature between outcomes.

Conclusion: Addition of P25/30 in the analysis of 20-30msec SSEP complex may potentially increase N20's positive predictive value for the short term favourable neurological outcome after OHCA. Analysis of P25/30 does not affect N20's already established negative predictive value.

Direct PTPA measurements of the 20-30 msec SSEP complex provides an easy to measure value for future objective quantitative assessments. Preliminary results suggest PTPA of <1.1 mcV is associated with an unfavourable neurological outcome whereas a PTPA of >1.3 mcV appears to be associated with a favourable neurological outcome. As the number of patients increases, it will become clearer whether the above suggestions will be consistently reproduced and are statistically significant.

Intensive Care Medicine Experimental 2020, **8(2)**: 000620

Introduction: Out-of-hospital cardiac arrest (OHCA) carries a low survival rate, especially in rural areas. Coronary artery disease (CAD) represents the most common cause of collapse. Predictors of survival have been described in the literature. However, most studies have been conducted in city areas. Therefore, little is known about the resuscitation performances of emergency medical services (EMS) in non-city areas.

Objectives: We sought to perform a quality control assessment on the management of acute coronary syndrome (ACS) complicated with OHCA in non-urban areas. We explored standard parameters, resuscitation settings, pre- and in-hospital response times, lactate level, cath lab findings and clinical outcomes at 30 days.

Methods: The location of our institution consists of non-urban areas with a low population density. Built at the top of a hill, the hospital was initially founded in 1903 to treat patients suffering from tuberculosis. In this context, we performed a retrospective mono-center study including 40 patients resuscitated from OHCA with ACS.

Results: Parameters associated with 30-day mortality included age, no-bystander CPR, no use of AED, non-convertible rhythm, duration of CPR, recurrence of cardiac arrest, epinephrine dose, cardiac dysfunction, LAD culprit lesion and delivery time intervals (cath lab/ICU admission). Particularly, lactate level, distance from hospital, duration of pre-hospital management (no-flow, low-flow) and delayed response times (EMS arrival, ER admission) were predictive of early mortality.

Table : 30-day mortality related to patient characteristics, resuscitation settings, time intervals and demographic parameters.

Age: <50 yrs=7 (17%), D30: 1 (14%); 50-60 yrs=10 (25%), D30: 3 (30%); 60-70 yrs=14 (35%), D30: 6 (43%); >70 yrs=9 (23%), D30: 5 (56%), D4: 4 (80%)	No bystander CPR: 12 (30%), D30: 11 (92%), D6: 7 (64%); bystander CPR: 28 (70%), D30: 4 (14%); No use of AED: 12 (30%), D30: 6 (50%); Use of AED: 28 (70%), D30: 9 (32%); Non convertible rhythm: 6 (15%), D30: 5 (83%), D5: 4 (80%); Convertible rhythm: 34 (85%), D30: 10 (29%); Recurrent cardiac arrest: 7 (17%), D30: 6 (86%), D0: 4 (67%)
No-flow: 0'=27 (67%), D30: 5 (18%); $<5'$ =30 (75%), D30: 6 (20%); $>5'$ =10 (25%), D30: 10 (100%); Low-flow: $<5'$ =2 (30%), D30: 0 (0%); $<10'$ =15 (37%), D30: 0 (0%); $<15'$ =22 (55%), D30: 1 (4%); >15 min=18 (45%), D30: 14 (78%), D6: 10 (71%)	Epinephrine: ≤ 1 mg=15 (38%), D30: 1 (7%); 2-5 mg=16 (40%), D30: 7 (44%); >5 mg=9 (22%), D30: 7 (78%); Lactate: <5 mmol/l=25 (63%), D30: 2 (8%); 5-10 mmol/l=11 (27%), D30: 9 (81%), D6: 6 (66%); >10 mmol/l=4 (10%), D30: 3 (75%), D6: 4 (100%)
LVEF: $<30\%$ =16 (40%), D30: 12 (75%); 30-50%=9 (22%), D30: 9 (22%); $>50\%$ =15 (38%), D30: 1 (6%); Cardiogenic shock: 11 (27%), D30: 9 (82%), D6: 6 (67%); Culprit lesion: LAD=24 (60%), D30: 12 (50%), D6: 9 (75%); RCA=13 (32%), D30: 3 (23%); LCX=3 (8%), D30: 0 (0%)	Distance from hospital: <10 km=23 (57%), D30: 5 (22%), D6: 2 (40%); <20 km=34 (85%), D30: 9 (26%), D6: 5 (55%); >10 km=17 (43%), D30: 11 (65%), D6: 8 (73%); >20 km=6 (15%), D30: 6 (100%), D6: 5 (83%)
MMT arrival: $<10'$ =19 (48%), D30: 0 (0%); 10-15'=15 (37%), D30: 9 (60%), D6: 6 (67%); $>15'$ =6 (15%), D30: 6 (100%), D6: 4 (67%); ER admission: $<50'$ =13 (32%), D30: 0 (0%); $>50'$ =27 (68%), D30: 15 (56%), D6: 10 (67%); $>80'$ =10 (25%), D30: 7 (70%), D6: 4 (57%)	Cath lab admission: $<30'$ =10 (25%), D30: 1 (10%); 30-60'=14 (35%), D30: 5 (36%), D6: 3 (60%); $>60'$ =16 (40%), D30: 9 (56%), D6: 6 (67%); ICU admission: $<60'$ =27 (67%), D30: 5 (18%), D6: 2 (40%); $>60'$ =12 (30%), D30: 8 (67%), D6: 5 (63%)

Conclusion: Pre-hospital emergency care of patients with cardiac arrest remains challenging, particularly in non-city areas. Beyond the usual prognostic factors, it would appear that demographic parameters and pre-hospital time intervals represent major determinants of mortality. Therefore, shortening response times and prompt delivery to hospital facilities may help to improve the prognosis, rather than prolonged pre-hospital management. Further RCTs are needed to assess the effect of the 'scoop and run' approach versus the 'stay and play' approach in this setting.

Association of dispatcher-assisted bystander cardiopulmonary resuscitation with the likelihood of an initial shockable rhythm after out-of-hospital cardiac arrestY. Goto¹; A. Funada²; T. Maeda¹; Y. Goto³¹Department of emergency and critical care medicine, Kanazawa University Hospital, Kanazawa, Japan; ²Department of cardiology, Saiseikai Senri Hospital, Suita, Japan; ³Department of cardiology, Yawata Medical Centre, Komatsu, Japan**Correspondence:** Y. Goto*Intensive Care Medicine Experimental* 2020, **8(2)**: 000624

Introduction: Data are insufficient to address the association of dispatcher-assisted bystander cardiopulmonary resuscitation (DA-BCPR) before emergency medical services (EMS) arrival with the likelihood of an initial shockable rhythm after out-of-hospital cardiac arrest (OHCA). We hypothesised that more patients who received DA-BCPR would have initial shockable rhythm than those without bystander CPR (No-BCPR) and that DA-BCPR has an equivalent effect on the likelihood of initial shockable rhythm to that of bystander CPR without dispatcher assistance (Non-DA-BCPR).

Objectives: We aimed to examine the incidence rate of initial shockable rhythm according to the type of bystander CPR performed after OHCA in relation to bystander CPR duration.

Methods: The study included 114,473 patients (age, ≥ 18 years) who had an OHCA with a presumed cardiac origin witnessed by a layperson in a prospectively recorded Japanese nationwide Utstein-style database from 2013 to 2017. Patients who received public-access defibrillation before arrival of the EMS were excluded. The patients were divided into 3 groups as follows: DA-BCPR ($n=42,709$), Non-DA-BCPR ($n=16,979$), and No-BCPR ($n=54,785$). The primary end point was initial shockable rhythm recorded by the EMS after arrival. A Cox proportional hazards model was applied to reflect the different bystander CPR durations before/after propensity score (PS) matching.

Results: The crude rate of the initial shockable rhythm in DA-BCPR (21.7%, 9254/42,709) was significantly higher than those in Non-DA-BCPR (18.5%, 3133/16,979) and No-BCPR (17.5%, 9569/54,785; both $p<0.0001$). Before PS matching, age (adjusted hazards ratio [aHR] for 1 year decrement, 1.01; 95% confidence interval [CI], 1.01–1.01), rural area (aHR, 1.27; 95% CI, 1.25–1.29, $p<0.0001$), male sex (aHR, 1.12; 95% CI, 1.11–1.14, $p<0.0001$), arrest witnessed by family members (aHR, 1.06; 95% CI, 1.05–1.08, $p<0.0001$), and presence of bystander CPR ($p<0.0001$) were associated with substantially higher initial shockable rhythm rate at EMS arrival. As for the type of bystander CPR, we found no significant differences between DA-BCPR and Non-DA-BCPR in the association with the likelihood of initial shockable rhythm as follows: before PS matching, aHR of DA-BCPR for initial shockable rhythm compared with Non-DA-BCPR, 1.00; 95% CI, 0.99–1.03 ($p = 0.52$); after PS matching, aHR, 0.99; 95% CI, 0.97–1.02 ($p = 0.56$). As compared with No-BCPR, DA-BCPR was positively associated with initial shockable rhythm before (aHR, 1.17; 95% CI, 1.16–1.19; $p<0.0001$) and after PS matching (aHR, 1.07; 95% CI, 1.05–1.08; $p<0.0001$). Non-DA-BCPR was also positively associated with initial shockable rhythm before (aHR, 1.16; 95% CI, 1.14–1.19; $p<0.0001$) and after PS matching (aHR, 1.03; 95% CI, 1.00–1.05; $p = 0.04$) as compared with No-BCPR.

Conclusion: The patients who received DA-BCPR after witnessed OHCA due to presumed cardiac causes were more likely to have an initial shockable rhythm than those who did not receive bystander CPR. Moreover, DA-BCPR had the same multivariable-adjusted association with the likelihood of initial shockable rhythm as Non-DA-BCPR.

Relationship between dispatcher-assisted bystander cardiopulmonary resuscitation and initial shockable rhythm in children with out-of-hospital cardiac arrestY. Goto¹; A. Funada²; T. Maeda³; Y. Goto⁴¹Emergency and Critical Care Medicine, Kanazawa University Hospital, Kanazawa, Japan; ²Department of cardiology, Saiseikai Senri Hospital, Suita, Japan; ³Department of emergency and critical care medicine, Kanazawa University Hospital, Kanazawa, Japan; ⁴Department of cardiology, Yawata Medical Centre, Komatsu, Japan**Correspondence:** Y. Goto*Intensive Care Medicine Experimental* 2020, **8(2)**: 000633

Introduction: The association of dispatcher-assisted bystander cardiopulmonary resuscitation (DA-BCPR) before emergency medical services arrival with the likelihood of initial shockable rhythm in children with out-of-hospital cardiac arrest (OHCA) is unclear. We hypothesised that more children with OHCA who received DA-BCPR would have initial shockable rhythm than those without bystander CPR (No-BCPR) and that DA-CPR has an equivalent effect on the likelihood of initial shockable rhythm to that of bystander CPR without dispatcher assistance (Non-DA-BCPR).

Objectives: We aimed to examine the incidence rate of initial shockable rhythm according to the type of BCPR after OHCA in children. We aimed to examine the incidence rate of initial shockable rhythm according to the type of BCPR after OHCA in children.

Methods: We included 2198 paediatric patients aged 8 to 17 years with a witnessed OHCA who were identified from a prospectively recorded Japanese registry from January 2005 to December 2017. Patients who received public-access defibrillation before arrival of the emergency medical services were excluded. The patients were divided into 3 groups according to the type of BCPR as follows: DA-BCPR ($n=564$), Non-DA-BCPR ($n=466$) and No-BCPR ($n=1168$). The primary end point was initial shockable rhythm recorded by the emergency medical service. A Cox proportional hazards model was applied to reflect the different bystander CPR durations before/after propensity score (PS) matching.

Results: The crude rate of the initial shockable rhythm in DA-BCPR (24.3%, 137/564) was significantly higher than that in No-BCPR (11.0%, 129/1168; $p<0.0001$). No significant difference was found between DA-BCPR and Non-DA-BCPR (27.0%, 126/466) in terms of the crude rate of the initial shockable rhythm ($p = 0.31$). Before PS matching, rural area (adjusted hazards ratio [aHR], 1.20; 95% confidence interval [CI], 1.07–1.35, $p<0.01$), male sex (aHR, 1.18; 95% CI, 1.07–1.31, $p<0.01$), and Non-DA-BCPR compared with No-BCPR (aHR, 1.14; 95% CI, 1.00–1.29, $p<0.05$) were associated with substantially higher initial shockable rhythm rate at EMS arrival. As for the type of bystander CPR, DA-BCPR was positively associated with the initial shockable rhythm after PS matching (aHR, 1.27; 95% CI, 1.11–1.45; $p<0.0001$) when compared with No-BCPR. Non-DA-BCPR was positively associated with the initial shockable rhythm after PS matching (aHR, 1.41; 95% CI, 1.22–1.63; $p<0.0001$) when compared with No-BCPR. However, we found no significant difference between DA-BCPR and Non-DA-BCPR in their association with the likelihood of initial shockable rhythm after PS matching (aHR, 0.98; 95% CI, 0.83–1.16; $p = 0.81$).

Conclusion: Paediatric patients aged 8 to 17 years who received DA-BCPR after a witnessed OHCA were more likely to have an initial shockable rhythm than those who did not receive bystander CPR. Moreover, DA-BCPR had the same multivariable-adjusted association with the likelihood of initial shockable rhythm as Non-DA-BCPR.

Prediction criteria for poor outcomes in children with out-of-hospital cardiac arrest in the fieldY. Goto¹; A. Funada²; T. Maeda³; Y. Goto⁴

¹Emergency and Critical Care Medicine, Kanazawa University Hospital, Kanazawa, Japan; ²Department of cardiology, Saiseikai Senri Hospital, Suita, Japan; ³Department of emergency and critical care medicine, Kanazawa University Hospital, Kanazawa, Japan; ⁴Department of cardiology, Yawata Medical Centre, Komatsu, Japan

Correspondence: Y. Goto*Intensive Care Medicine Experimental* 2020, **8(2)**: 000638

Introduction: The current guidelines for cardiopulmonary resuscitation (CPR) after out-of-hospital cardiac arrest (OHCA) recommend the use of a universal basic life support termination-of-resuscitation (BLS-TOR) rule for emergency medical service (EMS) providers that was developed to identify adult patients with refractory OHCA eligible for field termination of CPR. However, the BLS-TOR rule is not recommended for children with refractory OHCA due to lack of evidence. We hypothesized that the establishment of outcome prediction criteria in the field for children with OHCA may be useful for better utilization of hospital healthcare resources and reducing attendant hazards for the EMS personnel.

Objectives: We aimed to develop and validate outcome prediction criteria children with OHCA that may aid EMS personnel in deciding to which hospital should they transport the patients.

Methods: We analysed the records of 20,872 children (age <18 years) who experienced OHCA treated by the EMS providers. Data were obtained from a prospectively recorded Japanese nationwide Utstein-style database for a 13-year period (2005–2017). Outcome measures were specificity and positive predictive value (PPV) of the newly developed criteria in predicting 1-month poor outcomes, namely, unfavourable neurological outcomes, defined as Cerebral Performance Categories score 3 to 5 (CPC 3–5), and mortality. Patients were divided into the development (2005–2014, n=16,660) and validation (2015–2017, n=4212) groups.

Results: The overall 1-month mortality and 1-month CPC 3–5 rates were 88.5% (18,471/20,872) and 95.6% (19,944/20,872), respectively. Multivariate logistic regression analyses for the development group showed that the EMS personnel could predict poor outcomes in patients if the patients met all of the following three prehospital criteria before performing EMS-initiated interventions in the field: asystole as the initial rhythm recorded by EMS personnel, OHCA unwitnessed by laypersons, and no bystander-administered intervention. For patients meeting all three criteria, the specificity and PPV for predicting 1-month CPC 3–5 were 97.8% (95% confidence interval [CI], 96.4%–98.7%) and 99.6% (95% CI, 99.4%–99.8%), respectively, for the development group and 97.1% (95% CI, 94.1%–99.8%) and 99.6% (95% CI, 99.1%–99.8%), respectively, for the validation group. The specificity and PPV of predicting 1-month mortality were 91.9% (95% CI, 90.6%–93.1%) and 96.5% (95% CI, 95.9%–97.0%), respectively, for the development group and 91.8% (95% CI, 89.3%–93.7%) and 94.4% (95% CI, 92.7%–95.8%), respectively, for the validation group.

Conclusion: With high specificity and PPV for predicting the 1-month unfavourable outcome, the EMS personnel could predict poor outcomes if children with OHCA met all three criteria, namely, asystole as the initial recorded rhythm, OHCA unwitnessed by laypersons, and no bystander CPR, soon after arrival of the EMS personnel at the patients' site.

Introduction: Recent international out-of-hospital and in-hospital cardiac arrest statistics show that despite a decrease in heart disease and stroke mortality, the burden of disease remains on top of society's health problems. There is a high variation in survival to hospital discharge and survival with functional recovery between different regions and different countries. Early identification of predictors for mortality and poor long-term neurological outcome in patients who survive the initial phase of cardiac arrest may provide critical information for physicians and facilitate clinical approach.

Objectives: The aim of this study was to identify the mortality rate of out-of-hospital and in-hospital cardiac arrest in our institution and to determinate the association between variables available from the patient's history and status at intensive care unit admission with mortality rate and neurological outcome. In subgroup analysis, we intend to study the impact on mortality of performing emergent coronary angiography on non-ST-segment elevation myocardial infarction (NSTEMI) patients.

Methods: We performed a retrospective review of all patients with the first diagnosis of "cardiac arrest" (CA) admitted to our intensive care unit (ICU) from 31 May 2015 to 31 May 2020. Patient selection and information collection were obtained through medical records. Outcomes were early mortality, including in-hospital and 1 month after discharge mortality, and neurological function as defined by the Cerebral Performance Category (CPC) scale after CA.

Group comparisons between survivals and non-survivals were performed using the Student-T test or Mann-Whitney U-test for continuous variables and Pearson chi-square test or Fisher test for categorical variables. For mortality outcome, multivariate logistic regression analysis with forward stepwise selection was performed to assess the association between the variables with statistically significant differences between the two groups. Correct adjustment of the model was analysed by the Hosmer and Lemeshow Test, and the ROC curve. A *p*-value less than 0.05 is statistically significant. Statistical analysis was performed using SPSS software version 25.0 (IBM, Armonk, NY, USA).

Results: Of the 114 patients included, 42 (36.8%) admitted to our ICU with the diagnosis of cardiac arrest were non-survivors and 72 (63.2%) were discharged alive from the hospital and survive at least one month after. We observe no significant difference between mortality rates of in-hospital CA (64.6%) versus out-of-hospital CA (59.4%) (*p* = 0.60). Univariate logistic regression analysis found the following factors associated with mortality: age greater than 75 years old (*p*-value<0.01), asystole or pulseless electrical activity (PEA) as cardiac rhythm at presentation (*p*-value = 0.03), total cardiopulmonary resuscitation (CPR) time greater than 5 minutes (*p*-value = 0.02), Glasgow coma scale (GCS) after the return of spontaneous circulation (ROSC) less than 5 (*p*-value<0.01) and another cause for CA besides acute ST-elevation myocardial infarction (STEMI) (*p*<0.01). In multivariate logistic regression, only GCS after ROSC less than 5 (odds ratio = 3.63, 95%CI = [1.25;10.56], *p*-value=0.02) and another cause for CA besides STEMI (odds ratio = 4.88, 95%CI = [0.98;24.34], *p*-value=0.05) proved to be predictive factors of mortality. Regarding the predictors of poor neurological prognosis, we identified the following variables as significant: CPR time greater than 5 minutes (*p*-value=0.03,

95%CI = [-8.82;-0.37]) and GCS after ROSC less than 5 ($p < 0.01$, 95%CI = [2.26;5.34]). Analytic parameters at admission (pH, lactate, bicarbonate, calcium, magnesium, potassium, phosphate and haemoglobin) and comorbidities (hypertension, diabetes mellitus, prior myocardial infarction and heart failure) show no significant difference on mortality or neurological prognostic. In subgroups analysis of acute coronary syndromes ($n=35$), we observed 21 patients with STEMI and 14 patients with NSTEMI. Between NSTEMI patients, 12 were submitted to coronary angiography, which 7 required percutaneous coronary intervention (PCI). We show no significant difference between mortality on NSTEMI patients submitted to emergent coronary angiography versus conservative approach ($p = 1.00$).

Conclusion: Our risk prediction model identified GCS after ROSC and cause of CA as important factors determining survival outcomes. Others factors like patient age, CPR time and cardiac rhythm at presentation showed less importance. We identified CPR time and GCS after ROSC as major predictors of a poor neurological prognosis. We showed no difference in early mortality for NSTEMI patients submitted to immediate invasive strategy.

Intensive Care Medicine Experimental 2020, **8(2)**: 000729

Introduction: Within the UK, health care outcomes following admission to hospital either 'in-hours' or 'out-of-hours' has recently gained significant interest. Variation in service availability and staffing levels across the week may have an impact on this. However, specialist NHS services, such as *Heart Attack Centres* (HAC) and ICU are mandated to run a fully operational service 24-hours a day, 7-days a week.

Objectives: We have undertaken a service evaluation of all patients admitted to ICU at a Central London HAC, who suffered an OOHCA within the last five-years.

Methods: All patients who suffered an OOHCA and admitted to the ICU at a Central London HAC were identified and clinical notes were reviewed. We classified 'in-hours' attendance to HAC as Monday- Friday from 08:00 - 17:00 (excluding public holidays). All hours outside of these periods were considered 'out-of-hours'. This service evaluation was registered locally.

Results: Of the 279 patients admitted to ICU following an OOHCA, 102 (36.6%) patients attended in-hours with 177 (63.4%) out-of-hours. Despite the fact that the patient cohort attending in-hours was significantly older than those attending out-of-hours, timing of HAC admission showed no significant impact upon whether patients had

a primary percutaneous intervention (PPCI), time taken for admission to ICU, ICU length of stay or survival to ICU and hospital discharge or at 1-year post cardiac arrest (Table 1).

Table 1

	All patients	In-Hours	Out-of-Hours	p-value
Number of patients	279	102	177	N/A
Median age (years)	63.0	67.5	61.0	0.010
Survival to ICU discharge	58.8%	55.9%	60.5%	0.455
Survival to hospital discharge	52%	52.0%	52.0%	0.998
One-year survival	42.2%	50.0%	49.7%	0.964
MRS of survivors	1.89	2.13	1.75	0.219
Median Temperature	35.82	35.77	35.84	0.194
Frequency of PPCI before GICU admission	78.9%	83.3%	76.3	0.164
Median time taken for GICU admission (mins)	185	187	184	0.267
Median length of stay on GICU (days)	6.81	6.50	6.83	0.230

Irrespective of time of day, attending either during the week (67.4%) or at the weekend (32.6%) had no impact on frequency of PPCI or hospital survival rate (Table 2).

Table 2

	Week Day	Weekend	p-value
Frequency of PPCI before GICU admission	153 (81.4%)	67 (73.6%)	0.137
Survival to hospital discharge	98 (52.1%)	47 (51.6%)	0.940

Conclusion: In our hospital experience, timing of admission had no significant impact on patient outcome. There was no greater length of time taken to be admitted to the ICU or length of stay on the unit. However, although not statistically significant, there was a greater tendency to perform a PPCI before admission to ICU when attending in hours or during a week day. This may be due to greater availability of staff or laboratory space.

Intensive Care Medicine Experimental 2020, **8(2)**: 000730

Introduction: Survival following ROSC from OOHCA is poor. Data from the London Ambulance Service suggests admission to a *Heart Attack Centre* (HAC) may improve outcome with 45.1% of patients surviving to hospital discharge, independent of initial heart rhythm 1.

Objectives: We investigate the effect of patient demographics, coronary angiography, PPCI and temperature on survival and neurological outcomes in all patients admitted to our ICU in the last 5-years.

Methods: A single centre, retrospective analysis of all OOHCA patients admitted to ICU from 2015-2019. We used hospital data on patient demographics, coronary angiography reports, temperatures during the first 24 hours and patient survival. Neurological outcomes of survivors were determined by modified rankin scale (MRS).

Results: 279 patients were admitted to ICU, of which 58.8%, 52.0% and 42.2% survived to ICU discharge, hospital discharge and 1 year

post-cardiac arrest respectively. Although males were more likely to be admitted post-OOHCA compared to females (76.4% vs 23.3%), males had a significantly better 1 year survival despite equivalent survival at ICU discharge (males 45.5%, females 30.1%, $p = 0.033$).

Table 1: Outcome divided by gender.

Survival	Male	Female	p-value
ICU (%)	58.68	58.46	0.97
Hospital (%)	53.99	44.62	0.19
1-year (%)	45.54	30.77	0.03

Age did not affect survival at unit discharge (age of survivors 62.0 vs non survivors 65.0, $p = 0.215$) but there was a significant difference at hospital discharge (survivors vs non-survivors 60.0 vs 66.0 respectively, $p = 0.007$). Gender did not affect age of survivors at hospital discharge (median male age=60, female=63, $p = 0.190$) or by 1 year (median male age=60, female=58, $p = 0.38$) nor did BMI (median BMI of survivors 26.78 v non-survivors 27.68 ($p = 0.254$)). The median MRS for survivors at hospital discharge was 1.89. Univariate analysis showed that gender was not a predictor of neurological outcome (Median MRS for males=2, females=1, $p = 0.26$) nor was age ($p=0.25$).

Table 2: Effect of coronary angiography on patient survival, MRS scores and temperature.

	Angiography	No angiography	p-value
Total	220	59	-
% Hospital survival	53.6	45.8	0.448
% 1-year survival	52.3	40.7	0.114
MRS	1.94	1.59	0.271
Median Temp (°C)	35.86	35.64	0.478

Coronary stenting was not shown to be a predictor of survival, quality of survival or average temperature (Table 3). Temperature had a significant effect on survival but there was no correlation between mean temperatures and MRS in survivors ($p=0.24$).

Table 3: Effect of coronary stent insertion on outcome.

	Stent inserted	No stent inserted	p-value
Total	127	84	-
% Hospital survival	56.6	51.0	0.527
% 1-year survival	55.0	50.0	0.471
MRS	1.74	2.14	0.258
Median Temp (°C)	35.86	35.85	0.889

Table 4: Effect of temperature on outcome.

	Temperature on Admission	Mean
Total	35.1	35.8
Died before hospital discharge	34.7	35.5
Hospital Survival	35.4	36.0
p-value	< 0.0001	<0.0001

Conclusion: Our data suggests our hospital had favourable outcomes compared with London. Negative outcomes after OOHCA may be associated with a colder initial and first 24-hour average temperature and a poorer 1-year outcome for those of female gender. Further work is required to understand these associations.

Intensive care clinician's identification of poor neurologic prognosis for post-cardiac arrest patients from EEG patterns identified in neurophysiologist reports: a questionnaire survey

L. Lilja¹; S. Joelsson²; S. Lindgren¹; P. Redfors³; P. Lundgren⁴; C. Rylander¹
¹Anesthesiology and intensive care medicine, Sahlgrenska University Hospital, Gothenburg, Sweden; ²Clinical neurophysiology, Sahlgrenska University Hospital, Gothenburg, Sweden; ³Neurology, Sahlgrenska University Hospital, Gothenburg, Sweden; ⁴Cardiology, Sahlgrenska University Hospital, Gothenburg, Sweden

Correspondence: L. Lilja

Intensive Care Medicine Experimental 2020, **8(2)**: 000933

Introduction: "Highly malignant" EEG patterns are predictive of poor neurologic outcome in comatose survivors from cardiac arrest. To identify such patterns, the referring intensive care clinician depends on the neurophysiologist report. An alternative to plain text EEG descriptions could be a short report confirming or denying the presence of EEG patterns compliant with the standardized EEG pattern categories "highly malignant", "malignant" and "benign" as proposed by Westhall *et al*. We hypothesised that identification of EEG patterns known to have a specific prognostic association may be difficult in plain text EEG neurophysiologist reports.

Objectives: To test whether the plain text EEG reports, or the EEG short statements granted higher degree of correct identification of prognosis.

Methods: Volunteering ICU clinicians in two university clinics were introduced to 17 authentic plain text neurophysiologist reports and three reports limited to a short statement declaring that "highly malignant", "malignant" or "benign" EEG patterns were present. They were asked to classify how the described EEG patterns would impact the neurologic prognosis of a comatose patient. The standardised scenario included a high neuron specific enolase (NSE), but other neurologic tests and neuroimaging were inconclusive. In consequence, the clinician's perception of the prognostic value of the EEG neurophysiologist report would affect the neurological prognostication according to international guidelines. The primary outcome was the proportion of clinicians who correctly identified the poor neurologic prognosis inferred by the "highly malignant" EEG patterns. Secondary outcomes were how "malignant" and "benign" EEG patterns were classified.

Results: Fifty-seven intensive care clinicians, 36 of whom were specialists, participated in the study. "Highly malignant" patterns consistent with poor neurologic prognosis were correctly identified by 73% in the plain text reports and by 93% in the short statements. "Malignant" patterns consistent with no impact on prognosis were correctly identified by 27%. A "benign" pattern consistent with a positive impact on prognosis were correctly identified by 58% in plain text reports.

The ICU clinicians' (n=57) appreciation of prognosis listed per standardized EEG short statement.			
EEG short statement	"Highly malignant"	"Malignant"	"Benign"
Prognosis poor	53 (93%)	34 (60%)	0
Prognosis not affected	4 (7%)	23 (40%)	4 (7%)
Prognosis positive	0	0	53 (93%)

Conclusion: ICU clinicians exposed to standardized EEG short statements defining the presence or absence of "highly malignant" EEG patterns, compared to plain text EEG neurophysiologist reports, are to a higher degree able to correctly identify a poor neurological prognosis in comatose survivors of cardiac arrest.

Correspondence: C. Palau Marti

Intensive Care Medicine Experimental 2020, **8(2)**: 000950

Introduction: Evidence shows that the mortality rate and the effects derived from a CPR lower if care response is improved and the survival chain amongst hospital is optimised. In this sense, medical staff's life support techniques training is essential, as it goes without saying that this improves the survival rates. Having said this, we proceed to examine the assessment results from the CPR training programme which started in 2017 and 2018 in a university tertiary hospital.

Objectives: The main objective of this project is to provide training for basic and advanced life support based on clinical simulations to a certain number of healthcare workers (nurses and medical assistants). Furthermore, didactic methods will be assessed using quality surveys.

Methods: Theory and practice classes were conducted by qualified basic and advanced life support teachers in groups of 12-15 healthcare workers. Advanced CPR mannequins as well as airway material were used. The participants were also provided with online access to extra teaching material. Finally, the participants had to fill in the satisfaction survey.

Results: There were 38 sessions in which 695 healthcare workers took part. Only 60% of the nurses and 38% of the medical assistants who participated were familiar with CPR, and 22% of the participants had never been present during a CPR. The programme received positive feedback. 90% of the participants were satisfied with aspects such as the teachers' teaching skills, the possibility to participate and the understanding of the theory.

Conclusion: The CPR training conducted in 2017 and 2018 has allowed healthcare workers to update the CPR knowledge they need. The use of clinical simulations has been regarded as effective in order to acquire skills to deal with risky situations. The professionals considered the training they received was excellent.

Intensive Care Medicine Experimental 2020, **8(2)**: 001006

Introduction: Catecholamines are recommended as the first-line drugs to treat hemodynamic instability after out-of-hospital cardiac arrest (OHCA) [1,2]. However, the benefit-to-risk ratio of catecholamines in the critical setting is dose dependent and their effect on metabolism and organ function early after OHCA has not been investigated.

Objectives: The aim of the analysis was to investigate the association between catecholamine and metabolism and organ function parameters during the first 72 hours after OHCA as well as to assess the importance of catecholamines dose for short-term survival.

Methods: The Post-Cardiac Arrest Syndrome (PCAS) pilot study was a prospective, observational, multicenter study. The details of the project were described elsewhere [3]. The endpoints of the prespecified analysis presented here were: 1. Lactate concentration as an indicator of oxygen delivery/anaerobic metabolism and neuron-specific enolase (NSE) as a brain injury marker, both assessed every 24 hours, over the first 72 hours after OHCA, 2. in-hospital mortality. Risk factors: 1. Norepinephrine dose ($\mu\text{g}/\text{kg}/\text{min}$), 2. Cumulative dose of catecholamines ($\mu\text{g}/\text{kg}/\text{min}$), 3. Vasoactive-inotropic score (VIS)

Results: Simple and multiple linear regression analysis showed that norepinephrine dose and cumulative catecholamines dose are both independent predictors of lactate concentration on admission, at 24 and 48 hours after OHCA (Table 1). Furthermore, norepinephrine dose and cumulative catecholamine dose were independent predictors of NSE concentration on admission ($r=0.466$, $p<0.0001$; $r=0.158$, $p=0.01$) and at 24 hours after OHCA ($r=0.327$, $p=0.04$; $r=0.345$, $p=0.003$). The VIS was independently correlated with NSE concentration on admission ($r=0.61$, $p<0.0001$). Cumulative catecholamine dose as well as VIS on admission were significantly associated with in-hospital mortality in univariate and multivariate analysis. Norepinephrine dose on admission was associated with in-hospital mortality in univariate analysis (Table 1).

Table 1. Impact of catecholamine dose on lactate concentration within the first 48 hours after OHCA and on in-hospital mortality.

Multiple regression model*	β coefficient	r coefficient	t Stat	p-value
Norepinephrine dose on admission	2.264	0.238	2.743	0.007
Norepinephrine dose 24h after OHCA	3.283	0.36	4.138	<0.0001
Norepinephrine dose 48h after OHCA	1.856	0.314	3.21	0.001
Cumulative catecholamine dose on admission	0.073	0.184	2.091	0.03
Cumulative catecholamine dose 24h after OHCA	0.099	0.4291	4.959	<0.0001
Cumulative catecholamine dose 48h after OHCA	0.02	0.229	2.291	0.02
In-hospital mortality	Univariate OR (95% CI);p-value		Multivariable* OR (95% CI);p-value	
Norepinephrine dose on admission	2.330 (1.106 – 4.909); 0.04		11.95 (0.802 – 178.00); 0.07	
Cumulative catecholamine dose on admission	2.14 (1.876 – 2.654);0.02		1.09 (1.003 – 1.189); 0.04	
VIS on admission	3.54 (3.104 – 3.967);0.001		1.04 (1.011 – 1.073); 0.006	

Conclusion: Dose of catecholamines administered early after OHCA is associated with lactate and NSE concentration, which may suggest their importance for impaired tissue oxygen delivery, enhanced anaerobic metabolism and organ injury. Dose of catecholamines on admission is related with in-hospital mortality after OHCA.

Intensive Care Medicine Experimental 2020, **8(2)**: 001022

Introduction: Extracorporeal Cardiopulmonary Resuscitation (ECPR) is internationally recognised as an intervention to enable physiological support of patients in refractory cardiac arrest. The evidence base for this type of support comes from a mixture of both cohort and case series and is applied to specific group of patients. To assess the potential benefit of an ECPR service a review of 2 years of patients presenting to the Emergency Department with out of hospital cardiac arrest was undertaken.

Methods: Inclusion criteria were defined based on evidence available and the practice undertaken in other parts of the UK. These criteria were: age <60 years, witnessed arrest, immediate bystander CPR, >10 minutes of resuscitation but <45 minutes of CPR on arrival in the Emergency Department, the presence of electrical activity. Postcodes were also looked at to assess the distances from the department within a 10 km and 20 km radius. Timings of cases were assessed to give an overview of in hours (08:00 to 17:00) and out of hours (17:00 to 08:00) workloads. Data was taken from Emergency Department presentations recorded as cardiac arrest, with a presentation review from electronic systems.

Results: 109 patients were identified over a two-year period between January 2018 to December 2019. This was split into 46 patients in hours and 63 patients out of hours. Not accounting for age or CPR extending beyond 45 minutes, 17 patients (36.9%) met the criteria in hours and 19 patients (30.1%) out of hours. However, when excluding patients with CPR ongoing longer than 45 minutes on arrival there were 11 patients (23.9%) in hours and 11 patients (17.4%) out of hours. Further considering patients that were 60 years or younger found that only 6 patients (13.0%) in hours and 3 patients (4.7%) out of hours met criteria for extracorporeal resuscitation. Considering in hours cases there were 35 within 20 km and 30 within 10 km. Considering distances for cases out of hours there were 43 within 20 km and 40 within 10 km of Aberdeen Royal Infirmary. All the patients that met criteria died in the Emergency department.

Conclusion: Over two years the case load for patients that meet the criteria for ECPR in the local areas is low, and even when considering a 24-hour period it remains a small number of patients. However, when

considering service implementation, it is important to note that all the patients meeting criteria died in the Emergency Department and that there is a significant number of cardiac arrest cases within close traveling distance of Aberdeen Royal Infirmary. Due to this there may be an reasonable argument for the development of an ECPR service. Any service development would need to consider the pathway of care that is delivered from the pre-hospital setting as well as the instigation of ECPR in the hospital as timeframes for establishing a patient on VA-ECMO are crucial to overall outcome. More work is needed to further develop local cardiac arrest care in the North-East of Scotland.

Intensive Care Medicine Experimental 2020, **8(2)**: 001075

Introduction: The neurological prognosis of comatose survivors of cardiac arrest is recommended to be multimodal (1). Somatosensory Evoked Potentials (SSEP) is one of the methods used. Bilateral absence of cortical SSEP response is associated with poor prognosis. As a tool for hospitals lacking the SSEP modality, Daubin et al. constructed a scoring system based on clinical signs and electroencephalography (EEG) aiming to predict the absence of the cortical N20-signal (2).

Objectives: We applied this scoring system to assess the need for the SSEP modality as a potential addition to the current multimodal prognostic examinations of comatose survivors of cardiac arrest in the Sahlgrenska University Hospital, Gothenburg, Sweden.

Methods: Survivors of out-of-hospital cardiac arrests (OHCA) who remained unconscious >72 hours after return of spontaneous circulation (ROSC) were classified according to the scoring system. We had to assume that EEG patterns classified according to Westhall et al. scored similar points as EEG classified according to Synek which was used by Daubin (3, 4). Using the cut-off values defined by its authors, the proportion of patients with predicted absent N20-signal on SSEP was calculated.

Results: 37 patients with OHCA were included and 13 (35%) of these were predicted to have bilaterally absent N20-signals based on the total score on day 3, 48-72 hours after ROSC.

Conclusion: Using the scoring system constructed by Daubin et al. (2) with minor adaptations, we calculated that one third of patients with OHCA, who remained unconscious >72 hours after ROSC, would have absent cortical signals on SSEP. Hence, the use of SSEP would be meaningful in at least the other two thirds of OHCA patients. These results are essential for the dimensioning of a future SSEP service for the intensive care units in the Sahlgrenska University Hospital.

Intensive Care Medicine Experimental 2020, **8(2)**: 001115

Introduction: Extracorporeal cardiopulmonary resuscitation (ECPR) for refractory out-of-hospital cardiac arrest (OHCA) recently developed with disappointing limited survival (1) and still requires more selective inclusion criteria.

Objectives: To evaluate clinical benefit of an ECPR protocol in OHCA and to investigate potential predictive variables on admission.

Methods: Between 2011 and 2020, we analysed 80 ECPR candidates admitted in 2 Belgian reference centres. From 2016 an ECPR protocol based on 6 prehospital criteria was implemented (no flow < 3 minutes, low flow < 60 minutes, initial shockable rhythm, end-tidal CO₂ > 15 mmHg, age < 65 years and absence of comorbidities). Scoop-and-run strategy and admission metabolic criteria for resuscitation discontinuation were also evaluated.

Results: Twenty-six (32%) OHCA patients benefited from ECPR, their hospital survival rate was 43% (n=9/21) after protocol implementation. Prehospital inclusion criteria did not discriminate survivors and nonsurvivors (p=0.92). By contrast, any transient return of spontaneous circulation (ROSC) before ECPR (89 vs. 17%, p=0.002), higher serum bicarbonate (14.0 (10.6 -15.2) vs. 7.5 (3.7 - 10.5) mmol/l, p = 0.019), lower base deficit (14.9 (11.9- 18.2) vs. 21.6 (17.9 -28.9) mmol/l, p=0.039) and initial lactate < 900 mg/dl (5/9 vs. 1/12, p=0.046) were associated with a more favourable outcome. Best cut-offs were bicarbonate > 10 mmol/L, base deficit < 18 mmol/L, lactate < 900 mg/L and fibrinogen > 1,8 g/l (figure). Four patients became organ donors after brain death.

Conclusion: This observational study shows that, in ECPR candidates, base deficit on admission and any transient ROSC before cannulation were significantly associated with better survival. Integration of ROSC and base deficit into inclusion criteria for ECPR in refractory OHCA could improve resources allocation.

Intensive Care Medicine Experimental 2020, **8(2)**: 001152

Introduction: In-hospital cardiac arrest (IHCA) is common and associated with a high mortality rate. However, it has received little attention compared with other critical cardiovascular conditions.

Objectives: This study is aimed to analyze the association between IHCA patients and healthcare related risk factors.

Methods: Data for this study enrolled IHCA patients from 14 regional hospitals, 2 district hospitals, and 5 medical centers between 2013 June to 2018 December. Primarily, the registry enrolled patients once "collapse" event was disclosed regardless of the witness, and a total of 7,731 cases was included initially. Patients with index hospitalization for Out-of-Hospital Cardiac Arrest (OHCA), IHCA patients without acute life support (ALS) attempt, undetermined sex, Age \leq 18 or \geq 120 years old, and patients with "do not resuscitate (DNR)" consent were excluded. Finally, a total of 5,306 patients were included in the analysis

Results: As for overall IHCA patients, HR for mortality was higher in older patients (HR = 1.11), and those underwent vasoactive agents in ALS (HR = 1.20). While, initial rhythm as ventricular fibrillation (HR = 0.62) reduced the risk of mortality in IHCA patients. With regard to

subgrouping IHCA patients in ICU and ER, patients underwent vasoactive agents in ALS (HR = 1.19) had poor survival. Whereas, better survival was reported in patients with initial ventricular tachycardia (HR = 0.63) and ventricular fibrillation (HR = 0.59). Regarding patients in general wards, old age (HR = 1.21) and shift between 24:00 to 08:00 (compared to 08:00–17:00) (HR = 1.26) lead to poor outcome.

Conclusion: The majority of initial detected rhythm in IHCA patients was non-shockable. Factors for poor survival included old age, over-night shift, and vasoactive agents. While, better survival was noted in patients with witness, those underwent targeted temperature management, and those with initial detected ventricular fibrillation. With regard to conditions at discharge, patients with regained conscious and those with good neurologic performance had better survival.

Hemodynamic effect of hypertonic lactate infusion after resuscitation in an experimental model of cardiac arrest

F. Annoni¹

¹Intensive Care, Université Libre De Bruxelles / Campus Érasme, Anderlecht, Belgium

Correspondence: F. Annoni

Intensive Care Medicine Experimental 2020, **8(2)**: 000484

Introduction: Among cardiac arrest (CA) survivors, post CA syndrome is responsible for poor outcome and is one of the main causes of deaths in these patients^{1,2}. Lactate enriched solutions could exerts positive effects on the heart, where the myocardial reperfusion injury is responsible for a consistent fraction of the organ damage³⁻⁵. Several protocols have demonstrated how an ischemic post-conditioning strategy based on lactate-enriched solutions could reduce the magnitude of the reperfusion injury^{6,7}, but no study has investigated the impact of hypertonic sodium lactate (HSL) infusion on macro-hemodynamic variables after CA.

Objectives: To investigate the hemodynamic impact of the infusion of HSL after resuscitation in an experimental model of cardiac arrest

Methods: 27 adult domestic pigs were enrolled in the study. After proper sedation and preparation, including endotracheal intubation, invasive arterial pressure monitoring and pulmonary artery catheter, a ventricular fibrillation was induced via a pace-maker wire and left untreated for 10 minutes, when cardio-pulmonary resuscitation (CPR) were started at the rate of 100/minute with Lucas III device and continued for 5 more minutes. After the first minute of CPR and eventually after 7 minutes, an injection of Adrenaline was provided and at the end of the 5 minutes an electric shock (200 J) was delivered and repeated every minute to achieve Return of Spontaneous Circulation (ROSC). The animals were divided as follow: 9 as control group received a bolus of crystalloids during CPR and infusion during 12 h after ROSC (G0); 9 received HSL both during CPR and after ROSC (G1) and 9 received a bolus of crystalloids during CPR and HSL infusion after ROSC (G2). HSL solution was prepared by diluting into injectable sterile water a 2 mEq/mL solution (Monico spa, Mestre, Italy) to achieve a 1 M solution with calculated osmolarity of 2000 mOsm/L.

Results: All the animals in the study achieved ROSC. No differences were found between groups in the distribution of sex and weight, as well as in number of shocks needed to achieve ROSC, adrenaline dose, first end tidal CO₂ measurement or baseline pH. To investigate differences on dependent variables over time between groups, a general linear mixed model was used. Arterial lactate levels were higher in the group of animals which received HSL (G1-G2) compared to G0 during the study course ($p < 0.001$). To achieve the same mean arterial pressure level of 65 mmHg, there was a significantly lower requirements for vasopressors between groups over the study period ($p < 0.01$) and in the post-hoc analysis with Bonferroni correction, there was a significant difference between G0 compared to G1 ($p < 0.001$) and G2 ($p < 0.001$), but not between G1 and G2 ($p = 0.55$).

Conclusion: In animals treated with continuous HSL infusion there is a significantly lower requirements of vasopressors in the first hours following resuscitation after cardiac arrest.

Intensive Care Medicine Experimental 2020, **8(2)**: 000037

Introduction: Current international guidelines recommend the presence of a family member during cardiopulmonary resuscitation (CPR) as this has beneficial psychological effects for relatives witnessing the event [1;2]. Contrary, there is only sparse data on the quality of team performance and the psychological well-being of health-care workers during relative-witnessed CPR.

Objectives: This prospective randomized trial investigates the effects of a family witness on team performance and perceived stress levels in simulated cardiac arrests.

Methods: 325 teams of 3 to 4 physicians each were randomized to perform CPR in a simulated cardiac arrest in the presence or absence of a family witness (trained actor). Additionally, teams were randomized to designated or emergent leadership. Video-recordings obtained during CPR simulations were used for data analysis. The perceived task load was assessed by the NASA task load index (TLX). Primary endpoint was percentage of “hands-on” time. Secondary outcomes included adherence to treatment algorithms, the perceived task load and the effects of designated leadership on primary and secondary outcomes.

Results: In groups with a present relative, verbal interaction occurred cumulatively during 105 ± 66 sec, representing 27 ± 16% of the study time. Teams without a leader had significantly more verbal interaction with the relative (123 ± 75 sec vs. 96 ± 58 sec, $p = 0.014$) corresponding to 33 ± 20% vs 24 ± 14% ($p = 0.001$) of the study time. Primary outcome: percentage “hands-on” time was 86.6 ± 6.3% in the relative present groups vs. 87.3 ± 5.6% in the control groups ($p = 0.25$). Secondary outcomes: time to first defibrillation was 81 ± 38 sec in groups with a relative present and 77 ± 41 sec in control groups ($p = 0.49$). Designated leadership had no effect on medical performance markers. The presence of a relative was associated with significantly higher NASA-TLX ratings for the domains “temporal demands” ($p < 0.001$) and “frustration” ($p < 0.001$) while there was a borderline difference ($p = 0.057$) for the domain “mental demand” and no significant differences for “effort” ($p = 0.62$) and “performance” (0.96). Designated leadership had no significant effect on NASA-TLX ratings.

Conclusion: The presence of a relative during simulated CPR significantly increased the perceived task load for resuscitation teams without impairing their medical team performance measures. Having designated team leaders was associated with decreased verbal interaction with the relative but had no effect on the perceived work load or the team performance. Thus, resuscitation teams seem capable to cope with the additional psychological burden imposed by a family witness.

Intensive Care Medicine Experimental 2020, **8(2)**: 000003

Introduction: The population of ACHD patients continues to grow in the USA^{1,2,3}. There exists a paucity of data in the realm of evidence-based critical care medicine management of ACHD patients.

Objectives: To analyze our ACHD population with respect to clinical, anatomical, and physiological characteristics in order to understand associations to Intensive Care Unit (ICU) morbidity and outcomes. This information will serve to improve clinicians' ability to understand the various factors that influence outcomes in critically ill ACHD patients with unplanned and post-operative ICU admissions.

Methods: Retrospective chart review was completed on all ACHD patients with ICU admissions between 01/2015–12/2018. Demographic, anatomical, and physiologic characteristics were recorded. We examined associations between these characteristics and patient outcomes.

Results: There were 134 ICU admissions ages 18 to 79. 71% (n= 95) were admitted after elective cardiac surgery and 29% (n= 39) were non-surgical, unplanned admissions. Factors associated with ICU Length of Stay (LOS) in the elective, surgical cohort are shown in the table. Right Ventricle (RV) dysfunction was associated with more ventilator days (median 2.0 vs 1.0, p=0.009) and a higher rate of Acute Kidney Injury (AKI) after cardiac surgery (57% vs 19%; p=0.001). NYHA class 3 or 4 vs 1 or 2 was associated with increased post-operative complications (56% vs 22%; p=0.001) and AKI (44% vs 17%; p=0.004). Post-operative arrhythmia was associated with increased ventilator days (p=0.0002). For unplanned admissions, higher lactic acid was associated with AKI (p=0.01), increased ICU LOS (p=0.02) and ventilator days (p=0.016).

Planned Surgical Cohort (n=95)	Percentage (n=number)	ICU LOS Median days	P Value
Physiology class 3,4 vs 1,2	80(n=76) vs 20(n=19)	2.0 vs 1.0	0.03
NYHA 3,4 vs 1,2	43(n=41) vs 57(n=54)	3.0 vs 1.0	0.01
Tobacco use vs none	33(n=31) vs 67(n=64)	3.0 vs 1.0	0.03
LV Dysfunction vs none	13(n=12) vs 87(n=83)	5.0 vs 1.0	0.01
RV Dysfunction vs none	24(n=23) vs 76(n=72)	5.0 vs 1.0	0.0001
Shock vs no shock	47(n=45) vs 53(n=50)	3.0 vs 1.0	0.0001
Redo sternotomy vs none prior	48(n=46) vs 49(n=47)	2.5 vs 1.0	0.04
Arrhythmia	29(n=28) vs 71(n=67)	4.0 vs 1.0	0.003

Conclusion: Clinical characteristics of ACHD patients are associated with ICU morbidity and outcome. By better understanding these associations we may improve critical care management in the ACHD population.

Intensive Care Medicine Experimental 2020, **8(2)**: 000071

Introduction: Right ventricular (RV) function is increasingly recognised as a contributing factor to outcome in cardiogenic shock (CS) post ST elevation myocardial infarction (STEMI). This was previously demonstrated with regards to long term outcome¹, but not short term.

Objectives: In this study we sought to determine the correlation between RV dysfunction and 28-day mortality in CS post STEMI with impaired left ventricle (LV).

Methods: Retrospective analysis of 100 patients admitted to intensive care unit (ICU) with CS post STEMI. Medical history, culprit lesion, clinical data, echocardiography data including multiple parameters of RV and LV. Clinical and Echocardiographic parameters were correlated with 28-days mortality.

Results: 100 patients admitted over 3 years period were included. Mean age 62.6± 12.7y, 78% were male, 38% suffered out of hospital cardiac arrest and 28-day mortality was 37%. Non-survivors had no statistically significant difference in age, gender, medical history or culprit lesion. Non-survivors had significantly higher acute physiology and chronic health score II (APACHE II, 20±6 v 15±4 p .0001), creatinine (133 (IQR 114 – 210) v 103 (96 – 150) mmol/L, p .005), lactate (5.2 (IQR 2.5 – 8) v 3 (2.2 – 5.2) mmol/L p .03) and lower mean arterial pressure (50±1 v 55±7 mmHg, p .02). Tricuspid annulus peak systolic velocity by tissue doppler (RV S') was significantly lower in non-survivors (10±3.5 v 12±3.3 cm/s, p .03). Otherwise all parameters were comparable. In multivariate analysis of significantly significant clinical and echocardiographic parameters, RV S' was found to be an independent predictor of 28-days mortality. In univariate analysis RV S' significantly predicted outcome (OR 1.2, 95% CI 1.1 – 1.4 p .04) (Figure 1A). RV S' of 10.5 cm/s exhibited best sensitivity and specificity in receiver operator curve analysis (64% and 65% respectively, area under the curve 0.66 95% CI 0.52 – 0.80, p .02) for prediction of 28-days outcome. Kaplan-Meier survival curves revealed 85% survival for RV S' > 10.5 cm/s and 53% for RV S' < 10.5 cm/s and the curves were significantly different (log rank p .01) (Figure 1B).

Figure 1. RV S' prediction of survival. A. Univariate analysis of RV S' association with 28-days outcome. Kaplan-Meier survival curves of 28 days mortality using RV S' cut-off value of 10.5 cm/s.

Conclusion: RV dysfunction influences short term outcome in patients admitted with CS post STEMI and impaired LV. RV S' was an independent predictor of 28-days mortality and a cut-off of 10.5 cm/s was able to predict outcome with reasonable sensitivity and specificity.

Intensive Care Medicine Experimental 2020, **8(2)**: 000080

Introduction: Septic shock, a form of distributive shock, is characterized by decreased organ perfusion due to severe peripheral vasodilation in the setting of sepsis and dysregulated host inflammatory response to infection that is unresponsive to adequate fluid resuscitation. It is unclear what the ideal third line vasopressor is after norepinephrine and vasopressin.

Objectives: We conducted a retrospective cohort study, examining patients with septic shock who were not responsive to maximal doses of two vasopressors and required a third agent; we compared patients who received angiotensin II versus any other vasopressor as their third agent.

Methods: Patients included in the study were admitted to the ICU between July 2017 and March 2019. Eligible patients were at least 18-years-old, with catecholamine-resistant hypotension, defined as those who require a total sum catecholamine dose of >0.2 µg/kg/min to maintain MAP between 55 and 70 mmHg, typically a combination of norepinephrine and vasopressin. After screening patients who did not meet inclusion criteria and those with incomplete data points, a total of 50 patients were studied, 29 in the angiotensin II group, 21 in the control group. Primary endpoint was the change in mean arterial pressure- MAP. Secondary endpoints included total length of ICU stay.

Results: In our 50 patients, there was a statistically significant increase in MAP at three hours in the angiotensin II group compared to the control group (16.3 mmHg vs. 4.3 mmHg; $p = 0.0304$). Overall, calculated lactic acid clearance at 3 hours in the angiotensin II group was better than in the control group (13.39% vs -57.2%), but this was not statistically significant ($p = 0.1338$). There was no significant difference in ICU length of stay.

Conclusion: Initiation of an angiotensin II agonist as a third-line agent showed a statistically significant improvement in mean arterial pressure at 3 hours compared to a traditional third-line agent. Further prospective studies are required to evaluate clinical outcomes in the intensive care unit.

Intensive Care Medicine Experimental 2020, **8(2)**: 000083

Introduction: Pulmonary thromboembolism continues to be a high incidence pathology, with a high mortality rate, whose treatment depends on the risk of mortality at 30 days. In low and intermediate risk thromboembolisms the indicated treatment is anticoagulation, and in high risk thromboembolism fibrinolysis if it is not contraindicated. Patients with intermediate-high risk do not have a clearly defined treatment since fibrinolysis has shown an increase in the incidence of bleeding without an improvement in survival, with thrombectomy being a therapeutic possibility in this group of patients.

Objectives: Evaluate clinical and echocardiographic evolution in patients with acute intermediate-high and high risk pulmonary thromboembolism (PTE).

Methods: Patients collected between January 2016 and August 2019 with diagnosis of PTE of intermediate-high risk, defined by the guidelines of the European Society of Cardiology as positive markers of myocardial damage, right ventricular dysfunction measured by echocardiogram and stable hemodynamically; and high risk, hemodynamically unstable; who underwent mechanical thrombectomy in the first 24 hours of admission in ICU with aspiration of approximately 70 to 80% of the thrombus. Thrombectomy was performed in 42 patients, transthoracic echocardiogram (ETT) was performed at admission and 24 hours post-procedure, collecting parameters of right ventricle dysfunction (TAPSE, Wave S, right ventricle diameter [RV]), pulmonary hypertension [HTP]; arterial blood gas at admission and after 24 hours to calculate PaFi; and clinical assessment of the patient at admission and 24 hours after thrombectomy. The analysis of the data obtained comparing the situation before and after the procedure was carried out.

Results: Echocardiographically: significant improvement was obtained in the diameter of the RV ($46'34 \pm 4'71$ mm at $42'13 \pm 6'37$ mm, $p < 0.05$), TAPSE ($15'29 \pm 3'63$ mm at $18'49 \pm 3'98$ mm, $p < 0'05$), S wave ($9'45 \pm 1'93$ cm / sg at $11'9 \pm 3'26$ cm / sg, $p < 0'05$) and not significant of the HTP ($50'63 \pm 13'80$ mmHg at $46'81 \pm 19'14$ mmHg, $p0'256$). Analytically: significant improvement of the PaFi ($186'87 \pm 127'9$ to $287'58 \pm 97'348$, $p < 0.05$). Clinically there was no significant improvement in chest pain, dyspnea or hemodynamic instability.

Conclusion: Mechanical thrombectomy in patients with acute pulmonary thromboembolism of intermediate-high and high risk is an effective technique that significantly improves the parameters of right ventricular dysfunction and the oxygenation of patients. There was no significant improvement in clinical aspects such as dyspnea, chest pain or hemodynamic stability.

000149**Bilirubin—possible prognostic mortality marker in patients with VA-ECMO**S. Roth¹; S. Bunte¹; G. Lurati Buse¹; H. Aubin²; R. Walz¹; R. Huhn¹¹Department of anesthesiology, University Hospital Duesseldorf, Duesseldorf, Germany; ²Department of cardiovascular surgery, University Hospital Duesseldorf, Duesseldorf, Germany**Correspondence:** S. Roth*Intensive Care Medicine Experimental* 2020, **8(2)**: 000149

Introduction: Veno-arterial membrane oxygenation (VA-ECMO) is a promising therapeutic option for patients with refractory cardiogenic shock or circulatory failure. However, as mortality rate of VA-ECMO-treated patients still remains high, there is a need for early outcome parameters reflecting on therapy success or futility.

Objectives: In the present study we investigated whether the liver enzyme levels in patients that survived the first four days of VA-ECMO therapy could serve as prognostic marker, hypothesizing that Bilirubin has the potential to be a mortality marker in this cohort.

Methods: The present study is a retrospective single center cohort study approved by the Ethics Committee of the Heinrich Heine University Duesseldorf (Reference Number 5141R). Adult patients over 18 years of age who received VA-ECMO therapy for refractory cardiogenic shock or circulatory failure between 2011 and 2018 were included. VA-ECMO was deployed either at the home center or by the local team on-site in external hospitals. Only patients who survived the first four days of VA-ECMO therapy were included into the analysis. For quantification of liver function Bilirubin was analysed at predefined time points (day 0, 5, 10, 15). The primary endpoint was all-cause in-hospital mortality. The association between Bilirubin and mortality was examined by receiver operating characteristic curve (ROC) and the area under the curve (AUC) as well as univariate and multivariable cox regression. In a sensitivity analysis, patients with shock-liver (defined as GOT > 10 x cutoff (=35 U/l)) were excluded.

Results: A total of 438 patients received VA-ECMO therapy during the observation period. Based on the inclusion criteria, 298 patients (mean age 59±14 years) remained for statistical analysis. Overall mortality rate was 42.6% (n=127). The AUC in the ROC for Bilirubin on day five was 0.72 [95% confidence interval (CI): 0.66-0.78]. Youden-Index showed a cutoff for Bilirubin on day five of 2.23 mg/dl with a sensitivity of 0.70. Cox regression with multivariable adjustment revealed a significant association between Bilirubin on day five and mortality with a hazard ratio (HR) of 2.24 [95% CI: 1.53- 3.30]. After excluding patients with shock liver from the sensitivity analysis, this association was still significant (HR 2.08 [95% CI: 1.33-3.26]). ROC for patients without shock liver revealed an AUC of 0.67 [95% confidence interval (CI): 0.59-0.75].

Conclusion: Based on the results of the current study, an increase in serum Bilirubin on day 5 in patients receiving VA-ECMO therapy correlates independently with mortality regardless of the presence of shock liver. Thus, Bilirubin might serve as a prognostic marker in these patients and may be used as an indicator for early recognition of problems as well as optimization of VA-ECMO therapy.

000174**TIMI risk score: a valuable tool in the prognostic stratification of non-st-segment-elevation acute coronary syndrome**A. M. Garcia Bellon¹; A. M. González González¹; D. Gaitan-Roman¹; M. De Mora-Martin¹¹Cardiology, Regional Hospital of Malaga, Málaga, Spain**Correspondence:** A.M. González González*Intensive Care Medicine Experimental* 2020, **8(2)**: 000174

Introduction: Prognostic stratification of acute coronary syndrome is of vital importance, determining the strategy in these patients.

Objectives: The aim of this study was to analyze the importance of TIMI Risk score (TRS) as a prognostic tool of non-ST-segment elevation acute coronary syndrome (NSTEMI).

Methods: Retrospective analysis of all patients consecutively admitted with NSTEMI, from January 2016 to December 2018. Clinical and epidemiological characteristics and prognostic variables were studied, completing follow-up for a median of 24 months.

Results: We included 824 patients, 33.9% women. In 76.4% of cases the acute coronary event corresponded to an unstable angina and the other 23.6% to a non-Q wave myocardial infarction. 65.3% of the patients had a TRS moderate to high risk (C3), corresponding to patients with higher comorbidity (Charlson Index 2.9 ± 2.2 vs. 1.4 ± 0.6 , $p = 0.0001$).

Highest scores in the TRS associated with greater development of heart failure (3.6 ± 1.2 vs. 2.6 ± 1.3 , $p = 0.0001$) and mortality (3.9 ± 1.1 vs. 2.7 ± 1.3 , $p = 0.0001$) during in-hospital period. This relationship remained after completing the long-term follow-up (3.5 ± 1.2 vs. 2.6 ± 1.3 , $p = 0.0001$ for heart failure and 3.6 ± 0.9 vs. 2.6 ± 1.3 , $p = 0.0001$ for mortality).

After adjustment, the TRS predicted higher risk of presenting complicated forms of acute

Coronary events both during in-hospital and long-term follow-up (OR 1.6, 95% CI, 1.3–2.0 and OR 1.3, 95% CI, 1.1–1.4, respectively).

Conclusion: The TIMI Risk score is a valuable tool in the prognostic stratification of Patients admitted for non-ST-elevation acute coronary syndrome.

000197**Predictors of mortality in the first year after ACS in patients admitted to the ICU of a regional hospital**I. Fernández¹; R. Torcuato¹; A. Alvarez¹; M. Salgado¹; P. Rojas¹; A. Ubeda¹¹Intensive care unit, Hospital Point Europe, Algeciras, Spain**Correspondence:** A. Ubeda*Intensive Care Medicine Experimental* 2020, **8(2)**: 000197

Introduction: Acute coronary syndrome (ACS) continues to be one of the most frequent admission pathologies in an intensive care unit (ICU). There are some predictors and risk factors that could indicate a higher probability of mortality during the first year.

Objectives: To analyze factors associated with one-year mortality in patients with ACS admitted to the ICU.

Methods: Retrospective descriptive study conducted in a 12-bed ICU from January 2017 to September 2019. Demographic variables,

comorbidities, type of ACS and location, left ventricular ejection fraction (LVEF), Killip, severity scales, responsible artery, complications and mortality. Statistical analysis: categorical (frequencies and percentages) and numerical variables (mean and standard deviation or median and interquartile range). Comparisons: X2 test (percentages) and Student test (means). Multivariate logistic regression. Statistical significance with $p < 0.05$.

Results: 278 patients were included. Deceased in the first year after ACS 56 (20.14%) vs. 222 survivors (79.86%): male (58.9% vs. 80.2, $p = .001$), age (73.88 \pm 10.99, $p = .001$), smoking (21.4% vs. 43.7%, $p = .002$), high blood pressure (64.3% vs. 38.7%, $p = .001$), diabetes mellitus (DM) (51.8% vs. 33.8%, $p = .013$), previous coronary lesions (30.4% vs. 16.2%, $p = .016$), chronic heart failure (26.8% vs. 3.2%, $p < .001$), chronic kidney disease (CKD) (19.6% vs. 3.6%, $p < .001$), COPD (14.4% vs. 3.6%, $p = .006$), cerebrovascular disease (14.3% vs. 4.1%, $p = .009$), heart rate (97.32 \pm 27.18 vs. 79.70 \pm 17.19, $p < .001$), systolic blood pressure (100.04 \pm 25.49 vs. 119.54 \pm 20.99, $p < .001$), TIMI (5.91 \pm 3.42 vs. 2.84 \pm 2.12, $p < .001$), GRACE (216.73 \pm 50.56 vs. 149.01 \pm 38.53, $p < .001$), CRUSADE (59.17 \pm 15.79 vs. 29.45 \pm 17.0, $p < .001$), previous acute myocardial infarction (51.8% vs. 29.3%) $p < .001$, LVEF (38.03 \pm 15.48 vs. 52.84 \pm 11.51, $p < .001$), norepinephrine usage (38.5% vs. 1.8%, $p < .001$), dobutamine usage (25% vs. 1.4%, $p < .001$), shock (61.1% vs. 2.3%, $p < .001$), hypotension (18.5% vs. 5.9%, $p = .006$), cardiac arrest (18.5% vs. 4.1%, $p = .001$), atrial fibrillation / flutter (11.1% vs. 2.7%, $p = .016$), kidney complication (9.3% vs. 2.3%, $p = .028$), invasive mechanical ventilation (25.5% vs. 3.2%, $p < .001$). Multivariate analysis: age (OR 1.22, 95% CI [1.09-1.37], $p < .001$), Killip IV (OR 5871.59, 95% CI [1.06-32626571.9], $p = .049$), shock (OR 251.56, CI 95% [10.02-6317.5], $p = .001$), COPD (OR 12.5, 95% CI [1.10-141.72], $p = .041$), CKD (OR 88.1, 95% CI [7.87- 987.8], $p = .041$), LVEF (OR 0.92, 95% CI [0.88-0.97], $p = .010$). AUROC: 0.978, 95% CI [0.958-0.998].

Conclusion: Age, COPD, CKD, Killip IV on admission and shock during ICU stay behaved as independent predictors of mortality after 1 year from ACS. Higher LVEF and DM were associated with greater survival.

28-day mortality-related factors in patients with an acute coronary syndrome

I. Fernández¹; R. Torcuato¹; A. Alvarez¹; M. Salgado¹; P. Rojas¹; A. Ubeda¹

¹Intensive care unit, Hospital Point Europe, Algeciras, Spain

Correspondence: A. Ubeda

Intensive Care Medicine Experimental 2020, **8(2)**: 000199

Introduction: Acute coronary syndrome (ACS) is one of the main causes of death worldwide. The improvement in the control of cardiovascular risk factors, diagnosis and treatment, has increased the diseases' prevalence. Therefore, its mortality has diminished. However, the proportion of sudden death remains the same. Studying mortality related factors has proven crucial for the prevention of the disease.

Objectives: To analyze factors associated with 28-day mortality in patients with ACS admitted to the ICU.

Methods: A retrospective descriptive analysis on a prospective cohort, performed in a 12-bed ICU from January 2017 to September 2019. Variables: demographic, comorbidities, ACS type and location, left ventricular ejection fraction (LVEF), Killip, severity's scales, responsible artery, complications and mortality. Statistical analysis: categorical (frequencies and percentages) and numerical variables (mean and standard deviation). Comparisons: test of X2 (percentages), Student's t (means). Multivariate logistical regression. Statistical significance with $p < 0.05$.

Results: 389 patients were included, 292 male (75.1%) and 97 female (24.9%). 28 day mortality: 46 (11.8%). Deceased vs. survivors: male (56.5% vs. 77.6%, $p = .002$), age (73.30 \pm 11.17 vs. 62.72 \pm 12.16, $p < .001$), DM (56.5% vs. 32.9%, $p = .007$), hypertension (63% vs. 43.4%,

$p = .042$), smoking (23.9% vs. 42.9%, $p = .044$), previous coronary lesions (30.4% vs. 15.7%, $p = .014$), previous acute myocardial infarction (26.1% vs. 12.8%, $p = .016$), COPD (15.2% vs. 4.1%, $p = .007$), chronic kidney disease (15.2% vs. 5.5%, $p = .023$), chronic heart failure (30.4% vs. 4.1%, $p < .001$), NSTEMI (43.5% vs. 54.8%, $p = .148$), systolic blood pressure (94.67 \pm 20.89 vs. 117.61 \pm 20.97, $p < .001$), HR (100.22 \pm 26.29 vs. 78.30 \pm 17.50, $p < .001$), LVEF (32.62 \pm 12.73 vs. 53.36 \pm 11.49, $p < .001$), TIMI (6.30 \pm 3.55 vs. 3.07 \pm 2.28, $p < .001$), GRACE (226.06 \pm 53.11 vs. 150.30 \pm 38.84, $p < .001$), CRUSADE (59.74 \pm 17.56 vs. 29.58 \pm 16.97, $p < .001$), dobutamine usage (31% vs. 1.7%, $p < .001$), noradrenaline usage (45.2% vs. 2.3%, $p < .001$). Invasive mechanical ventilation (28.9% vs. 2.9%, $p < .001$), shock (72.7% vs. 2.6%, $p < .001$), cardiac arrest (20.5% vs. 4.4%, $p < .001$), hypotension (12.8% vs. 5.9%, $p = .008$), kidney-related complications (11.4% vs. 1.8%, $p = .004$). Multivariate analysis: age (OR 1.18, 95% CI [1.04-1.32], $p = .010$), LVEF (OR 0.85, 95% CI [0.77-0.93], $p = .001$), COPD (OR 7.66, 95% CI [1.01-57.84], $p = .048$), Killip IV (OR 628.42, 95% CI [7.28-54261.48], $p = .005$), shock during ICU stay (OR 95.35, 95% CI [6.85-1327.48], $p = .001$). AUROC: 0.989, 95% CI [0.979-0.998].

Conclusion: Age, COPD, Killip IV on ICU admission and shock during the patient's ICU stay, behaved as independent 28-day mortality predictors after an ACS. LVEF was associated with higher survival rate.

In-hospital mortality and major complications in acute coronary syndrome patients over 75 years. Russian single center study findings

Y. Kalashnikova¹; D. Pek¹; N. Glushkov¹; Y. Schneider¹

¹Icu, Kaliningrad Federal High Medical Technologies Center, Kaliningrad, Russia

Correspondence: J. Kalashnikova

Intensive Care Medicine Experimental 2020, **8(2)**: 000217

Introduction: Patients older than 75 years are often underrepresented in published acute coronary syndrome (ACS) studies, although they make up a significant and ever-increasing portion of this population. Mortality from ACS progressively increases with age and remains high among elderly and very elderly patients. It was shown that elderly receive optimal treatment and myocardial revascularization less often than young patients [1], however, if revascularization is performed, hospital mortality decreases, 6-month survival improves, and the risk of stroke does not increase [2]. Currently, further studies are needed on the ACS course features in patients of older age groups to develop optimal treatment tactics for this category of patients in order to reduce in-hospital mortality and the incidence of long-term complications.

Objectives: To assess the clinical status, comorbidities, complications, in-hospital mortality and its structure in depend of age and acute coronary syndrome (ACS) type in case of early invasive strategy.

Methods: Retrospective all-over study was carried out in ICU of High Medical Technologies Center, Kaliningrad, Russia. 1353 patients with ACS and emergency and urgent myocardial revascularization in the 2014–2016 years period were included in the study. The first group (gr.1) consisted of 984 patients younger than 75 years old, and the second group (gr.2) was compound of 369 patients aged \geq 75. We were performed the analysis of anamnestic, clinical and laboratory data from medical documentation.

Results: The average age in the gr.1 was 60 \pm 8,6 years old, in the second — 80,1 \pm 4,2. There was significantly myocardial infarction and stroke anamnesis burden, and reduced ejection fraction (EF), congestive heart failure, valve disorders, atrial fibrillation prevalence in very elderly patients.

There was no significant difference in ACS structure in studied groups (47,8% in gr.1 vs 45,5% in gr.2, $p=0,512$ for ST elevation myocardial infarction). There were more frequent severe manifestations of acute heart failure (AHF) and cardiogenic shock cases (Killip III—5,9% vs 11,4% ($p=0,002$); Killip IU 2,1% vs 9,1% ($p<0,0001$) in the first and second group respectively), higher score of GRACE ischemic risk and higher bleeding risk in very elderly patients in compare with persons younger than 75 years old. "First Medical Contact – balloon" time did not significantly differ in the studied groups ($86\pm 19,1$ vs $94\pm 21,3$ minutes, $p=0,072$ for emergency PCI or $48,6$ (95%CI 24-136) vs 34 (95%CI 25-45) minutes, $p=0,084$ for urgent PCI in group 1 and group 2. All-cases in-hospital mortality was 3,1% in the group 1, and 10% in very elderly patients, $p<0,0001$. ST elevation myocardial infarction mortality was 5% among patients younger than 75 years old and it was 20% among very elderly patients, $p<0,0001$. Non-ST elevation myocardial infarction+unstable angina mortality didn't significantly differ in studied groups and composed 0,97% and 0,99%, $p=0,52$. In-hospital mortality from AHF (2% in the group1 vs 6,5% in the group 2, $p<0,0001$) and percutaneous coronary intervention complications (stent thrombosis and no-reflow) (0,5% vs 2,4%, $p=0,01$) was significantly different depending on age. AHF mortality didn't differ among different age patients with preserved and mid-range EF, but it had significant difference in patients with reduced EF: 7,3% in the gr.1 vs 18,6% in the gr.2 ($p<0,0001$). Studied group didn't differ from the rate of gastrointestinal bleedings and major bleedings (0,7% in gr.1 vs 1,4% in gr.2, $p=0,225$).

Conclusion: ACS has more severe clinical course in very elderly patients in comparison with persons younger than 75 years old. Early invasive strategy is effective in spite of age and ACS type. Fatal outcomes from percutaneous coronary intervention complications and AHF are more frequent in very elderly patients. ACS in-hospital mortality with the AHF as main reason is the prevalent mortality reason in very elderly patients with reduced EF. Otherwise, the structure of complications and mortality is similar in patients of different ages.

Intensive Care Medicine Experimental 2020, **8(2)**: 000225

Introduction: Coronary heart disease (CHD) is a leading cause of death. Accurate prediction of risk of death after acute coronary syndromes (ACS) is important for prognostication and decision making about treatment and management of these patients.

Objectives: To analyze predictive factors associated to 90-day mortality in patients admitted to intensive care unit (ICU) with an ACS.

Methods: Retrospective descriptive analysis of patients admitted in a 12-bed ICU performed from January 2017 to September 2019. Demographic variables, comorbidities, type of ACS, left ventricular ejection fraction (LVEF), initial Killip, extension, coronary arteries affected, risk scores (TIMI, GRACE, CRUSADE), complications and mortality have

been registered. Statistical analysis: categorical (frequencies and percentages) and numerical variables (mean and standard deviation). Comparisons: test of X² (percentages), Student's t (means). Multivariate logistic regression. Statistical significance with $p<0,05$.

Results: 380 patients were included, 287 (75.52%) males and 93 (24.47%) females. 90-day mortality: 51 (13.4%). Non survivors vs. survivors: male (56.9% vs. 78.4%, $p=.001$), age (73.94 [± 10.94] vs. 62.44 [± 12.05], $p<.001$), diabetes mellitus (54.9% vs. 32.5%, $p=.008$), high blood pressure (64.7% vs. 43.2%, $p=.016$), smoking (21.6% vs. 43.2%, $p=.012$), previous coronary lesions (29.4% vs. 15.8%, $p=.018$), previous ACS (27.5% vs. 12.5%, $p=.005$), COPD (13.7% vs. 4.3%, $p=.014$), chronic kidney disease (15.7% vs. 5.2%, $p=.011$), congestive heart failure (27.5% vs 4.3%, $p>.001$), STEMI (39.2% vs. 55.6%, $p=.029$), systolic blood pressure (97.63 [± 24.13] vs. 117.75 [± 20.63], $p<.001$), heart rate (100.18 [± 25.68] vs. 78.06 [± 17.15], $p<.001$), LVEF (34.84 [± 13.47] vs. 53.46 [± 11.42], $p<.001$), TIMI (5.91 [± 3.43] vs. 3.04 [± 2.27], $p<.001$), GRACE (220.86 [± 48.89] vs. 149.09 [± 38.08], $p<.001$), CRUSADE (59.81 [± 16.75] vs. 29.10 [± 16.80], $p<.001$), number of implanted stents (2.48 [± 1.25] vs. 1.91 [± 1.25], $p=.045$), dobutamine usage (27.7% vs. 1.8%, $p<.001$), norepinephrine usage (42.6% vs. 2.1%, $p<.001$). Invasive mechanical ventilation (28% vs. 2.5%, $p<.001$), shock (67.3% vs. 2.4%, $p<.001$), cardiac arrest (20.4% vs. 4.3%, $p<.001$), infectious complication (6.1% vs. 1.2%, $p=.05$), kidney complication (10.2% vs. 1.8%, $p=.008$). ICU length of stay (LOS) (4.65 [± 7.05] vs. 2.43 [± 3.32], $p=.031$).

Multivariate analysis: age (OR 1.14, IC 95% [1.05-1.24], $p=.001$), LVEF (OR 0.91, IC95% [0.86-0.96], $p=.002$), Killip III (OR 80.40, IC 95% [2.45-2633.07], $p=.014$), shock (OR 27.65, IC95% [4.34-175.95], $p=.004$). AUROC: 0.976, IC 95% [0.958-0.993].

Conclusion: Age, Killip III at ICU admission and shock during ICU stay were found as independent predictive factors for 90-day-mortality in patients diagnosed of ACS. LVEF was an independent predictor of survival.

Correspondence: J.M. ROMEU

Intensive Care Medicine Experimental 2020, **8(2)**: 000244

Introduction: Pulmonary thromboembolism it's still a high incidence pathology with a high mortality risk. Depending on the hemodynamic situation of the patient, it is classified as massive, if the patient is hemodynamically unstable; or submassive if the patient does not have hemodynamic instability. But do the clinical, ecocardiographic and blood tests improve depending on the type of pulmonary thromboembolism?

Objectives: Analyze the clinical, echocardiographic and analytical differences between patients with acute massive (hemodynamically unstable) and submassive (hemodynamically stable) pulmonary thromboembolism (APE).

Methods: Recruited patients between January 2016 and August 2019 with a diagnosis of submassive pulmonary embolism (hemodynamically stable); and massive pulmonary embolism (hemodynamically unstable); who underwent mechanical thrombectomy in the first 24 hours of admission with aspiration of between 70 and 80% of the

total thrombus. 42 thrombectomies were collected, performing transthoracic echocardiogram (TTE) at admission and at 24 hours post-procedure analyzing parameters of right ventricle dysfunction (TAPSE, Wave S, right ventricle diameter [RV], pulmonary hypertension [HTP]); arterial blood gas at admission and at 24 hours to calculate PaFi; and clinical assessment of the patient at admission and at 24 hours. We compare between patients with massive and submassive pulmonary thromboembolism.

Results: A significant relationship was found between diabetes mellitus and massive thromboembolism (30/8% patients, $p < 0.05$); syncope being the significant manifestation among patients with massive PE (57.7%, $p < 0.05$). Radiologically, the involvement of the main pulmonary arteries was significantly associated with massive PE (100%, $p < 0.05$). Echocardiographically no significant differences were found in the parameters of right ventricular dysfunction (diameter, TAPSE, S wave or pulmonary hypertension) between massive or submassive PE. The echocardiographic improvement by TAPSE was significant among patients with submassive PE, improving the figures from $15'83 \pm 2'23$ to $20'17 \pm 2'85$ ($p < 0.05$) 24 hours after procedure.

Conclusion: Massive pulmonary embolism is significantly related to DM, syncope and involvement of major pulmonary arteries. Echocardiographic improvement of the right ventricle is significantly earlier in submassive PET after mechanical thrombectomy.

Tricuspid valve replacement: mechanical or biological prostheses? A Systematic review and Meta-Analysis

Z. Cheng¹

¹cardiovascular surgery, West china hospital Sichuan University, Chengdu, China

Correspondence: Z. Cheng

Intensive Care Medicine Experimental 2020, **8(2)**: 000343

Introduction: Tricuspid valve replacement (TVR) is seldom performed in cardiac valve surgery, and there are currently no clinical guidelines suggest which type of prostheses is better in tricuspid valve position. This meta-analysis was performed to compare the results of mechanical and biological prostheses for TVR.

Methods: We searched Pubmed, Cochrane, Embase, Clinical trial databases to collect all the related studies published during recent 10 years (from January 1, 2000 to October 31, 2019). A random-effects model was used to evaluate the OR (odds ratios) and its 95% CI (confidence intervals) of time-to-event related effects of the surgical procedures, every study's quality evaluated by the Newcastle-Ottawa Scale (NOS).

Results: A total of 13 retrospective studies including 1407 patients were analyzed. There were no statistically differences between mechanical and biological prostheses with respect to prosthetic valve failure [OR=1.35, 95% CI(0.21,2.96), $P=0.46$], bleeding[OR=0.68, 95% CI(0.33,1.40), $P=0.29$], reoperation[OR=1.00, 95% CI(0.59,1.72), $P=0.99$], early mortality [OR=1.13, 95% CI(0.58,2.18), $P=0.73$]and long-time survival [OR=1.06, 95% CI(0.68,1.66), $P=0.80$]. A trend toward greater risk of thrombosis can be seen in mechanical prostheses [OR=0.19, 95% CI(0.06,0.65), $P=0.008$, $I^2=0\%$].

Conclusion: In tricuspid valve position, mechanical valve prostheses has a higher risk of thrombosis than biological prostheses, but no statistically differences between mechanical and biological prostheses with respect to prosthetic valve failure, bleeding, reoperation, early mortality and long-time survival. The more specific conclusion need to be further proved by large-sample, multi-center, randomized, double-blind and control trials.

Vasopressin in patients with septic shock and dynamic left ventricular outflow tract obstruction

M. Balik¹; A. Novotny¹; D. Suk¹; V. Matousek¹; M. Maly¹; T. Brozek¹; G. Tavazzi²

¹Dept of anaesthesia and intensive care, General University Hospital in Prague, Prague, Czech Republic; ²Department of anesthesiology and intensive care, Fondazione IRCCS Policlinico S Matteo, Pavia, Italy

Correspondence: M. Balik

Intensive Care Medicine Experimental 2020, **8(2)**: 000345

Introduction: Left ventricular outflow tract obstruction (LVOTO) is a relatively uncommon but severe condition that may lead to hemodynamic impairment. It can be elicited by morphological (left ventricular hypertrophy, sigmoid septum, prominent papillary muscle, prolonged anterior mitral valve leaflet) and functional (hypovolemia, low afterload, hypercontractility, catecholamines) factors.

Objectives: We sought to determine the incidence of the most severe form of LVOTO in septic shock patients and describe the therapeutic effects of vasopressin.

Methods: 527 patients in septic shock were screened for LVOTO over a period of 29 months. All were mechanically ventilated and treated according to sepsis bundles, including pre-load optimization and norepinephrine infusion. Vasopressin was added in addition to norepinephrine to reduce the adrenergic burden and decrease LVOTO.

Results: 10 patients were diagnosed with the most severe form of LVOTO including SAM (systolic anterior mitral valve motion) and severe MR (mitral regurgitation) with pulmonary oedema. The median norepinephrine dosage to obtain a mean arterial pressure of ≥ 70 mmHg was 0.58 mcg/Kg/min (IQR 0.40-0.78). All patients had a hyper-contractile left ventricle, septal hypertrophy, significant LVOTO (peak gradient 78 [56-123] mmHg) associated with SAM and severe MR with pulmonary oedema. Vasopressin (median 4 IU/h) allowed a significant reduction of norepinephrine (0.18 [0.14-0.30] mcg/kg/min; $p=0.01$), LVOT gradient (35 [24-60] mmHg; $p=0.01$) and MR with a significant paO_2/FiO_2 increase (174 [125-213] mmHg; $p=0.01$).

Conclusion: Vasopressin allowed a reduction of norepinephrine with subsequent LVOTO reduction and hemodynamic improvement of the most severe form of LVOTO which represented 1.9% of all septic shock patients.

Antithrombotic therapy in cardiogenic shock: Could glycoprotein IIb/IIIa inhibitors be useful?

H. Miranda¹; H. Santos¹; S. Mariana²; C. Sousa¹; I. Almeida¹; L. Almeida¹

¹Cardiology, Centro Hospitalar Barreiro Montijo, Barreiro, Portugal; ²Cardiology, Centro Hospitalar Barreiro Montijo, E.P.E, Barreiro, Portugal

Correspondence: H. Miranda

Intensive Care Medicine Experimental 2020, **8(2)**: 000381

Introduction: Impaired enteral perfusion and mechanical ventilation, with inability to swallow, play a major role in the bioavailability of antiplatelets. Data on the use of glycoprotein IIb/IIIa receptor inhibitors (GPI) in acute coronary syndrome patients presenting with cardiogenic shock is sparse.

Objectives: Evaluate the impact of the use of GPI on the outcome (MACE/death) of patients (P) admitted with CS.

Methods: Retrospective study from 01/10/2010 to 08/01/2019. All P admitted for CS in the context of ACS were selected. Exclusion criteria: Killip class I-III, lack of information about APT during hospital length. We created 2 groups based in the use/absence of GPI during hospital length.

Results: 329 P were admitted, hypertension and dyslipidaemia were the most frequent comorbidities. Mean Systolic and diastolic pressure at admission of 96±33 and 59±21 mmHg, respectively. Haemoglobin at admission of 13,1±2 g/dl. platelets on admission of 221±89 x 10³/mm³.

Comparing the 2 groups we found out GPI was preferred in younger P (p<0,001), with higher levels of haemoglobin and platelets (p=0,04 and P00,046, respectively) and was associated with higher use of intra-aortic balloon (p=0,003). Also, 100% of patients with GPI performed coronary angiography.

Comparing the occurrence of MACE/death during hospital length we only found differences at cardiac arrest (higher in the group with GPI, p=0,003). There weren't any differences regarding other MACE and death between the 2 groups. Furthermore, we haven't seen any differences regarding bleedings complications in patients using GPI.

Conclusion: With a lack of specific randomized trials in CS the same recommendations apply as for other types of acute coronary syndrome. Our study suggests that GPI may be beneficial in this high-risk group of patients in whom a delayed onset of action of oral antiplatelet therapy would be expected. More selected trials are needed to clarify which is the best pharmacological option for these patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 000424

Introduction: Factors associated with time delay to angiography in acute st-elevation myocardial infarction - a retrospective cohort study in northern Finland

Objectives: Chest pain is a common mission (16.4%) for emergency medical service (EMS) but only in 10,5% there is a acute myocardial infarction (AMI) behind the symptom. (1) Delay in percutaneous coronary intervention (PCI) with AMI is associated with increased heart

failure and mortality (2). Aim of this study was to examine time intervals of EMS and factors associated

Methods: Study was conducted in hospital district of Northern Ostrobothnia, Finland between 2014- 2016. Study included all the patients diagnosed with STEMI that underwent angiography within 24 hours from arrival to hospital and had been transported to hospital by EMS. We defined angiography delayed if it was performed over 120 minutes from first medical contact.

Results: 330 patients met the inclusion criteria in the study period. Time from first medical contact to angiography (TFMCA) was <120 minutes with 231 patients (70.0%). In multivariate analysis, OR for TFMCA over 120 minutes was higher if there was absence of chest pain (OR 2.46 95% CI (1.18-5.13), P=0.016), dyspnea (OR 3.11 95% CI (1.54-6.28), P=0.002), treatment protocol not followed (OR 2.41 95% CI (0.99-5.80), P=0.050), treatment started at health care center (OR 3.64 95% CI (1.39-9.48), P= 0.008) and distance to hospital over 100 km (OR 11.87 95% CI (6.14-22.93), P<0.001).

Conclusion: We demonstrated patient and ems related factors, that were associated with TFMCA time over 120 minutes.

GRACE score vs ACTIVE ICU score: predicting MACE and intra-hospital death in NSTEMI

M. Santos¹; H. Miranda¹; I. Almeida¹; H. Santos¹; C. Sá¹; J. Chin¹; S. Almeida¹; C. Sousa¹; J. Tavares¹; L. Almeida¹

¹Cardiology, Centro Hospitalar Barreiro Montijo, E.P.E, Barreiro, Portugal

Correspondence: M. Santos

Intensive Care Medicine Experimental 2020, **8(2)**: 000466

Introduction: Regarding prognosis, patients with a non-ST elevation myocardial infarction (NSTEMI) are a heterogeneous population. Therefore, early risk stratification at admission is essential. GRACE score estimates risk of death, including in-hospital death. ACTION ICU score predicts the risk of NSTEMI complications requiring ICU care.

Objectives: To evaluate and compare GRACE and ACTION ICU scores as predictors of in-hospital death (IHD) and in-hospital major adverse cardiovascular events (IHMACE) in our center population using real-life data.

Methods: Based on a single-center retrospective study, data collected from admissions between 1/01/2016 and 11/12/2019. Patients with cardiac arrest or hemodynamically unstable patients at admission were excluded. GRACE and ACTION ICU scores were calculated, using Killip-Kimball classification as a surrogate of heart failure at admission. Logistic regression analysis and ROC curve analysis were performed to assess their performance as predictors of IHD and IHMACE.

Results: We identified 389 patients with NSTEMI, 63.5% were males with an average age of 68.7±12.6 years old. Regarding past medical history, 75.1% were hypertensive, 38.8% had diabetes, 54.8% had dyslipidaemia, 6.2% had chronic kidney disease, 3.1% had chronic obstructive pulmonary disease, 29.0% had a previous acute coronary syndrome (ACS) and 28.5% had been submitted to coronary revascularization.

Mean GRACE score was 132.4±1.8 and median ACTIVE ICU score was 4±4. Median heart rate was 77±23 bpm, median arterial pressure was 146±38 mmHg, 88.7% had Killip-Kimball classification II-IV, 25.7% had ST-depression at admission. Logistic regression analysis confirmed that GRACE score was a good predictor of IHMACE (p<0.001) and

IHD ($p=0.005$) in our population. ACTIVE ICU score was also a predictor of both IHMAE ($p<0.001$) and IHD ($p=0.005$). ROC curve analysis revealed that GRACE and ACTIVE ICU scores are accurate at predicting risk of IHMAE (area under curve (AUC) 0.726 and 0.737, respectively) and IHD (AUC 0.886 and 0.868, respectively).

Conclusion: This study confirms that, in our population, both scores are accurate at predicting the outcomes. As expected, GRACE score was slightly more accurate at predicting IHD while ACTIVE ICU score was more accurate at predicting IHMAE.

Intensive Care Medicine Experimental 2020, **8(2)**: 000471

Introduction: Acute coronary syndrome (ACS) and atrial fibrillation (AF) are frequent disorders and it is not uncommon for AF to be present at admission of ACS. However, the presence of an arrhythmia can make the diagnosis of ACS more challenging and, therefore, it may increase in pre-hospital and admission delay in diagnosis.

Objectives: To evaluate if the presence of AF or other rhythms at admission had influence in the period from symptom to first medical care, time from first medical care and admission and overall time from symptoms to admission.

Methods: Based on a multicenter retrospective study, data collected from admission between 1/10/2010 and 8/01/2019. Patients were divided into 3 groups: A – sinus rhythm, B – AF, and C – other rhythms at admission. Patients without data on previous cardiovascular history or uncompleted clinical data were excluded. Chi-square test, T-student test and Mann-Whitney U test were used in the analysis.

Results: 15927 patients were included, 14637 in group A (91.9%), 1049 in group B (6.6%) and 241 in group C (1.5%).

Group B (GB) patients were older (65 ± 13 vs 75 ± 10 vs 73 ± 13 , $p<0.001$) and had higher rates of comorbidities such as arterial hypertension (67.1 vs 83.2 vs 79.2% , $p<0.001$), diabetes (30.4 vs 36.0 vs 36.9% , $p<0.001$), previous history of stroke (6.7 vs 14.9 vs 11.7% , $p<0.001$), peripheral artery disease (4.8 vs 8.9 vs 4.6% , $p<0.001$), chronic kidney disease (4.7 vs 10.5 vs 10.4% , $p<0.001$) and dementia (1.5 vs 4.2 vs 3.1% , $p<0.001$) but fewer smokers (31.0 vs 8.7 vs 20.2% , $p<0.001$).

At presentation GB had lower rates of STEMI (42.6 vs 33.6 vs 50.6% , $p<0.001$), were more frequently admitted by the emergency room (53.8% vs 62.6% vs 61.3% , $p<0.001$) and had higher heart rates at admission (77 ± 18 vs 91 ± 29 vs 68 ± 30 , $p<0.001$).

The three groups were similar regarding times from symptoms to first medical care, times from first medical care and admission and overall times from symptoms to admission, rates of multivessel disease and culprit lesion in ST-segment elevation myocardial infarction (STEMI).

Regarding in-hospital adverse events, group B and group C had higher rates of *de novo* heart failure (13.0 vs 29.7 vs 26.6% , $p<0.001$), sustained ventricular tachycardia (1.5 vs 3.1 vs 3.7% , $p<0.001$), cardiac arrest (2.8 vs 4.9 vs 7.1% , $p<0.001$), stroke (0.6 vs 1.7 vs 0.4% , $p<0.001$) and death (2.7 vs 9.0 vs 10.4% , $p<0.001$).

Conclusion: The rhythm at admission does not seem to have an effect in the time until medical care. Nevertheless, it was associated to worse prognosis and complications.

Acute coronary syndrome and atrial fibrillation onset

M. Santos¹; H. Miranda¹; I. Almeida¹; H. Miranda¹; C. Sá¹; J. Chin¹; S. Almeida¹; C. Sousa¹; J. Tavares¹; L. Almeida¹

¹Cardiology, Centro Hospitalar Barreiro Montijo, E.P.E, Barreiro, Portugal

Correspondence: M. Santos

Intensive Care Medicine Experimental 2020, **8(2)**: 000472

Introduction: Atrial Fibrillation (AF) complicates approximately 10% of acute coronary syndromes (ACS) and it is, therefore, important to

access its impact on prognosis and identify patients with higher risk of AF.

Objectives: To evaluate predictors of early onset (<48 h) and late onset (≥ 48 h) *de novo* atrial fibrillation (AF).

Methods: Based on a multicenter retrospective study, data collected from admissions between 1/10/2010 and 8/01/2019. Patients were divided in two groups: A – patients that presented early onset *de novo* AF (EOAF), and B – patients that presented late onset *de novo* AF (LOAF). Patients without data on previous cardiovascular history or uncompleted clinical data were excluded. Logistic regression was performed to assess predictors of *de novo* AF in ACS. Survival analysis was evaluated through Kaplan Meier curve.

Results: Population – 257272 patients (pts) with ACS. Group A (GA) – 584 pts (2.3%); group B (GB) – 360 pts (1.4%).

GA were younger (73 ± 13 vs 77 ± 10 , $p<0.001$) with a higher prevalence of smokers (21.3% vs 12.1% , $p<0.001$). GB had higher rates of diabetes mellitus (40.1% vs 30.2% , $p<0.001$), angina (30.8% vs 21.4% , $p<0.001$), previous ACS (22.5% vs 15.4% , $p=0.006$), previous revascularization (percutaneous coronary intervention 14% vs 9.5% , $p=0.032$; coronary artery bypass surgery 8.4% vs 3.9% , $p=0.004$).

GA had more chest pain (76.1% vs 67.3% , $p=0.001$), more ST-segment elevation myocardial infarction (56.8% vs 46.9% , $p=0.003$) and were admitted directly to the cath lab more often (21.7% vs 13.4% , $p=0.001$). Normal QRS at admission was more common in GA (80% vs 70.2% , $p<0.001$) and complete right branch block (CRBB) was more frequent in GB (13.5% vs 6.7% , $p<0.001$).

GB had lower hemoglobin (Hb) levels at admission (12.9 ± 2 vs 13.4 ± 1.9 , $p<0.001$), first medical evaluation >120 minutes after symptoms onset (FME>120 m) more often (71.6% vs 57.8% , $p<0.001$) and more in-hospital diuretics usage (72.8% vs 54.3% , $p<0.001$). Logistic regression confirmed that FME>120 m (OR 1.6, $p=0.005$, CI 1.15-2.22), Hb ≤ 12 g/dL (OR 1.53, $p=0.018$, CI 1.02-2.18), CRBB (OR 1.72, $p=0.043$, CI 1.102-2.92) and diuretics usage (OR 2.18, $p<0.001$, CI 1.57-3.01) were predictors of late onset AF.

140 LOAF patients and 236 EOAF patients had 1 year of follow up. Event-free survival was higher in EOAF than LOAF (80.3% vs 5.9% ; $p=0.002$, OR 2.072).

Conclusion: LOAF patients seem to have a poorer prognosis compared to EOAF.

Intensive Care Medicine Experimental 2020, **8(2)**: 000477

Introduction: Left ventricular (LV) dysfunction is potentially harmful in the critically ill patient as it might compromise circulatory status. LV dysfunction can be triggered by many conditions in the critically ill e.g. myocardial infarction, toxic cardiomyopathy, hypoxia or severe stress (Takotsubo syndrome). The gold standard for diagnosing left ventricular function is echocardiography, but it might not be feasible to screen all ICU patients without discretion.

Objectives: This study evaluated troponin T, NTproBNP and ECG as more readily available surrogate markers for heart failure in critically ill patients.

Methods: This is a secondary analysis of a single-center prospective observational study which consecutive patients were examined with echocardiography (ClinicalTrialsID: NCT03787810). Included patients were examined with echocardiography according to the recommendations from ESC [1] within 24 hours from admission to the general ICU in our hospital. All echoes were recorded and blindly reviewed by an independent examiner. Blood samples were analyzed for high sensitive troponin T (hsTnT) and NTproBNP and an ECG was obtained in

conjunction with the echocardiography of the patients. Heart failure was defined as having an LV ejection fraction <50%.

Results: A total of 411 patients were included in the final analysis of whom 64 (16%) had an EF<50%. Measurement of hsTnT and NTproBNP was available in 314 (76%) and 277 (67%) patients, respectively. An ECG was obtained in 374 (91%) patients. A sensitivity analysis showed that the population having measurement of cardiac biomarkers or an ECG-recording was a representative sample of the whole study population.

Levels of hsTnT were higher in patients with an EF<50% (median, IQR 27 [12-64] vs 176 [62-503], $p<0.001$), as was also the case with NTproBNP (median, IQR 683 [212-2810] vs 4175 [1570-12900], $p<0.001$). An ECG with q-waves, ST-elevation, ST segment depression, negative T-waves or bundle block branch were all significantly associated with an EF<50%.

Using ROC curves, the area under the curve (AUC) for hsTnT to detect an EF<50% was 0.81. The best-cut off value was 68 ng/L with a sensitivity of 75%, a specificity of 75%, a positive predictive value (PPV) of 40% and a negative predictive value (NPV) of 93% in the detection of an EF<50%. The AUC for NTproBNP to detect an EF<50% was 0.79. The best cut-off value was 1230 ng/l with a sensitivity of 84%, a specificity of 60%, a PPV of 60% and a NPV of 95%. The ECG finding with the highest predictive value was an ECG with any pathology which had a sensitivity of 92%, a specificity of 38%, a PPV of 23% and a NPV of 95% for detection of an EF<50% (Table).

A lower ejection fraction was associated with an increased risk of 30 days mortality (<0.001). Levels of hsTnT and NTproBNP were both associated with an increased risk of 30-days mortality ($p<0.001$). Both biomarkers were also significantly associated with an increased risk of death when adjusting for SAPS 3 score, age and EF in % ($p=0.024$ and $p=0.025$, respectively). An ECG with any pathology was associated with an increased risk of 30-days mortality ($p=0.005$) but not when adjusting for SAPS 3 score, age and EF in % ($p=0.813$).

	hsTnT>68ng/l	NTproBNP>1230ng/l	ECG with any pathology
Sensitivity	75%	84%	92%
Specificity	75%	60%	38%
PPV	40%	60%	38%
NPV	93%	95%	95%

Conclusion: The cardiac biomarkers hsTnT and NTproBNP and ECG are only moderate in detection of heart failure in a mixed population of critically ill patients. However, the high negative predictive value of these biomarkers, as well as a normal ECG, could be used to rule out heart failure in the critically ill.

Introduction: Cardiac assistance with venoarterial ECMO (ECMO-VA) is increasingly being used in patients with heart failure as a bridge to cardiac transplantation in code 0. In our study, we study how this fact influences the evolution of transplanted cardiac patients in ICU.

Methods: Review of cardiac transplants between January 2013-March 2020 that required ECMO-VA pre-transplantation in a retrospective, descriptive study. Age, Euroscorell value, vasoactive drugs requirements and stay times, as well as troponin concentration values and mortality rates were analyzed. A basic descriptive analysis and comparisons were performed with the appropriate statistical tests.

Results: 74 patients were included in the study. Pre-transplant ECMO was implanted in 9 patients (12,2%), 2 of them in INTERMASC 1. No statistically significant differences in ECMO-VA group age were reported compared to elective transplant group[E1]. No significant differences were reported between the groups compared to Euroscore II, Apache II score or lactate and bilirrubine concentration levels. However, patients with pre-transplant ECMO-VA had higher average of ICU stay than the elective[E2] (40,4±21,5 vs 10,5±9,6, respectively) $p<0,001$. Ultrasensitive T troponin levels were significantly higher in ECMO (10568,8±16351,3 vs 2582,8±1975,3, $p<0,001$). Hours of treatment with vasoactive drugs as dobutamine (569,6±595,5 vs 133,1± 73,4, $p<0,001$) and norepinephrine (560± 370,9 vs 55,9±59,5, $p<0,001$) were significantly higher in the ECMO group compared to elective group, respectively. Mortality was significantly higher in the pre-transplant ECMO group (44.4%) compared to a elective transplants (10.8%).

Conclusion: Transplanted cardiac patients in urgency 0 with pre-transplant ECMO-VA had significantly higher ICU stay than elective patients, with higher troponin numbers, longer periods of vasoactive drugs treatment, and higher mortality rates than those reported in elective transplants.

Intensive Care Medicine Experimental 2020, 8(2): 000563

Introduction: Actually, copeptin is an additional biomarker for the early rule-out of myocardial infarction in patients in emergency department or with early-onset chest pain. It also, have been associated with severity of the post cardiac arrest syndrome, 1-year mortality in ST-segment elevation acute myocardial infarction patients or the identification of major trauma, hospital admission and blood transfusion in adult trauma patients.

Objectives: To explore the association between early measurements of copeptin and hepatocyte growth factor with hospital and 1-year follow-up mortality, in patients with acute myocardial infarction.

Methods: We prospectively measured hepatocyte growth factor and copeptin in blood samples collected at hospital arrival in consecutive patients diagnoses of type 1 acute myocardial infarction during 8 months, and prospectively we follow-up them to measure hospital and 1-year follow-up mortality.

Results: 84 patients were included in the study, 55 patients (65%) were male with a mean age of 70.3 (\pm 13.56) years. 25 patients (29.8%) had an ST-segment elevation myocardial infarction.

Hospital mortality was 11.9%, 1-year follow-up mortality was 21.4%. Mean copeptin levels were higher in patients who died during hospital admission (145.60 [52.21-588.50] vs. 24.79 [10.90-84.82] pmol/L, $p=0.01$) or during follow-up (112.28 [25.10-418.27] vs. 23.82 [10.96-77.30] pmol/L, $p=0.02$). There were no differences on hepatocyte growth factor levels between patients who died or no during hospital admission (381.05 [189.95-736.65] vs. 355.24 [175.55-521.76] pg/ml, $p=0.73$) nor during follow-up (350.00 [175.05-555.08] vs. 345.53 [183.68-561.15] pg/ml, $p=0.679$)

Copeptin measured at hospital arrival was found to be independently associated with hospital mortality, hazard ratio 1.004 [1.001-1.007], $p=0.011$; and 1-year follow-up mortality, hazard ratio 1.004 [1.001-1.007], $p=0.010$. Conversely, hepatocyte growth factor measured at hospital arrival was not found to be independently associated with hospital mortality (hazard ratio 1.000 [0.999-1.001], $p=0.794$) nor 1-year follow-up mortality (hazard ratio 1.000 [0.999-1.001], $p=0.396$).

Conclusion: Copeptin measured at hospital arrival, but not the hepatocyte growth factor, is an independent marker of mortality in patients with acute myocardial infarction.

Intensive Care Medicine Experimental 2020, **8(2)**: 000576

Introduction: Cardiac injury has been reported to be a major complication associated to COVID-19, with reported incidences ranging from 7 to 28% patients (1, 2). It has even been associated with increased mortality(1). Circulatory failure due to cardiogenic shock or fulminant myocarditis has been described in some case reports (3). It has been reported that 95% of COVID-19 patients on mechanical ventilation require norepinephrine (NE)(4), nonetheless, no systematic data have been reported about the hemodynamic profiles, cardiac function, or incidence of acute cor pulmonale (ACP), in critically ill COVID-19 patients.

Objectives: To perform a systematic characterization of cardiac function in COVID-19 mechanically ventilated patients using critical care echocardiography.

Methods: The echocardiographic group of Sociedad Chilena de Medicina Intensiva (SOCHIMI) prospectively included COVID-19 patients admitted to ICU and connected to mechanical ventilation. A comprehensive echocardiographic assessment has been done within the first 12 hours of mechanical ventilation in four University Hospitals of Santiago.

Results: 60 patients were consecutively included. The mean age was 58 \pm 12 y.o., 42 (70%) were male. APACHE II was 13 \pm 4 and SOFA 6 \pm 2.

Forty seven (78%) patients required low doses of NE (0.05 \pm 0.06 mcg/kg/min), median cardiac output was 4.9 [IQR 4.4-6.1] L min⁻¹ and Lactate was 1.4 [1.0-1.9] mmol/L.

Forty three (72%) patients exhibited a left ventricular ejection fraction (LVEF) >60% (hyperkinetic), 16 patients had LVEF between 45 and 60% (normokinetic) and one patients had hypokinetic heart function (LVEF <45%)(6). Right ventricle function was preserved in 55 (92%) patients (TAPSE >17 m)(7). In eighteen patients (30%) mild right ventricle dilation (right to left ventricular area ratio between 0.6-0.8) was observed and four (7%) patients exhibited moderate acute cor pulmonale (right to left ventricular area ratio between >0.8). In addition, no correlation was observed between LVEF and troponin levels. Echocardiography parameters are shown in the Table.

Echocardiography variables	N = 60
Left Ventricular Function	
Left ventricular outflow tract diameter, cm	2.13 [2.0-2.2]
LVEDV, ml	116 [76-137]
LVESV, ml	37 [28-52]
Left Ventricular Ejection Fraction, %	65 [60-70]
Stroke Volume, ml	68 [57-88]
MAPSE, mm	15 [14-17]
Mitral Tissue Doppler Image s' wave, cm/sec	11 [9.4-13]
LVOT VTI, cm	22 [18-24]
Cardiac Output, L·min ⁻¹	4.9 [4.4-6.1]
Right Ventricular Function	
TAPSE, mm	22 [20,24]
Tricuspid Tissue Doppler Image s' wave, cm/sec	13 [11-16]
Right end diastolic area, cm ²	17 [13-19]
Left end diastolic area, cm ²	30 [24-35]
RV/LV ratio	0.57[0.48-0.67]
Mild Cor Pulmonale RV/LV ratio (0.6-0.8), n (%)	18(30)
Moderate Cor Pulmonale, RV/LV ratio (>0.8), n (%)	4 (7)
Severe Cor Pulmonale, RV/LV ratio (>1), n (%)	0 (0)
Left ventricular D Shape, n (%)	0 (0)
Diastolic Function	
Doppler Trans-mitral E wave, cm/sec	71 [56-81]
Doppler Trans-mitral A wave, cm/sec	62 [46-76]
E/A ratio	1.1 [0.8-1.5]
Mitral Tissue Doppler Image e' wave, cm/sec	10 [8-12]
E/e' ratio	6.7 [5.3-9.1]
Fluid responsiveness predictors	
Maximum IVC diameter, mm	20 [14-24]
Minimum IVC diameter, mm	18 [11-22]
IVC distensibility index, %	8 [5-12]
Stroke Volume Variation, %	5 [3-7]
Pulse Pressure Variation, %	4 [3-5]

Conclusion: The most frequent hemodynamic profile of mechanically ventilated patients with severe COVID-19 pneumonia was a normodynamic circulatory state with hyperkinetic cardiac performance, associated with normal intravascular volume and normal tissue perfusion. In contrast with usual ARDS, severe acute cor pulmonale was not observed in this COVID-19 patient series. Although some cases of circulatory failure have been described, our data suggest that cardiac dysfunction is not a frequent feature of COVID-19. Further studies are necessary to assess the dynamic changes in cardiac performance over time.

A Shunt Demonstration: intracardiac gradients following left heart unloading as a cause of hypoxaemiaM. Hoy¹; N. Palomo-Lopez¹; S. Escalona-Rodriguez²; A. Simon³; M. Balakrishnan³; H. Soliman Aboumarie¹; N. Lees¹¹Critical care, Harefield Hospital, Harefield, United Kingdom; ²Critical care unit, Virgen del Rocío University Hospital, Seville, Spain; ³Cardiothoracic transplant surgery, Harefield Hospital, Harefield, United Kingdom**Correspondence:** M. Hoy*Intensive Care Medicine Experimental* 2020, **8(2)**: 000602**Introduction:** Atrial septal defects (ASD) are common but rarely symptomatic. Alteration of right (Rt) and left (Lt) sided pressures may create a gradient across the interatrial septum causing shunt. If right-to-left shunt (RLSh) occurs, systemic hypoxaemia may ensue.**Objectives:** To use 3 cardiac anatomical variants and physiological manipulation thereof to demonstrate how intracardiac gradients can be manipulated to both unmask and improve RLSh.**Methods:** Case 1: 77 year old male with good biventricular function underwent tissue aortic valve replacement for aortic stenosis with epicardial pacing postoperatively. He failed extubation due to hypoxaemia. CXR, bronchoscopy and CTPA were normal. With ongoing deterioration (P/F ratio 10, PEEP 14) transoesophageal echocardiography (TOE) showed a large secundum ASD with continuous RLSh. Reducing pacing from 100 bpm to 60 bpm reduced shunt and increased pO₂ from 10.1 kPa to 32.3 kPa on the same ventilator settings. Unfortunately, oxygenation could not be managed by manipulation of cardiac filling pressures non-invasively and he recovered after surgical correction of his ASD.

Case 2: 51 year old female with a background of Arrhythmogenic Right Ventricular Cardiomyopathy was admitted in cardiogenic shock on inotropes and underwent LVAD implantation. On day 7 postoperatively, she developed severe hypoxaemia. CXR was clear but oxygenation poor: P/F ratio 14 with PEEP 10. TOE demonstrated a previously undetected large PFO with continuous right to left shunt. Oxygenation could not be improved despite reducing PEEP or LVAD RPM. She underwent Amplatzer closure of the PFO and recovered before being listed for transplantation.

Case 3: 40 year old male presented with fulminant lymphocytic myocarditis requiring pVAECMO and subsequent Total Artificial Heart (TAH) placement. He was readmitted a year later with bacterial pneumonia and fluid overload requiring intubation. TAH rate was increased to optimise pulmonary offloading and Lt vacuums manipulated to maximise this. Despite improved radiographic appearances and pulmonary compliance, oxygenation failed to resolve with a P/F ratio of 11, PEEP 10. TOE was undertaken which showed a small PFO with continuous RLSh. Increasing Rt vacuum + iNO improved systemic oxygenation. After a few days, oxygenation worsened due to pulmonary congestion. Lt vacuum was increased coupled with diuresis. As chamber fills fell, both vacuums were increased. This maximised both systemic and pulmonary haemodynamics without provoking further shunt. He subsequently weaned from the ventilator before being discharged home.

Results: All 3 cases demonstrate a variety of techniques capable of managing RLSh across the IAS. Understanding of the physiology involved, particularly with mechanical devices is important.**Conclusion:** RLSh can be a consequence of iatrogenic unloading of the left side of the heart. Management may be physiological, interventional or surgical. In the setting of unexplained hypoxaemia and in the right clinical setting, TOE is an essential part of investigation whose utility should not be overlooked. A high index of suspicion is needed and this diagnosis should not be forgotten.**Reference(s) and grant acknowledgment(s)**

Individual and clinical characteristics associated with the presence of atherosclerotic coronary artery disease in patients with acute coronary syndrome in an intensive care unit in the city of BogotaF. Morales¹; D. Barrios¹; A. Buitrago²¹Intensive Care Unit, Clinica Nueva el Lago, Bogotá, Colombia; ²Cardiology department, Fundacion Santa Fe de Bogota University Hospital, Bogotá, Colombia**Correspondence:** F. Morales*Intensive Care Medicine Experimental* 2020, **8(2)**: 000623**Introduction:** Acute coronary syndrome (ACS) is a group of clinical diseases which occur as a result of acute myocardial ischemia, whether it be secondary to obstruction of coronary flow (atherosclerotic coronary artery disease) or to an imbalance in myocardial oxygen supply and demand, based on the fourth definition of acute myocardial infarction. Classic risk factors for coronary artery disease include older age, arterial hypertension, smoking, diabetes mellitus and family history of ischemic heart disease. In Colombia, the current scale of the disease in terms of risk factor prevalence is unknown.

We determine individual and clinical factors associated with acute coronary syndrome and their association with the presence of coronary atherosclerosis, documented using cardiac catheterization in patients in an intensive care unit during the first half of 2018, in the city of Bogota.

Objectives: To determine individual and clinical factors associated with the presence of atherosclerotic coronary artery disease in patients with acute coronary syndrome in an intensive care unit, during the first half of 2018 in the city of Bogota.**Methods:** It is a cross-sectional study which included 223 patients diagnosed with coronary syndrome, and who received cardiac catheterization during the first half of 2018. We performed a bivariate analysis of the individual and clinical characteristics, using the Chi-squared test to determine their level of association with the dependent variable, i.e., the presence of atherosclerotic coronary artery disease. We performed a multivariate analysis through logistic regression to determine the independent risk factors. A p-value ≤ 0.05 was considered significant.**Results:** We found that 1 in 5 patients diagnosed with acute coronary syndrome does not show significant atherosclerotic coronary artery disease in their catheterization. 25% of patients with acute coronary syndrome are under 50 years old. Men show a greater prevalence, at 65%. Contrary to what we expected, there was no statistically significant association in the variables that are widely described in literature, such as hypertension, smoking, or family history and personal history of ACS. Out of the individual and clinical characteristics assessed in this study, a history of Diabetes Mellitus (*OR* 4.9, *CI* 1.680 – 14.393, *p* 0.004) and the presence of changes in the admission electrocardiogram (*OR* 2.96, *IC* 1.285 – 6.854, *p* 0.011) had the greatest statistical significance.**Conclusion:** This study shows that the variables that better account for the probability of evidence of atherosclerotic coronary artery disease in the catheterization of patients with acute coronary syndrome are a history of diabetes mellitus and the presence of electrocardiographic changes at the moment of diagnosis. These findings can give the clinician additional tools when deciding on the risk stratification strategy, thus avoiding unnecessary invasive procedures, and reducing the risk of complications and other considerations that derive from this.**Reference(s) and grant acknowledgment(s)**

000639**The impact of end stage renal disease on long term outcome in patients after acute myocardial infarction: a nationwide observational study**T.H. TAI¹; W.C. Huang²; K.C. Lin¹; F.Y. Kuo¹; S.H. Kuo³; H.L. Liang⁴¹Critical care medicine and cardiovascular center, Kaohsiung Veterans General Hospital, Kaohsiung, Taiwan; ²Critical care medicine and cardiovascular center, Kaohsiung Veterans General Hospital, Taipei, Taiwan;³Department of Critical Care Medicine, Kaohsiung Veterans General Hospital, Kaohsiung City, Taiwan; ⁴Critical care medicine and cardiovascular center, Kaohsiung Veterans General Hospital, Kaohsiung, Taiwan**Correspondence:** T.H. TAI*Intensive Care Medicine Experimental* 2020, **8(2)**: 000639

Introduction: Although a possible association between chronic kidney disease and coronary artery disease or acute myocardial infarction has been identified, the impact of end-stage-renal-disease (ESRD) under dialysis on long-term prognosis after an acute myocardial infarction (AMI) is uncertain. Therefore, this study was to evaluate the specific impact of the patient with ESRD under dialysis on survival after a first AMI through a retrospective analysis of data from the Taiwan National Health Insurance Research Database.

Methods: This was a nationwide, propensity score-matched case-control study of patients admitted to hospitals between January 2000 and December 2012 with a primary diagnosis of a first AMI. Among the 186,326 prospective patients, 8056 patients with a confirmed diagnosis of ESRD under regular dialysis were identified. A propensity score, one-to-one matching technique was used to match 8056 controls to the AMI group for analysis. Controls were matched on the following variables: sex, age, hypertension, dyslipidemia, diabetes, peripheral vascular disease, heart failure, cerebrovascular accidents, end stage renal disease, chronic obstructive pulmonary disease, and percutaneous coronary intervention.

Results: The 12-year survival rate was significant lower in AMI with ESRD group than control group (log rank $p < 0.01$). No matter male or female, the survival rate was significant lower in AMI with ESRD group (log rank $p < 0.0001$). In both younger (Age < 65 years) and older category, the survival rate was also lower in AMI with ESRD group (log rank $p < 0.0001$). The survival rate of patients who had received PCI management was comparable among patients in the ESRD and control groups (log rank $p < 0.0001$). Similarly, the rate of survival among patients who did not receive PCI management was comparable for both the ESRD and control groups (log rank $p < 0.001$).

Conclusion: In this nationwide study, using matched-case control we provide evidence of a possible effect of end-stage-renal-disease on the survival after a first AMI. Independent of sex and age, and revascularization management, ESRD plays an important role in the long-term outcome of AMI patients.

000654**Control of arterial hypertension in critical patient with clevidipine: safe and effective therapy. descriptive study**M. T. Cruces Moreno¹; C. V. Ines²; J. Tejero Aranguren¹; P. A. Carranza²¹Intensive care unit, Hospital Universitario San Cecilio, Granada, Spain;²Intensive care unit, Hospital PTS, Granada, Spain**Correspondence:** M.T. Cruces Moreno*Intensive Care Medicine Experimental* 2020, **8(2)**: 000654

Introduction: It is common to find ourselves in intensive care units with patients with difficult blood pressure control. In many occasions, the impossibility of administering oral antihypertensive therapy is added.

Objectives: to describe the utility of the use of clevidipine as a safe and effective antihypertensive in different medical and surgical pathologies, in an Intensive Care unit.

Methods: Single-center, descriptive and retrospective study of a series of cases. We included patients admitted to our unit for any pathology between January 2018 and December 2019, treated with clevidipine for blood pressure control. The software used was IBM SPSS v.20.

Results: A total of 20 patients were included, 17 males (85%) and 3 females (15%) with a mean age in the range of 58 ± 14.9 years. The pathologies that led to admission were: 7 (35%) coronary, 5 (25%) neurological, 3 (15%) vascular, 2 (10%) hypertensive crisis, 2 (10%) heart failure and 1 (5%) postoperative period of general surgery. The mean APACHEII score was 14.4 ± 6.5 . It was recorded as a history of known arterial hypertension on admission in 15 patients (75%).

Different combinations of antihypertensive drugs were started prior to the use of clevidipine in 12 patients (60%), the most frequent being: a combination of three oral antihypertensive drugs plus IV nitroglycerin in 4 of them (20%); ACE inhibitors plus BB in 2 (10%) and IV nitroglycerin monotherapy in 2 (10%). In 8 patients (40%) clevidipine was chosen as the first option due to contraindication for the use of other antihypertensive drugs and / or the impossibility of oral intake.

The maximum average dose used was 6.24 ml / h (3.12 mg / h) for about 2.35 days until optimization and / or onset of action of the different oral antihypertensives. Very good tolerance to the drug was observed without registering any side effect for which the therapy had to be suspended.

Conclusion: The main indication for clevidipine is the reduction of blood pressure in the perioperative environment. We consider that it is also a useful alternative for a rapid control of blood pressure in other clinical settings, also reducing the length of stay in the Intensive Care Unit, with the consequent improvement in the therapeutic efficiency of this type of patient. However, more randomized prospective studies would be necessary to corroborate these conclusions.

000656**Pilot study: implementation of a protocol for the management of intermediate-risk pulmonary embolism**I. Cruz Valero¹; A. Carranza Pinel²; M.T. Cruces Moreno¹; J. Tejero Aranguren¹; A.M.E. Poyatos¹¹Intensive care unit, Hospital Universitario San Cecilio, Granada, Spain;²Intensive care unit, Hospital Universitario Clínico, Granada, Spain**Correspondence:** I. Cruz Valero*Intensive Care Medicine Experimental* 2020, **8(2)**: 000656

Introduction: High risk pulmonary embolism (PE) should be monitored in an Intensive Care Unit (ICU) because of the severity and high mortality it has. However, there is controversy regarding the monitoring and treatment of patients with intermediate-risk PE, since they are initially hemodynamically stable patients, but with a high risk of deterioration.

Objectives: In order to optimize its management, the ICU of the San Cecilio University Hospital has created a protocol in collaboration with the Emergency, Pneumology and Internal Medicine units.

Methods: Prospective, descriptive study over a period of four months. Patients with diagnosis of acute PE in the Emergency Department or in the hospital ward are included, with the following criteria:

- PE diagnosed by CT-scan.
- Hemodynamic stability.

- Suspected right ventricular dysfunction on CT-scan and elevation of cardiac markers (troponin and NT-proBNP).

A transthoracic echocardiogram was performed in the first 24 hours to evaluate right ventricular function.

Results: 29 patients met the inclusion criteria. The mean age was 69 years, being 41% women and 59% men. APACHE-II average of 9 and dyspnea as the main symptomatology (79% of patients). 100% presented some echocardiographic alteration consisting of RV dilatation, systolic dysfunction, or pulmonary hypertension. Three of the patients presented a torpid evolution towards high-risk PE, being able to be diagnosed and treated early with systemic fibrinolysis, which conditioned a favourable subsequent evolution normalizing RV systolic function.

The rest of the patients has a standard anticoagulant regimen and evolved properly, although all of them have persistent echocardiographic alterations 5-7 days after the treatment begin.

Conclusion: Patients with diagnosis of intermediate-risk PE benefited from closer monitoring thanks to the existence of a consensus protocol for the management of these patients, since the initial unsatisfactory evolution of three of them towards high-risk PE was diagnosed early, allowing an early approach.

Intensive Care Medicine Experimental 2020, **8(2)**: 000681

Introduction: Cardiac surgery produces a systemic inflammatory response syndrome (SIRS) that has been highly related with lung injury. This reaction is associated with abnormalities in gas exchange, such as increased pulmonary shut fraction. Inhaled nitric oxide (iNO) plays a roll of potent dilator of pulmonary vessels and improves such a ventilator/perfusion mismatch. Indirect indices for assessing impaired ventilation, such as dead space fraction and ventilatory ratio, have been used in acute respiratory distress syndrome (ARDS) and other respiratory failure. However, no studies have evaluated how much iNO improves shunt rate in cardiac surgery patients with postoperative pulmonary dysfunction using these formulas.

Objectives: We conducted to evaluate the effectiveness of iNO therapy for cardiac surgery patients with respiratory failure or right heart failure using indirect indices.

Methods: We retrospectively reviewed the medical records of 19 adult cardiac patients treated with iNO postoperatively between July 2018 and March 2020. iNO was used to pulmonary hypertension and respiratory failure in patients who had undergone total arch replacement (n=9), valve replacement (n=8) and coronary artery bypass graft (CABG) (n=2). Hemodynamic measurements, dead space fraction and ventilatory ratio before iNO and again 6 and 12 hours after administration were examined. The effect of iNO infusion on arterial oxygenation was quantified using the PaO₂/FiO₂(P/F) ratio. The data were analyzed by using student's t test. And we assessed the correlation between these indices and P/F ratio using Pearson correlation coefficient.

Results: Average administration duration of iNO (20 ppm) was 54.4 hours. Eight patients underwent emergency or urgent operation and all had type A aortic dissection. There was no significant difference in mean pulmonary artery pressure, however P/F ratio increased significantly from 182 to 265 (p<0.05) at 12 hours after initiation. Mean arterial pressure and cardiac index did not change before and after used iNO. Although P/F ratio at 6 hours after initiation increased, it did not

reached statistical significance. Improving oxygenation was associated with decreasing impaired ventilation measured by dead space fraction and ventilatory ratio at 12 hours after initiation. There was a significant negative correlation between VR and P/F ratio (Pearson, r=-0.5; CI, -0.78 to -0.05). The improvement of oxygenation due to the vasodilatory effect of iNO was proved.

Conclusion: In cardiac surgery patients, calculating dead space fraction and the ventilatory ratio during using iNO proved indirectly how iNO improve oxygenation without deterioration of the circulation indices. From these results, the vasodilatory effects of nitric oxide improved shunt fraction and oxygenation

Intensive Care Medicine Experimental 2020, **8(2)**: 000685

Introduction: Atrial fibrillation and atrial flutter are the most common cardiac arrhythmias in patients admitted to the intensive care unit (ICU) after cardiac surgery. Even in the ICU environment short episodes can be missed and left untreated.[1,2] If a clear increase of stroke risk in patients with postoperative AF/AFL (POAF) is established this might implicate that POAF should be detected meticulously and treated expeditiously.

Objectives: The primary aim of the current study was to establish thromboembolic stroke risk during hospital admission in patients with POAF in the first week after cardiac surgery in our institution. The secondary aim was to study the association of clinical characteristics including the occurrence of POAF with occurrence of thromboembolic stroke during hospital admission in patients after cardiac surgery.

Methods: A single-center retrospective observational study was performed with all consecutive cardiac surgery patients admitted postoperatively to the ICU of our institution between 2009 and 2010. [3,4] Brain imaging was studied for the occurrence of thromboembolic stroke (other subtypes of stroke were censored) during hospital admission and POAF was monitored meticulously for seven days after cardiac surgery. The proportion of patients with POAF among patients with thromboembolic stroke was compared to those without thromboembolic stroke and odds ratios (ORs) were calculated with corresponding 95% CI using logistic regression analyses. To assess which characteristics were associated with occurrence of thromboembolic stroke, a stepwise backward regression analysis was performed.

Results: Of the 910 patients included in this study POAF occurred in 360 patients (40%) during the first seven days after cardiac surgery, and 26 patients (2.9%) had a thromboembolic stroke during hospital admission. The proportion of patients with POAF among patients with thromboembolic stroke (65%) was higher compared to those without thromboembolic stroke (39%): adjusted OR 3.01 (95% CI; 1.13 – 8.00). POAF, a history of peripheral vascular disease, a higher EuroSCORE and a longer duration of surgery were associated with thromboembolic stroke.

Table 1. Odds ratio for in-hospital thromboembolic stroke with POAF <7d

Variable	Total (n=910) N (%)	TE stroke (n=26, 2.9%)	No TE stroke (n=884, 97.1%)	OR (95% CI)
		N (%)		
POAF <7d	360 (40%)	17 (65%)	343 (39%)	2.98 (1.13-8.75)
				3.01 (1.13-8.00)*

Conclusion: POAF within seven days after cardiac surgery was associated with a threefold increased risk for a thromboembolic stroke during hospital admission. POAF, a history of peripheral vascular disease, a higher EuroSCORE, and a longer duration of surgery were independent risk factors for thromboembolic stroke directly post-cardiac surgery of which POAF was the strongest independent predictor. Perioperative prophylaxis or expeditious treatment of POAF may therefore prevent early stroke after cardiac surgery.

Intensive Care Medicine Experimental 2020, **8(2)**: 000694

Introduction: In patient with shock, fluid therapy is tailored to optimize cardiac preload and tissue perfusion. Oral tap water administration is known to be associated with an improvement of blood pressure and cardiac output in non-critically-ill patients (1). Whether water digestive absorption is impaired in critically ill and whether tap water administration increase stroke volume in preload dependent patients remains uncertain.

Objectives: to determine the safety and effectiveness of tap water administration (via naso-gastric tube) in preload dependent patient with shock.

Methods: We performed a monocentric open label, randomize clinical trial in Dijon teaching hospital. Randomization was stratified on stroke volume (SV) change induce by passive leg raising. The study was approved by an independent ethics committee (Ethics Committee No. 2018-A03368-47, NCT03951519). Inclusion criteria were: aged 18 years or older, suffering from acute circulatory failure (systolic blood pressure < 90 mmHg, and/or mean blood pressure < 65 mmHg, and/or need for infusion of vasopressor amines, and/or skin mottling, and/or diuresis < 0.5 ml/kg/h for 2 hours ≥, and/or arterial lactate level > 2 mmol/l), with

stroke volume change following passive leg raising over 10%, and with no contraindication to a nasogastric tube. Exclusion criteria were: permanent atrial fibrillation, hypothermia, concurrent participation in another study, and pregnant women. Patients were assigned to receive either 500 ml of nasogastric tap water (at room temperature) or 500 ml of intravenous (IV) saline solution over a 15 minutes period. The primary endpoint was the change in stroke volume at the end of fluid administration expressed as percentage. Secondary endpoints were mean arterial pressure, cardiac output and oxygen delivery changes following fluid administration. Safety was assessed by the incidence of adverse events (arrhythmia, vomiting, abdominal distension, worsening arterial lactate and death).

Results: Fifty patients were randomized. Most of patients (70%) had septic shock. Baseline SV did not differ between the two groups. The median change in SV with fluid expansion did not differ between the two groups (22% [16;51] vs 21% [16;35], p=0.578). The number of fluid responsive patients (i.e. SV > 15% between baseline and end of fluid expansion) did not differ between the two groups (n=19 (76%) vs n= 18 (72%)). In the two groups, blood pressure and oxygen delivery increased, with no differences between groups (table 1). The incidence of adverse event did not differ between groups.

		Saline Group (n=25)	Water Group (n=25)	p-value intergroup
Heart rate (BPM)	Before	94 [80;107]	90 [80;109]	0.580
	After	86 [77;104]*	89 [79;104] *	0.892
MAP (mmHg)	Before	66 [62;72]	68 [62;73]	0.449
	After	74 [67;81] *	77 [72;84] *	0.105
CVP (mmHg)	Before	9 [6;11]	10 [8;12]	0.234
	After	11 [8;15] *	11 [9;12] *	0.967
SV (ml)	Before	36 [28;51]	38 [30;51]	0.900
	After	44 [36;60] *	44 [37;59] *	0.977
Cardiac output (ml min ⁻¹)	Before	3.40 [2.62;4.92]	3.89 [2.34;4.58]	0.839
	After	4.41 [3.47;5.13] *	4.46 [2.55;5.28] *	0.808
O2 delivery (ml min ⁻¹ m ⁻²)	Before	298 [188;364]	242 [209;327]	0.455
	After	299 [255;404] *	271 [181;369] *	0.607

Table 1. Change in the hemodynamic parameters induced by Tap water and IV saline administration.

Conclusion: There was no difference between SV change induce by the administration of 500 ml of enteral tap water and SV change induced by the administration of 500 ml of IV saline solution. The incidence of adverse event did not differ between groups. The administration of enteral tap water for fluid expansion appear to be safe and effective. Further studies are needed to confirm our results.

Intensive Care Medicine Experimental 2020, **8(2)**: 000868

Introduction: Extracorporeal membrane oxygenation (ECMO) is a fundamental tool in refractory cardiorespiratory failure, however, complications are common and can be severe (1).

Objectives: The purpose of this study was to evaluate the different complications occurring in patients with refractory cardiogenic shock (CS) supported with veno-arterial ECMO.

Methods: Data was collected prospectively from 2010 to 2020, patients with CS having received VA-ECMO were reviewed retrospectively. Baseline demographic variables, cause of CS, ECMO characteristics and complications were analyzed using SPSS software, version 20.

Results: We included 92 patients who received 101 VA-ECMO. Median age was 54 (interquartile range IQR 42–63), 64% were male. Causes of CS were mostly decompensated advanced heart failure (32%), acute myocardial infarction (26%), post-cardiotomy (21%), post-surgical pulmonary thromboendarterectomy (13%) and acute myocarditis (7%).

A peripherally VA-ECMO was established in 91% of cases. The median length of ECMO was 186 hours (IQR 5.4 – 13 days), median ICU stay 18 days (IQR 12–33 days). In our series, device related complications were as follows: bleeding from cannula site occurred in 35% of patients, requiring surgical intervention in 9% of them. One patient suffered an unintended decannulation. Lower limb ischemia after femoral cannulation occurred in 22%, which is comparable to the literature (2). Limb amputation was required in 3% of patients. Thrombi formation in the oxygenator membrane was found in 19% of cases, 3% required urgent membrane replacement.

Patient related complications may be due to profound shock at the time of ECMO cannulation, or to the ECMO itself. Acute renal failure occurred in 68% of patients, half of which received renal replacement therapy (RRT). Major neurological complications were recorded: 9% of patients suffered from anoxic brain injury frequently related to previous cardiac arrest, 2 patients had a central nervous system (CNS) hemorrhage and CNS infarction was observed in 4% of patients. Only three of these patients diagnosed with stroke, either hemorrhagic or ischemic, were weaned from ECMO and discharged with good neurological recovery. Infectious complications occurred on 48% patients, mostly catheter-related bacteremia (27%) and ventilator-associated pneumonia (19%).

Global survival rate during ECMO support was 68%, with 43% of patients being discharged home. Severe complications had an enormous impact in outcome, regardless of the initial CS cause. After hemorrhagic stroke or anoxic brain injury survival was as low as 21%. However, some complications as the need of RRT were met with 34% survival, maybe due to the removal of inflammatory cytokines (3).

Conclusion: Patients needing VA-ECMO for CS have an already slim chance of survival. Complications may further increase their morbidity and mortality. A better understanding of their incidence and characteristics is paramount to a better management of these patients and to achieving better outcomes in the future.

Introduction: MINOCA is defined by the AMI criteria, absence of obstructive coronary artery disease ($\geq 50\%$), and no other cause for the clinical presentation. Research studies of MINOCA reported a 12-month mortality of 4.7% (95% CI 2.6–6.9), consistently demonstrating a better prognosis than for those with AMI and obstructive coronary disease. Therefore we can no longer dismiss patients with MINOCA as having false-positive AMIs but need to consider the potential benefit of statins and ACE inhibitors/ blockers.

Objectives: To describe the characteristics of patients admitted in the ICU with acute coronary syndrome, differentiating between the groups of acute myocardial infarction with and without coronary obstruction (MINOCA)

Methods: An observational study that includes all patients (N = 498) admitted for ACS in HUVN- ICU's Coronary Unit from January to December 2015. The ARIAM registry was used and computerized medical records were reviewed to collect data not included in the registry. Patients who did not undergo cardiac catheterization, echocardiography, or did not have the study variables recorded in their history were excluded. The data obtained was collected in an SPSS sheet and was subsequently evaluated in terms of descriptive statistics with mean, standard deviation (SD) and frequencies, and comparisons were made between the groups with and without coronary artery disease, using Student's T test for quantitative variables and Chi square test for qualitative variables.

Results: The study includes 391 patients, 270 (69.2%) men and 120 (30.8%) women. The mean age was 62.9 (SD 12.6). The most common reason for admission was STEMI (49%) and 83.4% were in a Killip I clinical situation. The most prevalent cardiovascular risk factors were: hypertension (59.5%), dyslipidemia (50.5%), smoking (34.6%), type 2 Diabetes Mellitus (33.8%). LVEF at discharge was 53.2 (DS 10). 83.6% of the patients had coronary lesions, but only 62.4% were discharged with dual antiplatelet therapy. 16.4% had no coronary lesions; however, only 19 (3%) were considered MINOCA and received treatment. After 3 years, 7.7% of patients had another myocardial infarction, 16.4% were hospitalized due to cardiovascular causes, 0.8% had a recovered cardiorespiratory arrest, and mortality was 3.3% (17). Patients without coronary obstruction were more frequently women (56.5 vs. 44.5% p <0.01), younger (61 ± 10.8 vs. 65.7 ± 12.9 years, p = 0.06) and with a better cardiovascular risk profile (DM 15 vs 30.8% p <0.01, dyslipidemia 23.7 vs 55.8%, p <0.01, hypertension 33.4 vs 56.6%, p = 0.06 and tobacco 28.8 vs 54.6%, p = 0.02).

Conclusion: - Admissions to the ICU's Coronary Unit with significant coronary lesion are much more frequent, which makes a reliable comparison between both groups difficult.

- MINOCA patients were more frequently women, younger and with a better cardiovascular risk profile. They are underdiagnosed and undertreated at hospital discharge.

The use of carotid doppler to determine volume responsiveness following passive leg raising in hemodynamically unstable patients

M. Boraie¹; C. Ibtissam¹¹Icu, Burjeel Royal Hospital, Al Ain, United Arab Emirates**Correspondence:** M. Boraie*Intensive Care Medicine Experimental* 2020, **8(2)**: 000908

Introduction: Critically ill patients have a mixture of intravascular volume depletion, low systemic vascular resistance, and decreased cardiac output, which makes responses to attempts at volume resuscitation difficult to predict. The objectiveness of this study was to determine the value of passive leg raising (PLR)-induced changes in the carotid volumetric blood flow, as assessed by carotid Doppler, which can predict volume responsiveness in a heterogeneous group in the ICU.

Methods: The following patients were enrolled in the study: 1. Patients who present with clinical and laboratory evidence of sepsis/septic shock. 2. Patients who present with evidence of fluid loss due to hyperosmolar hyperglycemia syndrome (HHS). 3. Patients who present with a picture of acute renal failure with no obvious etiology. Common carotid artery Doppler is performed before and after PLR to determine the carotid volumetric blood flow using the formula: Carotid Volume Flow = Cross sectional Area (A) X Time Average Velocity (TAV) ml/s. A is obtained as $\pi \times \text{radius} (D/2)$, $A = D^2 \times 0.785$. A patient whose carotid volume flow increased by > 20% following PLR was considered a fluid responder. We based our estimate on the study done by Paul Mark et al¹.

Results: 36 patients were enrolled in the study, 67% were male; with an average age of 48 ± 18 years. The increase in carotid volume flow by > 20% following PLR was significant in fluid responders ($p < 0.05$). Eighteen patients (50%) had sepsis/septic shock, five of them were fluid unresponsive and required a vasopressor. In the other thirteen patients of the same group, hypotension and tachycardia resolved with limited fluid resuscitation. We also admitted twelve patients with HHS, ten of those patients were fluid responsive and required limited fluid resuscitation. The other two patients were fluid unresponsive and required maintenance fluid. We also admitted six patients with acute renal failure with no apparent etiology, three of those patients were fluid responsive and required controlled fluid resuscitation. The other three patients were fluid unresponsive and required inotropic support for heart failure.

Conclusion: Our study supports the concept of a hemodynamically-guided, restricted fluid resuscitation strategy in the hemodynamically unstable ICU patients. Initial fluid resuscitation in those patients should be limited and guided by an assessment of fluid responsiveness through the estimation of carotid volume flow following PLR.

Safety and effectiveness of temporary cardiac pacing with the new kronosafe system

R. Vicente-Mirallas¹; DA. Martín-Langerwerf¹; JM. Nuñez¹; A. Marco¹; AD. Sangio¹; C. Oliver¹; A. Davila¹; L. Montes¹; P. Gracia¹; S. Sanchez¹; MC. Prieto¹¹Intensive care unit - cardiac stimulation, Vinalopo University Hospital, Elche, Spain**Correspondence:** R. Vicente-Mirallas*Intensive Care Medicine Experimental* 2020, **8(2)**: 000048

Introduction: Temporary Cardiac Stimulation with active-fixation leads has demonstrated to be more effective and safer than the other done without fixation(1,2,3). Nowadays doesn't exist a pacemaker to do it and physicians usually use definitive cardiac stimulation devices

(leads and generator) off label. We have developed a new subjection system called KronoSafe[®], that allows us to hold all the external part of the temporary pacemaker. With our new subjection system, we provide the security that the procedure needs against device detachment or intravascular infection.

Objectives: The aim of this study was to demonstrate the effectiveness and safety of temporary cardiac stimulation with active-fixation leads subjected with the new KronoSafe System[®].

Methods: The study was approved by the Clinical Research Ethics Committee of our hospital. We include all consecutive patients underwent temporary cardiac stimulation over 6 months at our centre. A 65 cm active-fixation lead was implanted through the left jugular vein to right ventricle apex and connected to a reusable generator. We measure R wave sensed, lead impedance and threshold every 48 hours. Complications related with cardiac stimulation were collected: pace/sense failure, lead or generator detachment and right ventricle perforation. We also describe how much time the patient was in the intensive care unit and standard hospitalization floor under temporary pacing.

Results: 12 patients were included. Every 48 hours medium of R wave sensed was 10-9,56-9,98-9,71 mV; lead impedance was 673-584-573-569 Ohm and the threshold was 0,63-0,42-0,47-0,46 V No complication was registered. The average duration of temporary cardiac stimulation was 7,6 days (min 44 h– max 600 h), 24 hours in ICU and 157 hours in standard hospitalization floor.

Conclusion: 1- Temporary Cardiac Stimulation with active-fixation leads is safer than conventional temporary stimulation and a safe procedure outside ICU.

2- This kind of temporary cardiac pacing allows an early discharge from ICU.

3- KronoSafe® can provide the security that this procedure needs.

Correspondence: L. Hidalgo

Intensive Care Medicine Experimental 2020, **8(2)**: 001099

Introduction: The presence of No-reflow (NR) during primary coronary intervention (PCI) in STEMI is associated with worse outcomes and higher mortality. Different strategies have been studied to decrease NR's incidence without success.

Objectives: To assess if there is a reduction in NR's incidence depending on the time of administration of unfractionated heparin (UFH) in patients with STEMI, before or during PCI.

Methods: We perform a retrospective cohort study that includes patients diagnosed of STEMI treated with PCI during 2017 and 2018 in our hospital. Patients who had out-of-hospital cardiac arrest, those who were treated with fibrinolysis and those without reperfusion treatment or without obstructive coronary artery disease in PCI were excluded. We compare 2 groups, in the first one UFH was administered during PCI, and in the second one UFH was administered previously. Arterial flow was analyzed at the beginning and at the end of PCI, using TIMI scale. We also analyzed NR's incidence, mortality and complications.

Results: 389 patients were included, with ages between $61,38 \pm 12,6$ in group 1 vs $64,4 \pm 12$ in group 2 ($p=0,02$). The studied variables are shown in table 1, there weren't statistically significant differences in cardiovascular risk factors or previous pharmacological treatment between the groups. Arterial flow at the beginning of PCI and the incidence of in-hospital major bleeding were similar in both groups (TIMI > 1 -> 48,9% in group 1 vs 52% in group 2, $p=0,56$) (1,4% (n=2) vs 1,6% (n=4); $p=0,9$) respectively. Mortality rate was 5,9% (N=8) vs 4,4% (N=11) ($p=0,52$).

Statistically significant difference was found in NR's incidence, 12,9% (N=18) vs 6,4% (N=16) ($p=0,0028$), with an OR of 2,1 (IC 1,07-4,41) ($p=0,036$).

The multivariable analysis shows that the lack of previous administration of UFH is associated with an increase in NR (OR: 2.48 [1.20-5.33]; $p=0.014$) and major age too (OR 1.04 (1.009-1.07), $p=0.008$), getting renal insufficiency out of the analysis.

Table 1. Sample's baseline characteristics:

	Total N = 398	Group 1 (UFH during PCI) N = 139	Group 2 (previous UFH) N = 250	P
Age	63.4% +/- 12.4	61.38 +/- 12.6	64.4 +/- 12.0	0.021
Male	79,7 %	77,7 %	80,8 %	0.46
Arterial hypertension	29 %	27,3 %	30 %	0.6
Smoker	15,4 %	17,3 %	14,4 %	0.45
Diabetes	20,3 %	22,3 %	19,2 %	0.5
Dislipemia	64,2 %	51,8 %	51,6 %	0.7
Previous renal insufficiency	6,2 %	7,2 %	5,6 %	0.7
TIMI > 1 before angioplasty	50,9 %	48,9 %	52 %	0.56
Anti IIB/IIIA	36,8 %	38,8 %	35,6 %	0.52
NR	8,7 %	12,9 %	6,4 %	0.28
In-hospital bleeding	1,5 %	1,4 %	1,6 %	0.9
Stent thrombosis	2 %	0 %	0,5 %	0.54
Mortality	4,9 %	5,9 %	4,4 %	0.52

Table 2. Multivariable analysis with logistic regression; dependent variable: NR

Variable	OR	P
Previous UFH	2.48 (1.20-5.12)	0,014
Age	1.04 (1.01-1.07)	0,008

Conclusion: Early UFH administration is a protective factor against NR and is associated with a better outcome after PCI in STEMI.

Intensive Care Medicine Experimental 2020, **8(2)**: 001155

Introduction: Dipyridamole based triple antiplatelet therapy (TAPT) on stroke prevention and long-term outcome was unknown. Our study is aimed to evaluate long-term efficacy and safety of dipyridamole based TAPT after acute myocardial infarction (AMI).

Methods: This is a nationwide, case-control study involving 186,112 first AMI patients. We adopted a ratio of 1:4 propensity score matching based on multiple variables. Finally, we enrolled 4,540 patients in the dual antiplatelet therapy (DAPT) group and 1,135 patients in the TAPT group in our final analysis.

Results: Overall survival rate was comparable between two groups of patients (log-rank P = .0569), regardless of sex. In age subgroup, TAPT group showed poor survival in younger patients (log-rank P = .0072), but no survival difference compared with DAPT group in older patients. There was no extra benefit of TAPT for patients after AMI regardless of types of myocardial infarction (MI). DAPT was superior

to TAPT for patients underwent percutaneous coronary intervention (PCI) (log-rank $P = .0022$). TAPT did not reduce cumulative event rate of recurrent MI or recurrent stroke in patients after AMI. TAPT increased cumulative intracerebral hemorrhage (ICH) rate (log-rank $P = .0026$) but did not affect cumulative event rate of gastrointestinal (GI) bleeding free survival. Dipyridamole did not contribute to AMI survival.

Conclusion: TAPT did not contribute to overall AMI survival, and did not reduce recurrent rate of MI or stroke. TAPT increased ICH rate without effect on the incidence of GI bleeding compared with DAPT.

Intensive Care Medicine Experimental 2020, **8(2)**: 001156

Introduction: Early use of dual anti-platelet therapy (DAPT) in ST elevation myocardial infarction (STEMI) can reduce stent thrombosis and further save the patients. However, it is still difficult to set up ambulance paramedics DAPT system for patients after STEMI. Therefore, the aim of this study is to investigate improving use of DAPT in ambulance for acute myocardial infarction patients in a city-based program.

Methods: A multidisciplinary team among 15 hospitals, fire bureau and department of health, Kaohsiung city government was organized since 2016. The key interventions include Asian first innovative city-based pre-hospital ambulance paramedic STEMI dual anti-platelet medication on-line instruction system, direct chewing DAPT at ambulance, training program for ambulance paramedics, 24 hours STEMI interpretation and on-line intrusction team. The consecutive STEMI diagnosed by ambulance electrocardiogram system were enrolled from Jan. 2011 to Dec. 2018 in Kaohsiung city. The patients were divided into three groups: pre-interventional group from 2011-2015, Interventional group from Jan to Dec 2016 and post-interventional group from 2016 to 2018.

Results: The percentage of ambulance DAPT use in adequate STEMI patients increased from 0% in pre-interventional group, to 2.8% in interventional group and to 57.8% in post-interventional group ($p < 0.001$). In these STEMI patients received DAPT at ambulance, there was not any bleeding complications. Furthermore, the mortality was 0% in these patients.

Conclusion: This study showed, from 2011 to 2018, innovative city-based pre-hospital ambulance paramedic STEMI dual anti-platelet medication on-line instruction system can improve percentage of ambulance DAPT use and also outcomes in STEMI patients.

Application of sequential organ failure assessment (SOFA) score in patients who underwent cardiac surgery: a prospective study

A. M. Noble¹; C. Permejo¹

¹Department of Adult Cardiology, Philippine Heart Center, Quezon City, Philippines

Correspondence: A.M. Noble

Intensive Care Medicine Experimental 2020, **8(2)**: 000119

Introduction: After cardiovascular (CV) surgery, clinicians must identify patients at high risk to develop mortality/morbidity from multi-organ failure, and should quantify it through time to intensify treatment. The SOFA score is an objective tool in predicting outcomes in patients with severe sepsis¹.

Objectives: This study identified the association of SOFA score with organ dysfunction/failure, death or clinical improvement in patients who underwent CV surgery.

Methods: This is a single-center prospective cohort study that included 63 patients, ≥ 19 years old, admitted at the Surgical Intensive Care Unit (SICU) ≤ 3 days, who underwent any CVS (cardiopulmonary bypass, valve, congenital and vascular surgeries). The Institutional Ethics Review Board (IERB) of the institution approved the study in accordance with the ethical principles set forth in the Declaration of Helsinki and the National Ethical Guidelines for Health and Health-related Research of 2017. Informed consent was obtained prior to the conduct of the study.

The SOFA variables were obtained pre-operatively and post-operatively at day 0 and day 3. The score was computed using the Qx calculator[®]. Total maximum SOFA (TMS SOFA) and the delta SOFA (Δ SOFA) were also calculated.

Results: SOFA score analysis. The SOFA score was compared pre-operatively, on Day 0 post-operative and day 3 post-operative. In addition, the SOFA variables were also compared on these three periods. Table 4 compared the SOFA score and the SOFA variables on these periods. Δ SOFA score and the individual SOFA parameters (except for serum creatinine and bilirubin levels) were significantly different in the three periods ($p < 0.001$).

TABLE 4. SOFA score and SOFA variables

	Pre-operative	Day 0 Post-operative	Day 3 Post-operative	P-value
	Median (IQR)			
PaO ₂	95 (85.6 to 112)	203 (147 to 241)	130 (98 to 165)	<0.001
FiO ₂	21 (21 to 80)	60 (60 to 100)	21 (21 to 100)	<0.001
Platelet count	254 (217 to 288)	169 (116 to 195)	177 (125 to 261)	<0.001
MAP	83 (72 to 93)	93 (85 to 98)	84 (75 to 90)	<0.001
Use of inotropes	1 (1 to 1)	3 (1 to 4)	1 (1 to 4)	<0.001
GCS	15 (15 to 15)	10 (10 to 19)	15 (10 to 15)	<0.001
Creatinine	0.9 (0.79 to 1.13)	0.9 (0.68 to 1.13)	0.85 (0.68 to 1.03)	0.203
Urine output	1500 (1150 to 1900)	2450 (1790 to 3100)	1800 (1350 to 2120)	<0.001
eGFR	93.2 (68.8 to 106.5)	95.4 (68 to 112.9)	99 (72.2 to 115.8)	<0.001
Bilirubin	1.04 (0.81 to 1.58)	1.7 (1.23 to 2.68)	1.52 (0.92 to 2.14)	0.391
SOFA score	1 (0 to 2)	7 (6 to 9)	2 (1 to 3)	<0.001

PaO₂ partial pressure of oxygen FiO₂ fraction of inspired oxygen in the air MAP mean arterial pressure GCS Glasgow coma scale eGFR estimated glomerular filtration rate SOFA sequential organ failure assessment score

Predictors of organ dysfunction, failure and mortality. Valvular surgeries, platelet count and bilirubin levels, as well as the MAP, were shown to be predictors of outcome (P value 0.032, 0.006, 0.023 and 0.041 respectively). In patients undergoing valvular surgeries, they have more than 3 times risks to develop organ failure/dysfunction or mortality as compared to those who underwent other cardiovascular surgeries (OR 3.1429, 1.1068 to 8.9245 95% CI, 0.032 p-value). Post-operatively, for every unit increase in platelet count, the odds of developing organ failure/dysfunction or mortality decreased by 0.94% (OR 0.9906, 0.9839 – 0.9974 95% CI, 0.006 p-value). Post-operatively, for every unit increase in MAP, the odds of developing organ failure/dysfunction or mortality decreases by 5.31% (OR 0.9469, 0.8987 – 0.9977 95% CI, 0.041 p-value). Post-operatively, for every unit increase in bilirubin, the odds of developing organ failure/dysfunction or mortality increased by 103% (OR 2.0303, 1.1013 – 3.7429 95% CI, 0.023 p-value).

Conclusion: Exposure of patients undergoing CV surgery to the bypass machine may lead to deleterious sequelae explaining the high TMS SOFA and Δ SOFA score in the immediate post-operative period. As organ dysfunction improves or deteriorates in the succeeding days after intervention, it is coupled to a corresponding decrease or increase of the said scores. Our study showed that the SOFA score is a simple, reproducible, and readily available tool that could assist the clinician in intensifying treatment in this subset of patient; thereby, decreasing the risk for morbidity or death.

Correspondence: R. Sakaguchi

Intensive Care Medicine Experimental 2020, **8(2)**: 000139

Introduction: Right ventricular failure (RVF) after left ventricular assist device (LVAD) implantation increases morbidity and mortality¹. Nitric oxide inhalation (NOi) is frequently used to prevent and treat RVF. Previous studies reported a few preoperative hemodynamic predictors of RVF such as CVP/PCWP (pulmonary wedge pressure) ratio, RV stroke work index^{1,2}. However, the criteria to wean of and stop NOi are not fully standardized.

Objectives: The aim of our study was to investigate the risk factors and the outcome of restart of NOi after cessation in LVAD implantation.

Methods: A retrospective medical review was performed on 79 patients who underwent continuous flow type of LVAD (CF-LVAD) implantation and received NOi at the arrival of ICU (intensive care unit) from April 2014 to March 2019 at Osaka University Hospital. Patients under 18 years of age and those who underwent biventricular assist device implantation were excluded. Univariate and ROC analysis were performed to clarify the risk factors and cut-off value. This retrospective study was approved by the clinical research ethics committee of Osaka University Hospital (Ethical Committee number 19244).

Results: One patient without PA catheter was excluded. Of the entire 78 patients, 17 (22%) restarted NOi within 48 hours after cessation. In hemodynamic parameters just before cessation of NOi, CVP and CVP/dPAP (diastolic pulmonary pressure) ratio was higher in patients with restart of NOi ($p < 0.01$). ROC analysis showed Area Under the curve (AUC) of CVP was larger than that of CVP/dPAP ($p < 0.05$). Cut-off value were 11 mmHg in CVP (sensitivity 0.88, specificity 0.75), and 1.3 (sensitivity 0.77, specificity 0.79) in CVP/dPAP ratio. Compared with patients without restart of NOi, patients with restart of NOi had shorter ventilator-free days within 28 days [13 days (interquartile range, 0–20 days) vs. 23 days (interquartile range, 19–26 days), $p < 0.01$] and longer ICU

length of stay [22 days (interquartile range, 12–44 days) vs. 10 days (interquartile range, 7–16 days), $p < 0.01$].

Conclusion: CVP and CVP/dPAP ratio are useful criteria to discontinue NO inhalation. Also, restart of NO inhalation decreases ventilator-free days within 28 days and increases ICU length of stay.

000160**24 hours ABPM, vascular risk profile and ventricular function deterioration in patients type 2 diabetes mellitus with acute heart failure**

A. M. González González¹; A. M. Garcia Bellon¹; J. A. Cano-Nieto¹; M. De Mora-Martin¹

¹Cardiology, Regional Hospital of Malaga, Málaga, Spain

Correspondence: A.M. González González

Intensive Care Medicine Experimental 2020, **8(2)**: 000160

Introduction: Ambulatory blood pressure monitoring (ABPM) permits the evaluation of 24 hours blood pressure pattern.

Objectives: Our aim was to evaluate a possible negative influence of the presence of Type 2 Diabetes mellitus (T2DM) on 24 h. ABPM pattern, vascular risk profile and severity of left ventricular (LV) function in patients with Acute Heart Failure (AHF).

Methods: In 122 patients with AHF we compare clinical features of 42 (65±9 years / 87,5% males) with T2DM versus 80 (63±11 years / 68,3% males) non-T2DM.

In addition to clinical examination and analytical parameters, all patients underwent a 24 h, ABPM and echocardiogram and evaluation of degree of severity LV Dysfunction.

Results: Patients with T2DM had higher ($p < 0.001$) prevalence (%) of Hypertension (75 vs 46.7), dyslipidemia (65.6 vs 28.3), obesity (47 vs 43), and worse renal function (fGe: 64.7 vs 72.3 ml/min/1.75m²). Etiology IC: Hypertensive and/or ischemic heart disease: 75% vs 60%. Mean Values of 24 h ABPM measurements are in table 1.

Table 1

Mean Values (mmHg)	T2DM	p	NonT2DM
24. SBP	116 ± 16	<0.05	111 ± 15
Daytime SBP	117 ± 15	<0.05	112 ± 15
Nighttime SBP	114 ± 18	<0.04	108 ± 16
24h DBP	65 ± 7	ns	65 ± 8
Daytime DBP	67 ± 8	ns	67 ± 9
Nighttime DBP	64 ± 7	ns	69 ± 9
Pulse Pressure	50 ± 13	0.05	46 ± 11
Nocturnal PP	51 ± 15	0.05	47 ± 12

No significant differences in DBP between groups, but patient with T2DM present higher average values ($p < 0.05$) of SBP 24 h (mmHg): 116/111; daytime (117/112) and nighttime (114/108); higher 24 h Pulse Pressure (50 vs 46 mmHg) and non-dipper pattern frequency (84.7 vs 79.35), as well as a greater proportion of patients with moderate/severe LV dysfunction (87.6 vs 81.7%) ($p < 0, 05$).

We also observed worse NYHA functional class in T2DM patients: NYHA II-III 84,4 vs 58,3%, $p < 0,001$.

Conclusion: In patients with AHF, the presence of T2DM contributes to show greater hypertensive and/or ischaemic etiology, further deterioration of 24 h ABPM pattern and worse left ventricular myocardial function.

T2DM can be considered as a risk factor and worsening of heart failure. 24 h ABPM may contribute to a better prognostic evaluation in these patients.

Intensive Care Medicine Experimental 2020, **8(2)**: 000211

Introduction: Dynamic arterial elastance (E_{adyn}) has been shown to be a dynamic parameter for arterial load assessment and to predict arterial pressure response to volume administration. Since volume administration is a key part of hemodynamic resuscitation, arterial load assessment and knowledge of arterial pressure response to volume administration have lately become of particular interest. This is especially relevant in aortic repair, since maintenance of adequate spinal cord, renal and visceral perfusion pressure is a key element of peri-operative management. Although several studies could show that changes in cardiac preload and afterload influence E_{adyn}, the impact of changes in vascular properties, like aortic repair, have not been assessed so far.

Objectives: To date the effect of changes in vascular properties, like aortic repair, on dynamic arterial elastance have not been assessed systematically. Therefore the aim of this study was to test whether aortic repair affects dynamic arterial elastance and its ability to predict arterial pressure response to volume administration.

Methods: The study was designed as prospective observational trial in 18 domestic pigs. Animals were anaesthetized and mechanically ventilated. Hemodynamic data were obtained using transcatheter pulmonary thermodilution and pulse contour analysis. 4 consecutive volume loading steps each consisting of 6 ml/kg bodyweight hydroxyethyl starch were performed in baseline conditions and repeated 6 hours after hybrid aortic repair. Aortic repair was performed using a hybrid-graft technique consisting of a thoracic stent graft and open re-insertion of the abdominal and iliacal branches. An increase in mean arterial pressure (MAP) > 15% was considered as a positive pressure response. Values are given as mean (95% confidence interval), two-tailed p-values of <0.05 were considered significant.

Results: In baseline conditions E_{adyn} decreased (1.20 vs. 0.94, p<0.001) during volume loading and presented with an AUC of 0.84 (0.73-0.95). After aortic repair E_{adyn} also decreased (0.97 vs. 0.85, p=0.08) during volume loading while the ability to predict pressure response decreased to an AUC of 0.56 (0.38-0.74). Baseline values were significantly changed after aortic repair (1.20 vs 0.97, p< 0.05)

Conclusion: E_{adyn} values were significantly changed after aortic repair. Further E_{adyn} was not able to predict arterial pressure response to volume administration when vascular properties changed after thoracoabdominal aortic repair

Volume status assessment with cardiac variation of internal jugular vein

H. Nakano¹; M. Masaki¹; N. Hiromu¹; T. Yuji¹; S. Tomohiro¹; H. Hideki¹; N. Kensuke¹

¹Department of emergency and critical care medicine, Hitachi General Hospital, Hitachi, Japan

Correspondence: H. Nakano

Intensive Care Medicine Experimental 2020, **8(2)**: 000378

Introduction: Minimally invasive volume status assessments are highly required in emergency and critical care medicine, such as the respiratory variation of inferior vena cava (IVC) [1]. Previously, we focused on cardiac variation of major veins as a new index of it [2,3], and reported the association between cardiac variation of internal jugular vein (IJV) and stroke volume (SV) via venous return [3]. This is the first study which evaluated the cardiac variation of IJV in the emergency department.

Objectives: The purpose of this study was to confirm the efficacy of cardiac variation of IJV as an indicator for hemodynamics related to fluid volume.

Methods: This is a single-center prospective observational study. Patients over the age of 20 with need of fluid resuscitation who came in by ambulance were included from August 2019 to March 2020. Those who were severely ill and needed immediate treatments were excluded.

Cardiac variation of right IJV cross section area and respiratory variation of IVC diameter were evaluated by echography, SV, stroke volume variance (SVV) were evaluated by ClearSight system (Edwards Lifesciences, Irvine, CA, USA), and vital signs were recorded before infusion. Then, after infusion of 500 mL crystalloid, SV, SVV and vital signs were recorded again. To evaluate cardiac variation, we applied speckle tracking technique with ACUSON S2000 HELX EVOLUTION (Siemens, Munich, Germany). Collapse index was calculated by following formula; collapse index = (maximum – minimum) / maximum. Fluid responsiveness was defined as SV increase after infusion of 15% or more. The setting of age, gender, height, and weight were fixed in ClearSight measurement to shorten the evaluation time before treatment and provisional SV were recorded. Since the provisional SV is higher with age, we analyzed the provisional SV divided by age.

The primary outcome was fluid responsiveness. We evaluated the correlation with IJV cardiac variation, IVC respiratory variation or SVV. The secondary outcome was SV before infusion. We assessed correlation with IJV cardiac variation.

Results: Among 12,009 patients visiting emergency department during the study period, 103 patients were included in analysis. The mean age of patients was 74.0 years old, 55.3% were male, and 37.9% responded to fluid infusion. The mean collapse index of IJV cardiac variation was 15.6±13.6%. Collapse index of IJV cardiac variation (16.8±14.9% vs 13.6±10.9%, p=0.24) and collapse index of IVC respiratory variation (41.8±27.5% vs 45.6±27.6%, p=0.53) were not different between those with and without fluid responsiveness, and SVV (p= 0.02) before infusion showed significant difference. On the other hand, correlation was found between collapse index and SV/age (r=0.25, p=0.01).

Conclusion: Not IJV cardiac variation and IVC respiratory variation, but only SVV was correlated to fluid responsiveness. IJV cardiac index was associated with SV in emergency clinical setting similarly with the previous study.

Intensive Care Medicine Experimental 2020, **8(2)**: 000405

Introduction: To diagnose the cause of acute respiratory failure (ARF) in the emergency department (ED) is difficult. In particular, the differential diagnosis between hydrostatic pulmonary oedema (HPO) and other lung diseases is often challenging. Today, the diagnosis of HPO is mainly based on clinical criteria and the dosage of B-type natriuretic peptide, which is costly and suffers from some false positives, especially in case of renal failure. Since HPO is due to transfer of a significant volume of plasma through the pulmonary capillary barrier toward the interstitium and alveoli, it has been demonstrated that this volume is large enough for inducing haemoconcentration, whose level reflects the volume of lung oedema. However, the diagnostic accuracy of haemoconcentration in a population of dyspnoeic patients in the ED has never been investigated.

Objectives: To evaluate whether the variation of haemoglobin concentration (Δ Hb) over the first hours of treatment in dyspnoeic patients allows discriminating HPO from other causes of dyspnoea and ARF.

Methods: We retrospectively collected data of patients admitted to a medium-size ED for dyspnoea and ARF as leading problem, and for whom at least two Hb measurements (one at ED admission and one within the next 6 hours) were available. Patients were excluded if data regarding therapeutic management, radiological and biochemical investigations were not retrievable and if they were not subsequently admitted to a hospital ward. Two expert investigators, unaware of Δ Hb, defined *a posteriori* the cause of dyspnoea as HPO and non-HPO, according to clinical, instrumental and biochemical findings. The ability of Δ Hb to detect HPO as the main cause of dyspnoea was evaluated through the area under the receiver operating characteristic (AUROC) curve.

Results: Between November 1st, 2018 and December 31st, 2019, 1391 dyspnoeic patients were admitted to our ED. 572 patients were included in the analysis, among which 174 (30.4%) were diagnosed with HPO. HPO patients showed a significantly higher value of Hb at ED presentation compared to non-HPO (12.8[11.5–14.1]g/dL vs. 12.2[10.8–13.7]g/dL, respectively; $p=0.002$). At 6 hours from admission and the beginning of therapeutic management, relative Δ Hb was significantly higher in HPO than in non-HPO patients (-8.4[-11.4 to -5.8]% vs. 0.7[-1.9–3.6]%, respectively; $p<0.0001$). The AUROC for Δ Hb to detect HPO was 0.896[0.889–0.903] (sensitivity and specificity 0.81[0.80–0.84] and 0.90[0.87–0.92], respectively) with a cut-off of -4.3%. When absolute Δ Hb was considered, similar results were observed (-1.0[-1.5 to -0.8]g/dL vs. 0.1[-0.2–0.4]g/dL, respectively; $p<0.0001$), with an AUROC of 0.892[0.885–0.899] (sensitivity and specificity 0.82[0.80–0.83] and 0.88[0.87–0.90], respectively) and a cut-off value of -0.6 g/dL.

Conclusion: A reduction of Hb concentration $\geq 4.3\%$ over the first hours of treatment reliably identifies HPO as the main cause of dyspnoea and ARF in patients admitted to the ED.

Intensive Care Medicine Experimental 2020, **8(2)**: 000452

Introduction: Critical-care echocardiography (CCE) has been recently recognize by the Echocardiography Working Group of the Cardio-vascular Dynamics section of the European Society of Intensive Care Medicine (ESICM) and several studies have shown its growing importance in the critical patient.

Objectives: To evaluate biventricular systolic and diastolic function in ICU patients. To estimate the delay in performing the echocardiogram, as well as its prognostic influence in patients with different pathologies.

Methods: Echocardiographic studies conducted during the period 2018-2019 were reviewed and the parameters of systolic (LVEF by Simpson and Teicholz method, TAPSE) and diastolic (E/A and E/e' ratio) function as well as preload parameters (diastolic LV volume, inferior vena cava diameter) were collected. The delay in carrying out the study from the time of admission and the distribution by shifts (morning, afternoon, night) of these were analyzed. The influence of systolic and diastolic dysfunction on mortality and ICU stay was evaluated. The variables are expressed as a mean (95% CI).

Results: 197 patients with the following baseline characteristics were included. Age 68.8 (66.9-70.7) years, sex 64.6% men, weight 75.4 (72.6-78.2) kg, height 165.3 (163.9-166.7) cm, APACHE 17.8 (16.5-19.1), SAPS II 41.8 (39.2-44.3), SOFA 4.8 (4.2-5.4). The reason for admission was: sepsis/septic shock 14.8%, heart failure 12.3%, acute coronary syndrome 12.3%, pulmonary embolism 10.3%, acute respiratory failure 8.7%, cardiorespiratory arrest 7.2%, neurocritical 5.6%, acute on chronic respiratory failure 5.1%, trauma 2.6%, myopericarditis 2.6%, other 17.9%. The average stay was 7.8 (6.1-9.5) days, with a mortality rate of 20%. Systolic function was 41.7% (39.6-43.9) % Teicholz, 48.8% (39.7-57.8) % Simpson, 20.3 (19-21.6) mmTAPSE. Diastolic function was: E/A 1.8 (1.2-2.4), E/e' 12.5 (11-13.9). The LVEDV was 106.4 (99.9-112.9) ml and the IVC was 17.8 (16.5-19) mm. 4.1 (3.6-4.6) images and 2.9 (2.4-3.3) video clips were archived per study. The study was performed at 45.1 (31.9-58.3) hours after admission, the distribution by shifts was: morning 63.1%, afternoon 25.6% and night 11.3%. Statistically significant differences (ANOVA test) were observed in the Simpson LVEF ($p=0.006$) and the E/A ratio ($p=0.007$) between the different diagnostic groups, with the heart failure and cardiac arrest groups showing the highest degree of dysfunction. The presence of systolic or diastolic dysfunction did not influence ICU stay or mortality.

Conclusion: Conclusions: Routine echocardiographic evaluation of critical patients provides information on systolic and diastolic function. It can guide treatment and advise on prognosis.

Intensive Care Medicine Experimental 2020, **8(2)**: 000498

Introduction: Haemodynamic parameters play an essential role in intensive care units. Stroke volume variance (SVV) and pulse pressure variance (PPV) are used for predicting fluid responsiveness in mechanically ventilated patients.

Objectives: However, their applicability is limited as they require sinus rhythm and controlled ventilation modes which both is only available in 43% of ICU patients (Huber et al., 2018). This study's goal was to investigate the impact of change in ventilation pressure (Pinsp) on change in SVV and PPV in pressure-controlled ventilated patients. Due to former studies (Sakka, Becher, Kozieras, & van Hout, 2009; Vieillard-Baron et al., 2016), we hypothesized that there's a significant correlation between tidal volume (VT), Ppeak, Pmean, lung compliance and SVV or PPV. It was aimed to generate a formula using multiple regression to predict deltaSVV and deltaPPV in dependence of ventilation parameters.

Methods: In total 43 pressure-controlled ventilated patients from ICU were investigated. Transpulmonary thermodilution (TPTD; PiCCO, Pulson Medical Systems SE, Germany) was performed before and after a change in inspiratory pressure (Pinsp) on the ventilator machine (EvitaXL, Drägerwerk® AG & Co. KGaA, Germany and Carescape™ R860, GE Healthcare, Germany). Magnitude of change in Pinsp was based on medical indication due to arterial blood gas analysis or weaning. Patients were measured at least once and not more than eight times, resulting in 90 total measurements. We compared deltaSVV and deltaPPV to deltaVT, deltaPpeak, deltaPmean and lung compliance. Due to multiple measurements in some individuals we analysed the within-subject correlation using ANCOVA and between-subject correlation using subjects' means (Bland & Altman, 1994).

Results: No significant ($p < 0.05$) within-subject or between-subject correlation could be shown between deltaSVV/ deltaPPV and deltaVT, deltaPpeak, deltaPmean, lung compliance. No formula using ventilation parameters as predictors for deltaSVV and deltaPPV in multiple regression could be generated.

Conclusion: Former findings of correlation between VT and SVV or PPV could not be confirmed in our study. Further investigations need to be performed to find out more about these discrepancies in results.

Intensive Care Medicine Experimental 2020, **8(2)**: 000515

suggestions for improving the implementation performance of novel digital health technology in ICU.

Methods: The study was conceived June–November 2019 in an ICU of a German university hospital during the implementation of Vital Sync 2.4 (Medtronic plc) as an additional tablet computer based remote patient monitoring to the primary patient monitoring. After IRB approval (EA1/031/18), seven semistructured interviews with key stakeholders—closely involved in the implementation process—were conducted. The interview guideline was developed on the basis of findings of a previous study [3] and the Consolidated Framework for Implementation Research [4]. Transcripts were analyzed following an inductive approach [5].

Results: Main obstacles identified by interviewees were lack of staff commitment due to little and non-persistent leadership engagement, unequal distribution of workload for the project among professions, technical instructions not reaching all staff members, limitations of the intervention in its current version, and low perceived benefit of remote monitoring for ICU staff. High stress levels in the ICU and an increased workload due to a complex set-up of the system that was additional to the primary monitoring system obstructed regular usage.

Suggestions to improve implementation of novel digital applications in the ICU aimed to enhance staff engagement through the nomination of specific responsible staff members for the implementation process, continuous technical instructions and feedback workshops as well as transparent and early communication of the project aims. The intervention should provide a high intuitivity, interoperability with other devices, and a clear advantage for its usage. Regarding the implementation site, a ward with a lower staffing ratio per patient, less fluctuation of staff members, and less patient turnover was suggested. For example, patients with a relatively weak indication for admission to the ICU could be remotely monitored on a normal ward.

Conclusion: A technologized setting with many different devices and a high stress level of staff make the ICU a particular environment for the implementation of new technology. Staff engagement and identification with the intervention are essential for effective implementation and could be enhanced through persistent leadership engagement, regular instructions, and early, transparent communication of the intervention. Intuitivity and interoperability are indispensable intervention features for implementation success. However, the additional benefit of remote monitoring in the ICU was regarded as low, other settings were perceived as more suitable for this technology.

Intensive Care Medicine Experimental 2020, **8(2)**: 000530

Introduction: The end-expiratory (EEXPO) test detects preload responsiveness by observing changes in cardiac index (ChangeCI) during a 15-sec interruption of ventilation at end-expiration. First, it is not clearly established whether a simple measurement of the changes in arterial pulse pressure (ChangePP) during EEXPO could reliably reflect ChangeCI and detect preload responsiveness. Second, if it was the case, this should allow the shortage of the EEXPO test. Indeed, many devices measuring CI do not display the beat-to-beat value of CI but average it over several seconds, so that the EEXPO test must be long enough for allowing significant changes to appear. ChangePP, which are instantaneously measured, might require a shorter test to be evidenced, but this has to be proven.

Objectives: First, to test whether beat-to-beat ChangePP measured during a 15-sec EEXPO detect preload responsiveness. Second, to evaluate whether it is still the case when test's duration is shortened.

Methods: In 30 mechanically ventilated patients we performed a 15-sec EEXPO. PP was continuously and digitally recorded. CI was measured by pulse contour analysis (PiCCO2 device). Patients were defined as "preload responders" if CI increased $\geq 10\%$ during a passive leg raising.

ChangePP was calculated as the difference between the mean of PP values over the last 5 seconds of tests (both for 15-sec and 10-sec EEXPO) and the baseline value. The ability of ChangePP to detect preload responsiveness through the EEXPO test was evaluated through the area under the receiver operating characteristic curve (AUROC). The same analysis was repeated on a validation cohort of 126 patients enrolled from previous studies, in which real-time ChangePP during EEXPO had been already recorded.

Results: In the prospective cohort, 15 patients were preload responders and 15 preload non-responders. ChangePP during 15-sec EEXPO was significantly higher in responders than in non-responders (11[8–15]% vs. 2[1–4]%, respectively, $p < 0.0001$). ChangePP during 15-sec EEXPO detected preload responsiveness with an AUROC of 0.90 ± 0.05 (sensitivity 0.85, specificity 0.84, cut-off 5%). When the duration of EEXPO was shortened to 10 seconds, ChangePP during EEXPO was still larger in responders than non-responders (11 [8–14]% vs. 3[2–3]%; $p < 0.0001$). ChangePP during a 10-sec EEXPO detected preload responsiveness with an AUROC of 0.88 ± 0.07 (sensitivity 0.84, specificity 0.85, cut-off 5%). The analysis on the validation cohort showed similar results for ChangePP, with AUROCs of 0.89 ± 0.07 for 15-sec EEXPO and 0.91 ± 0.05 for 10-sec EEXPO.

Conclusion: Real-time measurement of PP during EEXPO detects preload responsiveness, even when the duration of the test is shortened to 10 seconds. This opens the possibility of assessing preload responsiveness without any need for cardiac output monitoring in ventilated patients.

Alarm fatigue reported by ICU staff: a survey study

A. S. Poncette¹; M. M. Wunderlich²; M. Schmieding¹; F. Schiefenhoevel¹; E. Salgado¹; M. Feufel²; F. Balzer¹

¹Department of anesthesiology and intensive care medicine ccm / cvk, Charité – Universitätsmedizin Berlin, Berlin, Germany; ²Fg arbeitswissenschaft, Technische Universität Berlin, Berlin, Germany

Correspondence: F. Balzer

Intensive Care Medicine Experimental 2020, **8(2)**: 000550

Introduction: Alarm fatigue on intensive care units (ICU) is defined as a sensory overload due to an excessive number of alarms from medical devices, which can result in desensitization to alarms and missed alarms [1].

Objectives: We assessed to what extent ICU staff at a university hospital experiences alarm fatigue from patient monitoring alerts, whether false alarms are perceived to disrupt patient care, and what strategies staff developed to handle alarms, such as adjusting or communicating thresholds or pausing alarms when examining patients. Because patient monitoring is a multidisciplinary team effort, we also aimed to uncover differences between health professions in the ICU.

Methods: A survey study was conducted with ICU staff from four ICUs of a German university hospital between November 2019 and January 2020 after IRB approval (EA1/031/18). We designed a web-based 12-item questionnaire based on literature analyses and focus groups [2–6], and distributed it by email to all 270 ICU staff members, which included both physicians and nurses. The response format was a 5-point Likert-type scale (e.g., never - always). We cleaned and analysed the data with R in combination with the packages tidyverse and infer [7]. Statistical analyses included median values with bootstrapped 95% confidence intervals and permutation tests to compare the distributions of responses of nurses and physicians. An item median was considered statistically significant (*) when the 95% bootstrap confidence intervals of the median did not include 3, which indicates the response *sometimes*.

Results: Eighty-nine of the 270 ICU staff members (33%) completed the questionnaire. 63%* of the respondents had always or often so much to do that they could not respond to alarms quickly enough. 45% always or often ignored alarms that keep repeating, 24% stated to overhear critical alarms often, and 22% were always or often overwhelmed by too many alarms. The majority strongly agreed or agreed that false alarms disrupt patient care (76%*), and reduce trust in alarms (63%*). 82%* of participants reported to always or often adjust alarm settings (e.g., alarm thresholds) individually for each patient, but documentation of adjustments of alarm settings in the patient data management system was always or often omitted by 76%*. 29% of the respondents stated to always or often set the alarms of patient monitors on *Pause* when examining the patient. Between nurses and physicians, no significant differences of the median values of the items were revealed.

Conclusion: Our results suggest that both ICU physicians and nurses experience noticeable alarm fatigue due to false alarms which could harm patients. To remedy this situation, alarm management in the ICU should be optimized such as by more targeted and regular use of the *alarm pause* function, and by introducing a hospital-wide standard operating procedure for alarm management.

Intensive Care Medicine Experimental 2020, **8(2)**: 000569

Introduction: Knowing trends in pulmonary blood flow (PBF) and shunt fraction (Qs/Qt) could guide hemodynamic and respiratory management and improve outcomes in critically ill patients. PBF and shunt fraction are typically determined invasively using systemic and pulmonary arterial catheters and repetitive blood gas analyses. We present a porcine study utilizing novel techniques to obtain PBF and shunt measurements via the breathing tube.

Objectives: We tested whether PBF and Qs/Qt can be measured via the breathing tube by means of a new monitoring system (VQm PHM™, Rostrum Medical Innovations Inc., Canada).

Methods: 9 pigs (70–88 kgs) were anesthetized, intubated and instrumented with a systemic and pulmonary artery catheter and a pump-driven extracorporeal circuit connecting the right and left atrium to produce shunt. Qs/Qt was measured at baseline and pump flows of 1L/min and 3L/min. Additionally, in four animals, cardiac output (CO) was increased to 130% of baseline using dobutamine. Measurements of PBF and shunt fraction from the VQm PHM and the reference were conducted at baseline and during interventional periods (increased CO or shunt, respectively).

VQm PHM estimated PBF using the differential Fick equation and sequential gas delivery (SGD). VQm PHM assessed Qs/Qt by measuring the decay of N₂O after breathing FiN₂O of 30% for 25 breaths (N₂O challenge). The number of breaths required to reach an end-tidal value of 2.5% of the end-tidal after cessation of the N₂O challenge was calculated and expressed as shunt index (SI). These values were compared to PBF and Qs/Qt calculated by means of bolus thermodilution and the Berggren equation, respectively. PBF was estimated by subtracting shunt fraction from thermodilution-derived CO. Agreement between the two methods was assessed by Bland-Altman analysis.

Results: For PBF, 17 paired measurements of the VQm PHM and reference were obtained. The mean difference between paired values was 0.21 L/min, and the 95% limits of agreement were –2.15 and 2.57 L/min. For Qs/Qt, 64 paired measurements of the VQm PHM SI and reference were obtained. The mean difference between paired values was –0.22, and the 95% limits of agreement were –1.34 and 0.89.

Conclusion: These results suggest that the VQm PHM measurements of PBF and Shunt Index were able to track changes in PBF and shunt fraction in anesthetized pigs.

Comparison of hemodynamic parameters derived by PiCCO and GE E-PiCCO

K. Putko¹; F. Wagner¹; D. Busch¹; H. Schuster¹; R. Schmid¹; W. Huber¹; T. Lahmer¹

¹Medizinische klinik und poliklinik ii, Klinikum rechts der Isar; Technische Universität München, Munich, Germany

Correspondence: K. Putko,

Intensive Care Medicine Experimental 2020, **8(2)**: 000606

Introduction: The monitoring of hemodynamic parameters to assess the cardiovascular status and the efficiency of therapy is of high importance in critically ill patients. Due to increased interest in advanced hemodynamic monitoring (AHM) several new devices were introduced within the last years. In this context, the new E-PiCCO device (GE Healthcare, Helsinki, Finland) recently became available.

Objectives: To compare the E-PiCCO device with the established PiCCO® device (PULSION Medical Systems, Munich, Germany) and to quantify the impact of proper and improper settings on AHM.

Methods: Both devices are based on pulse contour (PC) analysis and transpulmonary thermodilution (TPTD). Sixteen adult intensive care patients (8 female, 8 male, age 35–88 yr) undergoing clinically indicated AHM with PiCCO® were enrolled in this study. All patients had femoral (FEM) as well as jugular (JUG) central venous catheter (CVC). In these patients, 30 measurement sequences were completed, with one sequence consisting of 5 TPTDs (divided into 3 measurements by PiCCO® and 2 by E-PiCCO). Each of the 5 TPTDs included 3 cold saline injections of 15 ml. Usually, the measurements are performed in JUG site, whereas the PiCCO® device also allows the measurement in FEM CVC site by applying a built-in correction formula. The E-PiCCO device only allows correct JUG CVC site measurements. For comparison both devices were used in the proper and improper way. Proper use: JUG (PiCCO® and E-PiCCO) and FEM with correction formula (only PiCCO®); improper use: FEM (E-PiCCO and PiCCO® without correction formula). The following hemodynamic parameters were estimated by both devices: cardiac index (CI) by PC (PCCI) and by TPTD (TDCI), indexed global end-diastolic volume (GEDVI) and extravascular lung water (EVLWI). These were compared by Bland–Altman analysis. IBM SPSS 26.

Results: Mean PCCI in [L/min/m²] were 3.75, 3.64, 3.96, 3.92, 3.99 for PiCCO® JUG, E-PiCCO JUG, E-PiCCO FEM, PiCCO® FEM corrected, PiCCO® FEM uncorrected, respectively. In the same order, mean values for TDCI in [L/min/m²] were 3.73, 3.59, 3.90, 3.94, 4.01; for GEDVI in [ml/m²] 855, 810, 1067, 815, 1116; for EVLWI in [mL/kg] 9.33, 9.27, 10.3, 10.3, 10.4, respectively. The mean bias between E-PiCCO and PiCCO® in JUG site were: –0.11 (PCCI), –0.14 (TDCI), –47.3 (GEDVI), –0.07 (EVLWI), with limits of agreement (LOA, 1.96 SD, ±95% CI) of ±0.55, ±0.45, ±117, ±1.48, respectively, and the percentage error of 15, 12, 14, 16%, respectively. The bias results for the comparison of E-PiCCO in FEM and PiCCO® in JUG were: 0.21 (PCCI), 0.17 (TDCI), 212 (GEDVI), 0.97 (EVLWI), with LOA of ±0.71, ±0.74, ±286, ±3.83, respectively, and the percentage error of 18, 18, 26, 37%, respectively.

Conclusion: The E-PiCCO measurements showed only small differences to the PiCCO® device when used in JUG site. As in this study, PiCCO® JUG is considered as the gold-standard, the improper measurement with the E-PiCCO in FEM site shows a considerably higher error but except for EVLWI would still meet the “Critchley-Criterion” (1). In conclusion, the E-PiCCO device is a reasonable alternative to the PiCCO® device. When using the devices improperly, especially EVLWI and GEDVI showed higher discrepancies than TDCI and PCCI measurements.

Comparative study of two central venous catheter placement methods: conventional method vs a modified method guided by the intracavitary electrocardiogram

A. Palaguachi¹; B. Jaramillo¹; L. Calle¹; E. Ochoa¹; F. Moscoso¹; J. Cobos¹; S. Alvarez¹; H. Tirape¹; H. Aguirre-Bermeo¹

¹Intensive care unit, Hospital Vicente Corral Moscoso, Cuenca, Ecuador

Correspondence: H. Aguirre-Bermeo

Intensive Care Medicine Experimental 2020, **8(2)**: 000611

Introduction: The correct placement of the central venous catheter (CVC) has to be verified by chest radiography. The technique guided by intracavitary electrocardiogram (EKG-IC), allows a correct placement of the catheter avoiding radiological control. The classic method of CVC placement by EKG-IC places the test electrode at the end of the procedure (when passing the catheter through the guidewire). We have made a modification of this method by performing the check by connecting the electrode to the guidewire when it is placed through the dilator. This modification allows the guide to be repositioned through the dilator and avoids the new puncture and restart of the procedure if the guide is in an extrathoracic location.

Objectives: Compare the correct placement of the CVC in the two methods studied and validate the modified CVC placement method by EKG-IC.

Methods: Fifty patients in whom CVC was placed were prospectively collected. Two methods were evaluated, conventional method (seldinger technique) and a modified method guided by EKG-IC. The method to be used was indicated by the doctor responsible of the patient. The location of the catheter was evaluated by chest radiography. The radiologist who evaluated the radiography was unaware of the method used. Correct CVC placement was defined with radiologic landmark of the lower third of the SVC (zone2): under the carina but within the first 3 distal cm(1). The data are presented in median, interquartile range and number and percentage as appropriate.

Results:

VARIABLE	CONVENTIONAL N=25	EKG_IC MODIFICATED N=25	P=
Procedure Time, Minuts	12 (7,19)	13 (9,19)	0,66
Zone 1	9 (36)	3 (12)	0,05
Zone 2	3 (12)	18 (72)	<0,01
Zone 3	12 (48)	4 (16)	0,02
Zone out	1 (4)	0 (0)	0,31

Conclusion: In this patient sample, the modified CVC placement method by EKG - IC significantly allowed correct placement. This modified method, in addition to avoiding control radiology, would avoid puncturing again if the catheter location is extrathoracic.

Heparin resistance during ECMO—alternative anticoagulation with Argatroban

C. Efseviou¹; A. Kastoris¹; L. Palazis¹

¹Intensive care unit, Nicosia General Hospital, Nicosia, Cyprus

Correspondence: A. Kastoris

Intensive Care Medicine Experimental 2020, **8(2)**: 000736

Introduction: Prompt anticoagulation and coagulation monitoring is an essential aspect of patients during extracorporeal membrane oxygenation (ECMO) therapy. Heparin infusion is the gold standard

regarding anticoagulation during ECMO. Nevertheless, resistance to heparin may arise that may be difficult to diagnose and manage.

Methods: A search of the literature on PubMed, Google Scholar and Scopus with the keywords “ECMO or ECLS” and “heparin resistance” was conducted. Published case reports and series written in English were included with adult patients. Abstracts were not included in the review. A case of heparin resistance during ECMO from our ICU is also presented.

Results: The mechanism and pathophysiological process that leads to the development of heparin resistance is not fully understood, however acquired antithrombin (AT) deficiency is a recognized causative factor. The Extracorporeal Life Support Organization (ELSO) recommends that in established heparin resistance AT-III levels are maintained within the normal range in patients on ECMO by administration of fresh frozen plasma (FFP) or AT-III concentrate. Nevertheless, Ciolek et al (2017) mentioned in pediatric ECMO patients that AT-III depletion was associated with high cost, significant increases in anticoagulation parameters, and no significant change in the heparin infusion rate. In total 6 studies in the international literature were identified regarding heparin resistance during ECMO therapy. The studies identified are summarized in Table 1. Three of the 6 studies studied the use of Argatroban during heparin resistance in a total of 13 patients with good results regarding safety, cost, and ease of administration. The other three studies suggested the use of Bivalirudin, FFP and ATIII administration, respectively.

A 29-year-old woman with a history of obesity, hypothyroidism and polycystic ovary disease was admitted to the ICU of the Nicosia General Hospital with type I respiratory failure due to COVID-19 infection. On the 4th day of mechanical ventilation, she presented severe respiratory deterioration. A decision was made to proceed with VV ECMO support. Heparin infusion was initiated with a target to maintain aPTT 1.5 to 2 times initial patient values. During the first 48 hours of ECMO support the patient was unable to maintain anticoagulation targets despite progressively increased heparin dose, furthermore she presented signs of thrombosis on her left index finger. ATIII levels were in the normal range and the anti-PF4 test was negative. FFP administration was unable to reduce the heparin dose. Heparin infusion was stopped and anticoagulation with Argatroban was initiated. During Argatroban administration the patient presented a non-clinically significant bleeding from the tracheostomy and the ECMO intravenous cannulas. There were no apparent thrombotic events and the thrombosis on the index finger resolved without intervention. The patient was successfully weaned off the ECMO after 10 days and made a full recovery.

Table 1: Summary of included studies

Author, Date	Article type	Article Scope	Diagnosis of heparin resistance	Exclusion of HIT	Alternative anticoagulation methods	Summary
Atsachilaga et al. 2020	Cohort study	Anticoagulation with Argatroban in a cohort of 8 patients on ECMO with acute antithrombin deficiency in severe COVID-19	1. Reduced AT levels 2. Failure to achieve therapeutic heparin levels	Not reported	Argatroban infusion	Argatroban seems a suitable alternative for acute anticoagulation—little data to support safety.
Dingman et al. 2020	Cohort study	Argatroban dosing requirements in extracorporeal life support and other critically ill populations	Not reported	Not reported	Argatroban infusion	Argatroban in 4 ECMO patients with heparin resistance – possible alternative use other than HIT
Hagg et al. 2019	Case report	Sepsis induced heparin resistance during ECMO	1. aPTT remained subtherapeutic 2. low AT 3. Low platelet count 4. Inappropriate high doses of heparin	ELISA assay performed twice	1. Initially ATIII administration – due to failure 2. Argatroban administered	Argatroban used safely and effectively in heparin resistance (hypothesis of heparin resistance during sepsis)
Jyoti et al. 2013	Case report	Bivalirudin administration due to heparin resistance during ECMO	1. High heparin doses 2. Clot formation 3. Low ATIII levels	Not reported	Bivalirudin	Good results of bivalirudin in heparin resistance
Rhoad et al. 2018	Observational study	FFP as a solution to heparin resistance during ECMO	1. Increasing doses of heparin 2. ACT	Not reported	FFP administration	Use of FFP for heparin resistance seems effective
Saib et al. 2013	Case report	AT deficiency in a patient on ECMO	Thrombotic crisis in circuit	Not reported	ATIII administration	Heparin resistance with AT administration due to deficiency

Abbreviations: ECMO - extracorporeal membrane oxygenation; AT - Antithrombin; HIT - heparin induced thrombocytopenia; ACT - active clotting time; aPTT - activated partial thromboplastin time; ELISA - Enzyme-linked immunosorbent Assay; FFP - fresh frozen plasma

Conclusion: It seems that patients with heparin resistance have higher mortality rates during ECMO highlighting the need for developing alternative anticoagulation strategies. The recommended ELSO guidelines of ATIII or FFP administration in heparin resistance during ECMO may be costly, and ineffective. The role of Argatroban, as alternative anticoagulation, in this group of patients should be further researched to establish both safety and efficacy.

000809**An analysis of transthoracic echocardiography and its impact on patient outcomes in the Intensive Care Unit**M. Carton¹; F. O'riordan²; A. Fahy³; J. Coughlan²; D. Moore²¹Anaesthesia, Mater Misericordiae University Hospital, Dublin, France; ²Cardiology, Tallaght University Hospital, Dublin, Ireland; ³Intensive care, Tallaght University Hospital, Dublin, Ireland**Correspondence:** M. Carton*Intensive Care Medicine Experimental* 2020, **8(2)**: 000809

Introduction: Transthoracic echocardiography (TTE) is regularly requested in critically ill patients. However to date there has been limited data published on the association between TTE results and patient outcomes.

Objectives: The purpose of this study was to assess the prognostic function of transthoracic echocardiography in the intensive care unit.

Methods: A retrospective, cross sectional, single centre study, was performed. All patients admitted to the Intensive care unit (ICU) over the 13-month period (January 2018- February 2019) were included. Baseline characteristics were obtained from the Clinical Information System. All TTE's were performed by a cardiac physiologist with final approval of reports from a consultant cardiologist. Echocardiographic reports were extracted from the Cardiovascular Information System. ICU and hospital outcomes were extracted from the 'Acubase Ltd' system.

Results: Three hundred and fifty eight patients were admitted to the ICU over the 13 month period (55% Male, Mean age 59±17 years). Just under one-third of all patients received a TTE during their ICU admission (N=115/358).

Results included; normal left ventricular (LV) function; n= 56, left ventricular hypertrophy (LVH); n= 19, LV dysfunction; n=19, moderate to severe valvular pathology +/- LV dysfunction; n=9, right ventricular (RV) dysfunction; n= 7. Five TTE's were not reported therefore excluded from our study.

Each TTE subgroup was then tested against the study population as a whole to assess for any significant impact on patient outcome such as ICU and hospital length of stay and mortality.

Table 1. TTE results and patient outcomes

	All patients	All reported TTE	Normal LV function	RV dysfunction	LVH	LV Dysfunction	LV Dysfunction vs.	Valvular pathology	Valvular pathology vs.
Number	n= 358	n= 110	n= 56	n=7	n= 19	n= 19		n= 9	All patients
Age	59 ± 17	61 ± 16	58 ± 18	54±20	66 ± 13	64 ± 11	P =0.502	71 ± 12	P=0.03
Male	199 (55%)	69 (62%)	35 (62%)	3 (43%)	14 (73%)	12 (63%)	P = 0.4948	5 (55%)	P=1
ICU LOS	4 (2,9)	9 (4,17)	9 (5,20)	6 (4,9)	8 (5,16)	10 (3,17)	P = 0.018	6 (3,13)	P=0.12
ICU Mortality	81 (22%)	32 (29%)	14 (25%)	3(43%)	5 (26%)	8 (42%)	P = 0.0438	2 (22%)	P=1
Hospital LOS	19 (10,39)	25 (13,43)	28 (13,43)	11(9,16)	21 (16,35)	28 (17,51)	P=0.167	26 (16,34)	P=0.5
Hospital Mortality	112 (31%)	41 (37%)	19 (33%)	3 (43%)	6 (31%)	9 (47%)	P = 0.1450	4 (44%)	P=0.4

Patients with reduced LV function were found to have a significant increase in ICU mortality when compared to the study population (42% n=8/19 vs 22% n=81/358; p=0.04). This patient cohort was also found to have a longer ICU length of stay (10 vs. 4 days p= 0.018). Hospital mortality and length of stay did not differ significantly between groups.

Of note the patients with moderate to severe valvular pathology (+/- impaired LV function) were found to be older (71 ± 11 vs.59 ± 17 P=0.03) yet outcomes did not differ significantly when compared to the study population as a whole.

Patients found to have right ventricular dysfunction or left ventricular hypertrophy were not found to have a significant increase in mortality rate or length of stay.

Conclusion: A finding of moderate to severe LV dysfunction on Transthoracic Echocardiography in ICU setting, is associated with a significant increase in ICU mortality and length of stay.

000842**Milrinone concentration monitoring during continuous renal replacement therapy**H. T. Sørensen¹; S. Christensen¹; CU. Andersen²; DV. Nielsen¹¹Department of anaesthesia and intensive care medicine, Aarhus University Hospital, Aarhus, Denmark; ²Department of clinical pharmacology, Aarhus University Hospital, Aarhus, Denmark**Correspondence:** H.T. Sørensen*Intensive Care Medicine Experimental* 2020, **8(2)**: 000842

Introduction: Milrinone is an inodilator drug widely used in the treatment of both surgical and non-surgical patients with severe heart failure. These patients often present with acute renal failure (ARF), and a substantial proportion will require continuous renal replacement therapy (CRRT).

Several studies indicate an increased risk of supratherapeutic plasma Milrinone concentrations in patients with ARF not treated with CRRT. This has led to guidelines advising Milrinone dosage reduction for these patients, as supratherapeutic plasma concentrations may increase the risk of serious adverse effects such as arrhythmias and hypotension.

Data on Milrinone pharmacokinetics in patients receiving CRRT is sparse and based on one study of 6 patients [1]. Accordingly, no prescribing guidance exists for Milrinone dosing during CRRT.

Objectives: The objective of the present study is to describe Milrinone plasma concentrations in relation to the therapeutic index, in patients receiving intravenous Milrinone infusion while on CRRT.

Methods: A prospective observational descriptive study including intensive care patients > 18 years receiving intravenous Milrinone infusion while on CRRT. Both patients with low cardiac output syndrome following cardiac surgery, and patients with non-surgical acute decompensated heart failure are included.

Milrinone prescribing including dosage, and settings and duration of CRRT are at the discretion of the attending intensive care doctors. We expect to include approximately 15 patients.

Guided by results from a pilot study, arterial plasma samples are collected at 8, 16, 24, 36 and 48 hours after initiation of Milrinone infusion and/or CRRT, and once every 24 hours thereafter. Plasma sampling is continued until Milrinone infusion is discontinued. An additional plasma sample is collected prior to initiation of CRRT, in case Milrinone infusion is initiated before CRRT.

The arterial whole blood samples are centrifuged on site. Plasma is obtained and stored at -80 °C until analysis is performed. Milrinone plasma concentrations will be quantified using liquid chromatography tandem mass spectrometry (LC-MS/MS).

Milrinone plasma concentrations versus time after initiation of CRRT will be described and stratified according to different dosages of Milrinone infusion. Milrinone concentrations will be described according to therapeutic index. The study will not have power to evaluate relationship between Milrinone concentration and outcomes.

Results: The study is still recruiting. Inclusion is expected to finish October 1 2020. Results on the Milrinone plasma concentration analysis will be presented.

Conclusion: This study reflects common practice of the use of Milrinone while on CRRT. The results from this study will clarify further whether specific dosing recommendations should be considered for patients receiving Milrinone infusion while on CRRT.

Introduction: Obstetric hemorrhage is the main cause of maternal morbidity and mortality in developing countries.¹ Despite the fact that the anti-shock garment (AG) is an alternative for the management of obstetric hemorrhage, there is no evidence about when is the optimal time of its withdrawal.²

Objectives: To determine the predictive capacity of the shock index, and the delta of the shock index, to determine hemodynamic instability, after the removal of the antishock garment in obstetric hemorrhage.

Methods: This is a prospective diagnostic test validation study. It evaluates the shock index (SI) and the shock index delta (Δ SI) prior to removal of the AG as a predictor of hemodynamic instability after removal of the AG. This study focuses on patients with obstetric hemorrhage admitted to a second level ICU of a hospital in Ecuador between the months of March and December of 2019. Sensitivity (Se), Specificity (Sp), positive and negative predictive values were studied, and the positive and negative Likelihood Ratio (LR) calculated.

Results: Thirteen patients were included, with a mean age of 25.6 years (17–34), with an Apache II mean of 6.4 (2–17) and estimated mean bleeding volume of 1875 ml. (500-2500) The main etiology of bleeding was uterine atony (69%), 15% had placental retention, 7% had placenta previa, and 7% of women experienced a grade III vaginal tear at the time of childbirth, with the average shock index at ICU admission of 1.04 (0.8–1.6). The mean of the SI before the removal of the AG was 0.88 (0.71–1.03) in the patients who remained stable after their removal, and the mean of the SI was 0.89 (0.83 - 1.0) in those who showed instability, with an Se of 50% and Sp 66%, a positive LR 1.47 and a negative LR 0.75. Additionally a Δ SI of 0.21 (0.05-0.58) was found for those who remained stable, and 0.07 (0.01–0.22) for those who presented hemodynamic instability, with Se 75%, Sp 85%, positive LR of 3 and LR. negative of 0.33.

Conclusion: The Shock Index and shock index delta, are not good predictors of hemodynamic instability after removal of the shock garment in patients with obstetric hemorrhage. However, more studies are required with major samples.

The reliability of duplex ultrasound in the diagnosis of catheter-related thrombosis performed by general intensive care nurses in the critically ill patients

B. Pakostová¹; R. Skulec¹; L. Mikšová¹; V. Cerný¹

¹Department of anesthesiology, perioperative medicine and intensive care, Masaryk Hospital, Usti nad Labem, Czech Republic

Intensive Care Medicine Experimental 2020, **8(2)**: 000945

Introduction: It has been previously shown that general intensive care nurses are able to perform bedside examination of deep vein thrombosis by compression ultrasound test with a high degree of reliability.¹ Another challenge in critically ill patients is the diagnosis of central venous catheter-related thrombosis (CRT). Therefore, we conducted prospective observational study to compare the diagnostic reliability of vascular Point-of-Care duplex ultrasound (compression ultrasound test combined with colour doppler imaging) in diagnostics of CRT performed by general intensive care nurses in the setting of intensive care unit with the examination performed by intensive care physicians, the experts in vascular ultrasound.

Methods: Prior to the study, each nurse participating in the study completed two-hour training in duplex ultrasound and examined 5 patients under supervision. Then, intensive care unit (ICU) patients with central venous catheter placed more than 48 hours in the catchment area of the inferior or superior caval vein underwent duplex ultrasound performed by the nurse. On the same day, the examination was repeated by an ICU physician. In the case of catheter placement in the internal jugular vein or subclavian vein, jugular, subclavian

and axillar vein were examined bilaterally by a nurse and a physician. When a catheter was placed in the femoral vein, patients underwent duplex ultrasound of the femoral and popliteal region of both lower extremities. The results of the examinations of each patient were blinded until both tests were performed. The calculations evaluating the reliability of the test were applied.

Results: A total of 160 patients of age 62.9 ± 12.3 years were included. The prevalence of CRT of 41% has been found in our sample. The overall sensitivity, specificity, positive predictive value, negative predictive value, and accuracy of the examination performed by general intensive care nurses were 71.2%, 100.0%, 100.0%, 83.3% and 88.2%, respectively.

Conclusion: The results of our study indicate that general ICU nurses are able to perform bedside examination of CRT by duplex ultrasound with an excellent specificity but only with a moderate sensitivity after a brief predefined training.

Intensive Care Medicine Experimental 2020, **8(2)**: 001013

Introduction: Acute Kidney Injury (AKI) is a frequent complication for COVID-19 patients admitted to Intensive Care Unit (ICU) and is independently associated with higher mortality. The pathophysiology of COVID-19 related AKI is supposed to be multifactorial: haemodynamic alteration due to high levels of PEEP may play a role.

Objectives: We investigate if higher central venous pressure (CVP) and higher positive end expiratory pressure (Peep) were associated to higher incidence of AKI and if AKI was related to 28 days mortality.

Methods: 130 consecutive COVID-19 patients admitted to the Intensive Care Unit (ICU) at Bergamo General Hospital for acute respiratory failure from 22th February to 22th March were enrolled. AKI was defined by KDIGO criteria. Age, sex and SOFA score were collected at ICU admission. Mean values of PVC and Peep during the first 14 days in ICU were compared between AKI group and controls, using Mann Whitney test. The association between AKI and mortality was evaluated with Fisher exact test.

Results: In our population median age was 62 (IQR 14), 107 (82%) were male and median SOFA score was 6 (range 4–8). 74 (57%) patients developed AKI; 17 (13%) in stage 1, 16 (12%) in stage 2, and 41 (31%) in stage 3; 22 patients (17%) required continuous renal replacement therapy (CRRT).

28 days mortality among AKI group was significantly higher (46% vs 18% p-value 0.0008).

Furthermore mean values of PVC and Peep were higher in AKI group compared to controls; relevant data are represented in the Table 1.

Table 1.

	controls (n=56)	AKI (n=74)	p
Age (y)	59 (51-66)	63 (56-70)	ns
Gender M/F (%)	43/13 (77/23)	64/10 (86/14)	ns
SOFA (%)	5 (4-6)	6 (4-8)	0.011
Median Peep (cmH2O)	13 (10-14)	14 (13-15)	0.0028
PVC (mmHg)	11 (9-13)	13 (10-15)	0.0067
28 days mortality, n (%)	10 (18)	34 (46)	0.0008

Data are presented as median and interquartile range. Two groups are compared using Mann Whitney test for continuous variables and using Fisher's exact test for categorical variables

Conclusion: Our data confirm that AKI represent a risk factor for mortality in COVID patients (odds ratio 3.9, 95% IC 1.8–8.8). Both higher PEEP and PVC are significantly associated with AKI, suggesting that the haemodynamic impact of high intrathoracic pressure may be involved in its pathogenesis.

Cardiogenic shock and 28-days mortality in acute heart failure: possible role for 24-hour lactate clearance

Y. F. Borquez Lopez¹; M. G. Gómez García¹; A. Palacios Chavarria¹; J. Franco Granillo¹; J. Aguirre Sánchez¹; R. Chaires Gutierrez¹

¹Intensive care unit, The American British Cowdray Medical Center, Mexico City, Mexico

Intensive Care Medicine Experimental 2020, **8(2)**: 001036

Introduction: Implications of lactate clearance in patients with acute heart failure (AHF) in intensive care unit (ICU) setting is limited. A recent report suggests that a 24-hour lactate clearance ($\Delta 24\text{lac}$) of less than 19% could have a negative prognostic role in septic patients in ICU, therefore we conducted a study to assess the prognostic value of $\Delta 24\text{lac}$ for mortality in AHF.

Objectives: To compare the $\Delta 24\text{lac}$ with clinical variables and mortality in AHF.

Methods: We conducted an observational retrospective cohort with critical patients from a single center in an intensive care unit (ICU) in Mexico City, Mexico. Demographic, comorbidities and laboratory data was collected for all patients. We estimated the acute physiology and chronic health evaluation (APACHE) II score, and $\Delta 24\text{lac}$. Additionally, treatment with vasoactive agents, diuresis, fluid balance was assessed during first 24 hours and length of stay (LOS). Primary outcome was 28-days mortality.

Results: Data from 100 patients was included, 63% male, with mean age 63.1 (SD ± 10.6) years and mean BMI 28.8 (SD ± 2.7) Kg/m². Most frequent comorbidities were COPD, Hypertension and chronic kidney disease and diabetes in 34, 32, 19% and 13%, respectively. Cardiogenic shock was observed in 54%; Systolic and diastolic dysfunction was documented in 23 and 27%, respectively. APACHE II score with median of 25 (RIQ 22–27.5) and $\Delta 24\text{lac} < 19\%$ in 42%; Overall mortality 35%, median LOS 8 (7-9) days. Variables on admission were similar for mortality and $\Delta 24\text{lac}$ groups were similar. Treatment with levosimendan was higher in mortality group. 94.3 vs. 70.8%, $p=0.006$; when stratified according to $\Delta 24\text{lac}$, we found that patients with $< 19\%$, patients with requirement of inotropic support with levosimendan was a strong predictor for mortality [HR = 10.9 (IC95% 1.4–84.7, $p=0.02$)], in contrast to $\Delta 24\text{lac} > 19\%$ [(HR = 5.6 (IC95% 0.74–42.6, $p=0.09$)]. Further multivariate analysis and stratifications found no association with other $\Delta 24\text{lac}$ cutoff values, comorbidities, fluid balances and vasopressor support.

Conclusion: Cardiogenic shock with requirement for inotropic support in subjects with AHF was associated with mortality and inadequate tissue perfusion. Failure to establish associations with AHF clinical variables with mortality is likely explained by methodological limitations (e.g. lack of a control group). We present additional evidence supporting the use of $\Delta 24\text{lac}$ as prognostic marker of global tissue hypoxia in circulatory shock, however further controlled studies and a prospective design may be needed to explain the role of this marker in AHF.

Intensive Care Medicine Experimental 2020, **8(2)**: 001042

Introduction: Measurement of cardiac output (CO) is an important diagnostic maneuver and adds valuable information for the management of critically ill patients. However, estimation of CO in limited resource settings may be limited in terms of accessibility to non-invasive, continuous, reliable, reproducible methods. Pulse pressure variation (PPV) and plethysmographic variability (PV) are dynamic and widely extended indicators that in certain conditions may be useful to estimate CO, however, information regarding its reliability is scarce. Therefore, we propose a study with information obtained from PP and PV with other clinical variables and a proposed simplified equation to estimate CO with echocardiography as gold standard.

Objectives: To develop a simplified method to estimate CO with PPV and PV.

Methods: We conducted a transversal study in critical patients with sepsis recruited from a single center in an intensive care unit (ICU) in Mexico City, Mexico during 2019 through 2020. We calculated the real CO as stroke volume (SV) per minute measured by echocardiogram; PP was defined as the difference between systolic (DP) and diastolic pressure (DP); The proposed Estimated CO formula was calculated as follows: estimated CO = $PP^k \cdot \text{heart rate (HR)} \cdot k$; where k was defined as the estimated difference in SV in mm Hg and was adjusted according to variability of the PP and plethysmography patterns. We determined correlation with Pearson coefficient (r) and absolute agreement with intraclass correlation coefficient (CCI) of estimated CO compared to the gold standard.

Results: Data from 53 patients was analyzed. We included 6 PV wave patterns and k values: type 1 and 2 (group 1), $k = 0.9$; type 3 and 4 $k=1.2$ (group 2) and type 5 and 6, $k=1.4$ (group 3). Additionally, if patients showed clinical signs of hypoperfusion we adjusted the k value for groups 1,2 and 3 to 1.2, 1.6 and 2, respectively. Estimated CO correlated with echocardiogram $r=0.76$, ($p<0.01$) and CCI = 849 (IC 95% = 0.739 - 0.912, $p<0.01$).

Conclusion: We present a simplified and accessible approach for CO estimation with PPV and PV in critical care patients. This method may be cost effective and easily performed in low-income and limited resources settings, however, additional studies should be considered for further external validation and the possible role and clinical implications of PPV and PV for clinical outcome and mortality is yet to be defined in prospective clinical trials.

Intensive Care Medicine Experimental 2020, **8(2)**: 001053

Introduction: Evaluation of fluid responsiveness in critically ill patients is challenging. Echocardiographically obtained variation in inferior vena cava (IVC) and superior vena cava (SVC) have shown promise in their ability to address this challenge. However, they have been predominantly used to assess fluid responsiveness in patients with sepsis, and it is less clear whether they apply to patients undergoing cardiac surgery. Additionally, left ventricular surface area (LVSA) has been shown to be correlated with stroke volume and in a study by Cannesson et. al. respiratory variation in LVSA (ΔLVSA) obtained by transesophageal echo (TEE) automatic border detection was shown to predict fluid responsiveness (Cannesson et al., 2006).

Objectives: The primary purpose of this study was to assess whether variation in SVC diameter, during positive pressure ventilation, is predictive of volume responsiveness in cardiac surgical patients. Additionally, ΔLVSA was assessed for ability to predict fluid responsiveness.

Methods: This prospective study enrolled patients undergoing elective or semi-elective cardiac surgery and was conducted in operating theaters at a tertiary care academic hospital. Volume challenges were administered pre-sternotomy and cardiopulmonary bypass (pre-CPB) and after sternal closure (post-CPB) to patients under general anesthesia with standardized mechanical ventilation settings. Hemodynamic measurements and TEE images were collected before and after each volume challenge. Cardiac output (CO) was obtained from TEE images as previously described (Vieillard-Baron et al., 2004) and fluid responders were defined by an increase in CO of 11% or more after a volume challenge. The SVC diameters (D_{max} and D_{min}) were measured over a respiratory cycle and the SVC collapsibility index (SVC-CI) was calculated as $(D_{\text{max}} - D_{\text{min}})/D_{\text{max}}$ and expressed as a percentage. SVC-CI

was compared between fluid responders (FR) and non-responders (NR) to determine if there is a significant difference and the optimal SVC-CI threshold was determined for optimizing the sensitivity and specificity. Additionally, LVSA was measured over the respiratory cycle and Δ LVSA was calculated as (SA max- SA min)/SA max, expressed as a percentage. Δ LVSA underwent the same analysis as SVC-CI.

Results: 11 out of 20 enrolled patients (55%) were fluid responders. There was no difference in heart rate, mean arterial pressure or CVP between responders and non-responders. Pre-CPB SVC-CI was greater in R vs. NR but not statistically significant (0.18 ± 0.15 vs. 0.11 ± 0.05 ; $p=0.456$). Pre-CPB SVC-CI threshold of 15% was found to be most predictive of fluid responsiveness with an area under the receiver operating curve (AU-ROC) of 0.62 (0.41 – 0.84, 95% CI), NPV of 50% and PPV of 75%. Post-CPB SVC-CI was also greater in R vs NR but not statistically significant (0.18 ± 0.12 vs. 0.11 ± 0.05 ; $p=0.241$). Post-CPB SVC-CI >11% was most predictive of fluid responsiveness with an AU-ROC of 0.66 (0.41 – 0.84, 95% CI), 58% NPV and 75% PPV. Pre-CPB Δ LVSA was greater in R vs NR (0.08 ± 0.13 vs 0.01 ± 0.08) but did not reach statistical significance ($p=0.151$) and Post-CPB Δ LVSA was minimally greater in R vs NR (0.08 ± 0.06 vs 0.05 ± 0.11) and not statistically significant ($p=0.456$). Pre-CPB Δ LVSA >10% was predictive of fluid responsiveness with an AU-ROC of 0.79 (0.65-0.94, 95% CI), NPV of 62% and PPV of 100%. Post-CPB Δ LVSA >2% was predictive of fluid responsiveness with AU-ROC of 0.63 (0.42 – 0.84, 95% CI), NPV of 68% and PPV of 64%.

Conclusion: Our study shows that SVC-CI is not a useful measure for predicting fluid responsiveness in cardiac surgical patients either pre or post-operatively. Post-sternotomy there are multiple changes to the cardiopulmonary physiology (to PVR, SVR, venous capacitance, RV, pericardium, etc.) which may be some of the reasons why SVC-CI is not predictive of FR in this population. SVC-CI not being predictive of FR pre-CPB may be potentially due to the fact that these were elective or semi-elective surgical patients (and not ICU patients in septic shock, like in most other studies). These findings suggest that perhaps the lack of venous return is not the only mechanism for tidal changes in stroke volume with respiration. It is also possible that SVC-CI is not as good of a predictor of FR as was demonstrated in early studies since many later studies had different optimal thresholds and less impressive predictive values.

Although the differences in Δ LVSA pre-CPB did not reach statistical significance, Δ LVSA >10% was helpful in predicting fluid responsiveness pre-sternotomy with a PPV of 100% and NPV of 62%. These findings suggest that Δ LVSA is likely a marker of preload status with higher Δ LVSA indicating lower preload and therefore more potential for enhancing the CO with a preload challenge. Δ LVSA was not helpful in predicting fluid responsiveness post-sternotomy. It is possible that losing the integrity of the pericardium makes Δ LVSA a less reliable predictor of preload and therefore fluid responsiveness.

Intensive Care Medicine Experimental 2020, **8(2)**: 001140

Introduction: Survival after coronary revascularization surgery is influenced by many variables. Poor left ventricular function (LVF) is believed to be associated with worse outcomes (1).

Objectives: We aim to study the outcome measures at varying levels of LVF.

Methods: A single center retrospective descriptive study. According to the simplified American Society of Echocardiography classification (2), patients were divided into three groups: Group I - severe impairment of LVF; EF < 30% (38 patients), Group II - mild-moderate impairment of LVF; EF 30% to 51% (182 patients), and Group III - normal LVF; EF > 52% (186 patients). The outcome variables were compared, and mortality was used as the primary outcome.

Results: The mean age of patients was 55.34 ± 9.9 years. The mortality rate was significantly higher in Group I compared to the other groups (13.2% in Group I vs. 2.2% and 1.6% in Groups II and III, respectively; $p = 0.007$). Patients in Group I had a significantly higher incidence of postoperative acute kidney injury (AKI) (47% in Group I vs. 28.6% and 22.6% in Groups II and Group III, respectively; $p = 0.007$). No significant differences were found between the studied groups for postoperative atrial fibrillation (POAF), length of ventilation, length of stay (LOS) in intensive care, and length of (LOS) stay in the hospital.

Conclusion: Among patients undergoing coronary surgery, preoperative left ventricular function appears to influence short-term outcomes. Patients with severely impaired left ventricular systolic function had higher mortality, more complications, particularly AKI, and needed more pharmacological and mechanical circulatory support.

The intensity of rapid response team operation and general ward cardiopulmonary resuscitation incidence

D. Lee¹; J.E. Kim²; S. Kim³; T. Kim⁴

¹Intensive care medicine, Dong-a University Hospital, Busan, Republic of Korea; ²Emergency medicine, Dong-a University Hospital, Busan, Republic of Korea; ³Rapid response team, Dong-a University Hospital, Busan, Republic of Korea; ⁴Internal medicine, Gyeongsang National University, College of Medicine, Changwon, Republic of Korea

Correspondence: D. Lee

Intensive Care Medicine Experimental 2020, **8(2)**: 000027

Introduction: Rapid response team (RRT) was initially regarded as full-time working team. However, because of several reasons such as lack of professional manpower, cost effectiveness and size and requirement of each hospital, part-time RRT was introduced. Outcome of part-time RRT recently suggested similar efficacy compared to full-time RRT. However it is difficult to make a head-to-head comparison and there are no available data comparing the efficacy of part-time and full-time RRT. Authors sought to investigate the intensity of RRT and incidence of in-hospital cardiopulmonary resuscitation (CPR).

Methods: Dong-A University Hospital – a tertiary referral center with 1,000 beds – started to operate RRT in April 2017 as a part-time RRS operating 8 hours on weekdays. In March 2018, RRT operation time was extended to 15 hours on weekdays and finally, extended to 24 hours a day, 7 days a week on February 2019.

We retrospectively reviewed the incidence of in-hospital cardiopulmonary resuscitation (CPR) according to stepwise extension of RRT operation.

Results: For the study period (36 months before and 33 months after RRT implementation), 113,394 patients admitted and 127 cases of CPR occurred. For the 36 months before RRT implementation, the next

initial RRT period (11 months), the second RRT period (11 months), and the third RRT period (11 months), CPR per 1000 admission was 1.27, 1.08, 0.90 and 0.86 ($p = 0.381$).

In logistic regression analysis, Age, Hospital length of stay, Charlson-comorbidity score, and incremental intensity was independently associated with CPR development (Table 1).

<Table 1>

variables	Univariate			Multivariate		
	OR	95% CI	<i>p</i>	OR	95% CI	<i>p</i>
Age	1.040	1.026-1.055	<0.001	1.038	1.023-1.053	<0.001
Hospital length of stay	1.010	1.006-1.013	<0.001	1.009	1.006-1.013	<0.001
Charlson-comorbidity score	1.038	1.020-1.055	<0.001	1.044	1.025-1.063	<0.001
RRT intensity	0.849	0.719-1.002	0.053	0.787	0.663-0.934	0.006
Sex	0.646	0.452-0.924	0.017	0.715	0.499-1.025	0.068

Conclusion: The incremental intensity of RRT operation is associated with decremental tendency of in-hospital CPR rate suggesting the more CPR prevention efficacy with the more operation time of RRT.

Intensive care unit without barriers: impact on the forecast of patients with septic shock, after the implementation of an intensive care reference program in the colombian amazonia

A. Ortiz¹; D. Molano¹; M. Gómez¹; E. Beltran¹; M. Villabon²; L. Diaz¹

¹Medicina crítica y cuidado intensivo, Foundation University of Health Sciences, Bogotá, Colombia; ²Medicina crítica y cuidado intensivo, fucs, bogota, Colombia

Correspondence: A. Ortiz

Intensive Care Medicine Experimental 2020, **8(2)**: 000028

Introduction: Mortality due to septic shock is around 40% globally (1), these reach figures close to 70% in peripheral areas devoid of health systems with capacity to manage patients with intensive care requirements. Given the impossibility of opening intensive care units in these regions, several options have been raised, such as telemedicine, referral systems, training of non-intensivist health personnel, among others.

Objectives: We propose in this study, to establish the impact on mortality in patients with septic shock, of the establishment of an early identification program and transfer to a reference ICU, with 24-hour availability of acceptance of these patients.

Methods: Prospective observational descriptive study, between January 2016 and October 2019, in the intensive care unit of the Hospital de San José in Bogotá Colombia, of patients diagnosed with septic shock, who were treated by transfer from the region of Guainía-Amazonas, within the MIAS program (Integral model of health care) (2).

Results: Twenty-three patients with septic shock or multi-organ dysfunction secondary to sepsis were attended, mean age 44.1 years, APACHE II 16.68 with expected mortality of 24%. 25% of infections correspond to tropical infections, the most common being tuberculosis and secondly malaria. Within the non-tropical etiology, 40% sepsis of lung origin and 12% soft tissue sepsis. 60% of the patients required invasive mechanical ventilation and 80% vasopressor support. In 90% of patients the empirical antibiotic management was beta-lactam antipseudomonas + inhibitor. Only in 36% of the patients, the etiological germ was isolated, with 45% gram positive cocci, 30% gram negative bacilli and the remaining 30% atypical germs, viruses, fungi and mycobacteria. Gross mortality was 12%.

Conclusion: The implementation of rapid care models with immediate transfer services to intensive care units, reduces mortality by up to 50% in patients with septic shock in the region of the Colombian

Amazon. Tropical, respiratory and skin and soft tissue infections constitute the main and most serious diseases.

Intensive Care Medicine Experimental 2020, **8(2)**: 000077

Introduction: The strengthening of research infrastructure is key for the advancement of academic medicine in critical care. However, while there have been dramatic clinical developments in Asian critical care in the last few decades, research has lagged behind.

Objectives: The aim of this study was to describe the current status of academia in critical care in Japan, South Korea, and Singapore, particularly from the research environment perspective.

Methods: This was a cross-sectional questionnaire survey conducted between June 2019 and January 2020. We included all physician members of the Japanese Society of Intensive Care Medicine (JSICM) and the Korean Society of Critical Care Medicine (KSCCM) as of June 2019, and intensivists in Singapore as of November 2019. The questionnaire was drafted by two content experts and validated through pre-determined testing with a clinical sensitivity test and a specificity table. We collected data on the characteristics of the participants and their affiliated institutions, the research environment such as funding and support for personnel, and ethics boards and their role. We investigated the association between the presence of time dedicated to research and the number of research publications in English (1–10 versus >10) among the participants with at least one English original article.

Results: In total, 490 responded (response rate: 5.6%) to the survey and all responses were included for analysis. The clinical experience in critical care was 20 years or more in 41%, 10–19 years in 42%, 6–9 years in 14%, and 2–5 years in 3%. Forty-eight percent of the respondents held a university faculty appointment. Fifty-five percent worked for a university-affiliated hospital while 45% worked for a community hospital. Fifty-one percent reported that they used 50% or more of their work hours for bedside patient management in the intensive care unit. Thirty-four percent replied that there was at least one dedicated staff member for research work (epidemiologist or biostatistician) available in their hospitals. Twenty-four percent had dedicated time for research within their full-time work hours. When looking at the respondents with at least one original article in English language as a first or corresponding author, the odds to have more than 10 of the English publications for whom with protected time for research was 3.3 (95% confidence intervals: 1.8–6.1) compared to those without.

Conclusion: We found that many critical care physicians in the three countries had limited support for their research work and that dedicated time for research was positively associated with the number of research publications. The research environment and infrastructure in

these countries require substantial enhancement for better research productivity.

Intensive Care Medicine Experimental 2020, **8(2)**: 000107

Introduction: Mild traumatic brain injury (mTBI) is a frequent cause of emergency department (ED) visits in France, with a substantial impact on healthcare utilization and ED costs. Blood-based, brain biomarker tests such as S100B and a combination of glial fibrillary acidic protein (GFAP) and ubiquitin C-terminal hydrolase-L1 (UCH-L1) have been shown to accurately identify mTBI patients who do not have intracranial lesions (ICL), potentially reducing the need for computed tomography (CT) scanning.

Objectives: To assess the cost-effectiveness of the GFAP + UCH-L1 compared with S100B for screening adults with suspected mTBI presenting to an ED.

Methods: We developed a decision tree model to estimate the costs and health outcomes of using two biomarker tests in patients presenting to the ED with suspected mTBI (Glasgow Coma Scale of 13–15). Model parameters were extracted from peer-reviewed papers, clinical guidelines, and expert opinion. The diagnostic test accuracy measures were extracted from the pivotal trial (GFAP + UCH-L1) and a meta-analysis (S100B). Lifelong costs (2020 €) and health outcomes were calculated from a French healthcare system perspective and discounted over time at 2.5%. Cost for the GFAP + UCH-L1 test was assumed to be the same as the S100B test. In this model, patients with a positive biomarker receive a CT scan to confirm the presence of ICLs. Depending on the biomarker test outcome and the CT results (where relevant), patients may be discharged immediately from the ED, kept for <24-hour observation, admitted to a short stay general ward, or admitted to a neurosurgery ward. Patients with ICLs not identified by the biomarker (false negatives) could suffer from delayed treatment and poorer health outcomes. Clinical outcomes, including Glasgow Outcome Score and radiation-induced cancer were used to calculate quality-adjusted life years (QALYs). One-way and probabilistic sensitivity analyses were conducted to manage uncertainty.

Results: In a hypothetical cohort of 1,000 patients, the GFAP + UCH-L1 biomarker was associated with a decrease of 48 CT scans compared to S100B (769 versus 817, respectively). In the same cohort, the GFAP + UCH-L1 biomarker resulted in €4,785 overall savings and a minor improvement of 0.08 QALYs. In probabilistic sensitivity analysis, at the willingness to pay threshold of €50,000 per QALY, there is 63% probability of the GFAP + UCH-L1 test to be cost-saving and a 73% probability to be cost-effective when compared to S100B.

Conclusion: The findings of this cost-effectiveness model show that for patients with suspected mTBI who present to an ED, compared to S100B, screening with the GFAP + UCH-L1 test is associated with cost savings and a reduction in CT scans, while resulting in similar health outcomes.

Minimising extravasation risk with central venous catheters in critical care

E. McKemey¹; N. Manning¹; R. Chauhan¹

¹Itu, Queen Elizabeth Hospital Birmingham, Birmingham, United Kingdom

Correspondence: E. McKemey

Intensive Care Medicine Experimental 2020, **8(2)**: 000111

Introduction: Extravasation is the accidental injection or leakage of fluid into the subcutaneous or perivascular tissues. Risk of extravasation injury related to intra venous therapy is between 10-30% resulting in varying complications (1). Extravasation associated with Central Venous Catheters (CVCs) is rarer but consequences can be severe, potentially requiring skin grafts or even leading to death (2,3). This is minimised by ensuring the line is secured at appropriate depth and by potency (toxicity) of drugs in the line. Currently there is no guidance on selection of drugs to ports on CVC. On a Quad lumen CVC, there is 6 cm from the distal to the proximal port, increasing risk if toxic drugs are placed on the proximal port. Distal ports are traditionally utilised for Central Venous Pressure (CVP) however evidence suggests there is no difference in accuracy when CVP is on distal or proximal port (4).

Objectives: Minimising risks of extravasation with CVCs in Critical care.

Methods: Data was collected from a tertiary centre based in the West Midlands, UK. It is a large Critical care unit (CCU) with over 100 beds with specialised cardiac, neurology, trauma, burns, surgical and liver patients, over 4 units. Data was collected by 2 auditors in 2019 over 2 days across all patients within CCU who had a CVC. The following was assessed: were CVCs sutured to the hilt, what length/type of CVC was used, which port was transducing CVP and which "Toxic drugs" were on the proximal port. We defined "Toxic drugs" as inotropes, neat potassium and 50% magnesium.

Results: Of 61 Critical Care patients, 51 patients had an internal jugular, 4 femoral and 6 subclavian CVC. 21% of the lines were not sutured at the hub. 77% of lines used the distal port to transduce the CVP which is current practice and 6% on Proximal. 41% of the lines had a Toxic drug on the proximal line.

Conclusion: This quality improvement project demonstrated that extravasation risks for CCU patients could be further minimised by ensuring CVCs are sutured at the hub, and careful selection of toxic drugs to the most distal ports. Changing the location of CVP monitoring from the distal port may help facilitate this. This is a cost neutral

way or minimising extravasation risk and promoting patient safety in Critical care.

Delayed discharges from critical care unit and its impact

R. AGRAWAL¹; I. Dsouza¹; J. Reeves²

¹Critical Care Department, University hospitals of North Midlands, STOKE ON TRENT, United Kingdom; ²Pdms systems administrator, University hospitals of North Midlands, STOKE ON TRENT, United Kingdom

Correspondence: R. AGRAWAL

Intensive Care Medicine Experimental 2020, **8(2)**: 000168

Introduction:

Delayed Discharge : Defined as ‘the period of continued hospital stay after a patient is deemed medically fit to leave hospital but is unable to do so for non-medical reasons’.(1)

Costs of NHS in England associated with delayed discharge are approximately 100 million GBP per year and resulted in 1.2 million bed days lost in 2013-14.(2)

Objectives:

FICM Edition 2 June 2019: Guidelines for the provision of intensive care services.

Discharge from critical care to a general ward must occur within four hours of the decision and must occur between 07:00 and 21:59.

QIPP Reference 16-17 54-Trauma

National standard that all discharges from adult critical care should be made within 4 hours of a clinical decision to discharge.

Compliance of UHNM to national guidance and FICM guidance

Methods:

Retrospective observational study

12 month period from Jan-Dec 2019

All admissions to adult critical care

Extract CCMDs information from 4D auditing software

Wardable date input by nurses after consultant ward round and counter checked by validator

>4 hours after ready date

Convert hours delayed to days

HRG code * Days Delayed = Cost of delay

Results:

921 (86.4%) delayed discharges

1,096 days

Average 1.2 days delay per patient

Cost over the year £1,919,252

Average 3 beds/day

70 band 5 salaries

Conclusion:

Delayed discharge is recognised to be a system level problem requiring effective team working within hospitals and coordination between health and social care .

Adverse outcomes of delayed discharge include :

For patients:

an association with increased risk of mortality,Hospital-acquired infections, mental ill health

a reduction in patient’s mobility and activities of daily living

For health care staff

Stress, diversion from a primary focus on patient care and deleterious interprofessional relationships,all with potentially harmful implications for patient’s health and well being
As well as impact on inpatient costs, there are additional economic repercussions for other services.

National Early Warning Score (NEWS) and the outcomes of a district general hospital wards’ patients referred to Critical Care Outreach service, but not admitted to Intensive Care Unit due to their co-morbidities

M. Mazalkov¹; E. Kazantzidis²; R. Samanta³; M. Camilleri¹

¹Anaesthetics, Peterborough City Hospital, Peterborough, United Kingdom; ²Emergency department, Peterborough City Hospital, Peterborough, United Kingdom; ³Anaesthetics, Addenbrooke’s Hospital, Cambridge, United Kingdom

Intensive Care Medicine Experimental 2020, **8(2)**: 000224

Introduction: Critical Care consultant led outreach services (Outreach) are set to assist the hospital wards in the prompt detection and care of the acutely unwell and deteriorating patients. The patients on the general wards are referred to the Outreach if their National Early Warning Score (NEWS 2), which in the UK may range from 0 up to 20 maximal, reach certain thresholds or if there appear any other significant concerns. According to the algorithm printed on NEWS-2 charts: values 5 or more (or 3 in one parameter) trigger an urgent patient’s review by the parental team; values 7 or more trigger the urgent automatic referral to Outreach team. After a prompt review by an outreach consultant and a senior nurse, the decision is made whether the patient needs an urgent Critical Care admission. In more reassuring cases, patients continue to be managed on the wards under a close supervision by the Outreach. Unfortunately, some of the patients have multiple co morbidities and their physiological reserve is very limited. Therefore, any potential Level 2 or Level 3 technological organ support would be futile. In those cases a difficult (but necessary) decision is made that the ward based care should be the ceiling of treatment for the patient. This group of patients is very diverse in the setting of a district general hospital. Nevertheless, there are certain similarities within this cohort. Typically, these patients are frail and old with concurrent chronic illnesses and a poor exercise tolerance. The vast majority are medical patients with sepsis of various origins. Their increased NEWS reflects patients’ acute deterioration and impending organ failure. Therefore, it is paramount that such decisions are absolutely correct. Thus, we have conducted a retrospective, observational, single centre study of the relevance of NEWS magnitude to the outcomes of the hospital wards’ patients referred to the outreach service, but deemed not to be appropriate for critical care admission secondary to their comorbidities and a limited physiological reserve. The project has been approved by the Health Research Authority, reference number is 268879.

Methods: We followed up 152 patients admitted to our hospital between 1/12/2017 and 24/12/2018 who at any point were referred to Outreach, but deemed not appropriate for any critical care organ support as above. The ceiling of care would be at Level 1 (ward-based care only).

The analysed data included NEWS and a fraction of inspired oxygen (FiO₂) (delivered through an appropriate device) as documented at the time of Outreach referral; mortality in-hospital and for up to 3 months after the hospital discharge, if happened; length of hospital stay (LOS), age, gender and diagnosis on admission. The patients’ groups were defined as: “hospital non survivors or HNS”; if died within three months after the date of discharge - “3 months non survivors or 3mNS” and, if survived for more than 3 months - “3 months survivors or 3mS”.

The statistics are presented as medians with interquartile ranges or means with standard deviation. Comparisons between groups were made using Wilcoxon rank sum test for non-normally distributed data. We used logistical regression for associations and reported results as odds ratios with 95% confidence interval. Time dependent outcomes were assessed with Kaplan Meier analysis as hazard ratios. Length of stay data were modelled using Poisson regression.

Results: The hospital mortality (HNS) was 46.7% (71 patients). 3mNS comprised 15.8% (24 patients). 3mS constituted 37.5% (57 patients). Median (quartiles 1 and 3) NEWSs were: HNS – 7 (5.5-9), 3mNS – 7 (5-8.25), 3mS – 6 (5-8). There was no statistically significant difference between the groups.

Median FiO2 levels were: HNS – 35% (28-60), 3mNS – 28% (23.25-60), 3mS – 28% (24-40). There was a trend for a better survival in patients on lower FiO2.

Median patients' age was: HNS – 75, 3mNS – 74.5 and 3mS – 73 years. Median lengths of hospital stay (LOS) were: HNS – 8 (4-13) days, 3mNS – 19 (9.5-31) days, 3mS – 20 (11-30) days.

Subsequently, the sample was split in: patients with NEWS "5 and above" (123/152) median NEWS 7 (6-10) and with NEWS "4 and below" (29/152) median NEWS 3 (2-4)

Their respective: hospital mortality was 47.2% versus 44.8%, 3 months mortality was 15.4% versus 17.2% and 3 months survival was 37.4% versus 38%.

Conclusion: High NEWS scores are not associated with worse 30 days or 3 months mortality in this patients' cohort.

High NEWS scores are associated with shorter LOS within the survivors group.

Chronological age does not appear to be a risk factor.

No particular diagnosis strongly predicts in-hospital mortality.

ICU follow-up: a national survey in Belgium

D. Prevedello¹; FS. Taccone¹; JC. Preiser¹

¹Intensive Care, Hospital Erasme, Bruxelles, Belgium

Correspondence: D. Prevedello

Intensive Care Medicine Experimental 2020, **8(2)**: 000264

Introduction: The concept of ICU follow-up clinics arose in 1993 in the United Kingdom to identify and rehabilitate patients with post-intensive care syndrome (PICS)(1). Recently, an increasing number of ICUs had organized the same program to assess patient's conditions after ICU discharge. In Belgium, we do not have a national guideline or recommendation for the ICU follow-up program as in the UK and Netherlands for instance(2,3). We therefore performed a national survey to assess Belgian ICU follow-up practice.

Methods: This Survey was designed based on the International Handbook of Survey Methodology sponsored by the European Association of Methodology (EAM) and the Revised WAPOR Code of Ethics, 2011 (WAPOR – World Association for Public Opinion Research). The Survey has been endorsed by the Belgian Society of Intensive Care (SIZ). We developed a closed and self-enumerated questionnaire that had initiated its content validated by four experts and a pilot phase. After the validation process, in March 2019, the questionnaire and the cover letter were addressed to directors of ICUs in Belgian hospitals electronically (one per ICU). The questionnaire was anonymous, and no electronic tracker was used to identify the responders. Two weeks following the distribution, a reminder letter and the link to access the questionnaire were resent by email. After eight months, a new reminder was sent by the Belgium Society of Critical Care, trying to increase the response rate.

Results: Thirty-six out of 82 potential respondents (43%) completed the Survey. Specifically, 35% (16/46), 46% (12/26), and 80% (8/10) of respondents were considered from Flanders, Wallonia, and Brussels-Capital, respectively. Six centers (17%) have an ICU follow-up program currently running. When we analyzed the profile of patients involved, the ICU length of stay, and the duration of mechanical ventilation were the two mean criteria to select eligible patients. Only one of the six centers received external funding to support this program; two of the five remaining centers used internal financial support to afford the ICU follow-up activities. Thirty centers did not run an ICU follow-up clinic. The main reasons were the lack of human resources (20/30 67%) and financial constraints (12/30 40%). Seven centers (23%) also justified the lack of ICU follow-up program with the absence of clinical need and of current evidence for benefits. Only 4 (13%) centers were not interested in starting an ICU follow-up clinic if possible.

Conclusion: The use of an ICU follow-up program is implemented in a minority of Belgian ICUs. Funding and human resources are critical issues to solve and promote this activity in more centers.

Role of Levosimendan in heart failure patient undergoin cardiac surgery

F. Marchese¹; M. L.²; S. G.³; R. M.²; C. G.²

¹Ospedali Riuniti, Foggia, Italy; ²Anestesia e rianimazione, Hospital Oo Rr Di Foggia, Foggia, Italy; ³Cardiochirurgia, Città di Lecce Hospital, Lecce, Italy

Correspondence: F. Marchese

Intensive Care Medicine Experimental 2020, **8(2)**: 000307

Introduction: Levosimendan is a calcium sensitizer developed for intravenous use in hospitalized patients with acute heart failure (AHF) (1).

Aim of this study is to observe the cardiac function's index, Mean Arterial Pressure (MAP) and diuresis after the administration of Levosimendan (G1) rather than control group (G2) started 12 hours before cardiac surgery (2).

Objectives: In this prospective observational study 47 patients consecutive admitted in ICU of "Città di Lecce Hospital- GVM Care and Research" with AHF (Ejection Fraction <40%) were included.

Methods: Patients admitted in ICU were randomized to receive either Levosimendan infusion duration up to 24 hours(0,1 mcg/Kg/min) (G1) (18 patients).

Patients undergoing urgent cardiac surgery, severe hypotensive syndrome or left ventricular ejection stenosis were excluded (29 patients). Measurement were collected at TO (before to start Levosimendan infusion), T1 (in operation room before to start cardiac surgery), T2 (when

was interrupted extra corporeal circulation), T3 (in Intensive Care Unit) and T4 (24 h after Levosimendan administration). Were recorded major functional cardiac index such as Ejection Fraction, Stroke Volume, Cardiac Output and TAPSE with echocardiography transesophageal (T0, T1, T2) and transthoracic (T3, T4) and were collected Mean Arterial Pressure, ScvO₂, lactate in blood gas analysis, diuresis. Pvalue of 0,05% was considered statistically significant.

Results: Echocardiography showed no statistically significant difference in Stroke Volume (p=0.8) and Cardiac Output (p=0.99) between two groups. In both groups SV and CO parametres increased progressively rather than baseline, expecially in G1.

Ejection Fraction increased significantly at any time vs baseline in G1 (p<0,049), whilst they remained stable over time in G2.

TAPSE was stable during the study period in G2, while the trend increased progressively only in G1. However no statistically difference between groups.

Comparisons between groups showed similar ScvO₂ levels at baseline, whilst they significantly increased in G1 vs G2 at T2, T3 and T4 (p>0.05) as anaerobic metabolism' index.

In both groups lactate levels increased during the study period especially at T2, but not statistically difference between G1 vs G2. In post-operative times blood-gas assessment showed impaired lactate values in G1 vs G2.

The analysis found that diuresis was lower in patients treated with Levosimendan (G1) vs placebo (G2) in 24 hour after surgery. Perhaps no statistical difference between two groups.

No patient had adverse reactions or oversensitiveness to Levosimendan infusion.

Conclusion: The preliminary data of the study support these conclusions: (i) the optimal dosing is 0.1 mcg/kg/min for 24 hours of Levosimendan did not increased the SV and CO value, whilst increased EF statistically significant (ii)lactate concentration in gas analysis decrease in patients treated with Levosimendan, whilst also suggest that Levosimendan improved ScvO₂ (iii) levosimendan did not enhance the diuresis in G1 vs G2 and (iv) Levosimendan infusion should be started before surgery to exert its preconditioning effect.

Levosimendan infusion sustained haemodynamic improvement in the acute heart failure patients.

Developing a Family Liaison Team during the COVID-19 pandemic: the experience of a tertiary London teaching hospital

C. Lopez Soto¹; L. Flood¹; E. Bates¹; C. Anderson¹; V. Metaxa¹

¹Critical care medicine, King's College Hospital, London, United Kingdom

Correspondence: C. Lopez Soto

Intensive Care Medicine Experimental 2020, **8(2)**: 000357

Introduction: Communication with and participation of families and patients during their stay in an intensive care unit (ICU) has evolved over the last decades, by means of different approaches, such as: family-centred rounds, daily updates, electronic patient portals and interdisciplinary family meetings. Family-centred care is desired by patients and families, and evidence suggests that it may improve user outcomes, and reduce burnout and moral distress among clinicians. This patient/family-centred approach is challenged during large-scale disasters, where movement restrictions are implemented to preserve public safety/health.

In March 2019, our hospital following Public Health England guidance, restricted patients' family and friends (PFFs) visitation rights in response to the COVID-19 pandemic.

Objectives: We describe the setting up of a service to communicate with patients' families.

Methods: A service improvement project in a tertiary London hospital, during the 2020 novel COVID-19 pandemic. The Trust increased its beds from 81 to 140 to cope with the surge in patients and a total of 10 critical care (CC) areas were developed (increased from 5). As quarantine and national guidance prevented relatives from visiting the hospital, we explored the possibility of creating a dedicated team of professionals that would focus on communications with patients' families and friends (PFFs)

Results: A dedicated team of redeployed healthcare professionals was assembled on 25th March (family liaison team, FLT), with a total of 40 people volunteering. The vast majority (75%) were medical consultant grade. Their background specialty is shown in figure 1 and their main responsibilities in figure 2. The teams were allocated to each CC area, with a maximum ratio of 1:10 and underwent 2 1-hourly webinars around basic family communication skills. The following routine was followed: at 8am the FLT attended the doctors' handover and identified any patients who had deteriorated overnight in order to update their families. They then communicated with the medical team after the ward round and transferred the information to the next of kin of each patient. Video calls were facilitated during the day, depending on the availability of the family and the bedside nurse. Until May 10th, the FLT has facilitated over 12,000 (video-) calls and communicated with >90% of PFFs daily.

We defined the FLT responsibilities as follow: daily medical updates, facilitation of video calls, information, provision and support for families visiting (visiting was allowed for deteriorating patients or approaching end of life), obtaining social history if not completed at time of admission, communicate information to medical and nursing team and identification of families/friends with specific needs (young children, impending bereavement, social and psychological support) and refer them to the appropriate services.

We also developed a document to serve as a guide for the FLT during the communications with PFFs, which included: introduction to the team, how to give daily updates and how to manage difficult conversations if patients were deteriorating.

Figure 1. Specialties taking part in the FLT

Conclusion: Non-CC professionals have been pivotal in continuing the patient-family connection in our institution during the pandemic. The model is successful, requiring moderate training for the FLT. Further evaluation both for the team and around PFF satisfaction is currently underway.

Dependency and vulnerability of intensive care medicine in times of COVID-19 crisisM. T. Lingitz¹; G. Roth¹; C. G. Krenn²

¹Department of anesthesia and general intensive care medicine, Franziskus Spital Margareten, Wien, Austria; ²Department of anesthesia, general intensive care and pain medicine, Vienna General Hospital, Vienna Austria, Austria

Correspondence: M.T. Lingitz*Intensive Care Medicine Experimental* 2020, **8(2)**: 000383

Introduction: Since December 2019, Coronavirus Disease-2019 (COVID-19) spread rapidly all over the world, resulting in pandemic [1,2,3]. Through high hospitalization rates and via potentially exponential expansion of the disease, the COVID-19 crisis places a tremendous strain on healthcare systems, especially on limited numbers of hospital and Intensive Care Unit (ICU) – beds and equipment [4,5].

Objectives: The aim of this study was to elucidate the possible dependency of ICUs in European Countries with Austria as a pars pro toto in particular on long transglobal supply chains and its potential vulnerability by reported shortages of essential medicines and limited capacities in times of globalization and asserted economic advantages versus the pandemic threat of COVID-19 [4,5,6].

Methods: From 3 April to 8 April 2020 we performed a short survey with heads of Austria's ICU-wards in different institutions following a structured questionnaire to enquire their personal experience and assessment.

At that time containment measures with exit restrictions, starting on 16 March 2020, has lasted for a time span of three weeks. Due to the dynamic situation during pandemic with constantly changing export bans and travel restrictions especially represents a current snapshot of the situation in that time.

Results: We surveyed nearly half of the head physicians of ICUs (n=40) in Austria [7]. 55 percent (n=22) are already treating COVID-19 affected patients at their ICU department. Only 45 percent (n=18) of them had received the amount of personal protective equipment they deemed enough, and 90 percent (n=36) of surveyed ICUs were already informed about shortage supplies concerning personal protective equipment. (Fig. 1) 45 percent (n=18) already reported infections within their medical personnel. According to the estimation of heads of ICUs the duration of pandemic should not last more than 6 weeks averagely without facing difficulties in storage and availability of supply. 35 percent (n=14) already reported supply difficulties in several pharmaceuticals, whereas 73 percent (n=29) were informed or already warned by their economic or purchase departments about further potential or real shortages concerning essential pharmaceuticals in near future. Detailed results are illustrated in Fig. 2.

Fig 1. Results concerning equipment of all surveyed ICUs and in dependence of hospital type**Fig 2. Results concerning pharmaceuticals of all surveyed ICUs and in dependence of hospital type**

Conclusion: Summarizing the results of our survey we would like to draw attention to the lessons we can learn from the COVID-19 crisis in the EU: European Countries with Austria as a pars pro toto should establish a national production of key equipment and disposables, at least a minor part of PPE as well as key pharmaceuticals. European countries need to improve far distance supplies and invest in maintaining critical infrastructure especially in those with limited capacities such as health care in general and ICUs in particular.

Experience of repurposing the non-invasive V60 Ventilator for invasive ventilation to produce surge capacity during covid19S. Petty¹; M. Jeffrey¹; Y. Yang¹; A. Conway-Morris¹; R. Mahroof¹

¹Department of anaesthetics & intensive care medicine, Cambridge University Hospitals NHS Foundation Trust, Cambridge, United Kingdom

Correspondence: M. Jeffrey*Intensive Care Medicine Experimental* 2020, **8(2)**: 000416

Introduction: We present an early analysis and account of our experiences using our primary non-invasive ventilation (NIV machine), Respirationics V60 ventilator[®], as a first line expansion for invasive ventilation.

Objectives: Review how the V60 ventilator may be used for invasive ventilation

Methods: We obtained 25 V60 units for critical care. Our surge plan was shaped by staff familiarity with the V60 versus staff unfamiliarity/limited supply of consumables for Anaesthetic Machines

We maximised staff protection from aerosolised SARS CoV-2 during V60 use by adding a Clear-Therm 3 HMEF (1541)[®] to allow circuit breaks. We used Pressure Control Ventilation (PCV) as our mandatory mode, which was not used prior to COVID19. Spontaneous/Timed (S/T) mode was used for support ventilation.

Laminated setup guides for circuits and initial settings were attached to all machines supported by comprehensive face-to-face and video-conferencing training delivered to all relevant staff.

Results: The V60 ventilator has formed a significant part of our surge response, used in 30 out of 81 (37%) patients. These patients received 572 ventilator days, with 239 on a V60 (42%).

Key issues arising from use were filter saturation, oxygen consumption in PCV vs S/T mode, requirement for increased pressure support for CPAP equivalence and the lack of an inspiratory hold for recruitment manoeuvres.

The proximity of the HMEF to nebuliser caused frequent filter saturation and high resistance. Filter issues were noted in 11 (37%) patients. This was worse in cases using nebulised epoprostenol (epo). Using a trial of epo 15 ng/kg/min for 30 min we could identify patients better suited to ventilation with a full service (Servo-i) ICU ventilator.

Oxygen usage of V60 was much higher than the anticipated 10-15LPM. In PCV on 100% O₂ the V60 used 46LPM, at 60% 21LPM, making patient transfer difficult.

We created a recruitment manoeuvre which was used successfully in 9 (30%) patients. Settings of RR to 10, i-time 3 s, IPAP 40, EPAP 25 were used for this.

Though V60 ventilators were unable to invert ratios >1:1, 2 patients were prone on V60 ventilation, 1 died but the other has been discharged from intensive care.

Lastly, we noted the standby function would continue producing aerosol by blowing when disconnected. However the V60 loads its previous settings when switched on, and does this in <5 s, so on/off was used in place of standby.

Conclusion: The V60 ventilator is a viable invasive ventilator if problems are addressed. With appropriate patient selection it can spare full-service ventilator capacity, and at 25% of cost of our full-service ICU ventilator it allowed a cost-effective expansion of our ventilator fleet.

Family members' satisfaction in a Tunisian medical ICU

M. Zghidi¹; I. Ben Saida²; A. Elhadhri¹; W. Zarrougui¹; M. Boussarsar²
¹Medical intensive care unit, Farhat hached university hospital, Sousse, Tunisia; ²Farhat hached university hospital, medical intensive care unit, Université de Sousse, Faculté de Médecine de Sousse, UR N° LR12SP09. Heart Failure, Sousse, Tunisia

Correspondence: M. Zghidi

Intensive Care Medicine Experimental 2020, **8(2)**: 000433

Introduction: Family satisfaction is an important indicator for quality improvement of intensive care units. Compliance with implemented protocols are often poor.

Objectives: The purpose of this study was to describe levels of family satisfaction with the care provided in a Tunisian intensive care unit (ICU).

Methods: It was a prospective observational and descriptive study involving family members of patients admitted in a Tunisian medical ICU between November 2018 and Mai 2019. Family members of adult patients, staying at an ICU for ≥48hours, were included. A questionnaire to measure family satisfaction with care provided in the ICU was developed. Family members were asked to complete the questionnaire and to provide information about their own demographics. Data on patient's baseline characteristics were abstracted from charts retrospectively.

Results: Ninety-three family members completed the questionnaire. Demographic characteristics of study related patients were: male, 76(81.7%) mean age, 56.6±15.4 years; respiratory distress at admission, 79(84.9%); mean length of stay, 14.4±18.5 days. Respondents characteristics were: mean age, 39±13 years; female, 51(54.8%); first-degree parents 48(51.6%); mean waiting delay, 42.4±28.1mn.

Twenty-eight (30.1%) of respondents were satisfied with overall care. Families reported good satisfaction with the waiting room atmosphere, visitor's number and coordination and teamwork staff respectively in 56(60.2%), 33(35.5%) and 28(30.1%). Families reported the least satisfaction for the availability and communication by nurses. Responses to family satisfaction questionnaire are displayed in Table 1.

Table 1 : Responses to questionnaire : Family satisfaction with intensive care unit (ICU) experience (N=93)

	Good n(%)	Fair n(%)	Poor n(%)
-Waiting delay before visits	21(22.6)	58(62.4)	14(15.1)
-Visit duration	26(28)	46(49.5)	21(22.6)
-Visitors' number	33(35.5)	43(46.2)	17(18.3)
-Completeness of information about patient's condition	25(26.9)	43(46.6)	25(26.9)
-Atmosphere of the waiting room	56(60.2)	24(25.8)	13(14)
-Psychological support of family members	10(10.8)	59(63.4)	24(25.8)
-Availability of nurses	20(21.5)	42(45.2)	31(33.3)
-Availability of physicians	27(29)	50(53.8)	16(17.2)
-Management of anxiety and depression of their patients	24(25.8)	49(52.7)	20(21.5)
-Medical secret respect	25(22.6)	56(60.2)	12(12.9)
-Courtesy, respect, and compassion toward patient	21(22.6)	65(69.9)	7(7.5)
-Pain's patient management	17(18.3)	64(68.8)	12(12.9)
-Pain's patient management	28(30.1)	57(61.3)	8(8.6)
-Coordination and teamwork by staff	19(20.4)	40(43)	34(36.6)
-Communication by nurses	21(22.6)	60(64.5)	12(12.9)
-Psychological support of their patients	28(30.1)	54(58.1)	11(11.8)
-Global satisfaction of cares given to their patients			

Conclusion: Most family members were satisfied with the care provided in the intensive care unit. Communication and availability of nurses were areas with potential for improvement.

000434

Self-perceived discomforts in critically ill patients

M. Zghidi¹; I. Ben Saida²; AT. Ben¹; E. Ennouri¹; M. Boussarsar²
¹Medical intensive care unit, Farhat hached university hospital, Sousse, Tunisia; ²Farhat hached university hospital, medical intensive care unit, Uni-

versité de Sousse, Faculté de Médecine de Sousse, UR N° LR12SP09. Heart Failure, Sousse, Tunisia

Correspondence: M. Zghidi

Intensive Care Medicine Experimental 2020, **8(2)**: 000434

Introduction: Critically ill patients are exposed to stressful conditions and may experience discomforts from multiple sources. Modification of the physical and psychological stressors would contribute positively to the short-term and long-term outcomes during the ICU stay and after the discharge.

Objectives: To explore self-perceived discomforts in critically ill patients.

Methods: A prospective cohort study was performed in medical ICU and anesthesiology department between September 2018 and Mars 2019. All patients admitted during the study period were included. Patients with diminished mental capacity, unable to communicate or refusing to participate in the study were excluded. Patient discomforts were assessed using the 16 items self-reported discomfort questionnaire on discomforts in ICU patients (IPREA). Patients were asked to rate the severity of each discomfort experienced during their ICU stay using a 10-point numerical rating scale (example: 0 = no pain and 10 = worst pain possible). Patients characteristics were recorded from medical patients' charts.

Results: One hundred twenty patients completed the questionnaire. 51 (42%) patients were admitted in the medical ICU. Clinical characteristics were: female, 60 (50%); mean age, 47.9±18.5 years; mean length of stay, 10±2 days; acute respiratory failure, 39 (32.5%); invasive mechanical ventilation, 48 (40%); noninvasive mechanical ventilation, 72 (60%); tracheostomy, 18 (15%).

The four highest discomforts were the absence of a phone, pain, sleep deprivation and limited visiting hours and the 4 lowest discomforts were feeling of cold, hunger, bed-related discomfort and feeling of heat. Self-perceived discomforts of the 16-item IPREA are displayed in Table 1.

Table 1: IPREA questionnaire for assessing self-reported discomforts perceived by the critically ill patients

Items	Mean score ±SD/10
Noise	5.4±3.27
Excess of light	5.1±3.28
Bed related discomfort	5.0±3.25
Sleep deprivation	6.1±3.11
Thirst	5.7±3.07
Cold	4.6±2.99
Heat	5.0±3.07
Hunger	4.7±3.42
Pain	6.2±3.46
Discomfort du to tubes	5.6±3.53
Lack of privation	5.9±3.58
Anxiety	5.7±3.38
Isolation	5.3±3.54
Limited visits hours	6.1±3.12
Absence of phone	6.6±3.42
Lack of information	5.8±3.44

Conclusion: The findings of this study shed light on the difficulties that Tunisian ICU patients may experience and that could adversely affect their outcomes.

Correspondence: G. Salve

Intensive Care Medicine Experimental 2020, **8(2)**: 000440

Introduction: On February 18, 2020 the first Italian case of coronavirus disease 19 (COVID-19) was identified in Lombardy. It was centralized in our hospital Fondazione IRCCS Policlinico S. Matteo, in Pavia. [1] Because of the rapid outbreak, the number of dedicated ICU beds was increased up to 72, even adapting operating rooms (OR) to a 6-beds intensive care unit (ICU). As described in this case report, we treated there an obese COVID-19 patient with acute respiratory distress syndrome.

Methods: On ICU admission, a 33-years-old super-obese patient (body mass index, BMI 52 kg/m²) presented respiratory distress and critical hypoxemia, despite CPAP helmet. We promptly proceeded to video-laryngoscopy intubation for invasive mechanical ventilation (MV). Past medical history revealed diabetes mellitus and psoriasis. Respiratory symptoms and fever began a week before. COVID-19 was confirmed by the reverse-transcription polymerase chain reaction analysis of the bronco-alveolar lavage. We faced several problems during admission: the limited respiratory mechanics data of an anaesthesia workstation (Flow-i[®], Getinge, Göteborg, Sweden), the unfeasibility of oesophageal pressure measurement [2] and the difficulties to obtain a computed tomography scan due to the high BMI. However, we used available lung ultrasound (LUS) scan to quantify lung de-aeration [3] and set the positive end-expiratory pressure (PEEP) level up to 20 cmH₂O. [4] (Figure 1) According to the LUS posterior consolidations and the anterior-lateral interstitial pattern [5] we carried out 12-16 hours prone positioning cycles [6,7] on neuromuscular blocking agents continuous infusion and proper sedation. Prophylactic antimicrobial therapy was carried out with azithromycin, ceftriaxone and trimethoprim/sulfamethoxazole. Prophylactic heparin dosage (6000 IU q12h) was adjusted according to anti-FXa monitoring, without major bleedings. [8] On day 1 the patient was enrolled in the convalescent plasma experimental treatment protocol. [9] On day 15, *Klebsiella Pneumoniae* ESBL ventilator-associated pneumonia occurred, with clinical status worsening. Antimicrobial therapy was then adjusted with meropenem. On day 19, percutaneous tracheostomy was performed to facilitate MV weaning. Intravenous sedation was de-escalated implementing oral sedatives, [10] without delirium or agitation.

Figure 1: PaO₂/FiO₂ compared to PEEP (cmH₂O) and LUS score

Results: On day 41 the patient was transferred to another ICU on assisted MV. Discharging was mandatory: our ICU was closed after the COVID-19 cases reduction in Italy, to allow return to surgical activity.

Conclusion: According to our experience, despite the limited resources it is possible to treat successfully a super-obese patient with severe COVID-19 infection in an OR converted into ICU.

Coping with COVID-19 in a low resource country: ethical, social, and economic dilemmas

T. Jreis¹; H. Ashhab²

¹Anesthesiology & CCM, Hadassah Medical Center, Bethlehem, Occupied Palestinian territories; ²Internal medicine, Ahli Hospital, Hebron, Occupied Palestinian territories

Correspondence: T. Jreis

Intensive Care Medicine Experimental 2020, **8(2)**: 000488

Introduction: Palestinian authority, population 2.8 million, is a low resource country facing COVID-19 pandemic, neighboring high resource country fighting the epidemic. In preparing ourselves, we creating a disaster committee, included private and governmental hospitals CEOs, infectious disease specialists and Intensivists.

Objectives: To share lessons learned, barriers overcome, discuss ethical and social implications of decisions made in the low resource country.

Methods: Epidemiological and national statistics will be demonstrated, dealing with unestablished infrastructures and utilizing the existing resources. Enforced early total lockdown while saving lives had many ethical and social implications.

Results: 547 confirmed infected, 4 COVID-19 related deaths all in provisional, urgently created ICUs. 40513 COVID-19 tests were performed. High risk population testing positive COVID-19 were workers transiting daily into neighboring countries (75%), medical staff (3.7%), tourist industry related personnel (20.3%).

Conclusion: Early enforced lockdown the most effective governmental decision preventing population from getting sick. However, the burden of ethical, social and economic consequences is still being evaluated and will be discussed in this abstract.

Goals of care bundle via a critical care outreach team for critical care provision during the COVID-19 outbreak in Lombardy: baseline characteristics and outcomes

A. Messina¹; P. Andrea¹; A. Valeria¹; N. Maxim¹; M. Cecconi¹

¹Anesthesia and intensive care, Humanitas Research Hospital, Rozzano, Italy

Correspondence: A. Messina

Intensive Care Medicine Experimental 2020, **8(2)**: 000491

Introduction: During the Coronavirus disease 2019 (COVID-19) outbreak (1), the mission of our intensive care unit (ICU) team was to provide intensive care to whoever needed intensive care. Upon reaching the plateau of the outbreak in Italy, 7 wards were dedicated to high dependency units, counting approximately 100 beds [including 50 level-2 beds delivering forms of non-invasive ventilatory assistance such as continuous positive airways pressure (CPAP), non-invasive ventilation (NIV) and high flow nasal cannula (HFNC)] The outreach team provided senior ICU decision support using a Goals Of Care Bundle (Figure 1).

Methods: We retrospectively evaluated data from 125 patients referred to the outreach team from March 22– April 22, 2020 and outcomes after a minimum of 15-days follow-up. The data analysis refers to three subgroups of COVID-19 patients: patients admitted to the wards with respiratory symptom and receiving a ceiling of care decision (PCEI); patients requiring more detailed observation or intervention including non-invasive forms of ventilatory support and considered eligible level-3 care, if needed (PWARD); patients admitted to the ICU within 24 h after the after the evaluation of the outreach team (PICU).

Results: From March 22 to April 22, 2020, 125 consecutive adult patients with a confirmed diagnosis of COVID-19 [a median (IQR) of 25% (21%–27%) of the overall number of COVID-19 positive patients admitted to the Humanitas Research Hospital] have been referred to the outreach team (Figure 2). Overall, 61 patients (48.8%) were included in the PCEI group, 30 in the PWARD and, finally, 34 in the PICU. The median (IQR) number of patients receiving non-invasive respiratory support in the wards (including either helmet CPAP or NIV delivered by facemask or HFNC) was 9 (4–16), with a maximum of 19 patients on March 28.

The overall in-hospital mortality of COVID-19 patients (including the emergency department, wards and ICU) in the considered period was 26.8%, while the overall ICU mortality was 21.9%. At the end of the follow-up, 19 patients in the PCEI group (31.1%), 29 in the PWARD group (96.7%) and 26 in the PICU group (76.2%) were discharged from hospital, to either home or rehabilitation facilities. Moreover, 41/65 patients in the PCEI group (67.2%) died in hospital as compared to none in the PWARD and PICU groups ($p < 0.0001$).

Conclusion: In a context of hospital and ICU surge, implementation of a dedicated Critical Care Outreach was associated with proper allocation of ICU resources, a low rate of cardiac arrest calls and no emergency intubations in the ward.

Intensive Care Medicine Experimental 2020, **8(2)**: 000495

Introduction: The COVID-19 pandemic created many challenges for ventilator surge capacity. Solutions included use of anaesthetic machines and the repurposing of Non-Invasive Ventilators. Use of Philips Respironics V60 Non-Invasive Ventilator® in invasive, mandatory ventilation is previously unreported. Here, we describe our outcomes repurposing the V60 ventilator for COVID19 critical care admissions in a single UK tertiary centre.

Objectives: To describe the use of V60 Ventilators during a pandemic emergency. We focus on their utility, problems and place in our response going forward.

Methods: We performed retrospective analysis of all swab or BAL confirmed COVID19 positive cases admitted to intensive care in a University Teaching Hospital for 7 weeks upto 1/5/20. Descriptive statistics were performed using Microsoft Excel.

Results: 82 patients were admitted to intensive care with confirmed COVID19. Of these, 30 were ventilated with a V60. These 30 patients received 572 ventilator days with 239 days (42%) delivered by a V60. The mean ventilator days were 19.1 with 8 V60 ventilator days. A V60 was used for Mandatory ventilation in 19 patients, of these 12 were ventilated on a V60 immediately following intu. 11 used a V60 for spontaneous ventilation/weaning only.

In total 14 patients failed on a V60 and were changed to a full-service ICU ventilator (Servo-i): 2 for non-clinical reasons, 2 for bronchoscopy, 1 for ECMO, 2 for humidified circuits, 2 for proning and 2 for dyssynchrony. 93% of these failures occurred in the patients requiring mandatory ventilation and those with more severe ARDS, only 1 occurred in the spontaneous ventilation only group. Proning was performed in 2 patients whilst ventilated on a V60, of which 1 survived to ICU discharge.

A total of 64/82 COVID19 patients admitted to critical care have either been discharged from ICU or died. 39 (61%) were alive at ICU discharge and 25 (39%) died. For the patients ventilated on a V60 at any point 18/26 (69%) were discharged from ICU alive and 8/26 (31%) died. For those not ventilated on a V60 at any point 21/38 (55%) left ICU alive and 17/38 (45%) died.

Figure 1: Demographics of patients using V60 (n=30)

	Mean	Range
Age, years	59	33-82
Male, n (%)	21 (70)	9 (30)

Minimum P/F ratio	Number	Percentage
Mild(<13.3)	2	7%
Mod (13.3 - 23.2)	12	41%
Severe	15	52%

*1 patient excluded due to being a transfer with no clear way of finding minimum PF ratio

Figure 2: V60 use data across 83 ventilated patients patients

	Absolute number, n	Percentage, (fraction)
Total patient number using V60s	30	36% (30/83)
Primary ventilation (placed within 24 hours of admission)	12	14% (12/30)
Mandatory	7	8% (7/60)
Secondary	11	13% (11/30)

Total days spent on a ventilator, days	572
Average total ventilator days, days	19.1

Total ventilatory days on V60, days	239
Average ventilator days on V60, days	8

Average proportion of total ventilator days on v60	46%
--	-----

Figure 3A: Disease severity and outcomes among patients on V60 in those with an ICU outcome

	P/F ratio and severity in those with V60 as primary ventilator (within 24 h of intubation)				P/F ratio and severity in those with V60 for mandatory ventilation				Spontaneous
	Mild	Moderate	Severe	Total	Mild	Moderate	Severe	Total	
Number of patients	1	2	8	11	1	5	11	17	10
Did not fail on V60	1	0	1	2	1	2	2	5	9
Total deaths	0	0	5	5	0	0	6	6	2
Survived to ICU discharge	1 (100%)	2 (100%)	3 (38%)	6 (55%)	1 (100%)	5 (100%)	5 (45%)	11 (65%)	8 (80%)
Died on V60	0	0	1	1	0	0	1	1	1
Fail V60 or Died on V60 (%)	0 (0%)	2 (100%)	8 (100%)	10 (91%)	1 (0%)	3 (60%)	10 (91%)	13 (76%)	20%

Conclusion: When a V60 was used, it was able to provide 239/572 (42%) of ventilator days. However a universally high failure rate, 13/16 patients (81%), in those with moderate-severe ARDS when used for mandatory ventilation makes it clear that it cannot be used as a direct replacement for an ICU ventilator. If used in carefully selected patients, with experienced staff, it can contribute significantly to surge capacity by sparing ICU ventilators for those requiring advanced respiratory support. At 25% cost of a full-service ICU ventilator it can, when used

appropriately, allow for cost-effective surge expansion of ventilator capacity.

Intensive Care Medicine Experimental 2020, **8(2)**: 000496

Introduction: We present the experience of a UK single tertiary centre in managing supplies of essential critical care medications during the COVID-19 pandemic.

Objectives: To identify challenges and solutions in managing supplies of essential critical care medications during the COVID-19 pandemic.

Methods: During the surge of COVID-19 patients, shortages of propofol 2%, fentanyl, norepinephrine and atracurium were experienced. To facilitate safe sedation, a policy was developed to prioritise short-acting agents for light sedation and patients likely to accumulate other agents. Combinations of long-acting agents including morphine and midazolam were used for deep sedation and a nurse-led bolus dosing strategy was used in selected patients.

A coordinated switch to 1% propofol was made, requiring staff training and dietetic input for calorie differences. Shortages of atracurium were managed with bolus regimes of pancuronium.

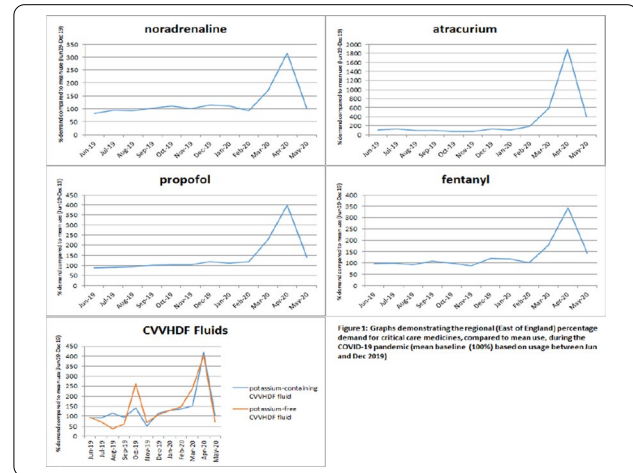

To maintain supplies of noradrenaline, an alternative unlicensed formulation was received. We coordinated the local setup of a Centralised Intravenous Additive Service for preparation of noradrenaline pre-filled syringes. This mitigated risks of incorrect concentrations or diluents and reduced nursing workload, particularly given use of non-critical care nursing staff.

Availability of Continuous Veno-Venous Haemodiafiltration (CVVHDF) sets and fluids has been challenging, requiring supply management on a regional level. Locally, risk of shortage was mitigated through elective filter breaks, requirement for Consultant approval for restart following clotting and judicious use of exchange rates. A protocol for the addition of potassium to potassium-free fluids was also developed. Figure 1 demonstrates the baseline and peak demand across the region for each of these therapies.

Throughout the surge, real-time administration data was able to be extracted from the local electronic prescribing system for all critical drugs, facilitating timely and more accurate planning of management strategies.

Results: There were challenges related to timely availability of drugs in areas where Aerosol Generating Procedures were performed. We installed additional controlled drug cupboards and fridges in isolation areas and emergency drugs in each bed space drug locker, so drugs could be available quickly whilst maintaining storage and governance requirements.

To manage the shortage of CVVHDF supplies, work to plumb reverse osmosis water supplies to our ICUs has been completed. This has allowed the use of Sustained Low Efficiency Dialysis (SLED) in selected patients.

Conclusion: Our response locally has focused on rapid-response amendments to formulary with new policies and adaptations to usual practice to support use of alternative agents. A prospective, pragmatic and flexible approach has been required with actions to mitigate, rather than eliminate, risk. This has minimised the need for emergency, unplanned changes in policy.

Establishing a rapid response system in an arctic hospital

S. Christiansen¹; P. Lennert²

¹Department of medicine, Queen Ingrid's Hospital, Nuuk, Greenland;

²Department of anaesthesiology, Queen Ingrid's Hospital, Nuuk, Greenland

Correspondence: S. Christiansen

Intensive Care Medicine Experimental 2020, **8(2)**: 000545

Introduction: The 1st of May 2019 a rapid response system (RRS) was established at Queen Ingrid's Hospital, Nuuk, Greenland to ensure immediate assistance to patients suffering from critical illness, trauma or are in cardiac arrest. A rapid response team (RRT) composed of physicians, nurses, patient transporters and laboratory technicians is triggered by an early warning system (EWS). The EWS is defined by certain thresholds, such as deviating vital parameters or mechanism of trauma. Queen Ingrid's Hospital have a capacity of approximately 100 beds, including 4 in the intensive care unit. The emergency personnel are on call from their homes.

Objectives: The objective of the study is to describe the incidence, typical location, type of event (i.e. critical illness, trauma or cardiac arrest) and triggers activating the RRT. Furthermore, we want to measure certain quality indicators and describe the outcome of the patients managed by the RRT.

Methods: From 1st of May 2019 until the 1st of May 2020, we plan to examine and collect data from the electronic health record each time the RRT is deployed. Here we obtain information on the type of event, vital parameters, mechanism of trauma and treatment given (e.g. intubation, medicine). Furthermore, we obtain information on the time of death.

Results: During the first 11 months the RRT have treated 88 patients corresponding to 1,83 per week. The patients had a median age of 55 (interquartile range (IQR) 31-67) and 53 (60.2%) being male. 25 patients (28.4%) have been in cardiac arrest, 25 (28.4%) suffering from traumas and 38 (43.2%) presented with critical illness. 71 (80.7%) were received as out-of-hospital patients while 17 (19.3%) were hospitalized. The 30-day survival for patients in cardiac arrest, critically

ill patients and patients suffering from trauma was 13.7%, 84.2% and 88.0%, respectively.

Conclusion: In 2019 a RRS was established at Queen Ingrid's Hospital, Nuuk, Greenland. To monitor and evaluate the system, we plan to collect data from the first year after implementation. Preliminary results from the first 11 months indicate that the system is frequently being activated and especially from the emergency room.

Correspondence: S. Pregnotato

Intensive Care Medicine Experimental 2020, **8(2)**: 000658

Introduction: After severe acute respiratory syndrome coronavirus 2 outbreak in Wuhan, China, coronavirus disease 2019 (COVID-19) spread out in a pandemic. [1] On February 20, 2020 the first Italian case of secondary transmission was centralized in our hospital Fondazione IRCCS Policlinico San Matteo, in Pavia. The rapidly growing numbers in Northern Italy [2] imposed our hospital to increase greatly the already available 31 intensive care unit (ICU) beds [3].

Methods: On March 14, 2020, after the surgical activities suspension, we converted in a short time (8 hours) a surgical unit (SU) into a 6-beds COVID-19 ICU, reaching the hospital total capacity of 72 ICU beds.

Results: This cardiothoracic SU was square-shaped with four operating rooms (OR) on the corners, connected by an interior passage. We isolated this area with a double filter system in the pre-operative holding areas: a "clean filter", at the entrance, was reserved for disposable personal protective equipment [4] wearing, while a "contaminated" one, at the exit, was for undressing procedures. In the interior corridor we allocated the drugs storage, while a blood gas analyser and a point-of-care coagulation monitoring system were already in place. An ultrasound machine, a fibre optic bronchoscope and a defibrillator were also available (Figure 1).

Outside this space we set up a "control unit" area, equipped with a centralized parameters monitoring system and a video surveillance system, with a camera in each OR.

Communications were possible thanks to an internal telephone line and professional walkie-talkies.

In a situation of ICU ventilators shortage, three beds were equipped with Servo 900 C[®] ventilators (Siemens Elema, Solna, Sweden) kept as back up machines till then, while the others had the Flow-i[®] anaesthesia workstations (Getinge, Göteborg, Sweden) routinely used in the SU. The wall gas aspiration system was connected to the ventilators expiratory valve, preventing airdrops dispersion. Essential devices, such as monitoring tools and aspiration systems, were already available in each OR. In a limited resources context this was an undoubted advantage, compared with the rearrangement of a traditional ward.

Many of the nurses and health workers employed were ordinarily working in this SU. Medical staff was composed of anaesthetist-intensivist physicians and residents, most of them with an anesthesiological background.

We performed daily bedside lung ultrasound (LUS) monitoring to minimize the use of traditional imaging, reducing transports to the radiology department. Moreover, with limited lung mechanic measurements availability, we used LUS to titrate ventilation settings. [5,6]

Figure 1: ORs rearrangement into a COVID-19 dedicated ICU.

Conclusion: According to our positive experience, during a health emergency OR represents a real and feasible source of ICU beds, quickly available and easy to set-up.

Shared decision making impact on hospice palliative care over terminal critical patient

HC. Chen¹; SY. Lin²; SH. Kuo³; JM. Chung⁴; SH. Tzeng⁴; MY. Lin⁴; RY. Chen⁴; HL. Liang⁵; WC. Huang¹

¹Department of critical care medicine, Kaohsiung Veterans General Hospital, Kaohsiung, Taiwan; ²Master program of school of nursing, Kaohsiung Medical University, Kaohsiung, Taiwan; ³Graduate institute of clinical medicine, Kaohsiung Medical University, Kaohsiung, Taiwan; ⁴Department of family medicine, Kaohsiung Veterans General Hospital, Kaohsiung, Taiwan; ⁵Department of nursing, Shu-Zen Junior College of Medicine and Management, Kaohsiung, Taiwan

Correspondence: H.C. Chen

Intensive Care Medicine Experimental 2020, **8(2)**: 000659

Introduction: The idea of shared decision making (SDM) was first proposed in 1972, with gradually increasing its importance as the upsurging interest in patient centredness and autonomy in health care interactions since the 1970 s. It has become the major care model

embodying patient centered care and physician-patient equality interaction. Hospice palliative care among terminal critical ill patient, determined by two separate specialist based on the Hospice Palliative Care Act definition, has long been poorly accepted owing to cultural mis-understanding, especially among Chinese. By retrospective cohort data analysis, we try to unveiled the impact of introducing SDM on hospice palliative care in terminal critical adult ICU patients

Methods: Medical record of medical center adult ICU admitted terminal critical ill patient from Jan. 1st, 2017 to Dec. 31th, 2019 was retrospectively reviewed, and further subdivided into pre-SDM and post-SDM (after Oct. 1st, 2018) intervention period for analysis. Terminal critical ill was defined as ICU admitted patient fit following criteria including advanced malignancy, end-stage motor neuron disease, decompensated heart failure with NYHA Fc IV, oxygenation or ventilator dependent pulmonary and airway disease, liver cirrhosis Child-Pugh C with episodes of hepatic encephalopathy, hemodialysis dependent acute or chronic renal failure, extremely elderly associated organic psychosis or central nervous system degeneration, and fulminant critical condition, which post tolerated available treatment without clinically improvement determined by two separate specialist. Decision about withdrawal, discontinuing, or refusing any add-on life supporting management was considered as palliative care. Data including SDM impact on palliative decision associated withdraw or withhold rate, ventilator dependent days, length of ICU stay, length of hospital stay, means of withdraw or withhold, and average medical cost were collected. SPSS was applied for statistically analysis, and a p value less than 0.05 was considered significant difference.

Results: Medical records from total 9198 patients from Jan. 1st, 2017 to Dec. 31th, 2019 were reviewed based on tertiary medical center adult ICU record. According to inclusion criteria, 56 patients out of 5209 patients fit terminal critical ill patient during the pre-SDM (before Oct. 1st, 2018) in compared to 153 patients from 3989 patients in post-SDM (after Oct. 1st, 2018), and 173% improvement over identifying terminal critical ill patient impressed. In compared to pre-SDM, post-SDM terminal critical ill patient had less ventilator dependent days (23.9+/-18.5 v.s 21.2+/-16.7, $p < 0.05$), shorter length of ICU stay (24.9+/-19.2 v.s 21.8+/-15.3, $p < 0.05$), and shorter length of hospital stay (31.2+/-25.9 v.s 27.6+/-23.3, $p < 0.05$). The most often chosen withdrawal is hospice endotracheal tube extubation, and the most frequent chosen withhold is vasopressor pump prescription. After SDM was introduced, ventilator days, length of ICU stay, and length of hospital stay of terminal critical ill patient was found reduced 2.7 days, 3.1 days, and 3.6 days individually in compared to each other. The average medical cost was also decreased after SDM introduced.

Conclusion: Our retrospective cohort study from a single medical center adult ICU revealed introducing shared decision making on hospice palliative care over terminal critical ill patient might improve palliative decision associated withdrawal or withhold rate, reduce ventilator days, length of ICU stay, and length of hospital stay. Introducing shared decision making on hospice palliative care over terminal critical ill patient reduce futile medical treatment and associated excessive medical cost.

Keywords: shared decision making, hospice palliative care, terminal critical ill patient.

Intensive Care Medicine Experimental 2020, **8(2)**: 000712

Introduction: The SARS-Cov-2 coronavirus partly spread via aerosolisation. To reduce nosocomial infection within our ICU it was necessary to effect equipment and behavioural changes. We provide an experiential narrative of a single UK tertiary centre of the adaptations to reduce viral particulate load, and steps to disseminate this

information. Subsequent issues and how these were resolved, are then described.

Objectives: To identify aerosol generating procedures (AGP) within ICU and to create a breathing circuit aiming to minimise viral transmission.

Methods: We adopted a pragmatic approach, intending a log 5-6 reduction in viral exposure. Equipment and procedural changes were implemented to effect this change. We replaced current heat and moisture exchangers (HME) with high efficiency filters (HEF) after comparing manufacturer values for bacterial vs viral efficiency. We adopted a modified RSI technique using apnoeic oxygenation was encouraged, with bagging avoided. An 'optimal' breathing circuit setup was proposed (see Fig 1). Setup then focused on ensuring expired gas always passed via a HEF, and that circuit breaks occurred distal to this. Specific high risk situations were considered; if circuit breaks were necessary, these occurred during apnoea with ventilators on standby and portable ventilators and bag valve masks ventilate to air, though not via expiratory limb - we focused on education to address this issue.

Results: Filter saturation was the most serious difficulty we encountered. The combination of Aerogen nebulisers, and in particular epoprostenol nebulisers, caused abrupt occlusions of HEF risking airway emergencies. We considered both modifiable and non-modifiable factors to manage occult respiratory gas loss:

Modifiable consideration included positioning of capnography sampling, which exhaust to air, post-filter. Aerogen nebulisers required distal placement relative to the HME. We received reassurance from the manufacturer that these nebulisers had not produced detectable leak during normal use.

Non-modifiable concerns included that 'suction above cuff' endotracheal tubes were not easily clamped, thus this was discouraged owing to ineffectiveness and risk of damage. We adopted a practice of paralysis with ventilator standby during planned disconnection. Similarly, portable suction devices lack viral filters and any use had to be treated as an AGP.

As a number of modifications to usual practice were required, multi-disciplinary education was necessary. Regular tutorials were available, with time for discussion regarding airway management. Teaching was available within ICU, dynamically changing as the situation developed.

Conclusion: Through consideration of changes to usual equipment and behaviours, we were able to achieve effective reduction in viral transmission in the context of an emergent pandemic.

Debriefing of critical situations: experiences and expectations of ICM residentsA. Trifi¹; M. Tobich¹; C. Abdennebi¹; Y. Touil¹; F. Daly¹; S. Abdellatif¹; S. Ben Lakhal¹¹Intensive care unit, Hospital la Rabta, Tunis, Tunisia**Correspondence:** A. Trifi*Intensive Care Medicine Experimental* 2020, **8(2)**: 000756

Introduction: At any moment of their exercise, residents of intensive care medicine (ICM) confront insurmountable stress. This is mainly due to the critical situations they encounter, especially as it is associated with lack of experience. Debriefing is a tool designed to relieve this stress and transform the error in learning.

Objectives: to assess the application of debriefing in clinical situations in residents of ICM and to inquire about their expectations.

Methods: Descriptive survey, focusing on residents of ICM from all over Tunisia after their consent. Data were collected using a 30-questions computerized questionnaire developed on the "Google Forms" platform which was sent to their personal email addresses. The topics investigated their experiences of debriefing after critical situations, the interest and expectations brought to debriefing in real practice.

Results: 100 responses were collected from 220 questionnaires sent representing a participation rate of 45.5%. 70% of participants were of female gender. The mean of cumulated semesters at the study time was 4 ± 2 . In 90% of cases, the senior doctor on call being at home with displacement and in 10% of cases the senior being on site. More than 10 calls per guard were recorded, in a quarter of interrogated residents, in order to manage a critical situation. 57 residents participated in a debriefing as part of simulation training whereas 86 have experienced it in clinical practice. In 40% of the cases, the Debriefing took place with a staff of several teaching doctors. 74 of the participants gave a satisfaction score between 3 and 5 out of 5. In this case, debriefing concerned the diagnostic discussion and the taken attitude. 95% preferred a collective debriefing than the individual one. 44% of the participants experienced at least one emotional shock during their course and they affirm the necessity of defusing even outside of a debriefing in 40% of cases. 52% of residents have claimed the ideal time for debriefing would be on day 1 of the managed critical situation and day 0 was considered in 32% of residents. Considering those who rated more than 6 out of 10, the expectations from debriefing in the studied population were: improvement of theoretical skills (92/100), improvement of technical skills (82/100) coordination within the team (89/100) and psychological interest (appeasement, guilt-free...) (87/100).

Conclusion: Our survey confirms the value of debriefing in clinical practice among ICM residents, both in the theoretical as technical skills and in psychological management.

Correspondence: G. Hernandez*Intensive Care Medicine Experimental* 2020, **8(2)**: 000764

Introduction: Shortage of both ventilators and ICU beds overwhelmed further health care systems during COVID-19 pandemic^{1,2}. Early tracheostomy (TRQ) can possibly reduce the duration of mechanical ventilation (MV) and ICU length of stay but counterbalanced with an increased risk for health-care workers³. COVID-19 is a clinical condition with easy-to-predict prolonged MV and a high mortality rate¹.

Objectives: Modified "failure-free days" combined outcome focused on resources (respirators and ICU beds) could contribute to decide the optimal timing of TRQ in consumed health care systems during future viral pandemic periods^{1,4}.

Methods: Multicenter retrospective cohort study including consecutive TRQ patients diagnosed with COVID-19 in 8 Spanish high-volume centers. The case selection, timing and technique of TRQ based on weekly burden degree in ICUs: the greater the burden the earlier and the higher the TRQ and surgical procedure rates. Modified ventilator and ICU bed-free days (VFD and BFD respectively) within 28 and 60-day time frame were defined as follows, respectively: VFD/BFD= 28/60-x if successfully liberated from MV/discharged to ward x days after initiation/admission and VFD/BFD= 28/60-x if subject dies within 28/60 days of MV/admission. Modified VFD and BFD were calculated for different timings (10, 14 and 20 days) and compared with multivariate ANOVA test. Matching bias was excluded with a propensity score.

Results: TRQ was performed in 48% of intubated patients; 504 tracheostomized patients were finally included. Table 1 shows the preliminary results of 143 patients. The median (IQR) time under MV was 23d (19-32); mortality rate was 49.2% and surgical TRQ was performed in 38.1% of patients. COVID-19 PCR was positive at any timing in all monitored patients (58.8%).

	Early TRQ ($\leq 10d / 14d / 20d$)	Delayed TRQ ($> 10d / 14d / 20d$)
Time under MV, d (median)	25.3 / 24.7 / 25.9	29.7 / 35 / 46.6
Mortality rate, %	54 / 45 / 50	50 / 60 / 57
VFD at 28d, d	6.6 / 6.1 / 5.2	4.1 / 2.4 / 1.4
BFD at 28d, d	3.9 / 3.1 / 2.7	1.9 / 1.2 / 1.4
VFD at 60d, d	34.7 / 35.7 / 34.4	31.3 / 26.4 / 17.3
BFD at 60d, d	30.5 / 32.1 / 30.6	27.9 / 22.9 / 14.8

Conclusion: Pending definitive results, we conclude that ICU resources could be optimized with early tracheostomy at 10d according to the 28-d modified VFD and BFD outcome under the conditions of the COVID-19 pandemic.

Intensive care communication with families during COVID: a national UK surveyA. Boulton¹; H. Jordan²; C. Adams³; A. Conway Morris⁴; N. Arora⁵

¹University of Warwick, Coventry, United Kingdom; ²Division of anaesthesia, department of medicine, University of Cambridge, Cambridge, United Kingdom; ³John v farman intensive care unit, Addenbrooke's Hospital, Cambridge, United Kingdom; ⁴Division of anaesthesia, department of medicine, University of Cambridge, Cambridge, UK, Cambridge, United Kingdom; ⁵Academic department of anaesthesia, critical care, pain

and resuscitation, Birmingham Heartlands Hospital, Birmingham, United Kingdom

Correspondence: A. Boulton

Intensive Care Medicine Experimental 2020, **8(2)**: 000792

Introduction: Frequent communication with a patient's relatives is a part of normal ICU care, however has been challenged by intensified clinical care demands of the COVID-19 pandemic.^{1,2} Regular visiting and communication with the ICU team is a priority for many families and crucial to coping.³ Visiting loved ones at the end-of-life is fundamental within many cultures and is a crucial part of the grieving process for the bereaved.⁴ Restrictions to hospital visiting policies during the COVID-19 pandemic have left relatives unable to visit their loved ones in ICU and receive face-to-face updates from clinicians and nurses.⁵⁻⁷ It is unclear how UK ICUs are dealing with this challenging situation.

Objectives: We aimed to investigate how UK ICUs are approaching relative communications and visiting during the COVID-19 pandemic.

Methods: This web-based snapshot survey was delivered between 16th April and 24th May 2020 and was open to UK ICUs. It was completed by individual clinicians regarding practices of the ICU they were currently working at during the COVID-19 pandemic.

Results: There were replies from 134 individual NHS ICUs with COVID patients for analysis. All units reported that visiting was more restricted than in normal times. Twenty-nine (22%) units reported that no relative visiting was allowed, 71 (53%) reported visiting was allowed at end of life only and 30 (23%) reported visiting was allowed for vulnerable or end of life patients.

Nearly all ICUs (n=130, 97%) were updating families daily. Most ICUs were initiating the family update (n=120, 92%). Daily phone calls were routinely initiated by the medical team in 75 (55%) ICUs and by the nursing team in 50 (37%) ICUs. Thirty-nine (29%) units used a dedicated team for regular family updates. Video calling was being used by 63 (47%) ICUs.

Do not attempt resuscitation and end of life family discussions were commonly done by consultants (n=132, 99%), followed by PGY4-7 doctors (n=60, 45%). Six (4%) units reported that PGY1-3 doctors may have these discussions. These discussions were most frequently phone calls initiated by the ICU medical team (N=129, 96%). Video calling was utilised by 24 (18%), and 15 (11%) reported that discussion may occur in person.

Conclusion: Relative visiting to UK ICUs during the COVID-19 pandemic has been severely restricted compared to normal times. Despite visiting restrictions, many units are adapting to support family visiting for end of life patients. ICUs are actively contacting families daily to provide updates, most commonly by ICU medical teams and many units have developed bespoke family communication teams. Modern technology has been utilised to deliver video calling by many ICUs.

Unindicated daily blood testing on ICU: an avoidable expense?

J. Sugarman¹; J. Malik¹; J. Hill¹; P. Morgan¹

¹Intensive care unit, East Surrey Hospital, Redhill, United Kingdom

Correspondence: J. Sugarman

Intensive Care Medicine Experimental 2020, **8(2)**: 000847

Introduction: ICU care often generates daily blood tests, which can provide essential diagnostic information. However, protracted blood sampling may contribute to anemia in ICU patients, with knock-on negative impacts on patient outcome. In addition, testing without clinical indication contributes to healthcare spending, creating an avoidable cost burden. We therefore set out to investigate the proportion of blood sampling that could have been avoided, as well as its total cost.

Objectives: We audited adherence to a departmental standard that no greater than 25% of blood sampling should be without clear clinical indication. This follows a 2015 audit of the same department, in which 46% of blood tests (n=339) were deemed unnecessary over 70 patient days, reducing to 41% with intervention.

Methods: We limited eligible patient data to blood samples collected after the first 48 hours of admission, to exclude stable post-surgical admissions. Patient data was collected between 21 January 2020 and 17 February 2020. Indications were listed for each of the seven most common blood tests: full blood count, urea & electrolytes, liver function tests, CRP, magnesium, phosphate, and clotting. These were stratified according to patient level of care in a 16-bed unit, with 10 Level 3 (ICU) beds and 6 Level 2 (HDU) beds. Daily blood tests were deemed indicated if the patient required advanced end-organ support (such as mechanical ventilation, vasopressors, or continuous veno-venous hemofiltration), if previous tests were acutely deranged, or if requested by a senior practitioner.

Results: 191 patient days were audited, with 1096 blood tests ordered total (Level 3: n=715, Level 2: n=388). Of all tests performed, 31.5% (n=345) were unindicated (Level 3: 22.4%, Level 2: 48.2%). The rate of blood sampling without clear clinical indication was within the departmental standard of 25% for CRP (13.1%), full blood count (15.4%), and urea & electrolytes (18.1%). Liver function tests (51%), magnesium (42.2%), phosphate (42.7%), and clotting (40.4%) failed to meet departmental guidelines, as did all blood tests requested for Level 2 patients. A potential cost of £2101 was estimated for all blood tests, with £505 unindicated.

Conclusion: We found that common blood tests in ICU are ordered regularly without clear clinical indication. We further determine that liver function tests, magnesium, phosphate, and clotting are ordered regularly without considering their diagnostic value.

This data also demonstrates that a regimen of testing without indication can significantly impact the running cost of an intensive care unit at a district general hospital. This may be a consequence of a critical care blood test set available on our electronic requesting system. Following the COVID-19 pandemic, we aim to introduce clearer guidelines on appropriate daily testing, to reduce the burden on patients and our healthcare system.

Our department will look to re-audit our practice following changes, to determine the degree of impact.

'Surviving an overwhelming COVID-19 ICU Surge': a case study and timeline from Northwick Park Hospital, UKD. Ball¹; M. O'Connor¹; O. Elsakra¹; J. Borkowski¹; V. Sathianathan¹¹Intensive Care Department, London North West University Healthcare NHS Trust, London, United Kingdom**Correspondence:** D. Ball*Intensive Care Medicine Experimental* 2020, **8(2)**: 000850

Introduction: In December 2019, a pneumonia of unknown cause was detected in Wuhan, China. A novel strain of coronavirus (SARS-CoV 2) was identified as the cause. The virus spread rapidly and the World Health Organization declared a Public Health Emergency of International Concern on 30 January. Worldwide, cases of new coronavirus disease (COVID-19) began to increase exponentially with Italy, Spain, France and the UK reporting the highest rates of new infections within Europe. Northwick Park Hospital, a large district general hospital in North West London was one of the first UK centres to experience a surge in COVID-19 admissions requiring ICU level care. In relation to its baseline critical care capacity, it was one of the worst hit centres in the UK and a substantial increase in transfers to neighbouring hospitals was necessary to ensure safe, quality care was maintained.

Objectives: We provide an overview of the ICU surge experience due to COVID-19 admissions from Northwick Park Hospital. We establish a timeline, focusing on several distinct themes including capacity, staffing, operational issues and training. Data on admissions, transfers and patient demographics is included.

Methods: All available data from the period 16 February to 12 May 2020 (coinciding with the peak ICU surge) was collected via audit of in-house electronic reporting systems (PathPoint, ePRO, ICE) and informal channels (NHSmail).

Results: We present a timeline detailing the challenges faced during the surge around establishing and maintenance of bed capacity; adoption of new staffing ratios, rotas and redeployment; equipment and medication supply; establishing new surgical pathways and 'returning to normal'.

A total of 257 patients with COVID-19 were admitted to the ICU. Length of stay on the unit ranged from 1 to 41 days. Maintenance of spare capacity was facilitated by transfers to other sites within the North West London Critical Care Network. 124 patients were transferred to satellite sites with 11 patients repatriated. Of the 22 admissions to the London Nightingale Hospital, 19 were from Northwick Park. The highest number of transfers off site in one day was 16. With the expanded ICU capacity, the peak number of inpatients in a 24-hour period was 57 and the highest admissions for one day was 15.

The ICU population had several risk factors which have since been shown to be associated with worse outcomes in COVID-19, namely age, ethnicity and obesity. Of the total admissions, 75% fell within the 51 to 80 years of age group, 84% were from a Black, Asian or Minority Ethnic background, and 58% were classified as either overweight or obese by BMI.

Conclusion: We report our experience of preparing for, receiving and management of the initial ICU surge of COVID-19 patients. We present a timeline, our patient population and report on several of the challenges we faced.

A rapid response to the COVID-19 pandemic: the North Central London Critical Care Transfer HubH. Rowley¹; S. Amdekar²; H. Hayakawa³; S. Mallory³; R. May⁴; A. Menon⁴; M. Abbink⁵; G. Emery⁵; T. North Central London Transfer Team⁶; D. Howell⁷¹Anaesthetics, Royal Free and Barnet Hospital Trust, London, United Kingdom; ²Anaesthetics, University College Hospital, London, United Kingdom;³Anaesthetics, Great Ormond Street Hospital, London, United Kingdom;⁴Anaesthetics, National Hospital for Neurology and Neurosurgery, London, United Kingdom; ⁵Inforcehub, Inforcehub, London, United Kingdom;⁶Ncl transfer hub, NHS England, London, United Kingdom; ⁷Critical care and anaesthetics, University College Hospital, London, United Kingdom**Correspondence:** H. Rowley*Intensive Care Medicine Experimental* 2020, **8(2)**: 000853

Introduction: The COVID-19 pandemic led to an unprecedented demand for critical care beds across the world(1). North Central London (NCL) Sustainable Training Partnership (STP) critical care capacity expanded by over 100%(2), presenting extreme pressures on staff and consumables, with significant logistical challenges.

Objectives: The NCL transfer team was established on 3rd April 2020, with the *primary* aim to manage the safe movement of critically unwell patients to decompress overwhelmed critical care units and optimise patient care. The *secondary* aim was to alleviate the workload of stretched referring units by organising the logistics of transfer, relaying clinical patient information and mobilising a dedicated transfer team to retrieve the patient, whilst protecting the resources at the referring site. (Diag. 1).

Methods: A central point of contact was established to streamline referrals with real-time updates of bed capacity across the sector. Three dedicated consultant-led teams were created and responsible for the movement of patients both in and out of the sector.

The Hub provided operational support to the transfer teams and sector hospitals. Ambulances provided by London Ambulance Service (LAS) were matched with teams at their base hospitals (Diagram 1). The Hub created a central gateway through which activity and outcomes could be recorded for quality improvement. A COVID-19 transfer app was designed in partnership with InforceHub (data analytics company), ensuring NHS data security governance.

Results: A total of 81 transfers were performed during April 2020, with a peak of 7 transfers per day. No critical incidences were reported. 60 patients were transferred in sector, follow up showed a 48% 30-day mortality, with men aged between 60-69 most affected, comparable to ICNARC data (3). 68% represented BAME groups, with a proportional mortality of 48%, comparable to Caucasian group at 50% in this data set.

The most prevalent complications within 30 days of admission were: PE/DVT (40%), renal failure requiring haemofiltration (36%), and ongoing ventilatory failure requiring proning, (42%). This is a small data set with inherent limiting factors.

Conclusion: NHS England (NHSE) project that the demand for critical care across London will continue to increase with plans to double the critical care capacity (2).

Critical transfers for specialist care and bed capacity will continue to require a co-ordinated response for the benefit of patients and workforce. The NCL transfer hub provided a valuable service during this novel pandemic. An NHSE advisory group is producing a National business case for a new Pan-London Critical Transfer Service.

As board advisors, our collective experiences and expertise will help to shape a broader and cohesive vision for critical care transfers in London.

Bath Tea Trolley as educational tool in Intensive Care. Analysis of theoretical framework

A. Serrano¹; F. Kelly²

¹Accp intensive care, Royal United Hospital, Bath, United Kingdom; ²Consultant intensive care, Royal United Hospital Bath, Bath, United Kingdom

Correspondence: A. Serrano

Intensive Care Medicine Experimental 2020, **8(2)**: 000865

Introduction: Bath Tea trolley is a teaching initiative that has shown excellent results improving knowledge, skills and satisfaction of health professionals. It is based on a bedside discussion between the instructor and the trainee about a topic always related to the current care of the patient. The teaching session does not last more than 5 minutes and always includes tea and cake as a refreshment. The combination of peer-to-peer bedside learning, relevant topic, and tea and cake as an element to facilitate the learning break, make the Tea Trolley a powerful learning tool. Vygotsky's, Wenger's, Bateson's levels of learning, Malinowski's, Akerlof strategy and Rich's class and gender construction concept support this educational tool.

Objectives: Discuss the theoretical framework behind Bath Tea Trolley as educational tool.

Methods: The interventions and results of the initiatives that included Bath Tea Trolley and elements of the intervention were reviewed and the theoretical framework behind them analysed.

Results: Bath Tea trolley has shown excellent results on either learning progress and trainee satisfaction. Bath Tea Trolley has been utilised as teaching tool with different learning topics related to critical care.

It has been tried in other clinical settings. From teaching sessions on airway rescue techniques and maternal sepsis, to acute kidney injury and hypoglycaemia, it has proved very successful—analysis feedback forms indicates that after receiving tea trolley training 98% of staff have felt more confident in one or more of the aspects that were covered.

This teaching technique has potential in many settings including anaesthetic rooms, wards, emergency departments, outpatient departments, GP surgeries, and administration areas. It can be adapted to suit different learning and teaching styles (visual, auditory, verbal, physical, one-on-one, group), grades of participants, and previous levels of experience.

So far, it has been included in 54 projects in Bath, with 2977 staff 'educational encounters' to date. It has been utilised in 39 other UK hospitals and internationally in countries as Australia, Canada, USA, France and Germany.

The elements of the intervention were analysed from the theoretical point of view. *The combination of peer-to-peer bedside learning, relevant topic and tea and cake as an element to facilitate the learning break make the Tea Trolley a powerful learning tool. Vygotsky's theory of "Zone of Proximal Development" and "Scaffolding", Wenger's hypothesis of "Situated learning", Bateson's levels of learning, Malinowski's concept of "Reciprocity", Akerlof's "Tit-for-tat" strategy and Rich's class and gender construction concept support this powerful educational tool.*

Conclusion: Tea trolley is based on a peer-to-peer bedside learning in which the instructor offers tea and cake to facilitate a short break that allows the intervention. It has shown to be an excellent teaching tool and has been utilised in different clinical settings nationally and internationally.

Every element of this intervention is supported on a solid theoretical framework. Peer-to-peer interaction is supported on Vygotsky's theory of "Zone of Proximal Development" and "Scaffolding", bedside offers the adequate learning context as per Wenger's hypothesis of "Situated learning" and Bateson's levels of learning, tea and cake leans on

Malinowski's concept of "Reciprocity", Akerlof's "Tit-for-tat" strategy and Rich's class and gender construction concept.

Evaluation of the impact of sideskilling workshops during Covid19 redeployment

H. O'mahony¹; R. Saleh²

¹Education and anaesthesia, St Bartholomew's Hospital, London, United Kingdom; ²Education and intensive care, St Bartholomew's Hospital, London, United Kingdom

Correspondence: R. Saleh

Intensive Care Medicine Experimental 2020, **8(2)**: 000879

Introduction: The Covid19 pandemic saw a large-scale redeployment of doctors in the UK. In expanding Intensive Treatment Unit (ITU) capacity, doctors at St Bartholomew's Hospital, often with little or no prior ITU experience, were asked to staff this area at short notice.

To support the transition we created a half day face-to-face Sideskilling Workshop (SW) prior to redeployment, aimed at non-ITU physicians. We surveyed them after two months of working in ITU to assess the impact of the SW on their self-assessed performance and morale.

Objectives: To assess the impact of the SW for non-ICU doctors being redeployed to ICU.

To assess perceived change in knowledge, confidence, and anxiety as a result of SW.

Methods: Senior ITU clinicians and the education team developed a syllabus of key topics which we felt would be most useful to doctors being redeployed.

The SW consisted of 4 stations:

1. Assessment and monitoring of the ITU patient
2. ITU observation chart, drug chart, and infusion pumps
3. Introduction to Invasive Ventilation
4. Proning a ventilated patient

Evaluation was performed as an anonymous, online post hoc survey.

Candidates were asked questions regarding:

their perceived knowledge pre-SW, immediately post-SW, and after working on ITU
 their agreement with statements regarding the impact of the SW on their anxiety and confidence surrounding redeployment
 their experiences, indicating the most beneficial element of the SW and suggested improvements

Answers were indicated on a 5-point Likert scale, and others given as comments.

Results: 34 of 104 candidates responded. 58% had no previous ITU experience. Candidates reported a mean of 1.6 point increase on a 5-point Likert scale (1 = no knowledge, 5 = expert knowledge) across all knowledge domains investigated. Ventilation knowledge had the lowest pre-SW score (1.4/5), and saw the largest mean increase: 1.94.44% indicated the 'crisis atmosphere' increased or strongly

increased their ability to take in information. 71% agreed or strongly agreed that knowledge gained from the SW was useful for working in ITU and 79% agreed or strongly agreed that the SW helped them deliver good patient care during redeployment.

82% reported decreased anxiety and 88% reported increased confidence regarding the prospect of working in ITU following the SW; 84% agreed or strongly agreed that the SW reassured them they would be well supported in ITU.

The structured patient assessment, ventilator knowledge, and reassurance/confidence featured prominently in the comments.

Suggested improvements included more interactivity and simulation.

Conclusion: The results demonstrate improved self-perception of knowledge in all aspects of ITU care explored by the workshops. Candidates also reported allayed anxiety, improved confidence, and increased camaraderie. Our workshops serve as a good model for future induction of doctors that are redeployed during further Covid19 surges, both for improving knowledge and maintaining well-being, and could serve as a foundation for further ITU education.

Introduction: Patients with persistent or chronic critical illness (P/CCI) require adaption of their clinical management plan and goals of care from an acute to a rehabilitative focus. Development and implementation of quality improvement (QI) tools such as daily or rounding checklists focused on actionable processes of care are needed as existing QI tools were not developed with P/CCI patients in mind. Actionable processes are those over which clinicians have direct control and are able to action.

Objectives: To develop end-user (patients, family, all professions of the ICU interprofessional team) consensus on the most important actionable processes of care for inclusion in tools designed to improve quality and consistency of patient/family-centred care for P/CCI patients and family.

Methods: Systematic review, end-user qualitative interviews with touch-point video, and 3 round (R) Delphi consensus of actionable processes. Participants rated actionable processes on 9-point Likert scales. Actionable processes considered critical for inclusion in future development of QI tools were those scored between 7-9 on the Likert scale by $\geq 70\%$ of participants and between 1-3 by $<15\%$ of participants.

Results: During item generation phase, we screened 13,130 references, included 114 primary studies (24,251 participants), 102 reviews and 94 abstracts and identified 40 distinct actionable processes of care. Interviews with P/CCI survivors/family (N=17) identified 15 actionable processes with 3/15 (20%) distinct from the systematic review. Interviews with clinicians (N=31) identified 35 actionable processes with 4/35 (11%) distinct from other item generation procedures (Total=47). Following iterative discussion to combine similar processes removing redundancy and to word as actionable processes in lay terms, 31 actionable processes were included in Delphi R1. Nine additional actionable processes suggested by Delphi participants were added to R2 (Total=40). Response rates were 83% (138/166) R1, 79% (109/138) R2 and 74% (81/109) R3. Of the 40 actionable processes, 34 (85%) were considered critical for inclusion in future QI tools. The top 3 actionable processes with the highest proportion of clinician, ICU survivor, and family participants considering them critical for inclusion were (1)

establish and track rehabilitation/physiotherapy goals including early mobilization while still in the ICU (99%); (2) assess and manage symptoms (i.e., pain, breathlessness, tiredness, thirst) (98%); and (3) review ongoing need for drugs used for sedation and decrease their use as able (98%). Actionable processes not considered critical for inclusion were (1) limit physiologic monitoring and routine blood tests (54%); (2) offer chaplaincy/spiritual support to the patient and family (57%); (3) provide activities to promote relaxation (e.g. music, pet visitation) based on patient preferences (62%); (4) de-escalate (including change to oral instead of IV drugs) or stop ICU pharmacotherapy and restart previous comorbidity pharmacotherapy (62%); (5) enable appropriate and timely discharge planning (67%); and (6) conduct multi-disciplinary rounds that include non-ICU subspecialty teams (68%).

Conclusion: The large number of items considered critical for inclusion in QI tools reflects the complex and multi-factorial needs of PCCI patients and families. Further consensus building work is planned to enable development and testing of QI tools.

Intensive Care Medicine Experimental 2020, **8(2)**: 000956

Introduction: Given the intense healthcare demand of COVID patients (COVp) during the pandemic, ICU beds had to be tripled. Non-COVID patients (nCOVp) were reduced to a lower number than they used to be. Ordinary hospital activity was interrupted due to the high COVID patients demand.

Objectives: To analyze the nCOVp admitted in our ICU during the pandemic in contrast to those admitted in the same period of time the previous year.

Methods: A retrospective descriptive observational study of nCOVp admitted in our ICU during the pandemic, from March 14th to June 1st 2020, versus the patients admitted in the same period of time the previous year. The number of COVp-nCOVp patients were analyzed, also: sex, age, provenance, diagnosis, severity, hospital stay and nCOVp mortality, as well as the admissions in the same period of time in 2019.

Results: From March 14th (admission of the first COVp) to May 4th 2020, 48 COVp were admitted in our ICU (last COVp the 1st June). In the meantime, 32 nCOVp were admitted, whereas 101 patients were admitted in 2019. It's a polyvalent ICU with 10 beds, which were expanded during the pandemic to 36 beds. High occupation period (HOP) was from March 14th to April 13th 2020, in which 40/48 (83,3%) COVp and 4/32 (12,5%) nCOVp were admitted. Over this period in 2019, 37/101 (36,7%) patients were admitted. 2020 nCOVp: 23 (71,9%) were males, with a mean age of 54,8 y.o. (CI 95% 49,5-61,2). 18 patients (56,2%) came from emergency department. Ten patients (31,2%) were admitted because of different etiologies of shock, which was the most frequent reason for admission, followed by: acute coronary syndrome (ACS) 6 (18,7%), cardiac arrhythmias (CA) 3 (9,3%), cardiorespiratory arrest (CRA) 3 (9,3%), neurological disorders (ND) 3 (9,3%), acute respiratory failure (ARF) 3 (9,3%), polytrauma (PT) 2 (6,2%), and 2 (6,2%) oncological surgery postoperative (OSP). The average APACHE II was 20,8 (CI 95% 16, 2-25,4) and 27 (CI 95% 19, 6-34,4) during HOP, with an average hospital stay of 5,5 days (CI 95% 2, 3-8,7) and 9 (28,12%) patients died, two of them during HOP. As for the patients admitted in 2019: 61 (60,4%) were males, with an average age of 63,8 y.o. (CI 95% 60,5-67,1). 80 patients (79,2%) came from the emergency department. The most frequent reason for admission was ACS with 23 patients (22,8%) followed by: ARF 15 patients (14,9%), shock 14 patients

(13,9%), CA 13 patients (12,9%), ND 7 patients (6,9%), OSP 7 patients (6,9%), CRA 5 patients (4,9%). The average APACHE II score was 15 (CI 95% 13, 6-16,4), and the average hospital stay of 3,8 days (CI 95% 2,8-4,7). 12 patients died (11,9%).

Conclusion: During the pandemic, there has been a significant reduction of non-COVID admissions in our ICU. 2020 patients had a higher APACHE II score, a longer hospital stay and an increase in mortality regarding 2019 patients.

A scoping review into the rationale and behaviours underpinning routine blood tests in critically ill patients, effect on patient outcomes and possible strategies to reduce this

F. Davies¹

¹Respiratory Medicine, Glan Clwyd Hospital, Rhuddlan Road, Bodelwyddan, Rhyl, UK, Bodelwyddan, United Kingdom

Intensive Care Medicine Experimental 2020, **8(2)**: 000963

Introduction: Unnecessary blood tests in the critically ill lead to adverse patient outcomes and significant financial cost. It has been shown that 90% of patients admitted to critical care will be anaemic by day 3 of their stay (1). Several physiological mechanisms that protect against anaemia are impaired in the critically ill (2), and repeated blood tests make a significant contribution towards iatrogenic anaemia. Unnecessary blood tests can also lead to organ dysfunction, prolonged length of stay, and increased mortality. Unnecessary blood tests also incur significant expense, with one study estimating blood tests cost £362,587.80/year was spent per year on blood tests (3).

Objectives: This review aims to identify the outcomes of routine blood tests, rationale and behaviours underpinning routine blood tests in critically ill patients, and possible strategies to reduce this in the future.

Methods: A scoping review was conducted in accordance with Arksey and O'Malley's principles (4). As there is not a large amount of quality data in this area, a scoping review was chosen over a literature review to allow greater flexibility. This review did not attempt to evaluate the quality of the literature as there is not enough quality data published yet. A PEO format was used to formulate the research question. OVID, EMBASE and Medline were searched with the key terms 'intensive care' and 'routine blood tests'. 432 articles were identified and reduced to 17 articles which were included in the final review. Thematic analysis was conducted on the texts included in the final review in accordance with Braun and Clarke's key steps (5).

Results: Three key themes were identified, with associated subthemes - *outcomes of routine blood tests, the rationale underpinning this, and strategies to reduce this*. Patient centred outcomes featured heavily in the analysis, as this is clinically most important, and widely undisputed. The literature demonstrated that unnecessary blood tests can lead to iatrogenic anaemia, organ dysfunction, increased length of stay and mortality. The relationship between iatrogenic anaemia and an increased need for transfusion was less concrete, with some studies demonstrating a reduction in RBC transfusion and others failing to demonstrate a difference. Significant financial costs were associated with unnecessary blood tests and the follow up incurred, as well as the cognitive demand on clinicians of reviewing blood results. Rationale behind routine and unnecessary blood tests was discussed in several papers. Rationale was influenced by clinicians knowledge, time constraints on the decision maker, and reflex ordering. It is often easier to adopt a 'one-size-fits-all' strategy when it comes to blood tests in order to minimize decision making. Additionally, less experienced clinicians have a tendency to order more blood tests and a lack of guidelines in this area means there is significant variation between clinicians. Environmental factors influencing routine blood tests were the presence of central/arterial

lines, increased frequency of blood tests in intensive care and increased use of point of care testing. Several strategies were employed by the literature, with bundled interventions demonstrating the best outcomes. Staff education for nurses and clinicians was a common theme. There were no local/national/international guidelines identified which needs addressing to underpin practice in this area. This can be further supported by equipment such as low-volume blood tubes, paediatric blood tubes and blood conservation sampling devices (BCSDs). Modification of checklists and electronic ordering systems also play an important part in reducing the amount of unnecessary blood tests.

Conclusion: This scoping review has identified several themes in the literature which provide evidence that routine blood tests can lead to adverse outcomes for patients, and unnecessary costs for healthcare organizations. Some key behaviours and influencing factors have been identified as important reasons for routine blood tests, that can be targeted in order to change practice. This review has identified several promising strategies to reduce the amount of unnecessary blood tests in ICU, which when combined can lead to better patient care.

The results of this scoping review will inform ongoing work in this area and may help to develop consensus led national guidelines and a gold standard model for blood tests in ICU. The authors hope to develop consensus around new guidelines and implementation of a package of change incorporating several of the strategies identified in this review. It is anticipated that this scoping review will help to inform core outcomes to measure future progress in this area.

Intensive Care Medicine Experimental 2020, **8(2)**: 000976

Introduction: To meet Covid-19 demands, intensive care units (ICU) had to rapidly expand capacities with help of health care workers redeployed outside their regular scope of practice. During the height of the pandemic, (re-)deployed ICU personnel was surveyed regarding level and quality of supervision, quality and safety of care provided, and interprofessional collaboration.

Methods: In an international, prospective, observational cohort survey study, physicians, nurses and allied health personnel, redeployed at ICUs in Utrecht, New York and Dublin completed the survey. Data analysis focused on: Supervision; Quality and safety of care; Collaboration, communication and atmosphere; Recruitment, scheduling and team composition; Organization and facilities.

Results: Quality and safety of care were perceived as lower than usual but acceptable by the majority respondents (n=368). Supervision, was rated less than optimal but overall quality was acceptable to good. Where IC-trained nurse-to-patient ratios decreased most critically (Utrecht), nurses were most critical about supervision and quality of care. The working atmosphere was overwhelmingly felt as collaborative and supportive. Continuity of working environment and team composition, informal ('curbside') consultations and availability of protocols were critical mediators.

Conclusion: A surge of critically ill patients can be accommodated by IC trained personnel on expanded or new ICUs when assisted by redeployed non-ICU trained personnel. Although quality of care, supervisory capacity, training background and experience were compromised to meet COVID-19 demands, key features to maintain acceptable quality of care included stable teams matching less with more experienced personnel allowing for adequate supervision, better than normal interprofessional collaboration and a robust culture of informal consultation.

Intensive care unit (ICU) referrals and admissions at a district general hospital (DGH) in light of the COVID-19 pandemic

J. Blair¹; E. Naughton¹; N. Pradhan¹

¹Intensive Care, The Shrewsbury and Telford Hospital NHS Trust, Shrewsbury, United Kingdom

Correspondence: J. Blair

Intensive Care Medicine Experimental 2020, **8(2)**: 001010

Introduction: The COVID-19 pandemic has led to an increase in ICU referrals and admissions across the UK during 2020 [1]. Intensive care beds are a limited and expensive resource and decisions on patient admission are often very challenging [2]. Proformas help to standardise documentation and decision logging during patient referrals [3]. They provide easily accessible evidence in case of a future referral and allow audit of decision-making processes. A preliminary survey of doctors working in a DGH ICU was undertaken to assess the current referral and admission process in expectation of an increased volume of work.

Objectives: As a result of the survey, three main areas for improvement were identified:

1. To maintain a record of all ICU referrals and decision-making processes
2. To reduce the time taken for documentation of referrals and admissions
3. To improve the quality and appropriateness of referrals from parent specialities

Methods: A proforma was designed for dual use as a referral and admission document. All referrals were recorded on paper and staff received training on how to apply the proforma. After assessment of each referral, irrespective of admission outcome, a completed copy of the proforma was placed in both the patient's notes and a dedicated referrals folder.

After one month, a further survey was designed to assess the response post-implementation of the proforma. All referrals made over a three-month period between April and June 2020 were audited.

Results: The initial survey received 12 responses. Prior to the COVID-19 pandemic, documentation of any referral or admission took on average 10-15 minutes. All survey participants felt that referring teams did not have a good understanding of the role of ICU care and estimated that up to 40% of all referrals received were inappropriate.

The follow-up survey received 14 responses. Implementation of the proforma reduced the time taken to document a referral or admission on average by 5-10 minutes. Twelve participants found the proforma a useful aid, helping to provide clear documentation and ease communication between ICU team members.

Less than 9% of the referrals made between April and June 2020 were admitted to ICU with over 32% of referrals deemed unsuitable for further escalation. Approximately 50% of referrals were made by registrars, with 13% discussed by consultants. The median age of patients referred was 67.5 and the most common reason was for respiratory deterioration.

Conclusion: This quality improvement project successfully reduced the time taken to document ICU referrals and admissions. Use of a proforma has provided many benefits, including standardisation of documentation, decision logging and improvement of intra- and inter-team communication.

Only a small proportion of patients referred to ICU have been suitable for admission. A teaching session is being designed so that referral information can be fed-back to parent specialities. Referrals will be re-audited after this.

Data analysis of this project has been limited by incomplete proforma documentation from participating users.

Correspondence: M. Watanabe

Intensive Care Medicine Experimental 2020, **8(2)**: 001027

Introduction: With early reports from other countries of the enormous strain COVID-19 had placed on healthcare systems, a decision was made at Buckinghamshire Healthcare NHS Trust to increase the capacity of Critical Care beds and redeploy junior doctors from other specialities to prepare for a rapid surge in patient numbers.

To facilitate ongoing daily review of patients, a structured assessment proforma was produced to be used in all Critical Care areas for COVID-19 patients.

Principles by which the proforma were designed included: easy and rapid to complete (by doctors with limited ICU experience), enables rapid decision-making by senior ICU doctors, ensures thorough and appropriate reviews.

The benefits of protocolisation in ensuring patient safety, standardising assessments, and minimising error have previously been detailed in the literature(1,2).

This project aimed to determine whether the implementation of a structured assessment proforma had enabled appropriate daily ICU reviews to be conducted despite the challenges posed by the pandemic.

Methods: A structured assessment proforma was produced by members of the Consultant body, agreed by the department, and subsequently disseminated to Critical Care areas in early April.

Clinical records of all patients admitted to ICU within a random one-week period were reviewed.

An online survey was sent out to all junior doctors working on ICU. The survey asked two key questions:

How confident they felt in conducting an ICU review prior to using and with the proforma.

How likely they felt they were to omit important information prior to using and with the proforma.

Answers were recorded as a score between 0 and 10 and paired-samples t-tests conducted.

Results: All proformas completed within a random one-week period (30/05/2020 to 05/06/2020) were reviewed (n=47), from a total of 8 patients admitted on ICU with COVID-19.

The date was written on 100% and time on 89.4% of proformas. 97.9% of the proformas contained an appropriate A to E assessment (as defined by completion of the proforma), 100% contained a summary of main clinical issues, and a documented plan. 100% of the proformas had a named doctor completing it and 85.1% had a clearly documented Consultant.

17 doctors completed the survey (sent out on 29/05/2020).

There was a significant difference in confidence prior to using (mean score = 6, SD = 3.41) and with the proforma (mean score = 8.76, SD = 1.09); $t(16) = -3.62$, $p = 0.003$.

There was a significant difference in how likely doctors felt they were to omit important information prior to using (mean score = 4.76, SD = 2.54) and with the proforma (mean score = 7.12, SD = 2.37); $t(16) = -2.59$, $p = 0.02$.

Conclusion: Implementation of a structured assessment proforma has enabled appropriate daily ICU reviews to be conducted despite the surge in patient numbers during the pandemic.

With a possible second wave on the horizon, it may be prudent for other hospitals to implement a similar proforma to facilitate daily reviews of COVID-19 patients on ICU.

Emergency planned Hub & Spoke system in support to COVID-19 ICUs in Lombardy: the experience of Niguarda Hospital

F. Fossi¹; F. Pozzi¹; F. Zumbo¹; C. Scattolini¹; L. Pressato¹; G. Chevallard¹; M. Zaniboni¹; F. Curto¹; A. Chieregato¹

¹Neurointensive care unit, Grande Ospedale Metropolitano di Niguarda, Milan, Italy

Correspondence: F. Pozzi

Intensive Care Medicine Experimental 2020, **8(2)**: 001072

Introduction: On March 8th a regional law planned a new Hub and Spoke system for time-dependent pathology in order to allocate resources for an expected increase in COVID patients [1] and to divide hospital pathways to prevent further diffusion of the pandemic. By Regional Decree Niguarda Hospital (Milan) become Hub, for direct admission of major traumas, strokes and neurosurgical emergencies as well as Hub secondary referral for 16 Spoke hospitals. The serving area was at least of 6376970 inhabitants (63.4% of the total Lombardy population). Duration of Hub function was from March 8th to May 8th .3.4 Therefore the Hospital augmented our NICU beds from 11 to 20 beds.

Objectives: The aim of the study was to report the main findings of the Hub activity.

Methods: All patients admitted since the 8th of March to the 8 of May to the Neurointensive care unit of the Niguarda Hospital were selected. The patients admitted in the same period of the previous year (2019) was also selected as control group. All the data were retrospectively obtained from the institutional clinical reports. The medical staff remained the same, increasing work commitments by 25%. The nursing staff was increased by 23 untrained nurses. Access to our ICU was allowed only after negative nasal swab and bronchoalveolar lavage for COVID-19 (patients were held in a dedicated room for 6 hours while waiting for the results). Family visiting and interviews were unchanged. The activity of the Hub center lasted 2 months, infact once the COVID epidemic the Regional Government declared since the 8th of May to revert the system [2].

Results: 151 consecutively patients were admitted to our ICU in 2020 compared to 60 in 2019. Table 1 shows patient characteristics. Twelve of them became utilized organ donor accounting for 2/3 of all the organ donors in Lombardy. In the same period of the 2019 utilized organ donors from Niguarda were 3 (7.8% of the 38 organ donors in our region)The absolute number of patients was 2.5 times compared to 2019, for all the quota of patients arriving from Spoke areas (Figure 1).Figure 2 shows the occupation rate trend showing a progressive increase in the occupation rate along the days even once the COVID patients in the Lombardy ICU was in a progressive and constant reduction. An increase of withdrawal-withholding was observed.

Table 1

		2019 march 8 to may 8 (Niguarda)	2020 march 1 to may 8 (Niguarda)
Overall (n, %)		60	151
Age (n, %)		35 (58.3%)	89 (59.6%)
age (years, Median (IQR))		52 (27-5)	52 (21-7)
age (years, Media -SD)		48.7 (26.3)	50.2 (27.6)

	not traumatic spine emergencies (n, %)	1 (1.7%)	5 (3.3%)
	other neurovascular diseases	1 (1.7%)	0 (0%)
ischemic Stroke (n, %)		5 (8.3%)	22 (14.6%)
Discharged alive (n, %)		51 (85%)	117 (77.5%)
	LOS (Median, IQR)	5 (1-5)	4 (1-3)
	Discharged alive inside the Hospital (n, %)	51 (85%)	107 (71.5%)
	LOS (Median, IQR)	5 (1-5)	3 (1-3)
	surgical regular ward (n, %)	19 (31.7%)	65 (43.1%)
	critical care unit (n, %)	14 (23.3%)	13 (8.6%)
	medical regular ward (n, %)	3 (5.0%)	11 (7.3%)
	intensive care unit (n, %)	11 (18.3%)	9 (5.9%)
	spinal injury unit (n, %)	3 (5.0%)	6 (3.9%)
	burns unit (n, %)	0 (0%)	3 (2.0%)
	Discharged to another hospital (n, %)	1 (1.7%)	11 (7.3%)
	LOS (Median, IQR)	11	6 (3-3)
	local transfer (n, %)	1 (1.7%)	4 (2.6%)
	by means of CR055 (n, %)	0 (0%)	4 (2.6%)
	by other means (n, %)	1 (1.7%)	4 (2.6%)
Death in ICU (n, %)		9 (15.0%)	34 (22.5%)
	LOS (Median, IQR)	3 (1-3)	3 (1-3)
	Death within 3 days	6 (10.0%)	26 (17.2%)
	Organ donor (n, %)	6 (10.0%)	19 (12.6%)
	Withdrawal (n, %)	3 (5.0%)	11 (7.3%)
	LOS (Median, IQR)	3 (1-3)	3 (1-3)
	Withdrawal (n, %)	1 (1.7%)	11 (7.3%)
	LOS (Median, IQR)	3	4 (1-3)

Conclusion: The comparison between the trends of the amount of COVID patients in Lombardy and of the amount of patients entering our Hub shows the support given to the system. In Lombardy a lack of available ICU beds was evident [3]. In such extraordinary condition the creation of an emergency Hub and spoke system seemed to have indirect benefits.

Intensive Care Medicine Experimental 2020, **8(2)**: 001080

Introduction: By previous collected retrospective cohort data analysis, our team revealed introducing shared decision making on early Tracheostomy (less than 14 days) in prolonged intubated critical patient improve total Tracheostomy rate, reduce ventilator days and length of hospital stay, and shorten the Tracheostomy decision time delay.

Methods: Medical record of tertiary medical center adult ICU admitted respiratory failure patient from Jan. 1st, 2018 to Dec. 31st, 2019 was retrospectively reviewed as post-SDM (after Jan. 1st, 2017) intervention follow up period for analysis. Data including total Tracheostomy rate, early and late Tracheostomy rate, ventilator weaning rate and ventilator days, in-hospital mortality, and length of hospital stay of prolonged intubated patient were collected. SPSS was applied for statistically analysis, and a p-value less than 0.05 was considered significant difference.

Results: By inclusion and exclusion criteria, medical records from 366 patients from Jan. 1st, 2018 to Dec. 31st, 2019, who were considered prolonged intubated s/p Tracheostomy SDM, were applied for further analysis. Among them the early and late Tracheostomy rate was 41% and 69% individually. In compared to previous reported pre-SDM data, ventilator weaning rate (289(79.2%) vs. 89(69.3%), p < 0.05), ventilator days (39.3 +/- 20.5 vs. 42.3 +/- 17.3, p < 0.05), in-hospital mortality (10.3% vs. 7(3.3%), p: 0.737), and length of hospital stay (61.2 +/- 23.4 vs. 64.3 +/- 29.2, p: 0.04) of prolonged intubated patient. The continued impact on introducing SDM was impressed, with improving ventilator weaning rate, reduced ventilator days, and shortening the length of hospital stay of prolonged intubated patient by 3 days for each in compared in between groups. The Tracheostomy decision making time delay was found 6 days less after SDM introduced was also consistently noted.

Conclusion: Our retrospective cohort study follow-up data revealed introducing shared decision making on early Tracheostomy in prolonged intubated critical patient persistently improve total Tracheostomy rate, improve ventilator weaning rate, reduce ventilator days and length of hospital stay, and shorten the Tracheostomy decision time delay.

Intensive Care Medicine Experimental 2020, **8(2)**: 001083

Introduction: Resuscitation Code Status is a controversial topic that often fails to obtain truly informed consent and is highly contextual depending on the nature and severity of illness. While studies have identified DNR status in ICU patients as a risk factor for mortality and

adverse events, no literature has targeted elderly, critically ill patients for whom these conversations were intended.

Objectives: Our study aimed to assess the relationship between code status and mortality in critically ill, elderly patients admitted to the ICU. As a secondary outcome, we sought to analyze the impact of an informed code status discussion on resource utilization. Specifically, our study focused on ascertaining if critically ill, elderly patients with DNR code status have different hospital outcomes relative to similarly ill patients who are full code.

Methods: Data for this retrospective study was obtained through a review of medical records at Sault Area Hospital, an accredited 289 bed large community hospital in Northern Ontario spanning a 5-year period. During this time, 613 patients were admitted to the ICU, 163 of whom met the inclusion criteria of being ≥ 70 years of age and APACHE II score ≥ 20 . A Kaplan-Meier Survival Curve examined survival to hospital discharge comparing DNR and full code groups. DNR code status was defined as omission of cardiopulmonary resuscitation in the event of a cardiac arrest.

Results: 64 patients (39.3%) had a DNR order based on a documented conversation within 72 hours of admission. The remaining 99 (60.7%) patients were deemed to be full code. There was a significant association between DNR status and increased mortality ($p=0.004$). Patients with DNR code status stayed fewer days in ICU (7.7 days (± 3.6) vs. 9.9 days (± 8.3), $p=0.03$) and used less resources (4.5 diagnostic images/pt (± 3.4) vs. 6.2 diagnostic images/pt (± 6.4), $p=0.02$; 0.9 consultations (± 1.1) vs. 1.1 consultations (± 0.9), $p=0.48$) than similarly ill patients who were full code with no benefit in long term survival at 21 days. Patients with full code status had a higher average cost of hospital and ICU admission in comparison to patients with DNR status (59,704.70CND/pt. vs 49,589.10CND/pt. respectively).

Conclusion: Our study has demonstrated the benefit of having early, informed code status discussions in the ICU. In our study population, DNR code status is associated with significantly reduced resource utilization. Furthermore, no mortality benefit was seen in DNR vs full code patients after 21 days suggesting that resuscitation limits may be objectively placed in long stay, elderly ICU patients.

LocSSIPs in an intensive care setting: generating solutions to improve compliance

C. Chaplin¹; N. Shah¹; N. Anderson²; R. Saleh²

¹Medical school, Queen Mary University of London, London, United Kingdom; ²Intensive care, St Bartholomew’s Hospital, London, United Kingdom

Correspondence: R. Saleh

Intensive Care Medicine Experimental 2020, **8(2)**: 001088

Introduction: In 2015, NHS England published the National Safety Standards for Invasive Procedures (NatSSIPs), based on analysis of Never Events, Serious Incidents and near misses. These standards provided the basis for the creation of Local Safety Standards for Invasive procedures (LocSSIPs). To meet our ITU standards, at least 90% of invasive procedures performed should have a LocSSIP completed: this takes the form of a specific checklist, conducted by a team pre-, during, and post-procedure.

Objectives: To assess LocSSIP compliance in our Intensive Treatment Unit (ITU) with a view to generating solutions for improved compliance

Methods: We consulted the paper notes for all patients resident on two ITU wards to take a ‘snapshot view’ of compliance at a single point in time.

In situ invasive devices and corresponding LocSSIPs were identified from the patients’ notes and recorded. Devices to be recorded included: Dialysis Catheters, Arterial Catheters, Peripherally Inserted Central Catheter (PICC) line, Central Venous Catheters, Tracheostomy, Bronchoscopy, Chest Drain, Extracorporeal Membranous Oxygenation (ECMO) Catheters, and Endotracheal Tubes.

Results:

There were a total of 27 devices in situ across both ICU wards. Only devices that were in situ at the time of data collection were audited for an accompanying LocSSIP. Of 27 invasive devices, LocSSIPs were only identified for 3, a compliance rate of 11.1%. The only devices for which LocSSIPs had been recorded were tracheostomies and CVCs

Device	Number in situ	Completed LocSSIPs	Compliance (%)
Dialysis Catheter	1	0	0
Intercostal Drain	2	0	0
PICC Line	2	0	0
Tracheostomy	4	2	50
Central Venous Catheter	9	1	11
Arterial Catheter	9	0	0

Conclusion: The barriers to implementing LocSSIPs in the 2018 NatSSIP implementation survey include: lack of time, staff culture, limited expertise, and poor clinical engagement.

Education on LocSSIPs is already part of doctors’ induction and nurse education. The time taken to conduct a LocSSIP checklist is not significant. Staff culture of LocSSIPs being considered ‘someone else’s problem’, and not in the forefront of the team’s mind may play a part. However, given that details of the procedure are often recorded electronically, it seems that the systemic culture of not having the LocSSIP easily available is a significant factor in its omission. The team is usually at least a doctor and a nurse, so educational reinforcement must target both groups. We are contacting our device manufacturers to try and attach our LocSSIP forms to the kit used for the procedures – this

would ensure a visual reminder and access to the form is easy for each procedure.

Communicating with relatives of patients admitted to critical care during the Covid-19 pandemic

D. El-Dalil¹; C. Morris²; G. Gibbon¹

¹Critical Care, Queens Medical Centre, Nottingham, United Kingdom; ²Critical care, Nottingham City Hospital, Nottingham, United Kingdom

Correspondence: D. El-Dalil

Intensive Care Medicine Experimental 2020, **8(2)**: 001101

Introduction: Relatives of patients in critical care experience high levels of stress and anxiety [1,2,3]. Prioritising good communication and facilitating visiting are the most important factors in meeting the needs of families [2]. During the COVID-19 pandemic, infection control procedures have prevented family and friends from visiting their loved ones, potentially having a negative psychological impact on patients' relatives [3].

Objectives: To develop a system to ensure comprehensive and effective communication with the relatives of patients admitted to critical care at Nottingham University Hospitals Trust during the Covid-19 pandemic.

Methods: A multidisciplinary forum developed a communication strategy whereby the next of kin was updated daily and then asked to relay information to other friends and family. This was an iterative process guided by online feedback from junior doctors and nursing interviews. Feedback from medical and nursing staff was explored using thematic analysis and utilised to refine the programme.

Results: Informal comments from patients' relatives have been largely positive and feedback from doctors and nurses suggest the process was achievable. Data collected from 55 online feedback forms and 16 nursing interviews were analysed and 7 main themes and 4 sub themes were identified. Overarching themes included 'Updates are Important' and that there is a 'Role for Doctor and Nurse Updates'. The theme 'Be Flexible' identified that daily updates were sometimes overwhelming and may contribute to relative anxiety. Other themes included 'Utilise Video Calling' and creating a 'Universal Communication Document'.

Conclusion: Feedback from Doctors and Nurses has shown that the process is feasible and acceptable to both groups of staff. Continuing to pro-actively contact a named relative daily is important and ensures relatives are well informed in the absence of visiting times. We aim to collect formal feedback from patients' relatives to evaluate how well we are meeting their needs. A communication booklet is in development to help aid clarity of documentation and to provide a single area for recording communications. We will be exploring simulation based teaching in managing difficult conversations over the phone.

Finding resilience against burn-out syndrome and moral distress in an academic intensive care unit

T. Witter¹; J. Hancock¹; S. Comber²; O. Kits³

¹Critical care, QEII HSC, Halifax, Canada; ²Economics, Dalhousie University, Halifax, Canada; ³Department of community health and epidemiology, Dalhousie University, Halifax, Canada

Correspondence: T. Witter

Intensive Care Medicine Experimental 2020, **8(2)**: 001139

Introduction: Burnout Syndrome (BOS) is the result of chronic exposure to stress in the workplace and is characterized by emotional

exhaustion, depersonalization and reduced personal accomplishment (1). Moral Distress (MD) occurs when individuals are placed in situations that are at odds with their core values and have little power to make changes (2). BOS and MD is a rising problem in Medicine and in Intensive Care in particular, not only affecting healthcare providers (HCPs) and their families but also affecting the quality of care provided by the HCPs (3,4). In a recent survey done in our ICUs, we found a high prevalence of BOS and MD amongst all groups of health care professionals using the MBI. While the MBI is well validated to detect BOS and MD, it lacks the depth to identify causes of BOS and MD.

Objectives: To perform an in-depth analysis of causes of BOS and Moral distress amongst HCPs in an academic intensive care unit using focus group methodology.

Methods: Focus groups were conducted with HCP groups and were cohorted based on professional designation to facilitate psychological safety. The session were open to all members of the health care team and participation was voluntary. The focus group interview guide used in the sessions underwent iterative review and explored the daily work environment at both the organizational and individual level. It probed around burnout, moral distress, team dynamics, currently used coping strategies and interventions that were thought to be helpful in building resilience.

All sessions were audiotaped and transcribed verbatim. A qualitative software (Quirkos - www.quirkos.com) was used to store, sort, index and code the information provided in the session. All transcripts were read individually and codes to relevant passages were collected under themes, disagreements were resolved by consensus.

Results: We were able to recruit 35 HCPs for 6 focus groups: 1 group with MDs, 1 group with RTs and 4 groups with RNs, capturing 19% of the RNs, 20% of the RTs and 43% of the physicians.

There was a great degree of overlap between themes associated with BOS and MD. We were able to identify three overarching themes causing BOS and MD: organizational issues, exposure to high intensity situations and poor team experience. These themes were further broken down into multiple subthemes, again with a high degree of overlap between BOS and MD.

When asked about coping strategies for dealing with workplace stressors participants in all groups named self-constructive (e.g. performing a workout) and self-destructive examples (e.g. excessive alcohol intake). Participants suggested multiple strategies around interventions that they felt would help build resilience. These interventions can be categorized according to the three major themes.

1. Organizational: Improved staffing and infrastructure, improved education
2. Exposure to high intensity situations: implementation of regular debriefing sessions, de-stigmatizing the need for support, mental health wellness days, long-term follow up of ICU survivors, and addressing workplace violence.
3. Poor team dynamics: improved relationship building (inter and intra-professional), teaching respectful communication and behaviour, acknowledgement of hard work and job well done, support for just-culture, hospital leadership engagement and management support.

Conclusion: We found three main themes when looking at associations with BOS and MD in our ICU HCPs: Organizational, exposure to high intensity situations and poor team dynamics. Some of the suggestions provided by the participants for interventions to reduce BOS and MD are challenging to execute while others are doable (e.g. regular debriefing sessions, improved communication) and should be considered for implementation.

Correspondence: W.C. Huang
Intensive Care Medicine Experimental 2020, **8(2)**: 001151

Introduction: Chronic obstructive pulmonary disease (COPD) in Asia was different from Europe in higher cigarette smoking rate and more severe air pollution. Varies inhaled COPD medications had safety concern in acute myocardial infarction (AMI). The aim of this study was to investigate the effect of COPD in Asia AMI patients and real world safety of COPD medications in AMI patients.

Methods: We conducted a nationwide cohort study extracted data from the Taiwan National Health Insurance Research Database. Patients who hospitalized between 2000 and 2012 with a primary diagnosis of first AMI were included. Among the 186,112 prospective AMI patients, COPD was diagnosed in 13,065 (7.0%) patients. AMI patients without COPD were 1:1 matched by propensity score matching. AMI cohort was further divided to STEMI and NSTEMI cohort. STEMI without COPD was matched by propensity score. Cox proportional hazards regression model was used to estimate adjusted hazard ratios (HR) with 95% confidence intervals (95% CI).

Results: During 12 years follow up, there were 18405 (77.65%) and 16093 (67.89%) deaths in AMI with COPD and without COPD group, respectively. The adjusted hazard ratio (aHR) of mortality in AMI with COPD group was 1.12 (95% CI 1.09 to 1.14). In STEMI with COPD group, aHR was 1.20 (95% CI 1.14 to 1.25). NSTEMI with COPD, aHR was 1.07 (95% CI 1.04 to 1.10). Using short-acting inhaled bronchodilators in AMI patients increased mortality (short acting beta-agonist: aHR 1.2, 95% CI 1.16 to 1.23, short acting muscarinic antagonist: aHR 1.3, 95% CI 1.26 to 1.34). Corticosteroids using also increased 10% mortality (aHR 1.10, 95% CI 1.07 to 1.14). However, long acting inhaled bronchodilators reduced mortality (long acting beta-agonist: aHR 0.87, 95% CI 0.81 to 0.94, long acting muscarinic antagonist: aHR 0.82, 95% CI 0.69 to 0.96).

Conclusion: In Asia, AMI patient with COPD was associated with higher mortality compared with those without COPD. Guideline recommended AMI medications decreased mortality in patient with or without COPD, but they were underused in Taiwan. Using inhaled short-acting bronchodilators and corticosteroids in AMI patient reduced survival. On the contrary, long acting inhaled bronchodilators were associated with survival benefit. Appropriate COPD medications and adequate standard AMI medications in AMI patient were equal crucial in improving long term survival.

The role of neuropathic pain in critical illness survivors. A prospective 12 month follow-up study

A. Calvo Barrera¹; A. Ojeda²; M. Chanza³; D. Christian⁴; C. Ferrando¹; V. Zafra⁵

¹ANAESTHESIOLOGY, CRITICAL CARE UNIT, Hospital Clínic de Barcelona, Barcelona, Spain; ²Aanesthesiology, ojeda@clinic.cat, BARCELONA, Spain; ³Anaesthesiology, Hospital del Mar, Barcelona, Spain; ⁴Anaesthesiology, pain unit, Hospital Clínic de Barcelona, Barcelona, Spain; ⁵Nurse of critical care unit, Hospital Clínic de Barcelona, Barcelona, Spain

Correspondence: A. Calvo Barrera
Intensive Care Medicine Experimental 2020, **8(2)**: 000014

Introduction: Post-intensive Care Syndrome (PICS) is a major health problem that describes impairment in their physical, cognitive, or mental health status. Neuropathic pain (NP) is related with worst pain-related interference and poor quality of life (QoL). Despite of that, the role of NP in Critical Illness survivors (CIS) and its relationship with PICS has been not establish.

Objectives: The goal of this study was to evaluate the prevalence and impact of NP in CIS, and its relationship with anxiety, depression and post-traumatic stress disorder (PTSD), majors PICS components

Methods: We conducted a prospective 12-month follow-up study. Patients admitted in ICU were consecutively recruited and were evaluated before ICU discharge, and at 3 and 12 months after. Evaluations included: NP (DN4: Douleur Neuropathique en 4 Questions); pain intensity and pain related-interference (BPI-LV: Brief Pain Inventory Long Version); anxiety and depression (HAD Test: Hospital Anxiety and Depression Scale); QoL (EuroQoL Test 5 dimension, 3 levels); PTSD (PTSD Checklist–Civilian Version).

Table 1. Evolution of pain, NP and PICS variable.

QUESTIONNAIRE	ICU DISCHARGE(%)	3 MONTHS(%)	12 MONTHS (%)
BPI INTENSITY >3	78,6	37	37,5
BPI INTERFERENCE>3	84,1	42,6	46,2
DN4>4	25,7	37	24,4
HAD ANXIETY		39,6	31,7
HAD DEPRESSION		28,3	31,7
PTSD POSITIVE		15,7	24,3

Results: A DN4 test positive was related with a major pain intensity (BPI intensity score >= 3), worse pain-related interference (BPI interference score >= 3), worse value of EuroQoL visual analogue scale and more depression in the 3 and 12-month follow-up, and more anxiety and PTSD in the 12-month (p<0,05).

Conclusion: Neuropathic pain is common in Critical Illness survivors, affects their QoL and interferes with their daily live activities. Moreover, its related with anxiety, depression, and PTSD, key components of PICS.

Correspondence: A.G. Vassiliou
Intensive Care Medicine Experimental 2020, **8(2)**: 000021

Introduction: The mineralocorticoid receptor (MR) belongs to the steroid receptor superfamily. Discoveries from the past two decades reveal that MRs are expressed in non-epithelial cells and exert numerous additional functions beyond electrolyte handling in the distal tubule of the kidney. The recent identification of MRs in immune cells has led to novel functions of MR, such as modulation of immunity and inflammation. The MR is unique in this family in that it has two ligands, aldosterone and cortisol. Aldosterone and cortisol have a similar affinity for the MR.

Objectives: To evaluate the expression of MR in peripheral polymorphonuclear cells in critical illness for a 13-day period.

Methods: Forty-two mechanically ventilated, steroid-free patients were studied. Blood samples were collected on admission in the ICU and on days 4, 8, and 13, to measure MR expression. Twenty-five age- and sex-matched subjects were used as controls.

Results: Compared to healthy controls, severely ill patients on admission in the ICU exhibited a 12-fold lower MR mRNA expression [0.08 (0.04-0.92); $p < 0.0001$]. During ICU stay, MR expression levels remained reduced up to day 13. More specifically, on day 4 patients exhibited 8-fold reduced levels [0.13 (0.04-0.41); $p < 0.001$], on day 8, 5-fold [0.20 (0.05-0.50); $p < 0.01$] and on day 13, 14-fold [0.07 (0.05-0.25); $p < 0.001$]. This was corroborated by the fact that compared to admission, MR expression levels during the stay period remained unaltered. The MR-downstream target gene galectin-3 (GAL3) also exhibited reduced expression on ICU admission, compared to healthy controls [0.51 (0.37-0.68); $p < 0.0001$].

Conclusion: MR exhibits a very low expression in critically ill patients, and remains low during the 13-day observation period. The downstream target of MR, GAL3, as expected is also low on ICU admission.

Healthcare utilization, costs and survival of a Canadian cohort of patients discharged from a specialized weaning centre with matched ICU controls: a retrospective longitudinal health administrative database study

L. Rose¹; E. Dvorani²; E. Homehauth²; L. Istanbulian³; I. Fraser³

¹Florence Nightingale Faculty of Nursing, Midwifery and Palliative Care, King's College London, London, United Kingdom; ²Ahrq, Institute of Clinical Evaluative Science, Toronto, Canada; ³Prolonged-ventilation weaning centre, Michael Garron Hospital, Toronto, Canada

Correspondence: L. Rose

Intensive Care Medicine Experimental 2020, **8(2)**: 000100

Introduction: Specialized weaning centres (SWCs) provide an alternate model of care to the ICU for patients requiring prolonged mechanical ventilation. Many studies representing numerous countries report short term outcomes of SWCs; limited data describe mortality beyond 1 year. Furthermore, comparative data on long term outcomes with a control group representing PMV patients who remain in an ICU setting are lacking. Quantification of long-term survival, healthcare utilization and costs of patients experiencing PMV informs patient/family decision making, healthcare spending policy, and understanding of specialized weaning centres (SWC) as an alternate care model.

Objectives: To compare long-term healthcare utilization, costs, and survival trajectory of Canadian SWC patients with a matched cohort of ≥ 21 -day stay ICU patients.

Methods: Retrospective longitudinal (2004-2016, 12-year) study. We linked patients discharged alive identified from the clinical/quality database of the Prolonged-ventilation Weaning Centre (PWC) (Toronto, Canada) to Canadian health administrative databases. We used 1:1 matching (age, sex, Charlson Comorbidity Index, income quintiles) to patients experiencing prolonged ICU stay only. We created multivariable Cox proportional hazard models of survival and time to home discharge.

Results: We matched 228 SWC to 228 prolonged ICU stay survivors (456 patient cohort); 42% had Charlson score of >4 . Mean (SD) duration of SWC admission was 62.2 (85.7) days with mean (SD) 95 (87.7) ICU days before SWC admission. Mean (SD) ICU LOS of the prolonged ICU cohort was 43.4 (32.7) days. SWC survivors required more ICU

admissions, hospital and ICU days 12 months before index admission. Six months and 12 months following unit discharge, more SWC patients required ICU admission (30.3% vs 16.7%, $P < 0.001$), with more frequent (and longer) hospital and ICU admissions, specialist visits, and billable procedures. Median costs were \$10,853 (6-months) ($P = 0.01$) and \$13,138 (12-months) ($P = 0.004$) higher for SWC survivors. At 12-years, hospitalization/ICU admissions and hospital days were similar. SWC survivors consumed more ICU bed days (25 (106.3) vs 7.8 (21.9), $P = 0.02$) and cost more healthcare dollars (\$135,975 vs \$119,763, $P = 0.02$). There was no difference in home discharge (hazard ratio (HR) 1.30, 95% confidence interval (CI) 0.95-1.80). Survival was not different (72% vs 61% dead at 12 years; HR 1.18, 95% CI 0.93-1.50). Longer length of index hospital admission (HR 1.02, 95% CI 1.00-1.04 per month increase) was associated with increased survival whereas increasing numbers of care location transfers was associated with decreased survival (HR 0.88, 95% CI 0.79-0.98).

Conclusion: SWC patients used more acute healthcare services before index admission suggesting greater medical fragility and after unit discharge with higher public healthcare costs. Repatriation of non-weaned patients to acute settings due to limited long-term care resources may have influenced this finding. Survival trajectory was similar.

The change in in-hospital mortality after discharge from intensive care over a period of 20 years

A. Coppola¹; S. Pararajasingam¹; P. Morgan¹

¹Critical care, East Surrey Hospital, Redhill, United Kingdom

Correspondence: A. Coppola

Intensive Care Medicine Experimental 2020, **8(2)**: 000123

Introduction: The Intensive care setting has undergone major paradigm shifts over the years with the ability to expand beyond the physical ICU setting and the transition to continuous monitoring and appropriately minimising invasive procedures. We performed a large retrospective cohort study to analyse the changes to in-hospital mortality after ICU discharge over time.

Methods: A retrospective cohort study on patients discharged from ICU in a District General Hospital between 2000-2020. Palliative patients and missing patient data were excluded. Patient search was obtained via ward watcher software. Total patient number was 12762 and following exclusion 9081 were included. The patients were grouped into in-hours (08:00-17:59) and out of-hours (18:00-07:59) depending on the hour of discharge. The mortality data was collected and then compared over 5-year increments to evaluate progression over time. The results underwent statistical Chi Square analysis.

Results: A total of 9081 patients discharged alive from ICU were studied. Mean age 62.7 years (range, 16-98), 4861 (53.5%) were male, 4220 (46.5%) were female. The overall in-hospital mortality was 744 (8.2%). The mortality rate in 5 year increments from 2000 to 2020 are 9.53%, 10.33%, 10.37% and 5.42% respectively. The most recent 5 years showed a statistically significant drop in mortality of 4.95% (p -value < 0.00001) to the 2010-2015 group. The results show a consistent higher mortality for those discharge out of hours.

Conclusion: Measure taken place over the years have shown improvement in in-hospital mortality after ICU discharge. Several factors have potential to influence the result such as demographics, improvements in ward care and ICU paradigm shifts. It is rational to note the significant changes have occurred over the latter 10 years, with little differences from 2000 to 2015. Essential work is require to highlight the key factors influencing the result.

Serum ammonia level is associated with mortality in critically ill patients: a multicenter retrospective cohort studyJ. Li¹; R. Li¹; Y. Gao¹; X. Jin¹; J. Zhang¹; J. Ren¹; Y. Hou¹; D. Su²; L. Sun³; X. Wang¹; G. Wang¹¹Department of critical care medicine, the Second Affiliated Hospital of Xi'an Jiaotong University, Xi'an, China; ²Department of cardiology, the Second Affiliated Hospital of Xi'an Jiaotong University, Xi'an, China; ³Department of ultrasound, the Second Affiliated Hospital of Xi'an Jiaotong University, Xi'an, China**Correspondence:** G. Wang*Intensive Care Medicine Experimental* 2020, **8(2)**: 000164

Introduction: Ammonia, generated from the deamination of amino acids, is a constituent of all human body fluids. Elevated serum ammonia is commonly observed in patients with hepatic diseases, but large and multicenter studies on the association of serum ammonia levels with clinical outcomes in a broad population of adult patients are scant.

Objectives: The study was aimed to assess the association of serum ammonia upon admission during initial intensive care unit (ICU) stay with ICU and in-hospital mortalities.

Methods: This retrospective observational cohort study included 2,703 adult patients with available admission serum ammonia measurements from 335 ICUs within 208 hospitals in eICU Collaborative Research Database (eICU-CRD). Ammonia levels were divided into deciles, and the ICU mortalities within ammonia deciles were assessed. Univariable and multivariable logistic regression analyses were performed to analyze the relationship between serum ammonia and mortalities. The covariates included demographics, Acute Physiology and Chronic Health Evaluation (APACHE) IV score, treatments, and diseases diagnosed during the first 24 h of ICU stay. Model discrimination was assessed by the calculation of the receiver operating characteristic curve and reporting the area under the curve (AUC). Interaction and subgroup analyses were conducted to determine whether the effect of ammonia on mortalities varied in patients with or without hepatic diseases.

Results: The median of serum ammonia was 39 (23–65) µg/dL. Totally, we defined three ammonia categories: < 47 µg/dL, 47 µg/dL to 111 µg/dL, and ≥ 111 µg/dL, corresponding to low, intermediate, and high ICU mortality. ICU and in-hospital mortalities in the three ammonia categories were 7.59%, 16.52%, and 32.72% and 14.05%, 22.96%, and 42.28%, respectively. Increased ammonia was significantly associated with increasing ICU mortality (per 10 µg/dL increase: odds ratio, 1.069 [95% confidence intervals, 1.048–1.091]; Intermediate vs. Low: 1.935 [1.445–2.592]; High vs. Low: 4.239 [2.916–6.162]), and in-hospital mortality (per 10 µg/dL increase: 1.060 [1.040–1.081]; Intermediate vs. Low: 1.440 [1.127–1.839]; High vs. Low: 3.249 [2.330–4.529]). Adding ammonia to APACHE IV score improved the AUC from 0.826 to 0.839 ($P < 0.001$) for ICU mortality and 0.806 to 0.813 ($P = 0.001$) for in-hospital mortality. Interaction and subgroup analyses demonstrated consistent results in patients with or without hepatic diseases. In patients with hepatic disease, serum ammonia levels were significantly associated with the ICU and in-hospital mortalities (1.053 [1.025–1.081], 1.040 [1.015–1.067], per 10 µg/dL increase), the results were similar in the non-hepatic disease group (1.078 [1.051–1.106], 1.071 [1.046–1.096], per 10 µg/dL increase).

Conclusion: Serum ammonia levels upon admission might be an early risk factor for higher ICU and in-hospital mortalities in ICU patients.

DoctorT. Ylimartimo¹; M. Koskela²; J. Liisanantti³¹University hospital of Oulu, Oulu, Finland, Finland; ²Surgery, University hospital of Oulu, Oulu, Finland, Finland; ³Study group of surgery, anesthesiology and intensive care, Oulu University, Medical Research Center, Oulu, Finland, Finland**Correspondence:** T. Ylimartimo*Intensive Care Medicine Experimental* 2020, **8(2)**: 000172

Introduction: Emergency laparotomy (EL) is among one of the most common surgical operations. Previous studies have shown that emergency surgery is associated with higher morbidity and mortality compared to elective surgery¹⁻⁴. It has also been reported that patients with direct intensive care unit (ICU) admission after EL have significantly high mortality⁵. However, there are no studies comparing the impact of direct and delayed admission from recovery room (RR) to ICU on the outcome.

Objectives: Aim of the study was to compare outcomes between direct and delayed ICU admission after EL.

Methods: The study was a retrospective single center registry study. Data were collected from operation registry and ICU patient data management system's database of Oulu University Hospital. All patients undergoing EL and admitted to ICU directly from the operation room (OR) or from the RR between the January 2005 and May 2015 were included. Appendectomies, cholecystectomies, laparotomies due to traumas or gynecological reasons and patients less than 16 years of age were excluded.

Results: There were a total of 450 patients in the study. A total of 323 (71.8%) patients were admitted directly from OR to ICU and 127 (28.2%) patients were admitted to ICU from the RR. The patients admitted directly to ICU were younger, had higher SOFA-scores and lower first postoperative day (POD) CRP-levels. There were no differences in short-term mortality between the groups, but 5-y mortality was higher in indirect ICU admission group (Table 1).

	Direct ICU admission	Indirect ICU admission	P-Value
	N323	N127	
Age (y)	65 [54-76]	71 []	<0.001
Male Gender	183 (56.7)	69 (54.3)	0.655
SOFA adm	6[4-8]	5[3-7]	0.02
1pod CRP	169[100-253]	238[159-302]	<0.001
Hospital mortality	47 (14.6)	16 (12.6)	0.591
30-d mortality	61 (18.9)	22(17.3)	0.700
90-d mortality	78 (24.1)	32 (25.2)	0.816
5y- mortality	54.3%	67.7%	0.015

Conclusion: Younger patients were more often admitted directly to ICU from OR. Patients admitted to ICU from RR had higher CRP at first postoperative day. Short-term prognosis was not dependent on timing of the ICU admission in this patient cohort. Higher long-term mortality can be explained by the age distribution of the study population.

Trained ICU doulas can provide early psychological support to the critically ill patientsL. Karnatovskaia¹; K. Varga²; P. Schulte³; G. Ognjen¹; K. Philbrick⁴

¹Division of pulmonary and critical care, Mayo Clinic, Rochester, United States of America; ²Affective psychology department, Eötvös Loránd University, Budapest, Hungary; ³Division of biomedical statistics and informatics, Mayo Clinic, Rochester, United States of America; ⁴Department of psychiatry and psychology, Mayo Clinic, Rochester, United States of America

Correspondence: L. Karnatovskaia*Intensive Care Medicine Experimental* 2020, **8(2)**: 000177

Introduction: Over a third of critical illness survivors suffer from mental health problems following hospital discharge. Memories of delusional experiences are a major risk factor. Research on the formation of fear demonstrates that if mitigating information about a traumatic event is introduced during the time of memory formation or upon its subsequent recall, the emotional experience of the memory may be modified. Given that semantic processing continues during altered states of consciousness, and that the thinking process of the critically ill is characterized by heightened suggestibility, we adapted an approach based on positive suggestions to provide early psychological support for the critically ill in parallel with medical treatment.

Objectives: We used trained ICU doulas to provide an intervention targeting the vulnerable time period when memories are being formed.

Methods: Adult patients on mechanical ventilation and/or vasopressors were recruited for this single-arm prospective study. Intervention was administered daily during the ICU stay in parallel with medical treatment. Approach consisted of three phases: informing the patient about details of their ICU treatment while providing positive reframing and pre-framing of the events in their clinical course; actively involving the patient in the treatment process once they were able to communicate; and debriefing prior to ICU dismissal to clarify potential memory distortions. As a secondary analysis, subjects were compared to a historic cohort of patients receiving standard care in the ICU using adjusted linear regression models. Interactions with mechanical ventilation assessed whether the relationship depended on ventilation status.

Results: Forty-three patients received the intervention provided by two trained ICU doulas for an average of 5 days with each session lasting an average of 20 minutes. Questionnaires were administered following ICU transfer. Compared to historical controls (N=299), intervention was associated with reduced Hospital Anxiety and Depression Scale (HADS) – Depression subscale (adjusted mean difference estimate=-1.3, 95%CI=(-2.6, 0.0), p=0.049). In a model with ventilation interaction, intervention was associated with reduced HADS-Anxiety subscale among ventilated patients (estimate=-2.0, 95%CI=(-3.6, -0.3), p=0.019), but not among those without mechanical ventilation (p=0.73). There was insufficient evidence to suggest an association with MoCA-Blind or IES-R subscores. These initial results suggest the intervention may be beneficial.

Conclusion: Positive therapeutic suggestion is a unique approach aimed to reduce formation of traumatic memories and to humanize critical care. It was feasible to successfully intervene on 43 critically ill patients. Testing the intervention on a wider scale with randomized treatment arms is warranted.

Correspondence: A.K.I. Wong*Intensive Care Medicine Experimental* 2020, **8(2)**: 000213

Introduction: Patients on mechanical ventilation (MV) can develop a ventilator associated event (VAE), which is associated with higher morbidity and mortality. The new Centers for Disease Control (CDC) VAE definition, updated early 2020, replaces prior surveillance criteria. [1] The most inclusive VAE definition is the ventilator associated condition (VAC), requiring at least two consecutive calendar days of MV stability followed by two consecutive calendar days of increased MV support (defined as lowest change Δ PEEP ≥ 3 or FiO₂ $\geq 20\%$ maintained ≥ 1 hour, hereafter Δ PEEP or Δ FiO₂). Although VAC is designed as a population-level surveillance definition, it was developed by expert consensus and has not been validated on population data.

Objectives: The aims are to evaluate VAC definition performance by clinical outcomes and to optimize the definition in prediction of clinical outcomes when applying different Δ PEEP, Δ FiO₂, and time-window combinations.

Methods: We utilized the multi-center eICU Collaborative Research Database [2-4][5] Inclusion criteria: ICU stay ≥ 4 days, MV ≥ 4 days, with PEEP and FiO₂ data availability. Exclusion criteria: age < 18 years. Δ PEEP was examined in a range of 1 to 7 and Δ FiO₂ was examined from 10% to 60% above stability baseline. The time-windows for stability and deterioration were varied by calendar days [CDC definition] and rolling 24-hour time windows from the start of MV. Within these time-windows, patients with VAC and without VAC were compared by in-hospital mortality log odds ratios.

Results: From a total of 200,859 patients in the eICU database, we identified 8,230 patients who met our inclusion criteria (Table 1).

For patients with VAC, the mortality log odds ratio heatmap by calendar day (Figure 1a) stratifies at Δ PEEP ≥ 4 and Δ PEEP ≥ 6 . Increasing the Δ FiO₂ criteria increases mortality log odds at the expense of sensitivity. Heatmap color gradations suggest greater increases of Δ PEEP and Δ FiO₂ clusters mortality into mild, moderate, and severe VAC. Similar trends are seen in 24-hour time-windows from the start of MV to determine stability and deterioration periods in Figure 1b. Unlike calendar day, the 24-hour time-window allows equitable comparison of MV periods between all patients.

Conclusion: This data-driven approach validates CDC VAC surveillance criteria in a publicly available ICU dataset. Furthermore, data analysis shows that the VAC definition can be improved to differentiate mild, moderate, and severe VAC by redefining time-windows, Δ PEEP, and Δ FiO₂.

Vancomycin trough concentration was associated with mortality in critically ill patientsY. Hou¹; J. Ren¹; J. Li¹; X. Jin¹; Y. Gao¹; R. Li¹; J. Zhang¹; X. Wang¹; G. Wang¹¹Department of critical care medicine, the Second Affiliated Hospital of Xi'an Jiaotong University, Xi'an, China**Correspondence:** G. Wang*Intensive Care Medicine Experimental* 2020, **8(2)**: 000216

Introduction: A series of previous guidelines recommended vancomycin trough concentration (VTC) should be maintained at 10–20 mg/L to avoid drug resistance and 15–20 mg/L to improve the clinical outcomes of patients with severe infections. However, the latest consensus suggested that VTCs with a target of 15–20 mg/L should no longer be recommended based on existing data of efficacy and nephrotoxicity in patients with serious MRSA infections. To date, the optimal target of VTC for critically ill patients who receive vancomycin remains unclear considering limited evidence.

Objectives: The aim of this study was to explore the association between serum VTC and mortality in intensive care unit (ICU) settings.

Methods: This multicenter, retrospective cohort study included 7,975 patients from 335 different ICUs at 208 hospitals in the eICU Collaborative Research Database. Serum VTC was continuously monitored, and mean serum VTC, calculated by dividing the sum of all collected VTCs by the frequency of VTC monitoring, was investigated as a continuous and categorical variable. Patients with different mean serum VTCs were classified into four groups: <10 mg/L, 10–15 mg/L, 15–20 mg/L, and >20 mg/L. Multivariable logistic regression, interaction, and subgroup analyses were performed to investigate the relationship of mean VTC with hospital and ICU mortalities.

Results: Hospital mortality rates were 13.7%, 15.1%, 19.4%, and 25.8% and ICU mortality rates were 7.8%, 8.8%, 12.1%, and 17.1%, respectively, in the four groups. After adjusting for age, sex, ethnicity, body mass index, Acute Physiology and Chronic Health Evaluation IV (APACHE IV) score, the use of ventilation, dialysis, and vasopressor, and diagnoses at ICU admission, mean VTC, as a continuous variable, was positively correlated with hospital (odds ratio [OR], 1.032, 95% confidence interval [CI], 1.024–1.041) and ICU (OR, 1.037, 95% CI, 1.028–1.047) mortalities. Moreover, as a categorical variable, a mean VTC of 10–15 mg/L failed to reduce hospital (OR, 0.973, 95% CI, 0.802–1.180) and ICU (OR, 1.002, 95% CI, 0.785–1.279) mortalities, and mean VTCs of 15–20 mg/L and >20 mg/L were significantly associated with higher hospital (OR, 1.232, 95% CI, 1.015–1.496; OR, 1.747, 95% CI, 1.437–2.123) and ICU (OR, 1.301, 95% CI, 1.021–1.658; OR, 1.858, 95% CI, 1.459–2.368) mortalities than mean VTC <10 mg/L. The interaction analysis had no statistical significance, and similar results persisted in the patients with different APACHE IV scores.

Conclusion: An increasing serum VTC was associated with incremental hospital and ICU mortalities in critically ill patients. Therefore, our results do not support the use of serum VTC as a monitoring indicator for vancomycin regimens in critically ill patients, and the necessity of vancomycin therapeutic drug monitoring based on VTC needs to be investigated in future prospective studies.

Impact of spontaneous respiratory rate variability on clinical outcomes in critically ill patientsY. Gao¹; X. Jin¹; R. Li¹; J. Li¹; J. Zhang¹; X. Wang¹; G. Wang¹¹Department of critical care medicine, the Second Affiliated Hospital of Xi'an Jiaotong University, Xi'an, China**Correspondence:** G. Wang*Intensive Care Medicine Experimental* 2020, **8(2)**: 000218

Introduction: Previous studies have explored several different approaches to assess breathing changes and to evaluate their prognostic value. However, the relationship between spontaneous respiratory rate variability (RRV) using the coefficient of variation (CV) and mortality in intensive care units (ICU) patients remains to be unclear.

Objectives: To investigate the association between spontaneous RRV and clinical outcomes in ICU patients.

Methods: Adult patients having spontaneous RR records during the first 24 hours after ICU admission with an ICU length of stay (LOS) ≥ 1 day were enrolled from eICU Collaborative Research Database. The CV of RR was calculated as standard deviation/mean $\times 100\%$. Then patients were divided into low RRV group (CV of RR $\leq 20\%$) and high RRV group (CV of RR $> 20\%$). The outcomes included ICU mortality, hospital mortality, and LOS in ICU. Logistic regression was performed to investigate the relationship between spontaneous RRV and outcomes. External validation was also conducted in patients from Multiparameter Intelligent Monitoring in Intensive Care II database.

Results: Based on the CV of RR results, 36,880 patients were divided into two groups: low RRV group (n=24490) and high RRV group (n=12390). The rate of ICU and in-hospital mortality, and long ICU LOS were found significantly higher in low RRV group than in high RRV group (2.7% vs. 2.3%, $P=0.034$; 5.7% vs. 5.1%, $P=0.018$; 5.6% vs. 4.8%, $P=0.001$; respectively). Multivariate regression analysis showed that compared with high RRV, patients with a low RRV had a higher ICU mortality (odds ratio [OR]: 1.225, 95% confidence interval [CI]: 1.056–1.422), higher in-hospital mortality (OR: 1.155, 95% CI: 1.041–1.282), and a longer ICU LOS (OR: 1.199, 95% CI: 1.084–1.327) after adjusting for covariates. Furthermore, external validation conducted in 13,506 patients revealed that low RRV showed an OR of 1.329 ($P<0.001$) for ICU mortality, 1.267 ($P<0.001$) for in-hospital mortality, and 1.357 ($P<0.001$) for long ICU LOS. In addition, the Cox proportional hazards models also confirmed the significantly association between spontaneous RRV and 90-day (hazard ratio [HR]: 1.295, 95% confidence interval [CI]: 1.165–1.439), 180-day (HR: 1.316, 95% CI: 1.195–1.450), and 1-year mortality (HR: 1.300, 95% CI: 1.191–1.418).

Conclusion: The low RRV may serve as an independent risk factor for ICU mortality, hospital mortality and LOS in ICU in critically ill patients. To our knowledge, this is the first attempt to measure the spontaneous RRV by CV based on continuously monitored records and confirm its prognostic value in two large multicenter ICU database.

Effect of admission serum chloride level on the prognosis of critically ill patients: a multicenter retrospective cohort studyX. Jin¹; R. Li¹; J. Li¹; J. Zhang¹; Y. Gao¹; J. Ren¹; X. Wang¹; G. Wang¹¹Department of critical care medicine, the Second Affiliated Hospital of Xi'an Jiaotong University, Xi'an, China**Correspondence:** G. Wang*Intensive Care Medicine Experimental* 2020, **8(2)**: 000231

Introduction: Critically ill patients are vulnerable to the alteration of acid-base homeostasis and plasma electroneutrality, which is profoundly influenced by the serum chloride level. Abnormally low or high serum chloride levels were associated with adverse outcomes in intensive care unit (ICU) settings. However, the serum chloride levels of most patients in ICU are within a relatively normal range, and

among those patients, the prognostic implication of serum chloride levels has scarcely been assessed.

Objectives: To analyze the relation of admission serum chloride levels with ICU mortality.

Methods: The multicenter retrospective cohort study recruited 59,807 patients from the eICU Collaborative Research Database (eICU-CRD), which includes data from 335 distinct ICUs throughout the continental United States between 2014 and 2015. The clinical records of adult patients with a single hospital admission and serum chloride level, measured during the initial 24 hours of first ICU stay, between 96 mEq/L and 111 mEq/L were analyzed in the present study. Restricted cubic splines were used to visualize the relationship between serum chloride levels and ICU mortality. Patients were categorized into low (<104 mEq/L) or high (\geq 104 mEq/L) chloride groups. And multivariable logistic regression models were further used to explore the association between serum chloride levels and ICU mortality. We also performed an external validation in the Multiparameter Intelligent Monitoring in Intensive Care II Database.

Results: The multivariable logistic regression models revealed that for every unit increase in serum chloride level, there was an 8% decline in mortality [odds ratio (OR) 0.92, 95% confidence interval (CI) 0.90–0.93]. And restricted cubic splines revealed that the risk of ICU mortality increased rapidly with serum chloride level decreased to lower than 104 mEq/L. In comparison to those with serum chloride levels \geq 104 mEq/L, patients with serum chloride level <104 mEq/L had a higher risk of mortality (OR 1.64, 95% CI 1.49–1.81). In external validation cohort with 16,543 patients, we found a consistent result that patients in the low chloride group also had an increased risk of ICU mortality (OR 2.16, 95% CI 1.82–2.56).

Conclusion: Our study revealed that, within a relatively normal range, the admission serum chloride level is still independently and inversely associated with ICU mortality. And a serum chloride level below 104 mEq/L may increase the mortality risk in critically ill patients, which may facilitate early risk stratification and improve fluid management for critically ill patients in the future.

Intensive Care Medicine Experimental 2020, **8(2)**: 000232

Introduction: Lactate dehydrogenase (LDH), widely synthesized in muscle, liver and red blood cells, is one of the key enzymes in the glycolytic pathway. Although serum LDH is correlated with the outcomes of septic patients, whether serum LDH impacts on mortality in unselected ICU patients remains unclear.

Objectives: To investigate the potential relationship between serum LDH levels and ICU and hospital mortalities.

Methods: Patients with serum LDH measurements during the initial 24 h of first ICU stay from 335 ICUs within 208 hospitals in eICU Collaborative Research Database (eICU-CRD) were included in this retrospective observational cohort study. Patients were divided into four groups according to quartiles of the serum LDH levels. The associations of serum LDH with ICU and hospital mortalities were assessed using univariable and multivariable logistic regression analyses. The covariates included Acute Physiology and Chronic Health Evaluation IV (APACHE IV) score, demographics, treatments performed between admission and LDH tested, and diseases diagnosed during the first 24 h of ICU stay. Interaction and subgroup analyses were performed for those patients who had different levels of APACHE IV score.

Results: The overall cohort comprised 1,981 patients. ICU and hospital mortalities in the four groups were 7.33%, 10.10%, 14.86% and 23.34%, $P < 0.001$; 11.0%, 15.56%, 22.09%, and 30.99%, $P < 0.001$; respectively. Univariable logistic regression analysis showed that serum LDH level was significantly associated with mortalities. Using

the Q1 (lowest quartile) as a reference, the odds ratios (95% confidence intervals) with ICU and hospital mortalities of Q2, Q3 and Q4 were 1.420 (0.907–2.222), 2.206 (1.450–3.356), and 3.848 (2.585–5.728) and 1.491 (1.027–2.164), 2.294 (1.612–3.266), and 3.633 (2.584–5.108), respectively. After further adjustment for all covariates, the influence of serum LDH on ICU and hospital mortalities were similar (ICU mortality, Q2 vs. Q1: 1.019 [0.606–1.713]; Q3 vs. Q1: 1.676 [1.037–2.710]; Q4 vs. Q1: 1.747 [1.086–2.809]; hospital mortality, Q2 vs. Q1: 1.193 [0.777–1.832]; Q3 vs. Q1: 1.931 [1.290–2.889]; Q4 vs. Q1: 2.066 [1.378–3.098]). In addition, a linear association between serum LDH quartiles and ICU and hospital mortalities (ICU: 1.243 [1.075–1.438]; hospital: 1.300 [1.148–1.473]) were found. When stratified by APACHE IV score < 61 (975 patients) and \geq 61 (1006 patients), no significant interaction was observed and similar results persisted in the patients with different APACHE IV scores.

Conclusion: The level of serum LDH may aid in the early identification of critically ill patients for higher risks of ICU and hospital mortalities.

000234

Serum albumin level may serve as a predictor of all-cause mortality in critically ill patients

Intensive Care Medicine Experimental 2020, **8(2)**: 000234

Introduction: Albumin plays an essential role in the maintenance of colloid osmotic pressure and is involved in several physiological and pathological processes, such as keeping vascular permeability, binding and transporting numerous endogenous and exogenous compounds, regulating of acid-base balance, scavenging free radical, and inhibiting platelet function as well as antithrombotic effect. An abnormally low serum albumin level (SAL) was common in intensive care unit (ICU) and was related to adverse outcomes. However, the optimal SAL was inconsistent across different studies. Albumin plays an essential role in the maintenance of colloid osmotic pressure and is involved in several physiological and pathological processes, such as keeping vascular permeability, binding and transporting numerous endogenous and exogenous compounds, regulating of acid-base balance, scavenging free radical, and inhibiting platelet function as well as antithrombotic effect. An abnormally low serum albumin level (SAL) was common in intensive care unit (ICU) and was related to adverse outcomes. However, the optimal SAL was inconsistent across different studies.

Objectives: The study was aimed to assess the association of SAL with hospital and ICU mortalities in critically ill patients.

Methods: This retrospective multicenter cohort study includes 36,448 patients extracted from the eICU Collaborative Research Database (eICU-CRD) from 335 distinct ICUs throughout the continental United States. Patients with single hospital admission and having albumin records in the initial 24 h of the first ICU admission in eICU-CRD database were included. The outcomes of this study were ICU and hospital mortalities. Restricted cubic splines and logistic regression were performed to investigate the relationship between SAL and mortalities.

Results: The restrictive cubic splines revealed a rapid increase of ICU mortality when SAL declined to around 3.5 g/dl. Thus, 36,448 ICU patients were divided into two groups according to the SAL \leq and $>$ 3.5 g/dl. Patients with SAL \leq 3.5 g/dl ($n = 28,972$) had higher ICU and hospital mortalities than those with SAL $>$ 3.5 g/dl ($n = 7476$; 9.8% vs 4.2%, $P < 0.001$ and 14.7% vs 5.9%, $P < 0.001$, respectively). After adjusted for demographic factors, Acute Physiology and Chronic Health Evaluation IV score, treatments before admission SAL examination and primary diagnoses, logistic regression models showed that SAL \leq 3.5 g/dl was independently correlated with higher risks of ICU and hospital mortalities [odds ratio (OR): 1.161, 95% confidence interval (CI): 1.012–1.331, $P = 0.033$ and OR: 1.415, 95% CI: 1.259–1.590, P

< 0.001, respectively]. Furthermore, the association between SAL, as a continuous variable, and mortalities in patients with SAL \leq or $>$ 3.5 g/dl were assessed, respectively. The results showed that SAL was inversely associated with ICU and hospital mortalities (OR: 0.976, 95% CI: 0.968–0.984, $P < 0.001$; OR: 0.958, 95% CI: 0.952–0.965, $P < 0.001$, respectively) in the SAL \leq 3.5 g/dl group, but the associations were not found in the SAL $>$ 3.5 g/dl group.

Conclusion: Patients with SAL \leq 3.5 g/dl had higher risks of ICU and hospital mortalities than those with SAL $>$ 3.5 g/dl. Among patients with SAL \leq 3.5 g/dl, increasing SAL was associated with an incremental improvement of survival in critically ill patients. Therefore, a SAL \leq 3.5 g/dl may serve as an optimal therapeutic target for exogenous albumin infusion in ICU.

Intensive Care Medicine Experimental 2020, **8(2)**: 000246

Introduction: Global warming leads to increased exposure of human-kind to meteorological variation, including short-term weather changes. Weather conditions involve changes in temperature, heat and cold, in air pressure and in air humidity. Every single condition influences the incidence and mortality of different diseases such as myocardial infarction and stroke.

Objectives: This study investigated the impact of weather conditions on short- and long-term mortality of critically ill patients admitted to an Intensive Care Unit (ICU).

Methods: A total of 4321 medical patients (66 \pm 14 years, 2638 male) admitted to a German ICU over five years were retrospectively investigated. Meteorological information (mean, maximum and minimum air temperature, air pressure and humidity) for the same period was retrieved. The influence of absolute weather parameters, different seasons, sudden weather changes (delta 24 h) including "warm" and "cold" spells on ICU- and long-term mortality was analyzed. Significant results ($p < 0.05$) were adjusted for SAPS-2 scores. Additionally, subgroups of patients older than 75 years, patients with myocardial infarction and with pneumonia were investigated.

Results: After correction for SAPS-2, no impact of meteorological conditions on mortality was found. Different seasons, sudden weather changes, "warm spells" or "cold spells" did not affect the outcome. In a subgroup analysis, none of the subgroups demonstrated increased mortality during the studied weather conditions. Additionally, no difference between males and females could be found.

Conclusion: Sudden weather changes and seasonal variations have no impact on short- and long-term mortality in critically ill patients.

Influence of serum anion gap on mortality in critically ill patients: a multicenter cohort study

R. Li¹; J. Li¹; Y. Gao¹; X. Jin¹; J. Ren¹; J. Zhang¹; X. Wang¹; G. Wang¹

¹Department of critical care medicine, the Second Affiliated Hospital of Xi'an Jiaotong University, Xi'an, China

Correspondence: G. Wang

Intensive Care Medicine Experimental 2020, **8(2)**: 000263

Introduction: Anion gap (AG), which is the difference between unmeasured anions and unmeasured cations, has been used to evaluate acid-base statuses and guide the management of intensive care units (ICUs) patients. However, there were controversies in the relationship between AG and mortality.

Objectives: To evaluate the association between AG and ICU mortality in a large sample of ICU patients.

Methods: We retrospectively enrolled adult patients with complete serum sodium, potassium, chloride, and bicarbonate in the first 24 hours of initial ICU stay from 335 ICUs at 208 hospitals across the United States in eICU Collaborative Research Database. AG and corrected AG by serum albumin (cAG) were calculated as [sodium]+[potassium]-[chloride]-[bicarbonate] and AG+2.5(4.4-albumin). The ICU mortalities in patients with different deciles of admission AG or cAG were assessed, respectively. Multivariable logistic regression models were applied to investigate the association between AG or cAG, as continuous and dichotomous variable, and ICU mortality. Interaction analysis between AG or cAG and acute physiology and chronic health evaluation (APACHE) IV score was assessed for the association with ICU mortality.

Results: A total of 15,927 patients with AG (10,442 patients with cAG) entered into the final cohort. After adjustment for demographics, APACHE IV score, lactate, and diseases diagnosed during the first 24 h of ICU stay, elevated admission serum AG or cAG, as continuous variable, were related with increased ICU mortality (odds ratio [95% confidence intervals]: AG, 1.024 [1.011-1.037]; cAG, 1.017 [1.002-1.032]). Furthermore, the ICU mortality was higher in patients with the highest three deciles of admission AG ($>$ 16.90 mEq/L, 18.9% vs. 9.8%, $P < 0.001$) or cAG ($>$ 21.45 mEq/L, 22.7% vs. 11.0%, $P < 0.001$) than those with the lowest seven deciles of admission AG (\leq 16.90 mEq/L) or cAG (\leq 21.45 mEq/L). In multivariable models, AG $>$ 16.90 mEq/L or cAG $>$ 21.45 mEq/L were associated with higher risks of ICU mortality (AG: 1.027 [1.077-1.354]; cAG: 1.171 [1.023-1.341]) compared with AG \leq 16.90 mEq/L or cAG \leq 21.45 mEq/L. Interaction analyses showed that the association between AG (P Interaction =0.226) or cAG (P Interaction =0.067) and ICU mortality could not be modified by APACHE IV score.

Conclusion: Elevated admission serum AG or cAG might be an early risk factor for ICU mortality.

Association between circadian variation of heart rate and mortality among critically ill patients

J. Zhang¹; J. Li¹; R. Li¹; X. Jin¹; Y. Gao¹; G. Wang¹

¹Department of critical care medicine, the Second Affiliated Hospital of Xi'an Jiaotong University, Xi'an, China

Correspondence: G. Wang

Intensive Care Medicine Experimental 2020, **8(2)**: 000275

Introduction: Heart rate (HR) variations, such as HR variability, HR turbulence, resting HR, and nighttime mean HR have been recognized as independent predictors of mortality. However, it is unclear whether the circadian changes in HR influence the risk of death in the intensive care unit (ICU).

Objectives: To evaluate the relationship between the circadian variation of HR and the mortality among critically ill patients.

Methods: The records of 4760 patients were extracted from the Multiparameter Intelligent Monitoring in Intensive Care II (MIMIC II) database. The circadian variation in HR was evaluated as nighttime mean HR/daytime mean HR. Participants were divided into two groups according to the median score of the circadian variation in HR: group A (≤ 0.98) and group B (> 0.98). The endpoints were ICU, hospital, 30-day, and 1-year mortality. Multivariable logistic regression models and Cox proportional hazards models were used to investigate the relationship between circadian HR variation and mortality in ICU. Sensitivity analyses were also conducted in different Sequential Organ Failure Assessment (SOFA) scores subgroups.

Results: Patients in group B ($n = 2471$) had higher mortality than those in group A ($n = 2289$). After multivariable adjustments, the associations of circadian HR variation with ICU mortality (odds ratio [OR], 1.419; 95% confidence interval [CI], 1.097-1.835; $P = 0.008$), hospital mortality (OR, 1.394; 95% CI, 1.122-1.747; $P = 0.004$), 30-day mortality (hazard ratio [HR], 1.283; 95% CI, 1.085-1.518; $P = 0.004$), and 1-year mortality (HR, 1.215; 95% CI, 1.064-1.387; $P = 0.004$) were statistically significant. Furthermore, the association became more statistically remarkable

in patients with higher SOFA scores (≥ 6 subgroup) in the sensitivity analysis.

Conclusion: The circadian HR variation may predict short-term and long-term mortality in critically ill patients, especially in patients with higher SOFA scores.

000276

The search for optimal range of platelets count in critically ill patients: an observational study from eICU databases

J. Zhang¹; X. Jin¹; J. Li¹; R. Li¹; J. Ren¹; X. Wang¹; G. Wang¹

¹Department of critical care medicine, the Second Affiliated Hospital of Xi'an Jiaotong University, Xi'an, China

Correspondence: G. Wang

Intensive Care Medicine Experimental 2020, **8(2)**: 000276

Introduction: Platelets are involved in coagulation system, immune system, inflammation and stress responses. Abnormal platelet counts have been linked to increased mortality in critically ill patients. However, the optimal platelets count target remains unclear.

Objectives: The study is designed to explore the relatively optimal range of platelets count in critically ill patients with real world data; Furthermore, the relationship between the platelets count and mortality in ICU was also studied.

Methods: This is a multicenter and retrospective cohort study using the eICU Collaborative Research Database (eICU-CRD) with authorized access. The restricted cubic splines were used to explore the crude relationship between platelets count and mortality. We derived an optimal range of platelet counts and analyzed the association between the optimal range of platelet counts and mortality. Multivariable logistic regression models were used to further explore the association between the level of platelet counts and mortality in intensive care unit (ICU). The sensitivity analyses were performed in patients with sepsis or not.

Results: In total, 49,875 adult patients with platelet counts within 24 hours of admission to the ICU were included. According to the restricted cubic splines, the optimal range of platelets count was $125\text{--}185 \times 109/\text{L}$ (reference group). Patients were divided into lower platelet group ($<125 \times 109/\text{L}$), higher group ($>185 \times 109/\text{L}$) and reference group ($125\text{--}185 \times 109/\text{L}$). Compared with those in the reference group, patients with lower platelet counts and higher platelet counts are associated with a higher hospital mortality (odds ratio (OR) 1.226, 95% confidence interval (CI) 1.116–1.347; OR 1.276, 95% CI 1.278–1.381; respectively) and ICU mortality (OR 1.260, 95% CI 1.127–1.409; OR 1.284, 95% CI 1.166–1.413; respectively) after adjustment for a series of variables. The results of subgroup analyses are consistent with overall population.

Conclusion: The optimal range of platelet counts was $125\text{--}185 \times 109/\text{L}$ in critically ill patients. Platelet counts lower than $125 \times 109/\text{L}$ or higher than $185 \times 109/\text{L}$ may increase the mortality in ICU.

A 16 year review of patients admitted to an adult Intensive Care Unit (ICU) following drug overdose at a district general hospital in Surrey, England

A. Nechowska¹; T. Samuels¹; S. Ranjan¹

¹Critical care, East Surrey Hospital, Redhill, United Kingdom

Correspondence: A. Nechowska

Intensive Care Medicine Experimental 2020, **8(2)**: 000322

Introduction: An annual review of suicides in the UK (Office for National Statistics) for 2018 showed a significantly higher rate of deaths by suicide than the previous year [1]. This was the first reported increase since 2013. Deliberate and accidental drug overdose cases that result in critical care admission often require a period of artificial ventilation and may also require renal replacement therapy. Identifying trends in admission could improve the ability for ICU to plan with regards to budget and resources.

Objectives: To review whether there has been a change in the number of patients admitted to a 16-bed adult ICU during a 16 year period and whether it is possible to identify seasonal variations.

Methods: The WardWatcher database for a single 16-bed adult critical care unit was interrogated for the period January 1993 to September 2019. To account for different classification and coding, search terms containing the following were deemed suitable: overdose, self-harm, poison, suicide. Hanging and asphyxia were not included in the search. Duplicated information was removed manually. Data was analysed according to year, season and outcome (ie. death or survival to ICU discharge). There was insufficient information available to investigate method of overdose. Statistical analysis was performed using R version 3.6.3 (Austria-Vienna).

Results: A database of 12,671 patients was reviewed and 331 cases involving drug overdose were identified. The dataset showed a minimum of 2 and maximum of 33 overdoses per year, with a median number of 10 (IQR 5–16). The raw time series for the data demonstrates an increasing trend. Using a bias-corrected and accelerated bootstrap percentile method, we estimated the 95% confidence interval for the r^2 value of 0.41 to be between 0.17 and 0.64. This suggested there was a small positive association between the number of total overdoses over time.

Analysis by season suggested that the highest percentage of overdoses were admitted in Spring (annually 20th March to 20th June), accounting for 28.01% (93) of total overdose admissions. The numbers were, however, closely clustered for all four seasons.

Out of the 331 patients, 315 (95%) survived to discharge from ICU. There was not enough data to study their course following this, such as their neurological outcomes. No trends by year or season were observed due to the small number of deaths in this period.

Conclusion: By reviewing a large dataset over a prolonged period of time we were able to show that an increase in suicide death rates at a national level, as reported by ONS, was not accompanied by an increase in ICU admissions at a local level. This study showed that there has been a relatively poor increase in the annual number of overdoses admitted to this particular ICU since 1993 with a median of 10 per annum.

Intensive Care Medicine Experimental 2020, **8(2)**: 000351

Introduction: Ventriculo-arterial coupling (VAC), is a major determinant of cardiovascular efficiency in terms of the ratio between work required for the stroke volume relative to the total work for the contraction.

Objectives: Aim of this study was to investigate the relationship between ventricular-arterial coupling (VAC) and in-hospital outcomes and to evaluate its prognostic value in critical ill patients.

Methods: We evaluated 333 (age $66,8 \pm 15,4$ years, male 67,3%) consecutive patients admitted in ICCU of our hospital. Blood pressure and trans-thoracic cardiac ultrasound were collected for assessment of left ventricular elastance (Ees), arterial elastance (Ea) and VAC calculated through Chen's method. In-hospital we recorded events related with acute heart failure and study population was stratified according to events development (need for invasive and NIV, amine, IABP, CVVHD, anuria, MOF, and death).

Results: In our population 190 pts (57%) presented in-hospital complications, and 143 (43%) didn't. Ea and VAC were found to be significantly higher in the first group than in the latter, and a trend toward decrease for Ees was observed in the first group (Figure). VAC resulted a strong and independent predictor of in-hospital clinical outcomes [odds ratio (95% confidence interval): 2,016 (1.287–3,159); $P=0.002$] even after univariate and multivariate analysis adjusted for age, dyslipidaemia, diabetes, obesity, coronary artery disease and chronic kidney disease.

Conclusion: Assessment of VA coupling might be an additional non-invasive parameter that can be used to determine prognosis in critically ill patients. Although those encouraging results, the benefit of such an approach for understanding the pathophysiology of altered hemodynamic profiles and to guide the therapeutic strategies, has to be confirmed in larger clinical trials.

Post-intensive care syndrome in patients and their caregivers

J. Tejero Aranguren¹; C. M. Mt.¹; I. Cruz Valero¹; F. M. Purificación¹; A. Carranza Pinel¹

¹Intensive care unit, Hospital Universitario Clínico San Cecilio, Granada, Spain

Correspondence: J. Tejero Aranguren

Intensive Care Medicine Experimental 2020, **8(2)**: 000376

Introduction: During the first year, ICU survivors show a greater use of health services and a high percentage become chronic patients in addition to presenting high rates of hospital readmission (up to 47%) and mortality (17%). The most common consequences, after admission in ICU, are included in what has recently been called Post-Intensive Care Syndrome (PICS).

Objectives: To determine the frequency of appearance of the Post-Intensive Care Syndrome (PICS) in patients and their main caregiver, treated in an Intensive Care Unit (ICU), 3 months after discharge.

Methods: Prospective observational study in a 14-bed ICU for 12 months. Inclusion criteria were admission > 7 days and at least one of the following: mechanical ventilation (invasive or non-invasive) > 3 days, sepsis or shock. Patients with cognitive impairment or severe dependency prior to admission were excluded. The variables analyzed (physical, cognitive and psychoemotional), were assessed using validated scales and physical examination in the follow-up consultation. The presence of overload from the main caregiver was assessed using two validated scales. Prevalence was measured as the percentage of cases of patients with PICS identified of the total number of patients discharged with risk criteria.

Results: Of the 52 patients who presented risk factors for developing PICS, 36 were discharged from the unit. Of the 25 patients who attended the follow-up consultation at 3 months, 18 had PICS. The fundamentally affected dimension was physical 55.5%, followed by psycho-emotional 27.7% and cognitive 16.6%. In all the cases of patients with PICS, the main relative had caregiver overload.

Conclusion: The frequency of PICS at three months after ICU discharge is at least 50% in patients with risk factors. In all cases presented by the patient, their primary caregiver is affected too. The high frequency of this syndrome would require adopting measures for it to be forward, and follow-up as well as therapeutic approach, both for patients and for their main caregivers.

Intensive Care Medicine Experimental 2020, **8(2)**: 000388

Introduction: Cardiogenic shock (CS) is the fatal common path of some of the most prevalent diseases in the world (1), yet its management is not straightforward. Veno-arterial extracorporeal membrane oxygenation (VA-ECMO) use as a rescue therapy for refractory cases is growing in popularity (2).

Objectives: The purpose of this study was to evaluate the different outcomes of patients with refractory CS supported with VA-ECMO, stratified by etiology, in the short-term and after 1-year follow-up.

Methods: Data was collected prospectively from 2010 to 2020, patients with CS having received VA-ECMO were reviewed retrospectively. We analysed baseline demographic variables, cause of CS, ECMO characteristics, complications and global survival (at ECMO weaning, hospital discharge, and after 1 year), using SPSS software, version 20.

Results: We included 92 patients who received 101 VA-ECMO. The median age was 54 (interquartile range IQR 42-63), 64% were male. Causes of CS were: decompensated advanced heart failure (32%), acute myocardial infarction (AMI) (26%), post-surgical pulmonary thromboendarterectomy (13%), post-cardiotomy, (10%), acute myocarditis from infectious, toxic or metabolic causes (7%).

Before VA-ECMO cannulation 61% of patients were supported by an intraaortic balloon pump.

A peripherally VA-ECMO was established in 91% of cases. The median length of ECMO was 186 hours (8 days, IQR 5.4 – 13 days), median ICU stay 18 days (IQR 12-33 days).

The global survival rate during ECMO support was 68%, with 43% of patients being discharged home, and all of them were alive one year later. Patients with reversible causes of cardiogenic shock (acute myocarditis, right ventricular failure following pulmonary embolism) fared better overall, with a 100% survival rate.

In 50% of patients with CS secondary to AMI (with previous normal or unknown cardiac function) a “bridge to decision” strategy was implemented. Sixty-four percent were weaned from ECMO, but only 37% of weaned patients survived. A heart transplantation was made in 83% of the survivors of this subgroup.

Patients with CS secondary to acute decompensation of previous cardiopathy were usually placed in the “bridge to transplant” category.

Out of 32 patients, half of them died, but in those succeeding into getting a heart transplantation (59%), global survival was of 83%.

Postcardiotomy CS patients requiring VA-ECMO had a global survival of 43%, the most common surgeries needing this kind of support being pulmonary thromboendarterectomy and valvular surgery with previous systolic dysfunction.

One year after hospital discharge, 39 out of the 40 surviving patients remained alive and out of the hospital.

Conclusion: Refractory CS patients are a very heterogeneous cohort. Outcomes were far better in potentially reversible causes of CS like acute myocarditis. VA-ECMO offers an effective support tool for these patients, achieving favorable results at hospital discharge and after 1-year follow-up.

Mechanical ventilation in octogenarians, intensive care and subsequent hospital survival in a medium sized district general hospital in the UK

M. Allsop¹; M. Mazalkov²

¹Peterborough City Hospital, Peterborough, United Kingdom; ²Anaesthetics, Peterborough City Hospital, Peterborough, United Kingdom

Correspondence: M. Allsop

Intensive Care Medicine Experimental 2020, **8(2)**: 000406

Introduction: With an increasingly aging and co-morbid population coupled with the increasing demand on NHS intensive care beds it is more important than ever to have a clear understanding of the benefit added by admission to intensive care for mechanical ventilation. In addition there is an increasing drive to provide patients with the information allowing them to make an informed decision regarding their escalation plan. Currently despite making up only 4% of the population, octogenarians account for around 10% of ICU admissions in the developed world [1].

We set out to perform a retrospective study looking at the previous 4 years of intensive care admissions for mechanical ventilation at Peterborough City Hospital. We then compared the survival of all patients <80 years old with the survival of patients 80 years and over. For the 80 and over age group we then compared the medical admission vs surgical admission survival outcome.

It should be noted that the intensive care department already puts a strong emphasis on requiring a good pre-morbid state prior to admission to the ICU, and all admissions are approved by an intensive care consultant. Therefore, the patients with a high frailty score deemed unlikely to benefit from mechanical ventilation, are not reported in these figures.

Objectives: To compare intensive care survival between patients younger than 80 years and those patients 80 years and over. To compare the above patient's hospital survival once they have been stepped down from intensive care.

To compare whether medical vs surgical admission in 80 and over affects survival.

Methods: Data was extracted from Intensive Care National Audit & Research Centre (ICNARC) and is based on data exclusively from PCH.

Results: Over a 4-year period (2015–2019) 1025 patients received ventilatory support in PCH's ICU. Of these 99 (9.7%) were ≥80.

52.5% of ≥80 survived ICU and 41.4% were discharged home (11.1% dying in hospital post ICU). Compared with 74.4% of <80's surviving ICU and 68.3% being discharged home (6.1% dying in hospital post ICU).

Even though the vast majority of octogenarians admitted to PCH's ICU for mechanical ventilation had a very good pre-morbid status, compared to all those <80, they had a 21.9% lower chance of ICU survival and 27.1% lower chance of being discharged home.

Overall 91.7% of all patients <80 discharged from ICU were subsequently discharged from hospital. This is to be compared with only 78.8% of the ≥80 cohort who are stepped down, showing they are 12.9% less likely to be discharged after an ICU admission. The data also shows a year on year increase in numbers of patients admitted for mechanical ventilation 232 patients in 2015-2016, 244 in 2016-2017, 261 in 2017-2018 and 288 patients in 2018-2019. There is also a general trend of increasing numbers of octogenarians being ventilated ie: 18 in 2015-16 and 31 in 2018-2019.

Age	Total patients	Survived ICU	Survived Hospital
<80 years	926	689	632
≥80 years	99	52	41

Table 1. Total numbers of patients admitted to ICU for mechanical ventilation 2015-2019.

Results: part 2, medical Vs surgical admission for ≥80 year olds between 2015–2018.

Medical patients represented 63.2% of ≥80 ICU admissions for mechanical ventilation with 35% of these patients surviving to be stepped down to the ward. Of those stepped down 100% were discharged home.

Of the surgical patients a higher percentage of 77% survived to be stepped down to the ward with 67% of these being discharged home. Therefore hospital survival was 35% for medical patients ≥80 and 52.4% for surgical admissions ≥80.

(Patients were excluded from part 2 of this study if it wasn't clear if they were medical or surgical (16 patients). 2019 data for part 2 was not readily available at time of this project (31 patients)).

Conclusion: The data from this study, shows that overall an octogenarian with a good pre-morbid status stands a 41.4% chance of surviving the acute hospital admission. This percentage varies from some of the reported data, however in our study, we only include those who have received mechanical ventilation.

It can be speculated that should all octogenarians requiring mechanical ventilation be admitted to ICU, rather than those with a good pre-morbid status, mortality among this group of ≥80 s would be significantly increased.

Intensive Care Medicine Experimental 2020, **8(2)**: 000411

Introduction: Hyperlactacidemia is a marker of organ dysfunction widely used in critically ill patients with a direct relation with tissue hypoxia, but it is difficult to draw conclusions with isolated lactate values.

The topic of lactate kinetics has been gathering increased interest and decreasing blood lactate concentrations have been associated with better outcomes.

However, controversy remains over what is the better cut-off value to use when considering prognosis. In studies that were conducted in a 24-hour period a 10% cut-off has been proposed. A new study from 2019 proposed 19% as the ideal cut-off.

In the present study we aimed to investigate the prognostic impact of two different values of lactate variation in the first 24 hours of critically ill patients admitted to a polyvalent intensive care unit (ICU).

Methods: We conducted a retrospective investigation of a prospectively gathered database collecting subjects admitted to a single ICU from January 2014 to December 2018. Inclusion criteria stated a lactate value above 2,0 mmol/L on admission.

The maximum value of lactate concentration in the first 2 days was collected in order to calculate its variation in the first 24 hours after admission. Data on ICU mortality, ICU length of stay, days of invasive mechanical ventilation (IMV), need for vasopressors and renal replacement therapy (RRT) were also collected.

We performed the same statistical analysis for the two cut-off values: 10% and 19%. The primary end-point was the association between lactate variation in the first 24 hours and ICU mortality. The secondary end-points were association between lactate variation and ICU length of stay, days of IMV, need of vasopressors and need of RRT.

Results: A total of 674 patients (male=409, age (mean \pm SD) = 63.4 \pm 16,3 years) were included. The global mortality rate was 39,9%. Analysis of mortality showed a statistically significant association with both cut-offs ($p < 0.001$), higher with a lower lactate variation.

A decreased lactate variation was associated with the need for vasopressors ($p = 0.001$ for 10% and 19%) and RRT ($\leq 10\%$ with $p = 0.003$; $\leq 19\%$ with $p = 0.010$). The ICU length of stay had a statistically significant association with a lactate variation $\leq 10\%$ ($p = 0.015$) but not with $\leq 19\%$ ($p = 0.057$). We did not find a significant association between IMV days and lactate variation ($\leq 10\%$ with $p = 0.647$; $\leq 19\%$ with $p = 0.312$).

The 10% cut-off showed a sensitivity of 71% (95% CI 67-76) and specificity of 54% (95% CI 48-60) for mortality compared to a 64% sensitivity (95% CI 59-68) and 62% specificity (95% CI 56-67) for the 19% cut-off.

Conclusion: Both cut-offs were associated with ICU patients' mortality. Only the 10% cut-off was significantly associated with the ICU length of stay.

When analyzing sensitivity and specificity, we could not find a statistically significant difference between cut-offs. However, given that the 10% cut-off has a greater sensitivity we would select this value for our clinical practice.

Intensive Care Medicine Experimental 2020, **8(2)**: 000421

Introduction: Negative psychological sequelae following an ICU admission remain a prevalent issue for critical illness survivors. Delusional memories are the biggest modifiable risk factor. Mitigating the negative character of formed memories may be possible during a critical window of initial memory consolidation when the memories

are malleable. Previously, psychological support based on positive suggestions (PSBPS) was identified as a viable psychotherapeutic intervention in the ICU setting. Given that the spectrum of emotional support doulas provide is very similar to PSBPS, we trained doulas to work in the ICU setting. Introducing themselves as "members of the team", doulas provided daily PSBPS sessions throughout the patients' ICU stays.

Objectives: Acceptance of the intervention is a vital part of the intervention's success. We have therefore evaluated feedback from patients and their families regarding the intervention.

Methods: Following ICU discharge, patients and their family members who were present during the intervention were asked to provide their impressions of the intervention including open-ended and multiple choice questions.

Results: Of the 48 patients who received the intervention, all provided feedback. 40 patients recalled a team member explaining what was happening to them and 37 found this comforting. 29 recalled a team member holding their hand and 28 found this comforting. When asked what made them feel better while in the ICU, 34 recalled specific aspects with themes summarized in the table; others had no factual memories. Nine family members who had witnessed an interventional session also provided feedback. When asked what they thought about the intervention, all provided positive feedback. Family members were also asked if the doula interaction was helpful to them, and again all also responded positively. Representative themes are provided in the table.

Patient Perspective (number of responses)	
Things that made me feel better in the ICU	-Positive Interaction with team/feeling cared for (15)
	-Being comforted/feeling secure (8)
	-Reassurance/explanations of medical course (5)
	-Family presence (4)
	-Being alive (2)
Family Perspective (number of responses)	
Things I liked about the intervention	-Relaxing/soothing/calming (3)
	-All aspects (3)
How the intervention was helpful to me	-Spending time with family (1)
	-Providing compassion (1)
	-Helped to understand what was going on (1)
	-Explaining things/answering questions (4)
	-Providing comfort/human touch/reassurance (4)
	-Showing caring team approach (1)

Conclusion: Patients and their families welcomed ICU doulas providing psychological support during the ICU stay. Patient responses highlight the importance of personal interaction with care team members during the ICU stay. Family member responses are uniformly positive regarding the intervention.

Intensive Care Medicine Experimental 2020, **8(2)**: 000431

Introduction: Many mental disorders can arise after critical illness, including anxiety, depression and post traumatic stress disorder (PTSD). Those psychiatric disorders can impair the quality of life of ICU survivors.

Objectives: The study aimed to estimate the frequency PTSD, anxiety and depression among ICU survivors and to investigate the relationship between those psychiatric disorders.

Methods: It is a mixed method study conducted in a 9-bed medical ICU of Farhat teaching hospital from January 2017 to January, 31 2018 including all ICU survivors beyond 3 months after discharge. Information regarding demographic and clinical characteristics were obtained from medical records. At 3 months post-ICU discharge, the patients were contacted by phone to complete the Hospital Anxiety and Depression Scale (HADS) and Impact Event Revised Scale (IES-R). Spearman's correlation test was done to find the association between PTSD, anxiety and depression among ICU survivors.

Results: Three hundred ninety-three patients were admitted during the study period. One hundred ninety-one (48.6%) were discharged alive, 56 (29.3%) were never successfully contacted and 21 (11%) died within the 3 months' period. One hundred fourteen patients fulfilled the inclusion criteria and were enrolled in the study.

Clinical characteristics were: mean age, 56 ± 17.8 years. The majority of patients were males, 66 (57.9%); current alcohol consumers, 13 (11.4%); median Charlson comorbidity index, 1 [1-2]; Respiratory distress, 79 (69.3%); median SAPS II at admission, 25 [17-31]; invasive mechanical ventilation, 47 (41%); vasopressors, 13 (26%); median of duration of IMV, 0 [0-4]; length of stay, 6 [4-10]; Median IES-R, 19 [14-28]; median HADS A, 4 [3-10]; median HADS D, 5 [4-6]. Twenty-five (21.9%) patients met diagnostic criteria for PTSD (IESR ≥ 37). Twenty-four (21%) patients had anxiety (HADS A > 11) and only eleven (9.6%) had depression (HADS D > 11).

There was significant correlation between PTSD and anxiety ($r=0.662$; $p=0.000$) and PTSD and depression ($r=0.473$; $p=0.000$). There was also a statistically significant correlation between anxiety and depression ($r=0.196$; $p=0.037$).

Conclusion: Psychiatric disorders after clinical illness are common. There was a strong and significant statistical correlation between anxiety and PTSD, PTSD and depression, and anxiety and depression in ICU survivors at 3 months post ICU discharge.

Intensive Care Medicine Experimental 2020, **8**(2): 000443

Introduction: A substantial number of patients treated in ICUs suffer from a loss of health-related quality of life (HRQoL) in the aftermath of their critical illness. This is due to new or worsened physical, cognitive or psychological impairments, collectively referred to as the Post-Intensive Care Syndrome (PICS). As a result ICU survivors have more consultations with their general practitioner (GP) after their ICU treatment (1). Relatives of ICU patients are also at risk of developing psychological impairments, referred to as PICS Family (PICS-F). The General Practitioner (GP) may have a pivotal role in the aftercare of ICU survivors and their relatives. However data on the perceived boundaries for GPs to become involved in PICS (-F) care is largely lacking.

Objectives: To identify perceived boundaries for GPs to become more involved in post-ICU care and identify possible targets for improvement.

Methods: 769 Dutch GPs were approached to fill out a self-composed questionnaire to assess the following questions: 1) What is the current state of knowledge regarding PICS and PICS-F? 2) How often is the GP confronted with PICS-related symptoms in his practice? 3) Who is responsible for recognition and treatment of PICS in the opinion of the

GP? and 4) What is the current state of information sharing between the hospital/ICU and the GP concerning ICU treatment and is the GP satisfied with this information?

Results: 258 GPs responded to the questionnaire. As much as 58% of these GPs was not familiar with PICS and 44% not with PICS-F prior to receiving the questionnaire, although annually 2 (median, IQR: 1-3) patients and 3 (median, IQR: 1-3) relatives of ICU patients visit their GP with impairments compatible with PICS(-F). Patients most frequently present themselves to GPs with fatigue, psychological or cognitive impairments. GPs refer these patients to a psychologist or to a general practice assistant, while only 15% of the GPs were familiar with the concept of dedicated ICU follow-up clinics. GPs report that they feel responsible for both recognition and treatment of PICS-related sequelae in their patients, but they have insufficient knowledge. Up to 87% of GPs expressed a wish to obtain more knowledge about PICS(-F) via an e-learning or by providing education for GPs. Furthermore, information sharing between the hospital/ICU and the GP in its present state is suboptimal and could therefore be improved, for instance by including information regarding the long-term consequences of ICU treatment in the discharge letter of patients.

Conclusion: Although PICS(-F) is a widely recognized problem within the ICU community, the majority of Dutch GPs is not familiar with PICS(-F)-related sequelae, but nevertheless feel a responsibility to recognize and treat them. GPs want to be educated preferably via an e-learning or educational programs, and informed about the long-term consequences of ICU treatment and existing ICU follow-clinics in the discharge letter, to improve GP's involvement in post-ICU care.

Epidemiology and outcome of elderly patients after renal replacement therapy in the intensive care unit: an observational study

C. Salathé¹; M. Altarelli²; E. Poli²; P. Eckert²; A. Schneider²

¹Hospital Neuchâtel - Pourtalès, Neuchâtel, Switzerland; ²Service of adult intensive care & burns, Lausanne University Hospital, Lausanne, Switzerland

Correspondence: C. Salathé

Intensive Care Medicine Experimental 2020, **8**(2): 000487

Introduction: Renal replacement therapy (RRT) is commonly performed in patients admitted to the intensive care unit (ICU). However, it is associated with high morbidity and mortality and its relevance is sometimes questioned in elderly patients in particular when they suffer from other pre-morbid illnesses.

Objectives: We sought to evaluate the long-term outcomes and quality of life (QOL) of elderly patients who survived critical illness requiring renal replacement therapy (RRT).

Methods: We retrospectively identified all patients aged over 55 admitted to our ICU between January 2015 and April 2018 who received RRT for acute kidney injury (AKI). We assessed their vital status by cross-referencing our hospital database and the Swiss national death registry. Mortality and time to death were recorded. Patients still alive at the time of the study underwent a phone interview. They were asked about their dialytic status and their quality of life was evaluated using an EQ-5D survey with visual analog scale (VAS). Results were stratified according to patients' age group (group 1, G1: "55-64 yo"; group 2, G2: "65-74 yo"; group 3, G3: ">75 yo") and comparisons between these groups and European standards were made.

Results: During the study period, 354 eligible patients were admitted to our ICU. Of those, 173 (48.9%) died during the index hospital admission (150 in ICU and 23 on the ward). After a median follow-up of 2.7 years (IQR 1.6), a further 62 had died with a mean time to death for hospital survivors of 149.9 days (IQR 450.4). Hence, 119 patients were still alive at the time of the study. We successfully contacted 96

(80.7%) of them and 83 (69.7%) were included in the study (G1: 24, G2: 44, G3: 15). Among the survivors, only 6 (7.2%) were still RRT dependent at time of the study. Median EQ-5D and VAS scores were respectively 6 (IQR 2) and 75 (IQR 30). Pain and mobility issues were the most frequent items quoted in the survey. Group comparisons are shown in figure 1. Both score were lower in patients in G3 compared to the other two groups (both p values < 0.01). However, they were comparable with EQ-5D index population norms of aged matched patients (1).

Conclusion: The need for renal replacement therapy identifies a population at very high risk of mortality with a survival of 33% at 2.5 years. However, quality of life for survivors was acceptable and comparable to age matched control population.

Intensive Care Medicine Experimental 2020, **8(2)**: 000556

Introduction: The ability of first responders to deliver appropriate care after medical emergencies determines positive outcomes for patients. Clinicians' skills, best practice, and knowledge are gained from basic life-support courses, unfortunately often lost due to a lack of hands-on practice. The purpose of debriefing is to facilitate the identification of errors, and eventually develop plans to improve future performances specifically to both individual and team achievement. It also refers to a valid approach for correcting clinical behavior, and allows clinicians to reflect on knowledge, skills, attitude or teamwork revealed during a clinical event that if modified would benefit other patients in similar situations. At our institute a well-structured Rapid Response System (RRS) has been implemented; when a patient deteriorates a Medical Emergency Team (MET) is called to the bedside of the patient in crisis. The MET is summoned to the bedside between 80 and 100 times a year, and is composed of health care responders: an anesthesiologist, 3 nurses, an aide, and a clinical clerk who is involved in alerting and initiating the RRS. Anesthesiologists and nurses are trained in basic life support (BSL)/advanced cardiac life support/pediatric advanced life support, and aides are trained in BLS regularly (once every two years). So far, at the end of a crisis, the debriefing has been left as optional for the team despite the fact that it has always been taught and performed regularly during ACLS/PALS training sessions.

Furthermore, anesthesiologists and senior nurses have been receiving training in how to conduct a structured debriefing after clinical crisis. The questionnaire was submitted as a part of a larger and multifaceted quality improvement project aimed at implementing regular post crisis debriefing, and to detect areas of improvement.

Methods: This is a descriptive, structured and voluntary, anonymous, non-funded, self-administered cross-sectional survey conducted at a 78-bed medical institute accredited with Joint Commission International standards and focused on all solid organ transplantation medicine. The Quality and Patient Safety Department approved the conduction of the survey. The need for ethics committee approval was waived given the voluntary nature of the survey. The aim of the survey was to generate hypotheses and identify critical issues among responders, to guide educational activities, and to detect the attitudes of the personnel toward debriefing implementation as routine. The survey was developed by three investigators based on a review of the theoretical basis of survey elaboration, reappraisal of the relevant literature in the field of communication, team dynamics, and debriefing, which later was piloted by the quality department for clarity of the questions. We conducted a Web-based survey sent by e-mail with a link to a total of 593 potential responders involved in clinical activity: 118 physicians, 342 clinical nurses, 97 aides, and 36 unit clerks. The survey was anonymously self-administered on a voluntary basis by the respondents, and submitted online using a Survey Monkey system. The survey was conducted using 17 multiple-choice questions organized in four domains: Respondent characteristics; adherence to resuscitation guidelines and assessment of value of training; teamwork and leadership and awareness of mutual respect; professional development and debriefing. We recorded respondents' characteristics inherent to work activity: years of service at the institute, clinical role, ward of principal activity, and number of emergency conditions experienced in previous years. The survey was checked for content validity by members of the quality coordinating team at the hospital. Survey results were analyzed using descriptive statistics (numbers and percentage). Chi-square test or Fisher's exact tests were applied where appropriate. Exploratory data analyses with contingency tables were prepared to illustrate different responses among groups according to roles, years of service at the hospital and number of yearly-managed conditions experienced. Data management and statistical analysis were done with SAS 9.4 by SAS Institute Inc., Cary, NC, USA.

Results: Response rate to the survey was 25% (148 healthcare workers). Of all respondents, 86% were employed >10 years, 75% were involved in ≤5 emergencies over the previous year. Resuscitation guidelines were considered fully applied by 55%; 64% of respondents considered the teaching program as sufficient. Of all participants, 97% were aware of the importance of teamwork dynamics, 79% were aware of the importance of the personal performance, and 52% considered emergencies as valid opportunities for professional growth. Leadership was considered important by 45% of respondents; debriefing implemented by 41%, and considered a potentially useful tool by 85%.

Conclusion: We hypothesize that quality improvement programs based on debriefing implementation and communication may improve the outcome during emergency conditions, and increase satisfaction for the operators. Future prospective studies are needed to substantiate this hypothesis.

Intensive Care Medicine Experimental 2020, **8(2)**: 000557

Introduction: Fragility assessment in very elderly patients (≥ 80 years) is inversely associated with short-term survival. In this regard, we believe that the implementation of this scale to all ICU patients on admission, regardless of age, can provide us with additional objective information.

Objectives: To assess the impact of fragility, defined by the Clinical Frailty Scale (CFS), on hospital mortality of ICU admitted patients regardless of their age.

Methods: Prospective observational study evaluating the role of frailty on patients admitted to a medical-surgical ICU from October 2016 to April 2019. Patients who required transfer to another centre during their admission were excluded. Analysed variables were age, sex, comorbidities, SAPS 3, SOFA, type of patient, hospital stay before ICU admission, length of stay and outcome at discharge. We also included other variables of clinical interest during ICU admission. Fragility was estimated using the CFS scale, using a cut-off value of ≥ 3 . Continuous variables are presented as median and interquartile range. To analyse the association with hospital mortality, a univariate and multivariate analysis was performed using backward logistic regression and recursive partitioning using CHAID tree to estimate special risk populations.

Results: 1462 patients were included. Mean age of 66 years (55-74), 42% women. Medical reason for admission in 54.5%. SAPS 3 46 (38-56), SOFA on admission 2 (0-10). Average ICU length-of-stay of 2 days (1-4), and time in-hospital after ICU discharge of 6 days (3-12). ICU survival was 96.8%, and hospital survival was 93.8%, with a rate of ICU readmissions of 3.2%. The CFS was 3 (2-3). The significant results regarding hospital mortality obtained from the multivariate analysis are shown in Table 1. Recursive partitioning model established that the greatest risk factor for mortality in the population was the development of neurological failure during ICU admission, with a mortality rate of 31% (51% in frail patients vs 17% in non-frail patients: $p < 0.0001$). Regarding patients without neurological failure, the main risk factor for mortality was presenting a CFS > 3 before ICU admission, with a mortality rate of 3.2% (11.2% in frail patients vs 1.2% in non-frail patients: $p < 0.0001$).

Conclusion: The fragility index is an independent factor of hospital mortality in patients requiring ICU admission. The other factors identified are the need for mechanical ventilation, the need for preventive isolation or the development of organ failure.

Intensive Care Medicine Experimental 2020, **8(2)**: 000565

Introduction: The ideal intensive care unit (ICU) design creates a 'healing environment' humanizing the medical setting, minimizing environmental stressors for healthcare professionals (HCP) and families while supporting patient recovery^{1,2}. Due to the multifactorial nature of ICU design, understanding the effect on patient, family and staff outcomes is complex and remains limited.

Objectives: To conduct a scoping review of studies of ICU design features. Specifically, to map outcomes and measures evaluating the effect of these features on patients, family and HCPs. Data will inform future studies evaluating new or existing ICU designs.

Methods: In consultation with an information specialist, we iteratively designed and executed a search strategy across seven databases from January 2007 to May 2020. All research designs were eligible as long as studies explored the effect of ICU design features on patients, family and/or HCPs. Reviewers independently confirmed study eligibility, one reviewer extracted data with accuracy confirmed by a second.

Results: Of the 18,577 citations screened; 49 studies met inclusion criteria; most (41/49, 84%) were published after 2012. 28 (57%) studies evaluated a newly built or renovated ICU/ICU room, the remainder evaluated existing ICU designs or features. We grouped studies into 12 design feature categories, the most common being light (25/49, 51%), single vs multi-occupancy rooms/pods (19/49, 39%), and family-centred (13/49, 27%).

Types of design features	n (%*)
Light	25 (51)
Occupancy	19 (39)
Family centered	14 (29)
Workspace Layout	13 (26)
Equipment related	11 (22)
Noise	10 (20)
View	9 (18)
Outside Space	9 (18)
Aesthetics	8 (16)
Privacy	7 (14)
Unit Layout	7 (14)
Visibility	5 (10)

*All categories were categorised for multi-design feature studies and therefore the % do not sum to 100.

We identified 67 distinct outcomes. Patient clinical outcomes were included in most studies with the most commonly reported being length of stay (13/49, 26%), mortality (10/49, 20%) and psychological outcomes such as delirium occurrence (9/49, 18%) and duration (5/49, 10%). Objective ICU/ICU workspace physical environment outcomes were reported in only 8/49 (16%) studies and included physical/visual accessibility (3/49, 6%), sound levels (3/49, 6%), light levels (2/49, 4%), and corridor utility/traffic patterns (1/49, 2%). Most commonly measured HCP reported outcomes were staff experience/perception (12/49, 24%), staff stress (4/49, 8%), team interaction (3/49, 6%) and team collaboration (3/49, 6%). Only 5/49 (10%) studies measured patient reported outcomes; 7/49 (14%) studies measured family reported outcomes.

Conclusion: The last decade has seen an increase in studies evaluating the effect of ICU design. However, few studies characterise objective environmental characteristics and fewer use patient or family reported outcome or experience measures. Our findings can inform design of future studies evaluating new or existing ICU designs.

000581**Sex and gender differences in the intensity of intensive care**E. Zettersten¹; G. Jäderling¹; M. Bell¹; E. Larsson¹¹Departement of physiology and pharmacology, Karolinska Institute, Stockholm, Sweden**Correspondence:** E. Zettersten*Intensive Care Medicine Experimental* 2020, **8(2)**: 000581

Introduction: It has been previously reported that there are differences in the care given within the ICU between men and women^{1,2}, and that men have a lower probability of being discharged from the ICU given equal disease burden as women³. To date there are no satisfactory explanation as to why that is. The aim of this study is to investigate if any differences exist between men and women regarding the level of intensive care provided, given equal disease burden.

Objectives: To investigate differences in mechanical ventilation, invasive monitoring, vasoactive treatment, placement of dialysis catheters and central venous catheters between men and women in the ICU.

Methods: This is a retrospective cohort study of 9067 ICU patients admitted to the Karolinska University Hospital Stockholm, Sweden, between 2006-2016. Data was extracted from the ICU medical record (PDMS, Clinisoft[®], GE Healthcare). Differences in use of mechanical ventilation, invasive monitoring, vasoactive treatment, echocardiograms, placement of dialysis catheters and central venous catheters based on the sex of the patient were analysed using univariate and multivariable logistic regressions, adjusted for Estimated Mortality Rate (calculated using SAPS3 and Apache II), Charlsons comorbidity index and age. Subanalyses were performed on patients diagnosed with sepsis, cardiac arrest and respiratory disease.

Results: Approximately one third (36.4%) of the patients were women. Overall, men received more mechanical ventilation (57.7% vs 51.9%, OR 1.28 95% CI 1.17 – 1.40), more central dialysis catheters (11.8% vs 9.9%, OR 1.21 95% CI 1.05 – 1.40) and vasoactive treatment (49.3% vs 46.6%, OR 1.61 95% CI 1.06 – 1.28). Of the 1799 patients admitted with a respiratory disease, men were more likely to receive mechanical ventilation (55.5% vs 50.0%, OR 1.22 95% CI 1.01 – 1.49). Among patient diagnosed with cardiac arrest (n=536), men were more likely to receive a central venous line (80.3% vs 71.9%, OR 1.60 95% CI 1.04 – 2.45). Women did not receive more of any of the items investigated.

Conclusion: We conclude that differences in the level of intensive care provided to men and women exists. Knowing that baseline level of disease has been adjusted for, it is clear that this finding warrants further investigation.

000583**Patient centred care and early rehabilitation for enhanced ICU outcome and recovery**A. Ersson¹; L. Orvelius²¹Anaesthesia and Intensive Care, Region Sormland, Nykoping, Sweden;²Anaesthesia and intensive care, Region Ostergotland, Linkoping, Sweden**Correspondence:** A. Ersson*Intensive Care Medicine Experimental* 2020, **8(2)**: 000583

Introduction: The development in critical care during the past decades have improved ICU outcome and long-time survival (1), even in highly co-morbid patients. This, in combination with increasing frailty in the ICU case mix, have increased the number of ICU survivors with a poor physical and psychical capacity at the time of discharge (2) and thus, a rising demand for individualised rehabilitation. Furthermore, increasing awareness of post intensive care syndrome (PICS) related sequels, further increases the demand for an adapted and individualised aftercare to preserve function and improve health-related quality of life (HRQoL) (3).

Current data suggests that rehabilitation actions should be initiated early and that programs for PICS prevention and family/ patient centred care (PCC) have favourable effects on ICU outcome and potentially reduce anxiety and PTSD in patients and relatives (4). Early initiation of rehabilitation actions has been shown both feasible and safe to perform (5).

Objectives: To investigate the feasibility and safety of a PCC and early rehabilitation program in a general ICU.

Methods: Setting: A feasibility and safety study in a 12 bed ICU in a university hospital in Sweden.

Population: 21 consecutive adult ICU patients with an ICU LOS > 48 h and on mechanical ventilation were subjected to a PCC program containing early initiated rehabilitation. A multi-professional team performed daily physiotherapeutic interventions and psychosocial activities parallel with normal ICU care procedures. During the study period the mean age of the ICU population was 58 years (73% male). Mean length of stay was 3 days and mean time on ventilator was 59 hours.

Endpoints:

Protocol adherence

Achievement of sedation (RASS)/ pain (BPS, NRS), physiotherapeutic targets (MMS) and Psychosocial assessment (MoCA)

Ability to perform PCC/ family support

Patient/ family participation

Frequency of ICU Diaries

Risk assessment for physiotherapy

Adverse events

Results: The full program was completed in 88% of the patients. The physiotherapy program was fully applicable in all patients while patient cognitive limitations prevented cognitive assessment during the study period.

Sedation (RASS </= -2) targets were met within 4d. BPS /NRS were completed in 80% of the patients during the first week

Interactive rounds were feasible in > 80% after two days and diaries were kept in 80% of all patients. Integrity issues at rounds and inability for relatives to participate were common (>70%).

Low risk for rehabilitation procedures were scored in 66% of the patients, 27% at intermediate and 7% at high risk

No adverse events were recorded

Conclusion: The suggested program was highly feasibly, could be safely performed and could be executed with a high level of participation. Dropouts or late initiation were commonly due to the level of sedation and cognitive impairment which also limited the progression

rate of the physical rehabilitation and made cognitive assessment impossible during the ICU stay. Co-morbidity or severity of organ dysfunction did not prevent execution of the program but required minor adaptations. Interactive rounds were well received by all staff and patients but required procedural and timely adaptation for ensuring patient integrity and to encourage family participation. To enhance and facilitate paramedical participation and integration of relatives, ICU work schedules have to be adapted accordingly.

Intensive Care Medicine Experimental 2020, **8(2)**: 000604

Introduction: COVID 19 pandemic affected thousands of people in Spain. Younger and older people have been infected, even some people without any previous medical history were admitted in a critical care units.

Objectives: Determine if there are any comorbidities related to the increased length of stay in ICU and the prognosis of the patients with COVID 19 pneumonia.

Methods: Retrospective observational study conducted in an intensive care unit of a university Hospital. During the pandemic, ICU beds went from 14 to 39. We analysed the patients admitted to the ICU with the diagnosis of respiratory failure due to COVID 19 pneumonia between 6/3 and 21/4 2020. Patients who are still admitted at the time of data collection and those who moved to another centre due to lack of beds are excluded. Demographic data (age, sex), APACHE II, comorbidities (arterial hypertension, previous pulmonary pathology, dyslipidemia, diabetes mellitus and obesity) are analyzed. We describe the relationship between comorbidities, length of stay and mortality rate. Statistical analysis is performed using the IBM®SPSS Statistics 23 tool.

Results: 67 patients are analysed. Male: 65.6% (44/67). Average age 60 years, APACHE II 14.3 ± 5.2, average stay 14.1 ± 10 days. 80.5% (54/67) had previous pathology: cardiovascular 44.8% (30/67) (HT 41.7% (28/67)). Pulmonary 19.4% (13/67) (asthma 7, 4% (5), SAHS 5.9% (4), COPD 2.9% (2)). 71.6% had other comorbidities (48/67) (dyslipidaemia 40.2% (27), diabetes 22.3% (15)). 19.4% (13/67) did not present any disease prior to their admission to the ICU. 100% of patients received invasive mechanical ventilation since admission. Characteristics and prognosis are shown in Table 1.

Medical history	CV			Pulmonar			No			DL		
	Yes	No	P	Yes	No	P	Yes	No	P	Yes	No	P
Characteristics	30	37		13	54		13	54		25	42	
Sex (male)	76,6 %	59,4 %	0,1	76,9 %	64,7 %	0,3	76,9 %	64,8 %	0,3	64 %	69 %	0,43
Apache II	14,7	14	0,68	14,3	14,3	0,9	11,89	14,9	0,125	17,1	12,35	0,002
Ferritine	1526	2856	0,14	2440	2285	0,9	3000	2100	0,4	2156	2389	0,8
Creatininie	1,69	1,31	0,2	1,2	1,55	0,37	1,3	1,5	0,6	1,9	1,22	0,02
Bilirrubin	2,27	1,8	0,4	1,6	2,1	0,48	2,5	1,9	0,47	2,65	1,6	0,07
Prone	66,6 %	64 %	0,34	53,8 %	68 %	0,24	60 %	66 %	0,48	80 %	57 %	0,04
Traqueostomy	50 %	41,6 %	0,34	50 %	44 %	0,48	30 %	50 %	0,19	43,4 %	46,6 %	0,5
Mortality rate	46,6 %	59 %	0,2	53,8 %	53,7 %	0,6	30 %	50 %	0,174	40 %	61 %	0,06
Length of stay	13,6	14,6	0,67	11,2	14,9	0,24	13	14,4	0,6	15	13,5	0,6

Conclusion: In our sample, we did not find statistically significant differences between the medical personal history of cardiovascular pathology (AHT), pulmonary disease or dyslipidemia and length of stay or mortality rate of critically ill patients on mechanical ventilation for COVID 19 pneumonia. Medical history of dyslipidaemia is related with higher creatinine values in our sample.

Evaluation of the relationship between body mass index with sepsis and intensive care outcomes in critically ill patients

Z. çınar¹; B. Öztürk²; M. Aydoğdu³

¹Department of anaesthesiology, division of critical care, Gazi University School of Medicine, Anaesthesiologist, fellow of critical care, Ankara, Turkey; ²Department of pulmonary critical care medicine, Gazi University School of Medicine, Resident of Pulmonary Diseases, Ankara, Turkey; ³Pulmoner diseases department intensive care unit, Gazi University Faculty of Medicine, Professor of Respiratory Medicine, Ankara, Turkey

Correspondence: Z. çınar

Intensive Care Medicine Experimental 2020, **8(2)**: 000616

Introduction: Conflicting results have been reported regarding the potential impact of obesity on intensive care unit mortality and sepsis. Sepsis and obesity independently have high incidence and mortality rates. Physiological consequences of obesity increase the risk of complications and the possibility of slow recovery from sepsis. However, obese patients with sepsis had a lower mortality rate than non-obese patients for the first time in 1999 and it was described as obesity survival paradox.

Objectives: To evaluate the relationship between body mass index (BMI) and intensive care outcomes and development of sepsis in critical patients.

Methods: A retrospective cohort study involving > 18-year-old patients who were followed up in a tertiary care medical intensive care unit from January 2015 to December 2019. Patients' age, gender, arrival diagnosis, APACHE II score, SOFA score, BMIs, comorbid diseases, presence of infection during ICU admission and follow-up, invasive (IMV) and noninvasive mechanical ventilation (NIMV) states, CRP and Procalcitonin levels were recorded. According to their BMI patients were classified as, "underweight" <20 kg / m², "normal" 20-25 kg / m², "overweight" 25-30 kg / m², "obese" 30-40 kg / m² and "morbid / super obese" > 40 kg / m² and compared for intensive care outcomes and sepsis development. IBM SPSS version 23 program was used for data analysis.

Results: A total of 410 patients, 54% of whom were male and the mean age was 71 ± 15, were included in the study. When categorized according to body mass indexes, 6% of patients were underweight, 36% were normal, 32% were overweight, 20% were obese, 6% were morbidly obese. Overweight, obese and morbid obesity were significantly higher in women than in men (p = 0.001). Hospitalization

APACHE II score was significantly higher in the underweight and normal patient groups than in the other patient groups ($p = 0.013$). Sepsis was detected in 113 (28%) cases; 4% of them were underweight, 35% normal, 32% overweight, 21% obese and 7% morbidly obese. There was no statistical difference in terms of sepsis and SOFA scores between the groups ($p = 0.232$ and $p = 0.111$). Besides no difference was identified in terms of hospital acquired and ventilator associated pneumonia development and the causative pathogens. Ninety-three patients (23%) resulted in mortality; 8% was in underweight, 43% in normal, 33% in overweight, 13% in obese and 3% in morbidly obese groups ($p = 0.031$). BMI was evaluated as one of the significant risk factors for mortality (26 ± 5 in exitus group and 28 ± 7 in discharge group; $p = 0.007$). One hundred and twenty-eight (31%) patients received IMV and 187 (46%) patients received NIMV. There was no statistical significance in the distribution of patients who underwent invasive MV (49% in normal group, 51% in overweight and obese group, $p = 0.285$). NIMV administration was higher in overweight and obese patients group (61%) ($p = 0.008$). While no difference was observed between the groups in terms of invasive MV duration, NIMV duration was found to be longer in obese and morbidly obese patients ($p = 0.018$). There was no statistically significant difference between the groups in terms of length of ICU and hospital stay ($p > 0.05$).

Conclusion: With this study, it has been shown that disease severity and mortality were lower in overweight and obese critical patients; the rate and duration of NIMV usage is higher. But there was no relationship between BMI and sepsis and length of ICU and hospital stay. Studies with more patient number are needed to demonstrate the exact effect of BMI on sepsis development and ICU results.

Impact of neurological problems on icu outcome in pulmonary icu patients

Z. Çınar¹; E. Macit Aydın¹; N. Navruzvai²; A. Mammadova²; S. Kodalak²; A. Abbasova²; G. Gursesel³

¹Department of anaesthesiology, division of critical care, Gazi University School of Medicine, Anaesthesiologist, fellow of critical care, Ankara, Turkey; ²Department of pulmonary critical care medicine, Gazi University School of Medicine, Resident of Pulmonary Diseases, Ankara, Turkey; ³Department of pulmonary critical care medicine, Gazi University School of Medicine, Professor of Respiratory Medicine, Ankara, Turkey

Correspondence: Z. Çınar

Intensive Care Medicine Experimental 2020, **8(2)**: 000617

Introduction: There are many risk factors for impaired cognitive function and neurologic damage in intensive care patients including pre-existing cognitive impairment, metabolic factors, mechanical ventilation, prolonged exposure to sedative drugs, sepsis and systemic inflammation. Neurologic problems are frequently associated with other critical illnesses in ICU patients and they may have an influence on ICU outcome.

Objectives: Aim of this study was to investigate whether neurologic problems have any impact on ICU outcome and to determine what are the risk factors for the development of neurologic problems after ICU admission in pulmonary ICU patients.

Methods: This retrospective observational single center study was performed in a University hospital ICU and patients admitted between 2015 and 2019 years were included in the study. Frequency of

neurologic problems at admission, their impact on mechanical ventilation (MV), infections, ICU length of stay and mortality, development rate of neurologic problems during ICU stay and risk factors for them were investigated.

Results: 360 patients were included in the study and there were neurologic problems in the 130 of them (36%) (Group 1). They were stroke, parkinson's disease, Alzheimer, neuromuscular diseases, delirium and muscle weakness acquired in intensive care unit. NIV requirement rate was less than the patients without neurologic problems (group 2) and requirement of mechanical ventilation was significantly more frequent in this group (37% & 19%, $p < 0.05$). Duration of MV was significantly longer in the Group 1 also (19 ± 27 & 8 ± 6 , days $p < 0.003$). Lastly neurologic problems were independent risk factor for extubation failure (OR:3). In the presence of neurologic problems length of ICU stay was significantly longer and they were independent risk factor (OR:3) for the increased length of ICU stay more than 10 days.

When infectious findings were analyzed sepsis rate was significantly higher before and after ICU admission. Urinary and pulmonary infection rates were also significantly higher in these patients.

Neurologic complications developed median 7 days after ICU admission in the 19% of the patients. Most frequent ones were delirium and muscle weakness acquired in intensive care unit. Neurologic problems developed after ICU admission increased mechanical ventilation requirement 3 times as an independent risk factor. Risk factors for ICU acquired neurological problems were existence of sepsis during admission (OR:2.01, 95%CI:1.02-4, $p < 0.045$) and longer MV durations before ICU admission (OR:1.05, 95%CI:1.004-41.103, $p < 0.033$). Neurological problems were not independent risk factor for mortality.

Conclusion: Neurologic problems did not increase mortality but caused more frequently mechanical ventilation requirement, more extubation failure and longer ICU stay in this study population. Additionally our data suggest that having sepsis during admission and longer length of MV prior to admission may increase neurological complication rate.

Liver injury in critically ill ECMO patients with COVID-19: a case series

C. mccarthy¹; H. J¹; H. J¹

¹Icu, Barts Health NHS Trust, London, United Kingdom

Correspondence: C. mccarthy

Intensive Care Medicine Experimental 2020, **8(2)**: 000622

Introduction: Infection with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) has become a rapidly spreading pandemic. Extracorporeal Membrane Oxygenation (ECMO) has become a rescue therapy for some refractory critically ill patients. COVID-19 studies to date showed that patients with abnormal liver tests are at higher risk of progressing to severe disease^{1,2,3}. ECMO patients being the most critically unwell patients, we have used our case series of all patients with COVID-19 on ECMO admitted to the intensive care unit to describe the dysfunction of blood liver tests and some potential causes.

Methods: We included into our case series a total of 18 SARS-CoV-2 positive patients undergoing VA/VV/VAV ECMO as rescue therapy at a university-affiliated tertiary care centre from March 1st to May 28th 2020. Liver test abnormalities were defined as the elevation of the following liver enzymes in serum: ALT >40 U/L, AST >40 U/L, gamma-glutamyltransferase (GGT) >49 U/L, alkaline phosphatase (ALP) >135 U/L, and total bilirubin (TBIL) >17.1 μmol/L. Patients who had raised ALT and/or AST more than 3× the upper limit unit of normal (ULN) were classified as hepatocyte type; patients who had raised ALP or GGT twice the ULN were classified as cholangiocyte type; and patients who had a combination of both ALT/AST elevated more than 3× the ULN and ALP/ GGT twice the ULN were classified as mixed type.

Results: Of the 18 patients mean age was 47.5(27-59)years with 94% being male.100% had abnormal liver results. No patient had documented liver disease prior to hospitalization. Average BMI was 30.4,64% having pre-existing T2DM and 52% having essential hypertension. Average APACHE2 Scores was 19[6-32]. 88% commenced VV-ECMO, 12% VA-ECMO with average duration of 30.4 days. 23% had a hepatocellular picture, 13% cholangiocyte, 11% mildly raised LFTs and 43% a mixed type picture. 83% had preserved synthetic function. On examination of causes, 70% had normal echocardiography, 11% global biventricular failure and 19% mild- moderately impaired RV function. 70.5% patients were on piperacillin/tazobactam, 47% clarithromycin, 41% co-amoxiclav 23% levofloxacin, 11.7% had oseltamivir at the time of the liver injury. 5% (1 patient) was on parenteral nutrition. 11.7% had documented fatty liver on US during their ICU stay. Mortality was 11.7%. Ferritin levels were wide ranging [390-38,000] with mean of 5800 and median of 3100. Average platelets count 150 x109/L.

Conclusion: From previous studies, we know those who had abnormal liver test results, especially in hepatocyte type or mixed type, had significantly higher risks of developing severe disease secondary to SARS-CoV-2. 100% of our patients had abnormal liver tests while requiring ECMO representing the most critically unwell SARS-CoV-2 population. Mixed hepatocellular/cholangiocyte picture was the most prevalent at 43%, as seen in previous studies⁴ with no correlation between type of liver dysfunction and mortality. The liver dysfunction in our study was higher than previously reported^{3,4} and with no previous history of underlying liver disease, suggesting that liver damage in patients with coronavirus infection might be directly caused by the viral infection of liver cells as suggested by previous studies due to SARS-CoV-2 might directly binding to ACE2-positive cholangiocytes to dysregulate liver function⁵. It is also possible that the liver impairment is due to drug hepatotoxicity, which might explain the large variation observed across the different cohorts. There was no direct correlation appreciated between antimicrobials and liver dysfunction in our population. In addition, immune-mediated inflammation, such as cytokine storm and pneumonia-associated hypoxia, might also contribute to liver injury or even develop into liver failure in patients with COVID-19 who are critically ill³. Ferritin levels were wide ranging [390-38,000] with mean of 5800 suggesting systemic inflammatory process. High positive end expiratory pressure and aggressive ventilator strategies can cause RV strain/ pressure overload. While our patients had reduced ventilation on ECMO 33% had RV dysfunction. This right ventricular dysfunction can be associated with severe hepatic congestion. The primary pathophysiology involved in hepatic dysfunction is either passive congestion from increased filling pressures or low cardiac output and the consequences of impaired perfusion. Cardogenic ischemic hepatitis may ensue compounding the insult⁶. It is important to identify RV strain on echo and avoid precipitating factors such as fluid overload and aggressive ventilation. Early consideration for extracorporeal support is important in these patients to avoid RV failure from medical management of respiratory failure. Our case series suggests that there might be concomitant liver injury as a consequence of the critical illness or than direct viral damage on the hepatocytes C19. Attention to modifiable factors and further research into liver injury in SARS-CoV-2 is key with the emphasis on clinical management of these severely ill patients that may consequently impact on liver function.

Survival characteristics of COVID-19 patients requiring invasive ventilation in a district general hospital in East London

S. B. Tay¹; L. Fletcher¹; C. Tai¹

¹Anaesthetics and intensive care, Whipps Cross University Hospital, London, United Kingdom

Correspondence: C. Tai

Intensive Care Medicine Experimental 2020, **8(2)**: 000628

Introduction: There is limited evidence to guide UK based critical care management in patients with novel coronavirus disease 2019 (COVID-19) despite high demand for this service. Throughout the pandemic, emerging trends and initial outcome data have been important to modifying practice. Risk factors for severe disease in the general population have been described [1] but their impact on intensive care outcome is unclear.

Objectives: This is a detailed assessment of local management and outcomes for an east London district general hospital, following the first peak of infection and aims to inform future patient care.

Methods: Adult patients (>18 years) who tested positive on PCR for COVID-19 or those with strong clinical suspicion for COVID-19, admitted to critical care for intubation and ventilation between 14/03-01/05/2020 were identified. Patients transferred to other hospitals pre-extubation, were excluded, as were four patients who remained on invasive ventilation. Epidemiological, clinical, biochemical, temporal and outcome data was collected. Continuous data was analysed with Student's t-test /Mann Whitney's U test and Fisher's exact test was used for categorical data.

Results:

		Survivors (n=15)	Non-survivors (n=24)	p
Age	(years)	62.0 (36.0-76.8)	67.5 (38.5-77.2)	0.095

	Proning	5 (33.3%)	16 (66.7%)	0.055

Table 1. Survivor and non-survivor cohort characteristics. Values are mean(SD), number(proportion), median(range)

Thirty-nine patients met the inclusion criteria; overall there were 15 survivors. There was no significant difference in co-morbidity prevalence, however Asian ethnicity was more highly represented in non-survivors. Illness duration prior to hospital or critical care admission did not differ significantly, nor did time from hospital to ICU admission, during which the majority received advanced respiratory support. Pre-intubation PaO₂/FiO₂ ratio was not statistically different between survivors and non-survivors (median 78.3 vs 82.5 respectively; p = 0.584). Median ICU stay in survivors was 9.0 days (range 3.0-24.0) and hospital admission 17 days (range 11.0-35.0). CRP values were significantly higher in those who died at the initial hospital presentation (p=0.032) and ICU admission (p=0.013). Neutrophil to lymphocyte ratio (NLR) was significantly higher in non-survivors at both hospital admission (p=0.020) and ICU admission (p=0.0003). ICU admission D-dimer showed a trend towards higher levels in the non-survivors.

Conclusion: The APACHE II score appears helpful in predicting COVID-19 mortality and may aid clinical decision making. Higher ICU admission CRP and neutrophil count in non-survivors may suggest a bacterial

superinfection or increased pro-inflammatory response. $NLR \geq 3.13$ plus age ≥ 50 has been proposed as a useful early indicator of severe disease [2]. Higher NLR in our non-survivors could suggest extension to its use as an early indicator of ICU mortality. Lack of significant difference in comorbidities, age, PaO₂/FiO₂ ratio, ferritin and D dimer may suggest these indicators of more severe disease do not impact so greatly on critical care survival, though noting our sample size is small. Significantly higher noradrenaline and paralysis use, plus trend towards proning in non-survivors is likely reflective of disease severity. Patients who are from Black, Asian or minority ethnic (BAME) backgrounds are over-represented in our study, consistent with emerging national evidence [3].

The ICU Impact: results from a short-term follow-up programme

R. Neto¹; M. Carvalho¹; A.I. Paixão¹; A.L. Rios¹; D. Adrião¹; P. Fernandes¹; P. Castelões¹

¹Intensive care department, Centro Hospitalar de Vila Nova Gaia/Espinho, Vila Nova de Gaia, Portugal

Correspondence: R. Neto

Intensive Care Medicine Experimental 2020, **8(2)**: 000637

Introduction: Transition from the Intensive Care Unit (ICU) to the general ward represents a challenge for the critical care patient. Some patients will have an unfavourable evolution, which may be potentially avoidable. A short-term follow-up programme (FU-P) may identify patients at risk of deterioration, with a potential to improve quality of care [1].

Objectives: Evaluate the impact of a post-discharge short-term FU-P on patients from a Critical Care Department (CCD).

Methods: Prospective interventional study performed in a tertiary hospital in Northern Portugal. All patients with an ICU stay > 48 hours or intermediate care stay >72 hours or tracheostomized patients were included in the follow-up programme. Patients were excluded if not eligible to be readmitted in the ICU. Follow-up programme consisted of a medical evaluation by an intensivist at 24, 48 or 72 hours after discharge to the ward and a review of the clinical case with the attending physician. Patients were discharged from the follow-up programme if they presented no organ dysfunction after the visit.

Results: Between September 15th 2019 and March 15th 2020, 29.6% of the patients admitted to the CCD (n=153) were included in the FU-P. The majority were male (65.4%) with a median age of 66 years [52.5 – 76]. Median ICU length of stay was 6 days [4-12.5], 56% of patients required invasive mechanical ventilation (IMV), for a median of 6 days [3-13], and 10.1% were tracheostomized. Most patients were evaluated at 48 hours post-discharge. 20 patients were discharged from the hospital and 1 died before the first evaluation. Median Glasgow coma scale (GCS) and median Barthel Scale at follow-up were 15 and 60, respectively. At follow-up, 16.4% of patients presented some level of pain according to visual analogue scale (VAS). ICU-acquired weakness (ICUAW) was diagnosed in 23.1% of patients. Length of ICU stay ($p < 0.001$) and duration of IMV ($p < 0.001$) were significantly associated with ICUAW. Intensivist's visit resulted in a medical action in 15.0% of patients. 2 patients were readmitted. Admission due to urgent surgery was significantly associated with the need for medical intervention (OR 3.38, $p = 0.01$), as well as longer IMV duration ($p = 0.03$) and higher VAS pain levels ($p = 0.03$). Ten patients died and the median time to hospital discharge was 7 days [3.0-16.5]. Longer duration of IMV ($p = 0.015$) and lower GCS scores ($p = 0.05$) were significantly associated with hospital death. No other variables were associated with hospital mortality.

Conclusion: This short-term follow-up programme was essential to improve the quality of care provided to our patients, while maximizing communication between Intensivists and attending physicians. This is a feasible programme that helps to identify deteriorating patients and further analysis will allow to improve eligibility criteria to better allocate resources.

COVID 19 - experience from a 400-bedded District General Hospital in the North West of England, UK

V. N. Gotz¹

¹Critical Care Unit, University Hospitals of Morecambe Bay NHS Foundation Trust, Lancaster, United Kingdom

Correspondence: V.N. Gotz

Intensive Care Medicine Experimental 2020, **8(2)**: 000675

Introduction: To date, there are about 280,000 confirmed COVID 19 cases in the UK with about 40,000 deaths. Reviewing Public Health England data, the first wave of the COVID 19 pandemic seems to have passed. Our national peak was at the end of March and the beginning of April 2020. The same trend we observed at our local critical care unit and in view of preparedness for a second wave, we analysed our own data from COVID 19 positive patients.

Objectives: We are reviewing our performance during the COVID 19 pandemic and are using the data and reflection to prepare for a second wave.

Methods: We collected demographic data and other variables of all adult male and female patients confirmed positive with COVID 19 by nasal/oropharyngeal swab. All patients were admitted to critical care at Royal Lancaster Infirmary, University Hospitals of Morecambe Bay, Lancashire, UK, in March and April 2020.

Results: We had 21 admission in total, 16 males (76.2%) and 5 females (23.8%), with an average age of 62.14 years. The clinical frailty score was on average 2.05, characterising our patients as 'generally well' with 'no active disease symptoms'. The APACHE score on average was 15.43 and length of symptoms (defined as shortness of breath, cough, pyrexia) pre admission to hospital was 8.05 days on average. The predominant past medical histories were hypertension, diabetes mellitus and hypercholesterolaemia and 57.1% presented with fulminant four quadrant consolidation on admission chest x-ray (due to ARDS). Patients admitted to critical care were either in the emergency department (47.6%) or on the respiratory ward (42.9%). Patients that came to us from the emergency department were on a 15 l/min non-rebreather mask and patients from the respiratory ward were treated with High Flow Nasal Cannulae, CPAP or Venturi. Average length of hospital to critical care admission was 17 hours, but when patients were admitted directly from the emergency department the time reduced to 2-5 hours. We observed markers for multi-organ involvement: positive D-dimer (on average 611.5 ng/ml), elevated procalcitonin (6.43 ng/ml), elevated highly sensitive cardiac troponin HsCTNI (on average 1035.92 ng/l). Average length of stay on ITU was 8.33 days with intubations of 7.85 days. Our patients were all ventilated by Draeger Evita XL ventilators and modes included CPAP/ASB, BiPAP and APRV. 6 patients were proned, 3 patients were referred for ECMO (all declined) and 1 patient received a tracheostomy to support weaning from the ventilator. Cardiovascular support was delivered for 8.5 days on average and 3 patients also received renal replacement therapy (CVVHDF). Patients were extubated to High Flow Nasal Cannulae based on better patient tolerance than CPAP mask and ability to deliver higher concentrations of oxygen when compared to usual face mask. 52% of our patients died (11 in total) and 43% survived (9 in total). One patient is still on critical care past day 60 of the admission. All patients that survived to ITU discharge also survived to hospital discharge and are still alive as per our Lorenzo electronic record system (3 months post admission). Stay on the respiratory ward pre discharge home lasted for an average of 3.6 days. One out of the 21 patients developed a pulmonary embolism after discharge from ITU. The patient was subsequently

anticoagulated by direct oral anticoagulants. All patients will be followed up in 6 months time in our local respiratory out-patient clinic.

Conclusion: Reviewing our local data, outcomes are very much in line with the national COVID 19 ICNARC data. Our predominant patient on ITU would be a male diabetic hypertensive patient, over 60, well & independent in activities of daily living with primarily two organ failures, respiratory and cardio-vascular. Mortality was 52%. Those that also progressed to multi-organ failure involving the renal system displayed a 100% mortality. The most hypoxic patients were prone and ventilator modes were changed to APRV, but numbers are too small to deduct correlations with survival benefit. The review of data has helped us to strategically plan for a potential second wave of COVID 19.

Outcomes of frail critically ill patients

L. Wilson¹; A. Waite¹; N. Main¹

¹Intensive care unit, Royal Liverpool University Hospital, Liverpool, United Kingdom

Correspondence: A. Waite

Intensive Care Medicine Experimental 2020, **8(2)**: 000680

Introduction: Clinical frailty describes a syndrome of reduced physical, physiological and cognitive reserves. Frail patients who are admitted to critical care have a higher mortality rate and prolonged hospital stays [1,2]. However, the Clinical Frailty Score (CFS) [3] has only been validated for use in patients aged 65 years and older.

Objectives: We aimed to assess the prevalence of clinical frailty and the associated mortality and morbidity in all admissions to a tertiary mixed medical and surgical intensive care unit (ICU) during a 6 month period.

Methods: We retrospectively reviewed electronic records of adult patients admitted to the Royal Liverpool University Hospital ICU between July and December 2018. Clinical Frailty Scores (CFS) were calculated using information documented in patient notes. Patients with a CFS of ≥ 5 were categorised as frail. Demographic data, mortality and length of stay (LOS) were also collected.

Results: During the period reviewed 424 patients were admitted to ICU, of which 62% were medical and 38% surgical patients. The prevalence of frailty was 32.5% (138 patients). Both ICU and hospital LOS were longer in frail patients (7.3 and 30.8 days, respectively) compared to non-frail patients (6.5 and 23.4 days, respectively).

The table below outlines the ICU, hospital and one year mortality rates of frail and non-frail patients aged <65 years compared to those ≥ 65 years. Frail patients in both age categories were less likely to survive ICU and hospital admission and less likely to survive to one year.

	<65 years			≥ 65 years		
	Non-frail	Frail	Total	Non-frail	Frail	Total
Number of patients	199/267 (74.5%)	68/267 (25.5%)	267/424 (63.0%)	87/157 (55.4%)	70/157 (44.6%)	157/424 (37.0%)
ICU mortality	23/199 (11.6%)	14/68 (20.6%)	37/267 (13.9%)	20/87 (23.0%)	24/70 (34.3%)	44/157 (28.0%)
Hospital mortality	31/199 (15.6%)	18/68 (26.5%)	49/267 (18.4%)	23/87 (26.4%)	30/70 (42.9%)	53/157 (33.8%)
1 year mortality	39/199 (19.6%)	30/68 (44.1%)	69/267 (25.8%)	30/87 (34.5%)	45/70 (64.3%)	75/157 (47.8%)

Conclusion: Frail adult patients admitted to ICU are less likely to survive their admission and less likely to survive to one year compared to non-frail patients, irrespective of age. Further research should be conducted to validate the Clinical Frailty Score in patients <65 years of age, in order to facilitate evidence-based discussions regarding admission to critical care.

Intensive Care Medicine Experimental 2020, **8(2)**: 000753

Introduction: The most common indications for peripartum ICU admissions are hypertensive diseases of pregnancy and obstetric hemorrhage. Admission indications are well-reported, (1,2) but hemodynamic and laboratory details rarely are. We characterize laboratory values and vital signs according to admission diagnosis in peripartum ICU admissions.

Methods: Retrospective study, IRB approval, 2011-15, an annual birth rate >11000. General maternal characteristics, obstetric characteristics, management and ICU admission details including hemodynamics and laboratory test results were assessed. P-value of 0.05 or less was considered statistically significant.

Results: 96 out of 56,865 women had a peripartum ICU admission. The most common admission diagnosis was PPH (post-partum hemorrhage) (n=35, 38.5%), followed by hypertensive diseases of pregnancy (n=19, 20.9%), and respiratory complications (n=13, 14.3%). 98.9% were admitted post-partum. Mean (SD) ICU LOS was 4.5 (9.2) days. 62.6% required mechanical ventilation. Demographic and obstetric data according to ICU admission diagnosis are shown in Table 1. We compared women with each diagnosis to the rest of the ICU cohort. Women with PPH had a lower platelet count and temperature, table 2. Women with hypertensive diseases of pregnancy had higher blood pressure and different laboratory results including higher creatinine, urea and liver enzymes, table 3. Women with respiratory complications had lower oxygen saturations, and a higher temperature, table 4.

Table 1. Maternal demographic and obstetric data, details of current pregnancy and delivery hospitalization and blood product administration according to ICU admission diagnosis

DNIBP, mmHg, mean ± SD	79.38±15.23	80.86±19.86	0.844
O2 Saturation, mean ± SD	93.69±6.06	98.03±2.62	0.000
Temperature, °C, mean ± SD	37.12±0.77	36.01±1.18	0.001

Key: SD=standard deviation; ICU=intensive care unit; WBC= white blood cell count; SNIBP= systolic noninvasive blood pressure; DNIBP= diastolic noninvasive blood pressure

Conclusion: In characterizing demographic, obstetric, hemodynamic and laboratory data according to the admission diagnosis, we report unique findings. Notable findings included a lower admission temperature among women with PPH, possibly associated with a higher rate of packed cells administration, and a lower gestational age and higher incidence of liver and renal dysfunction among women with hypertensive diseases of pregnancy. Considering our findings, the maternal ICU population might be more heterogeneous than previously reported and patient assessment and care should be individualized accordingly.

Intensive Care Medicine Experimental 2020, **8(2)**: 000791

Introduction: Studies indicate high rates of psychological morbidity amongst patients following admission in an intensive care unit (ICU), including acute stress disorder which is predictive of post traumatic stress disorder (PTSD).[1-3] The recent emergence of covid-19 has had a profound impact on patients, with additional psychological burdens implicated with ICU admission.

Objectives: We aimed to establish the prevalence of acute stress disorder in a single cohort of covid-19 patients discharged from ICU, and to assess which variables could be correlated to their psychological outcomes.

Methods: Data was prospectively collated following local audit approval in a UK district general ICU over a 3 month period between March and May 2020. Patients diagnosed with covid-19, who survived ICU care and were discharged to the ward, were eligible for inclusion. A validated screening questionnaire called the "Acute Stress Disorder Scale" was used to assess the acute stress disorder score (ASDS), the primary outcome.[4] Variables including APACHE II score; CAM-ICU score; duration of stay and sedation in ICU; insertion of tracheostomy; and receipt of invasive ventilation were recorded. A "covid-19 score" was formed to observe the impact of covid-19 specifically on a patient's psychological experience of social isolation.

Results: 75 patients were admitted to ICU, with 22 patients discharged to the ward. 9 patients were included for screening; the other 13 patients eligible for inclusion had been discharged to the community on commencing screening so were unable to participate. The median ASDS score was 39 (IQR 33-54). 3 patients recorded ASDS scores of ≥ 52 , which as an independent cut-off score can predict PTSD with a sensitivity and specificity of 91% and 86% respectively. There was a strong positive correlation between ASDS and duration of stay in ICU and sedation (Table 1). There was a weaker correlation with "covid-19 scores" and APACHE II scores. 8 patients had documented CAM-ICU scores, with 6 patients screened as positive.

Table 1: ASDS Scores by tertiles for recorded patient variables

Total Patients (N=9)	ASDS Score/95	Median "COVID-19" Score /10	Median APACHE Score	Median Number of Days in Critical Care	Median Number of Days Sedated	Invasively Ventilated	Number Undergoing Tracheostomy
n=3	50-<65 (52,56,60)	8 (6,8,8)	14 (7,14,19)	37 (26,37,43)	26 (18,26,28)	3 of 3	3 of 3
n=3	35-<50 (37,39,40)	9 (6,9,10)	16 (8,16,17)	30 (21,30,33)	16 (10,16,20)	3 of 3	1 of 3
n=3	20-<35 (27,32,34)	7 (4,7,8)	14 (8,14,15)	21 (4,21,31)	14 (0,14,15)	2 of 3	2 of 3

Conclusion: In this cohort of covid-19 patients, there is a high incidence of acute stress disorder following admission into ICU. There appears to be a strong correlation between ASDS and duration of ICU stay and sedation. No statistical significance can be derived from these data. Further large studies with long-term follow-up are required to assess if acute stress disorder in this cohort of covid-19 patients is statistically linked to PTSD.

Intensive Care Medicine Experimental 2020, **8(2)**: 000803

Introduction: Patients admitted at the ICU and their family members experience many different stressors, which make them prone for developing psychological disorders like Post Traumatic Stress Disorder (PTSD), anxiety, depression and cognitive dysfunction, also called the post-intensive care syndrome (PICS and PICS-Family). Patients with SARS-CoV-2 infection with acute respiratory failure requiring ICU care and mechanical ventilation are isolated from their loved ones and face an uncertain course of the disease. Most patients have long ICU length of stay with prolonged sedation, analgesia and even muscular blocking agents. Due to longer sedation and mechanical ventilation post-ICU COVID-19 patients will have impaired recall of the ICU stay accompanied by hallucinations or delusions with increased risk of PTSD. The use of an ICU diary for the patient could help fill in memory gaps, gain a sense of reality and complete their fragmented illness narrative.

Objectives: The aim of this study is to evaluate the effect of a doctor and nurse driven ICU diary on the occurrence of impaired mental health in patients admitted with a SARS-CoV-2 infection and their family members.

Methods: An observational cohort study of SARS-CoV-2 patients treated in the ICU of Elizabeth-Tweesteden Hospital in Tilburg, The Netherlands will be conducted. Adult patients admitted at the ICU because of respiratory insufficiency due to SARS-CoV-2, who are mechanically ventilated, are included. During treatment in the ICU the ICU staff initiates a written diary with additional photographs of the patient during treatment. Family members will also be stimulated to make a contribution to this diary. After discharge to a ward, the ICU diary will be continued by nurses of the ward and an ICU nurse practitioner, who is guiding the transfer and treatment on the ward.

After hospital discharge patients' mental health will be monitored on our post-ICU aftercare clinic at 3, 6 and 12 months after discharge. Anxiety, depression and PTSD, cognitive dysfunction and quality of life will be screened in patients and their relatives. The Psychosocial Screening Instrument for adult trauma patients (PSIT), a validated tool, will be used for screening for anxiety, depression and PTSD. Cognitive dysfunction will be screened using the Cognitive Failure Questionnaire (CFQ) and quality of life will be assessed by the Short Form Health Survey 36 (SF-36). The recollection of patients' memory of the ICU stay will be evaluated by the ICU memory tool.

Results: The quantitative data of the PSIT, CFQ, SF-36 will be compared over time and between patients and their relatives. Participants' characteristics including the recollection of memory will be reported and if necessary multivariate analysis will be computed.

Conclusion: This study will contribute to the research on ICU diaries and pioneers on the psychological problems of PICS of SARS-CoV-2 patients and the use of ICU diaries in this group.

000804**The effect of ICU diaries on the recollection of memories and the occurrence of impaired mental health in post-ICU patients: a prospective cohort study**

Intensive Care Medicine Experimental 2020, **8(2)**: 000804

Introduction: Post-intensive care syndrome (PICS) affects 50-70% of ICU survivors. ICU patients as well as their close relatives are at risk of developing PICS symptoms comprising Post Traumatic Stress Disorder (PTSD), anxiety or depression. Post-ICU patients having delusional memories may have a higher risk for developing PTSD symptoms. (Jones, Griffiths, Humphris, & Skirrow, 2001). Little is known about the mental health of patients who have complete loss of memory without fragmented or delusional memories. ICU diaries may contribute to the recollection of memories or completion of a fragmented illness narrative. We hypothesize that the use of ICU diaries will increase memory recollection of patients' ICU stay.

Objectives: The aim of this study is to evaluate the effect of ICU diaries on the recollection of ICU memories. Secondary, we investigate the occurrence of impaired mental health in patients with and without memories of their ICU stay.

Methods: Post-ICU patients, admitted to the ICU from January 2015 to January 2017, were included. During ICU treatment the diary was written by either ICU staff and/or patients' relatives. During follow-up at the outpatient ICU aftercare clinic, 12 weeks after hospital discharge, patients were screened for complete loss of memory of the ICU period. PTSD symptoms were screened by the Impact of Event Scale-Revised (IES-R). The Hospital Anxiety and Depression scale (HADs) was used to assess anxiety or depression symptoms.

Results: A total of 174 patients were included, of which 83 men and 91 females, with respectively a mean ICU stay of eleven and nine days. Of the males 48 had an ICU diary and 35 had memories of their ICU stay. Of the females 33 had an ICU diary and 49 had memories of their ICU stay. A multivariate analysis was conducted on the factors that may influence having memories of the ICU. Patients with a diary had three times higher odds of having memories (OR 3.37 (95%CI: 1.51 – 7.51, p=0.003). Of the patients who had an ICU diary, there were significantly more men than women who had no ICU-recall (p=0.013). Patients were divided into two groups; 1. Complete loss of ICU memory. 2. Complete recall, fragmented or delusional memories. Ten patients without any memory of their ICU stay had an IES-R score of ≥ 33 , considered a probable case of PTSD, compared to twenty-two patients with any memory of their ICU stay (p= 0.04). HADs scores were not significantly different between both groups.

Conclusion: ICU diaries may contribute to the recollection of memories of an ICU stay. Having any kind of memory of the ICU admission seems to result in a higher risk for developing PTSD symptoms. This study suggests a difference of the effect of ICU diaries between males and females, however further research is needed to elucidate whether this matter is clinically relevant.

Intensive Care Medicine Experimental 2020, **8(2)**: 000805

Introduction: Survivors of acute subarachnoid haemorrhage (aSAH) may suffer from long-term neurological disability but also from cognitive impairment, anxiety and depression. These symptoms can also be related to the Post Intensive Care Syndrome (PICS) defined as new or worsened impairment in physical, cognitive, psychological domains after ICU treatment. The prevalence of PICS after aSAH is not exactly known and the syndrome is poorly understood.

Objectives: The aim of the study was to investigate the prevalence of PICS and examine ICU- and patient related risk factors.

Methods: We conducted an observational cohort study of post-ICU patients after aSAH, who were evaluated in our post-ICU aftercare clinic three months after hospital discharge. Patients were included between January 2012 and December 2016. Patients were screened for physical complaints, anxiety, depression and PTSD symptoms using respectively an in-hospital developed questionnaire, the Hospital Anxiety and Depression scale (HADS) and the Impact of Event-Revised questionnaire (IES-R). Subjective cognitive complaints were assessed by asking three questions about short-term memory deficits, concentration problems and speed of thinking.

Results: In total, 110 patients visited the post-ICU aftercare clinic after aSAH. When looking at the separate domains of PICS the prevalence of anxiety and depression was 24.3% and 19.6%, respectively. PTSD was seen in 28.6% of the patients. There was a high prevalence of cognitive complaints; lack of concentration (63.6%), short-term memory problems (45.8%) and reduced speed of thinking (60.9%). Fatigue (75.0%) and limitations in daily activity (74.1%), muscle weakness (42.6%), pain (37.4%) and weight loss (32.1%) were the top five most reported physical complaints. Thirty per cent of patients had PICS symptoms related to all three domains of physical, cognitive and psychological functioning. Only 6 (5.5%) patients had no complaints. High prevalence of PICS symptoms was reported even in good outcome aSAH patients.

Conclusion: In post-ICU patients suffering from aSAH there is a high prevalence of PICS. Even in patients with good outcome after aSAH high prevalence of PICS symptoms was reported. Future studies concerning PICS should focus on the full domain of complaints comprising PICS.

000852**A retrospective study of obstetric admissions in an intensive care unit**

Intensive Care Medicine Experimental 2020, **8(2)**: 000852

Introduction: Obstetric admissions to an Intensive Care Unit (ICU) may be considered a marker of morbidity but are a rare event because pregnant women are usually young and healthy. The incidence varies between 0.4 to 16% of critical care admissions or 0.7 to 13.5 per 1000 deliveries. Reasons for admissions are conditions related to pregnancy (haemorrhagic events, preeclampsia, eclampsia or puerperal

infections) or conditions unrelated to pregnancy (congenital and valvular heart disease, pulmonary hypertension, etc). These patients represent a challenge to intensivists due to the physiological adaptations and pathological concerns during puerperium.

Objectives: The aim of present study is determining the incidence, epidemiological characteristics and outcomes of postpartum women who required ICU admission.

Methods: A retrospective cohort study of all obstetric admissions in a Portuguese 10-bed ICU between January 2015 to January 2020.

Results: In the period from January 2015 to January 2020, 17 obstetric patients were admitted to our ICU, representing 1.3% of all ICU admissions and 1,7 per 1000 deliveries. The mean patient's age was 32.5 years (21-45 years old) and the mean of gestational age was 36.9 weeks (28.1-40.7 weeks). Out of all women, 55.6% were primiparous, all of them were single pregnancies and all were admitted in postpartum care, most patients (76.5%) were admitted in immediate postpartum period.

Most common delivery type was caesarean in 88.2% women, instrumented delivery in 5.9% and eutocic delivery in 5.9%. The three most common causes of admissions were obstetric haemorrhage in 6 cases (33.3%); HELLP Syndrome in 4 cases (22.2%) and pneumonia in 3 cases (16.7%). Both instrumented and eutocic deliveries had obstetric haemorrhage as cause of admission.

The median length of ICU stay was 4 days. The most common interventions during ICU admission were transfusion of blood products in 8 patients (47.1%), mechanical ventilation in 9 patients (52.9%), with 3 patients for a period <24 hours. Only 2 patients needed vasopressors and 1 patient needed Renal Replacement Therapy. The mean of APACHE II score was 10 and SAPS II was 23. One patient died, with a maternal mortality rate of 0,1 per 1000 deliveries. This casualty was a 45-years-old woman who was admitted with a pulmonary thromboembolism.

Conclusion: Although obstetric admissions to ICU may be considered a marker of morbidity, there are few national studies to investigate these admissions. In our study, these patients accounted for 1.3% of total admissions or 1,7 per 1000 deliveries. These rates are very heterogeneous between ICUs and it may be explained by several factors, including the number of ICU beds or the existence of maternal and child centres where women are followed when there is a potential problem in pregnancy or prepartum.

The length of ICU stay is 4 days and the most common reasons for ICU admission are hypertensive disorders of pregnancy and obstetric haemorrhage and it is comparable with other studies. These patients typically have a short length of ICU stay and low hospital mortality. The only fatality case reported is the oldest pregnant woman. Increased maternal age is related to many complications during pregnancy and delivery, thus we need to be considered as a risk factor. Obstetric patients in ICU are a challenge that needs a multidisciplinary approach.

Intensive Care Medicine Experimental 2020, **8(2)**: 000873

Introduction: According to European Directorate for the Quality of Medicines & HealthCare “traceability is the ability to trace each blood component unit from donor to its final destination (patient, medicinal products manufacturer, disposal) & vice versa.” It is mandatory procedure & prerequisite for Hemovigilance Networks. Ideally, Blood Transfusion Services (BTS) should be able to trace every blood unit they issue.

Traceability is achieved by recording transfusion data (component’s unique identification number, patient’s data) in electronic files of computer systems and/or in paper-forms, both in BTS & clinical ward.

Nurses contribute to implementing traceability since their actions mark the beginning & the end of a transfusion. Therefore, it is vital to train them on traceability-issues.

Objectives: To measure effectiveness of educational interventions regarding traceability, which were implemented in 2018 in the 8-bed-ICU of an oncology hospital, by recording the change in traceability levels, the years before (2017) & after (2019) implementing relevant educational activities.

Methods: During 2017 & 2019, 84 & 91 patients respectively were hospitalized in the ICU. All 20 ICU nurses were trained on traceability issues during 2018 (lectures, distribution of printed material in the ward, training in small groups or individually) by a BTS doctor. Training effectiveness was checked in two ways:

1. Nurses answered a traceability-relevant questionnaire in 2017 & 2019 (before & after implementing educational activities). Change in percentage of correct answers was recorded.

2. All blood products transfused before (2017) & after (2019) training interventions were traced (both as a whole & per blood component category). In our hospital, transfusion-data are recorded in paper files (ICU) & in electronic files (BTS). A BTS Health Visitor checked & collated all data recorded in both files. Transfusions were described as “confirmed” only when the patient’s & unit’s data were identical in both files- otherwise, they were described as “probable”.

Results were statistically evaluated (t-test).

Results: 1. A significant improvement in the percentage of questionnaire correct answers before & after training interventions was recorded (81.66% and 95.83% respectively).

2. Results regarding traceability are depicted in Table 1. The lack of statistical significance in platelet/plasma results is attributed to low transfusion numbers.

Table 1: Traceability of blood transfusion (years 2017 and 2019)

	2017 (84 patients)				2019 (91 patients)				Statistics	
	C	P	Total	T (%)	C	P	Total	T (%)	I (CI 95%)	p value
Red Blood Cells	224	5	229	97.81	201	1	202	99.5	1.69 (0.8-2.4)	<0.0001
Platelets	145	6	151	96	137	2	139	98.56	2.56 (0-4)	0.0613
Fresh Frozen Plasma	129	5	134	96.27	51	1	52	98.07	1.8 (0-4.5)	0.181
Total	498	16	514	96.88	389	4	393	98.98	2.1 (1.1-2.5)	<0.0001

C: Confirmed transfusion, P: Probable transfusion, T: Traceability (confirmed/total)
I: Improvement, CI: Confidence Interval

Conclusion: 1. Implemented educational interventions contributed to the improvement of ICU nurses’ knowledge & practices on traceability issues.

2. Auditing cases of non-traceability per nurse, could help in planning targeted training to nurses with frequent “probable transfusion” results.

3. Repeated training can strengthen & consolidate proper traceability practices, enhance safety of all involved in transfusion chain (blood donor, patient, staff) & upgrade quality of health services provided.

Intensive Care Medicine Experimental 2020, **8(2)**: 000891

Introduction: Outbreaks of the coronavirus disease 2019 (COVID-19) epidemic have been causing worldwide health concerns since December 2019. Most of the patients admitted in ICU fulfill acute respiratory distress syndrome. Little is known about the heterogeneity of those patients and their outcomes.

Objectives: Identification of more homogeneous subgroups of COVID-19 patients admitted in ICU with similar characteristics, independently of any outcome measures.

Methods: We included patients admitted for COVID-19 disease to one of the French ICU participating in the French Outcomerea[®] prospective cohort between March 1st and April 31st 2020 and having a ICU length of stay longer than 72 hours. We recorded baseline characteristics including age, comorbidities, BMI and severity and main laboratory features at day 3 including blood cell counts, Ferritin, CRP, D-Dimer and the evolution of all those indices between admission to day 3.

Heterogeneity was explored using a Hierarchical clustering in a principal component approach. Random forest algorithm allowed the identification of the most important predictors in each sub group.

Results: 357 patients still alive at day 3 could be included. The median age was 61 [52; 70] years, 277 (77.6) were male, the median body mass index was 28.4 [25.4; 32], the median charlson score was 1 [0; 3]. At day 3, the median SOFA without respiratory was 3 [1; 4] and the median SOFA respiratory was 3 [2; 3]. At day 28, 147 (41.2) were still under mechanical ventilation or died including 104 (29.2) dead patients.

Finally, 5 sub-groups could be identified.

Cluster A (N=76, 21%, 28% mortality) was characterized by quite old patients (63 [55; 72.5] years old), with multiorgan failure at day 3, and low lymphocytes, monocytes and neutrophils levels which tended to decrease from day 1 to day 3 with a moderate increase of CRP and ferritin levels.

Cluster B (N=79, 22%, 23% mortality) had younger patients (53 [48; 61] years old), mainly with respiratory failure and the lowest inflammatory syndrome at day 3.

Cluster C (N=95, 26.7%, 31% mortality) gathered quite old patients (64 [55; 73] years), with a less severe respiratory failure, but others organ failures, and with a moderate inflammatory syndrome.

Cluster D (N=100, 28%, 34% mortality), was remarkable for the severity of their patients at day 3 with multi organ failures and for their inflammatory profile with high level of ferritin, CRP and neutrophils at day 3.

Cluster E (N=7, 2%, 29% mortality) gathered young, obese patients with multi organ failure and high level of inflammation.

Conclusion: This clustering approach revealed several profiles of COVID-19 patients, with several levels of organ failures and variations in inflammation markers, highlighting for some immunosuppression and others hyper-inflammatory conditions.

Effect of smoking on COVID-19 severity: a systematic review and meta-analysis

W. N. Charles¹; R. K. Reddy²; A. Sklavounos³; A. Dutt¹; P. T. Seed⁴; A. Khajuria⁵

¹Department of surgery and cancer, Imperial College London, London, United Kingdom; ²Department of medicine, Hull York Medical School, York, United Kingdom; ³Department of medicine, King's College London, London, United Kingdom; ⁴Department of women and children's health, King's College London, London, United Kingdom; ⁵Nuffield department of surgical sciences, University of Oxford, Oxford, United Kingdom

Correspondence: W.N. Charles

Intensive Care Medicine Experimental 2020, **8(2)**: 000914

Introduction: Various comorbidities have been described as risk factors for severe COVID-19. The impact of smoking on COVID-19 severity has been previously reported in several meta-analyses limited by small sample sizes and poor methodology.

Objectives: To rigorously quantify the effects of smoking on COVID-19 severity, including hospital and critical care outcomes.

Methods: This review was registered on PROSPERO a priori, CRD42020180920, and adhered to PRISMA guidelines. Two authors independently searched Medline, Embase, CENTRAL and Web of Science for studies published between December 1, 2019 and April 24, 2020, with an updated search on June 2, 2020. The COVID-19 resource centres of major journals were also screened for relevant studies. All clinical studies reporting the smoking status of hospitalised patients presenting with different severities of disease and/or at least one clinical endpoint of interest (disease progression, ICU admission, need for mechanical ventilation and mortality) were included. Smoking history included current and former tobacco smokers or e-cigarette users. Studies with insufficient information to distinguish outcomes based on smoking status were excluded. Random effects meta-analyses of pooled raw data were employed for each outcome with sufficient data. Results are presented as risk ratios (RR) with corresponding 95% Confidence Intervals (CI). Study quality was independently assessed using the Newcastle-Ottawa Scale.

Results: After screening 1050 papers, we analysed the findings of 47 eligible studies reporting on 32849 hospitalised COVID-19 patients. Of these, 8417 (25.6%) reported a smoking history, comprising 1501 current smokers, 5676 former smokers and 1240 unspecified smokers. Current smokers had an increased risk of presenting with severe COVID-19 (RR 1.80, 95% CI 1.14-2.85; p=0.012), as well as severe or critical COVID-19 (RR 1.98, 95% CI 1.16-3.38; p=0.012), compared to former and never-smokers. However, the increased risk of in-hospital mortality was not statistically significant (RR 1.46, 95% CI 0.83-2.60; p=0.192). Compared to never-smokers, patients with a smoking history had a significantly increased risk of severe COVID-19 (RR 1.31, 95% CI 1.12-1.54; p=0.001), severe or critical COVID-19 (RR 1.35, 95% CI 1.19-1.53; p<0.001), in-hospital mortality (RR 1.26, 95% CI 1.20-1.32; p<0.001), disease progression (RR 2.18, 95% CI 1.06-4.49; p=0.035), and need for mechanical ventilation (RR 1.20, 95% CI 1.01-1.42; p=0.043).

Conclusion: Smokers are vulnerable to increased severity of COVID-19 and worse in-hospital outcomes. In the absence of current targeted therapies against COVID-19, governments, policymakers and other key stakeholders must focus on preventative and supportive strategies to reduce morbidity and mortality in this patient population.

Clinical parameters that affect the outcome in ICU patients with severe influenza infection

A. Vakalos¹; N. Tsikliras¹; S. Patsatzakis¹

¹Icu, Xanthi General Hospital, Xanthi, Greece

Correspondence: A. Vakalos

Intensive Care Medicine Experimental 2020, **8(2)**: 000038

Introduction: Influenza virus infection is an important cause of mortality worldwide, leading to 250000 to 500000 deaths each year in the developed world. Mortality is caused by the primary viral infection, but also by influenza-associated pulmonary co-infections.

Objectives: Our retrospective observational study aimed to test the hypothesis that there is a difference in mean values of clinical data on ICU admission day, among patients with confirmed influenza infection who died and patients who survived in both Medical and Surgical ICU served to a community hospital.

Methods: From January 2006 to October 2019, 1332 patients admitted to our ICU. From these, 25 (1.87%), 14 males and 11 females, were indicated with the diagnosis of severe influenza infection. Mean age 61.08 years, length of stay (LOS) 17.68 days, days under mechanical ventilation (MVD) 13.6 days. The patients separated into two groups. Group A involved all patients who survived ICU and group B all patients who died in ICU. We looked for statistically significant differences (p-value two-tailed) between the medians values of two groups, using the unpaired Mann - Whitney test or the unpaired t-test Welch corrected according to the normality test, according to clinical data on the ICU admission day.

Results: We detected no statistical difference between the two groups according to Temperature: (p=0.3022), MAP: (p=0.1750), HR: (p=0.1410), RR: (0.2800), Na: (p=0.4029), k: (p=0.1539), BUN: (p=0.1384), Cr:

($p=0.0675$), WBC: ($p=0.1340$), Ht: ($p=0.4889$), PaO₂: ($p=0.3680$), pH: ($p=0.1096$), albumin: ($p=0.0576$), glucose: ($p=0.1139$), Bilirubin: ($p=0.9359$), PaCO₂: ($p=0.2966$), glucose: ($p=0.1139$), PaO₂/FiO₂ ratio: (0.2364). We only detected statistical significant higher group B value according HCO₃: (0.040).

Conclusion: According to our data, there was no statistical difference detected between the two groups according to all clinical parameters we measured, except HCO₃ values, which were lower in patients who died. Our data suggest that even though pH didn't achieve to make a difference, acid-base disorders may be so important to make as give a priority to these patients, as more likely to have a more severe illness.

Intensive Care Medicine Experimental 2020, **8(2)**: 000046

Introduction: Many advances in the care of high-risk surgical patients have been made. Nevertheless, temporal trends in outcomes in this population of patients in developing countries are lacking.

Objectives: This study aimed to investigate trends in mortality and complications in high-risk surgical patients over a ten-year period.

Methods: Ethical approval was obtained N. 1.570.327-2016. Data from two prospective multicenter cohort studies (SCORIS AND BRASIS studies) conducted by AMiB Network from 2008 to 2018 to address the outcomes of high-risk surgical patients in Brazil were compared. All non-cardiac surgical patients admitted to intensive care units (ICU) were daily followed up to hospital discharge to determine complications and mortality.

Results: Individual patient data from 1,491 high-risk surgical patients (904 patients from BRASIS study and 587 from SCORIS study) in 50 ICUs were enrolled in this analysis. table 1.

Variable	Baseline characteristics		P	Matched Cohort		
	Original Cohort Scoris (n= 587)	Brasis (n=904)		Scoris (n= 509)	Brasis (n=509)	P
Male, n (%)	363 (61.9%)	605 (67%)	0.40	277 (54.4%)	265 (53.3%)	0.56
Age (y), mean±SD	71.1± 7.4	69.5± 7.0	0.07	62.2±16.5	61.9±16.5	0.83
ASA Score			0.16			0.76
P 2 score, n (%)	301 (51.3%)	522 (57.8%)		272 (53.6%)	278 (54.8%)	
P 3 score, n (%)	275 (46.9%)	381 (42.2%)		230 (45.2%)	230 (45.2%)	
SOFA score median (mi- max)	5.0 (0-20)	4 (0-19)	0.04	4.0 (0-19)	3.0 (0-19)	0.06

The crude hospital mortality rate decreased from 20.6% (95% CI, 17.1 to 24.6%) in 2008 to 8.9% (95% CI, 7.0 to 11.2%) in 2018. After adjusting for baseline Sequential Organ Failure Assessment (SOFA) Score, age and type of ICU, patients enrolled in 2018 (10.1%; 95% CI, 7.5 to 13.4) compared those enrolled from 2008 (16.1%; 95% CI, 12.8 to 20.0) exhibited a lower risk of hospital death (OR, 0.58; 95% CI, 0.40 to 0.85; $P=0.005$) and ICU mortality rate, 5.5% in 2018 and 11.2% in 2008 (OR, 0.46; 95% CI, 0.29 to 0.75; $P=0.001$).

The frequency of infection decreased significantly from 19.8% in 2008 to 2.9% in 2018 (OR, 0.12; 95% CI, 0.07 to 0.21; $P<0.001$) while general rate of complications did not differ between the two periods, 34.8% (95% CI, 29.8 to 40.3%) in 2008 and 33.8% (95% CI, 28.9 to 39.2%) in 2018.

Conclusion: Over the 10-year period between 2008 and 2018, mortality and incidence of infection improved in high-risk surgical patients admitted to Brazilian intensive care units, however general complications rate remained unchanged.

"A tidal wave of patients": effects of COVID-19 on a busy district general hospital serving a large BAME population

S. Bakare¹; M. Wilson²; J. Borkowski³

¹Anaesthetics and Intensive Care Medicine, London North West University Healthcare NHS Trust, London, United Kingdom; ²Anaesthetic, London North West University Healthcare NHS Trust, London, United Kingdom; ³Intensive care, London North West University Healthcare NHS Trust, London, United Kingdom

Correspondence: S. Bakare

Intensive Care Medicine Experimental 2020, **8(2)**: 000931

Introduction: Northwick Park Hospital (NPH) is a busy District General Hospital in Northwest London serving the Harrow, Brent and Ealing Councils which are very multi-ethnic areas with a dense BAME population. NPH has a tertiary Infectious Diseases Unit, is one of the busiest A&E Departments in the UK and is in close proximity to London Heathrow, one of the busiest airports in the world. (1) NPH became the epicentre of the COVID-19 Pandemic in the UK in Mid-March as the country transitioned from the containment to the delay phase of pandemic management. A "Tidal Wave"(1) of COVID-19 patients hit NPH early with cases doubling every two days before moving across the country. NPH was reconfigured and its services upscaled (one of the first in the country) in anticipation and duly surpassed its baseline 22 Intensive Care Unit (ICU) beds during the transition. (2) Over 4 weeks, ICU Beds increased to 70, and CPAP capabilities also quadrupled separately. Despite this increase, half of the over 260 COVID patients admitted to our ICU were transferred to other hospitals within our North West London critical care network (NWCCN) to manage the significant increase in demand and alleviate pressure

Objectives: We aim to illustrate the increased burden the COVID-19 pandemic put on our critical care services and the impact of the pandemic on the largely BAME population served by our hospital by comparing our admissions between March and May 2020 to the same time period in 2019.

Methods: Data was collected from our ICNARC Database and analysed using Simple Statistical Method.

Results:

- 87% higher admissions between March and May 2020 compared to the same period in 2019. A total of 379 Patients admitted to the ICU. 70% of which were diagnosed with COVID-19.
- Mortality Rate in 2020 was 26% vs. 22% in 2019. COVID-19 Subgroup (CS) analysis showed a mortality rate of 44%.
- Average APACHE Scores were lower in 2020, 17% vs. 23% in 2019. CS was also 17.
- Organ Support
 - Increased Ventilatory Support 74% in 2020 vs. 54% in 2019. 85% in CS.
 - Decreased RRT 21% in 2020 vs. 37% 2019. 22% in CS.

- Significantly Increased CVS Support 95% in 2020 vs. 38% in 2019. 100% in CS

Ethnicity

- Increased BAME admissions 73% in 2020 vs. 49% in 2019. 83% in CS

Gender

- Increased Male admissions 74% in 2020 vs. 60% in 2019. 80% in CS

Conclusion: Our Data shows there was both an increase in the number of patients and the proportion of patients requiring organ support, with BAME and Male patients disproportionately affected in line with recent publications (3). Despite the 4-fold increase in our critical care capacity (the generally accepted protocol that left other centres with excess capacity), our systems were stretched during these unprecedented times to the extent we had to transfer half our patients out (4). The mutual aid response by NWCCN and the dedication of the hospital multidisciplinary teams at all levels whose lives were also severely disrupted helped maintain patient care and safety throughout this period.

Neutrophil-to-lymphocyte ratio as a risk marker of bad outcome in patients hospitalized with COVID-19

R. Thouny¹; P. Goffin¹; J. Guntz¹; L. Jadot¹; C. Legrain¹; D. Noiro¹; I. Noiro¹; S. Verscheure¹; P. Demaret¹

¹Department of anesthesia and intensive care, MontLegia Hospital - Groupe Santé CHC, Liège, Belgium

Correspondence: P. Goffin

Intensive Care Medicine Experimental 2020, **8(2)**: 000980

Introduction: The fast worldwide spread of Coronavirus disease 2019 (COVID-19) and the resulting dramatic pandemic have stimulated clinical research to describe patients risks and evolution. Neutrophil-to-lymphocyte ratio (NLR) has shown its prognostic value in cardiovascular diseases, cancer, infections or inflammatory diseases, probably because it is correlated to the level of dysregulation of the immune response. We therefore studied the association between NLR and in-hospital death or intensive care unit (ICU) admission in patients hospitalized with COVID-19.

Methods: We retrospectively analyzed a cohort of patients with confirmed COVID-19 admitted to the MontLegia Hospital (Liège, Belgium) between 15/03/20 to 04/05/20. We recorded baseline data including biological and clinical features, as well as ICU admission and hospital mortality.

The independent association between NLR and the composite outcome of ICU admission and/or hospital mortality was assessed with multivariable logistic regression.

Results: Two hundred and thirteen patients were admitted to our hospital with a confirmed diagnosis of COVID-19 (polymerase chain reaction positive for SARS-CoV-2) during the study period, among which 92 (43.2%) were admitted to the ICU and/or died during the hospital stay (composite primary outcome).

The median (interquartile range (IQR)) NLR was significantly higher for patients with the composite primary outcome (7 (4.8-11.6) versus 4.6 (3.1-6.6), $p < 0.001$). At hospital admission, patients with the composite primary outcome had a worse oxygenation (SpO₂ / FiO₂ 3.8 (223-399) versus 323 (304-424), $p < 0.001$), a higher creatinine level (1.14 (0.84-1.66) versus 0.92 (0.79-1.21) mg/dL, $p = 0.006$) and a higher C-reactive protein (CRP) level (108 (64-183) versus 67 (32-125) mg/L, $p < 0.001$).

The area under the receiver operating characteristic curve describing NLR as a predictor of ICU admission and/or death was 0.71 (95% confidence interval (CI) 0.63-0.77), which was significantly different from the non-discrimination line ($p < 0.001$). The threshold with the best global predictive value for ICU admission and/or death, according to the Youden index, was 6.1 (sensitivity 66.3%, specificity 74.4%).

After adjustment for potential confounders, NLR remained associated with ICU admission or death: adjusted odds ratio (OR) 1.1, 95% CI 1.04-1.17, $p = 0.002$. Patients with an NLR ≥ 6.1 had a 5.72-fold increased risk of ICU admission or death (adjusted OR 5.72, CI95% 2.80-11.71, $p < 0.001$).

Conclusion: The NLR is independently associated with ICU admission or death during hospital stay for the patients hospitalized with COVID-19. In association with other clinical and biological variables, this risk marker should be useful in helping the clinicians to identify the patients needing a close monitoring.

Evaluation of hepatic injury definitions in pulmonary ICU patients

E. Macit Aydın¹; A. Mammadova²; Z. çınar¹; N. Navruzvai²; S. Kodalak²; G. Gursel³

¹Department of anaesthesiology and reanimation, division of critical care, Gazi University Faculty of Medicine, Anaesthesiologist, fellow of critical care, Ankara, Turkey; ²Department of pulmonary critical care medicine, Gazi University Faculty of Medicine, Resident of Pulmonary Diseases, Ankara, Turkey; ³Department of pulmonary critical care medicine, Gazi University Faculty of Medicine, Professor of Respiratory Medicine, Ankara, Turkey

Correspondence: E. Macit Aydın

Intensive Care Medicine Experimental 2020, **8(2)**: 001034

Introduction: Hepatic injury (HI) and failure are observed in up to 20% of patients in intensive care units and are associated with increased morbidity and mortality. Secondary or acquired liver injury and failure such as hypoxic liver injury, cholestatic dysfunction in critical illness, sclerosing cholangitis in critical illness, and drug-induced liver injury (DILI) represent the most frequent forms of hepatic injury in critical illness. More importantly, retrospective population studies showed that liver injury was not mentioned in the diagnosis or in the physician's discharge letter in 52–68% of cases. On the other hand definition of HI influences the incidence, prognosis, mortality, and treatment management of the diseases.

There is no uniform definition of hepatic injury in critically ill patients. According to some studies, total bilirubin levels greater than 2 mg/dL represent a cutoff in daily practice. Others use 2-fold to 3-fold elevation of ALP/AST, alkaline phosphatase (AP) and/or gamma-glutamyl transpeptidase (GGT) to define it.

Objectives: Aim of this study is to compare HI definitions in pulmonary ICU patients with secondary hepatic injury.

Methods: This retrospective cohort study was performed in an University Hospital Pulmonary ICU. Patients with hepatic injury included in the study. 478 patients were included in the study. We compared 3 definition of hepatic injury 1. hepatic criteria of the SOFA score (HI-SOFA: bilirubin > 2 mg/dl), 2. 2017 definition of American Collage of Gastroenterology (HI-ACG1), 2017 definition of American Collage of Gastroenterology without borderline patients (HI-ACG2) and 3. 2019

EASL DILI definition (HI-EAS). To define if HI is cholestatic, hepatocellular or mixed we calculated R ratio. We also calculated severity of HI in all patients.

Incidence, consistency (level of agreement-Kappa statistics), correlations, sensitivity and specificity of the definitions were also calculated for each definition taking one of them as gold standart. Lastly mortality rates according to 3 different definition were also calculated.

Results: As can be seen in table 1 and 2 HI incidence and mortality rates are highly variable across the definitions and there is no good agreement and correlation between them. Sensitivity and/or specificity numbers were also low in general also.

Table 1. Hepatobiliary injury incidence and mortality rates according to different definitions

	Incidence	Mortality
HI-ACG2, n (%)	121 (25.3 %)	49/121 (41 %)
HI-EASL, n (%)	88 (18.4 %)	50/88 (57 %)
HI-ACG1, n (%)	210 (44 %)	79 /210 (38 %)
HI-SOFA, n (%)	49 (10.3 %)	27/49 (55 %)

HI: Hepatobiliary injury, HI-ACG2: 2017 definition of American College of Gastroenterology without borderline patients, HI-EASL: 2019 EASL DILI definition, HI-ACG1: 2017 definition of American College of Gastroenterology, HI-SOFA: hepatic criteria of the SOFA score

Table 2. Consistency and correlation between the definitions

	Kappa test		Correlations	
	Kappa	p-value	r	p-value
HI-SOFA-HI-ACG2	0.325	0.0001	0.374	0.0001
HI-SOFA-HI-ACG1	0.227	0.0001	0.340	0.0001

HI-ACG2: 2017 definition of American College of Gastroenterology without borderline patients, HI-ACG1: 2017 definition of American College of Gastroenterology, HI-SOFA: hepatic criteria of the SOFA score.

Conclusion: These results showed that definition of HI according to bilirubin or ALT/AST or together changes HI diagnosis. To standardize epidemiologic data, diagnosis, severity assessment, treatment of HI we need a generally accepted definition for ICU patients.

The link between risk factors and mortality rate in coma patients

D. Adukauskienė¹; V. Jasinskas¹

¹Intensive care unit, Lithuanian University of Health Sciences, Kaunas, Lithuania

Correspondence: V. Jasinskas

Intensive Care Medicine Experimental 2020, **8(2)**: 001096

Introduction: Coma - a formidable disorder of consciousness caused by a various etiological factors. According to some authors, the mortality rate of patients in coma may be higher than 87.0% [1]. For this reason more and more factors, increasing the mortality of coma patients rate, are being sought and investigated.

Methods: 82 Intensive Care Unit patients retrospective analysis was performed. Chosen patients who had a score of 8 or less, according to the GCS and were not medically suppressed. Mortality rate and influence of the risk factors of the patients in coma were observed. 95.0% significance level $p \leq 0.05$ was chosen for significance evaluation.

Results: Male patients made 53.7% ($n = 44$). The average age of patients was 67.6 ± 15.2 years. The outcomes of coma patients' mortality makes 65.9% ($n = 54$).

In 74.0% of the dead patients had metabolic etiology coma, $p = 0.004$. According to the ROC test, metabolic etiology coma increased the odds ratio for mortality by 3,8 times, the area under the curve 71.8%, the sensitivity 61.5% and the specificity 80.0%. In 80.6% of the dead patients had 5 or less score by Glasgow coma scale, $p < 0.001$. According to the ROC test, 5 and less points in the GCS

increased the odds ratio for mortality by 16.7 times, the area under the curve 81.7%, the sensitivity 92.6% and the specificity 57.1%.

In 83.3% of the dead patients experienced tachycardia which occurred more than 100 beats per minute, $p < 0.001$. According to the ROC test, tachycardia more than 100 beats per minute increased the odds ratio for mortality by 7.1 times, the area under the curve 78.0%, the sensitivity 74.1%, and the specificity 71.4%.

In 88.9% of the dead patients creatinine concentration was higher than $170 \mu\text{mol/l}$, $p = 0.038$. According to the ROC test, creatinine value more than $170 \mu\text{mol/l}$, increased the odds ratio for mortality by 5.5 times, the sensitivity 30.0%, and the specificity 92.6%.

In 76.9% of the dead patients had lactate value more than 3.5 mmol/l , $p = 0.05$. According to the ROC test, lactate concentration more than 3.5 mmol/l , increased the odds ratio for mortality by 5.9 times, the sensitivity 82.0%, and the specificity 57.0%.

Conclusion: 1. Mortality rate of coma patients was 65.9%.

2. Mortality rate of coma patients increases due to coma of metabolic origin, $\text{GCS} \leq 5$, tachycardia > 100 beats per minute, creatinine concentration $> 170 \mu\text{mol/l}$, lactate concentration $> 3.5 \text{ mmol/l}$.

How "door-to-icu" time influences outcome

A. L. Rios¹; N. R.¹; A. D.¹; A. Marques¹; P. Castelões¹

¹Medicina intensiva, Centro Hospitalar de Vila Nova Gaia/Espinho, Vila Nova de Gaia, Portugal

Correspondence: A. L. Rios

Intensive Care Medicine Experimental 2020, **8(2)**: 001157

Introduction: The pandemic of COVID-19 has overcrowded our ICUs. In Italy, the country besides China with the most patients with COVID-19 until March 29, 2020, up to 12% of all positive cases required ICU admission. The median time from symptom onset to the development of pneumonia was approximately 5 days, and the median time from symptom onset to severe hypoxaemia and ICU admission was approximately 7–12 days.(1)

Data from Wuhan, China, concluded that older patients (> 60 years) were more likely to exhibit severe and critical COVID-19 conditions; patients with chronic disease were more prone to severe forms of COVID-19 and regarding the symptoms, dyspnea, chest tightness, diarrhea, fatigue, dizziness, muscle ache, and unconsciousness were significantly linked to severe COVID-19 cases.(2) Prediction of trajectory of illness from symptom onset is difficult, and prognostic tools and biomarkers are urgently needed. (3)

Objectives: determination of factors that predict this rapid respiratory deterioration may help to anticipate rapid need for intubation and respiratory support. This work relates patient status at ICU admission and the time to invasive ventilation, complications and outcome.

Methods: This is a retrospective study of all patients admitted to a tertiary hospital ICU in Portugal. Primary outcomes were mortality, time of mechanical ventilation; Secondary outcomes were association with higher APACHEII, SAPSII and greater need for invasive ventilatory maneuvers (like pronning).

Results: Between March 17th and May 10th 2020 were admitted 36 SARS-CoV-2 patients to our ICU, 10 of those were direct admissions from the emergency department. The other 26 ICU admissions were transfers from wards and the majority (35%) only after 72 h of hospital stay. 31% during the first 24 h after admission.

There was no difference in APACHE II and SAPS II scores between the two groups at ICU admission: direct admissions from the emergency department or from the wards. There was a positive association

between the need for proning maneuvers and longer time-to-ICU ($p=0,008$), although there was no difference in admission PO₂/FI_O₂ ratio.

Conclusion: There was no identified correlation between mortality and time-to-ICU admission.

We should look into other parameters as predictors of prognosis.

Impact of clinical frailty score and the national early warning score 2 on ICU and 30-day mortality

G. Azzopardi¹; J. Hill¹; P. Morgan¹

¹Intensive Care, East Surrey Hospital, Redhill, United Kingdom

Correspondence: G. Azzopardi

Intensive Care Medicine Experimental 2020, **8(2)**: 001158

Introduction: ICU outcome can be predicted using multiple methods, these tend to be retrospective, time consuming and require a large number of data points.

The National Early Warning Score 2 (NEWS2) is a widely used severity of illness scale to detect the acutely unwell and deteriorating patient from the end of the bed (1). A Rockwood Clinical Frailty Score (CFS) (2) can be easily calculated following discussion with the patient, their family or review of clinical notes. It has been demonstrated that a higher CFS correlates with a worse ICU outcome (3), studies looking at NEWS2 and ICU outcome are not widely published.

We hypothesise that a higher CFS and NEWS2 will correlate with a higher ICU and 30-day mortality. Combined, both provide a snapshot assessment of the patient and may help inform future decision making with regards to ICU admission and predicted outcome.

Objectives: To determine the effect of CFS and NEWS2 on ICU mortality and 30-day mortality.

Methods: Observational data was collected on 106 patients admitted in ICU between 9/01/2020 and 12/03/2020. CFS was calculated by ICU clinicians from reviewing the patient, nursing and therapy notes, as well as speaking to the patient or family members where possible. This score was based on the patients status two weeks prior to admission to ICU. NEWS2 was calculated from the last set of observations performed prior to admission to ICU. The primary outcome was ICU mortality, secondary outcomes were 7-day and 30-day mortality. The data was collected in Microsoft Excel and analysed.

Results: Data was collected on 106 patients. There were 62 patients admitted under medicine, 32 emergency surgical cases and 12 elective surgical cases. The average age of patients was 64. Overall ICU mortality was 20.8%.

A CFS of 5 or more was used as a cut off to indicate frailty. 24.5% of patients had a CFS of 5 or more. Patients were further stratified into a low (0-4), medium (5-6) or high (>7) NEWS2 category. Patients with a CFS ≥ 5 (38.5%) had a higher ICU mortality than those with a CFS <5 (15%). Patients with a high NEWS2 had a higher ICU mortality (32%) than those with a low NEWS2 (11%) (Figure 1).

Figure 2 shows survival at 7 and 30 days in each of the NEWS2 categories, divided into those with a CFS <5 and ≥ 5 .

Conclusion: Our data shows that frail patients, with a high NEWS2 have a higher ICU and 30-day mortality rate than patients without frailty and a low NEWS2. Larger scale studies should be performed to further investigate this, as well as correlating this data with existing ICU outcome predictor tools such as APACHE II. Future use of the CFS and NEWS2 as an 'end of the bed' assessment tool may help to augment decision making with regards to ICU admissions and predicted outcomes.

Does age always matter for the outcome in the Intensive Care Unit ?

G. Koukoulitsios¹; K. Tsikritsaki¹; M. Anifanti¹; I. Tsoni¹; S. Bakouli¹; I. Ionna¹; G. Maglaras¹; A. Koutivas¹; C. Mandila¹; S. Antonopoulou¹; V. Koutsoukou¹; V. Salma¹; A. Kalogeromitros¹

¹ICU, General Hospital of Athens "G. Gennimatas", Athina, Greece

Correspondence: G. Koukoulitsios

Intensive Care Medicine Experimental 2020, **8(2)**: 001184

Introduction: Aged patients represent a significant proportion of patients who require admission to the Intensive Care unit (ICU). Advanced age is associated with higher mortality and adverse outcomes in ICU, however according to some studies is not only the age that determines the prognosis, co morbidities and previous health status could affect the outcome as well.

Objectives: The aim of this study was to evaluate the possible effect of age, co morbidities, reason for admission to the ICU, length of stay in ICU and the final outcome.

Methods: Our study included 157 patients aged 68 and older that were admitted to the ICU from January 2018 till September 2019. Demographic parameters, admission diagnosis, underlying diseases, ICU length of stay and finally outcome were recorded.

Results: We enrolled 157 patients, 85 males, 72 females with mean age 74,6 years. They main reasons for admission were 1st. post operative (after elective operation) 64 patients 2nd. trauma 40 patients, 3rd. acute respiratory failure 30 patients, 4th. sepsis 23 patients. Out of 157 patients the 112 had co morbid medical illness (e.g. ischemic heart disease, arterial hypertension, diabetes mellitus, COPD, chronic renal failure). The mean length of stay was 23 days but it ranged from 1 to 65 days. Out of 157 patient 95 were discharged from the ICU and 62 patient died. Post operative patients independently from the age and co morbidities had the best outcome and discharged earlier from ICU than other etiological groups. There were not differences in the outcome as far as the gender was concerned,

Conclusion: Reasons for mortality appear to be multifactorial in elderly patients. High age alone is not a factor to predict morbidity and mortality in ICU patients. Previous health state-co morbidities and the reason for admission in the ICU play a very important role for the final outcome.

Association of Sequential Organ Failure Assessment (SOFA) components with outcome in contemporary critical care

A. Pölkki¹; PT. Pekkarinen²; M. Reinikainen³

¹Department of anesthesiology and intensive care, Kuopio University Hospital, Kuopio, Finland; ²Division of intensive care medicine, department of anaesthesiology, intensive care and pain medi, Helsinki University Hospital, Helsinki, Finland; ³Department of intensive care, Kuopio University Hospital, Kuopio, Finland

Correspondence: A. Pölkki

Intensive Care Medicine Experimental 2020, **8(2)**: 000327

Introduction: Sequential Organ Failure Assessment (SOFA) score is a practical method to describe the severity of multi-organ failure. It has been suggested that SOFA score could be employed as a tool to predict outcome and as an endpoint in interventional trials (1). To justify these assumptions all SOFA components should carry comparable weights as outcome predictors. SOFA score was introduced in 1996 and has remained unchanged to date, although there have been changes in clinical practice (2).

Objectives: The aim of this study was to investigate if SOFA score components are comparable in association with in-hospital mortality.

Methods: We performed a national observational cohort study on adult (18 years of age or older) patients admitted to 26 Finnish intensive care units (ICUs) between 2012-2015. SOFA score was determined as the most severe SOFA score component value within the first 24 hours after admission to ICU. We performed statistical analysis employing age- and sex-adjusted multivariable logistic regression.

Results: We included 67 095 admissions after excluding 4 289 readmissions and 112 admissions with missing in-hospital mortality data. Total in-hospital mortality was 11.4%. Multivariable logistic regression revealed that increase in SOFA points was associated with higher risk of in-hospital death in respiratory (age-adjusted odds ratio [OR] 1.40, 95% confidence interval [CI] 1.36-1.44, $p < 0.001$) per point; in coagulation (OR 1.22, 95% CI 1.18-1.26, $p < 0.001$); in hepatic (OR 1.36, 95% CI 1.31-1.42, $p < 0.001$); in cardiovascular (OR 1.16, 95% CI 1.14-1.19, $p < 0.001$); in neurologic (OR 1.72, 95% CI 1.69-1.75, $p < 0.001$), and in renal component (OR 1.63, 95% CI 1.59-1.66, $p < 0.001$).

Conclusion: We found that all SOFA score components have independent predictive value. However increased risk of in-hospital death per SOFA score point was not comparable between components. Cardiovascular component has the weakest and neurologic component has the strongest association with increased in-hospital mortality (Figure 1).

GRACE versus CHADS2: a paradigm change in ACS stratification?

H. Miranda¹; H. Santos²; S. Mariana³; I. Almeida²; C. Sousa²; L. Almeida²

¹Intensive Medicine Care, Hospital São Pedro de Vila Real (Centro Hospitalar de Trás-os-Montes e Alto Douro, EPE), Vila Real, Portugal; ²Cardiology, Centro Hospitalar Barreiro Montijo, Barreiro, Portugal; ³Cardiology, Centro Hospitalar Barreiro Montijo, E.P.E, Barreiro, Portugal

Correspondence: H. Miranda

Intensive Care Medicine Experimental 2020, **8(2)**: 000382

Introduction: The GRACE Score is a prospectively studied scoring system which stratify patients with diagnosed ACS to estimate in-hospital and 6-month to 3-year mortality. Knowing patient's risk earlier may help with management and prognostication. Recent studies refer that CHADS2 could be as useful as GRACE score in this scenario.

Objectives: To compare GRACE and CHADS2 scores regarding MACE, in-hospital mortality and 1-year mortality in Portuguese population.

Methods: Retrospective study during a period of 8 years + 8 months. Only NSTEMI patients were admitted in the study. GRACE and CHADS2 groups, based on mortality risk, were created and compared regarding MACE and mortality.

Results: 7537 patients were admitted. Male predominance (70,9%) and mean age of 67 ± 13 years. Hypertension (73,2%), diabetes (34,4%) and dyslipidaemia (61,4%) were the most frequent comorbidities. 85% were submitted to angiography with DA being the most common culprit vessel (33,2%). Multivessel disease in 55,1% of the patients. MACE occurred in 5,1% of the cases with 1,9% of the patients dying in hospital.

60,8% of the patients presented a high risk (GRACE score) compared with CHADS2 score (7,6%). We verified a predominance of low risk patients in this last score. ROC curves were created and the results were compared. Comparing the occurrence of MACE during hospital length we found that GRACE was a better predictor than CHADS2 (AUC(grace) 0,708 versus AUC(chads2) 0,598, $p < 0,001$). We also point out the best performance of GRACE score when we compare in-hospital (AUC(grace) 0,834 versus AUC(chads2) 0,669, $p < 0,001$) and 1-year death (AUC(grace) 0,667 versus AUC(chads2) 0,645, $p = 0,045$).

Conclusion: Our study has reinforced the idea that the GRACE score remains an extremely reliable score today.

"Patients' quality of life with critical ill and the support of family's members after discharge from the intensive care unit"K. Augeri¹¹Medical, UNIVERSITY OF THESSALY, Larisa, Greece**Correspondence:** K. Augeri*Intensive Care Medicine Experimental* 2020, **8(2)**: 000446

Introduction: Patients following intensive care unit hospitalization may present disability and dysfunction in their physically and cognitive function.(1)(2)

Objectives: We investigated the quality of life of patients following discharge from the intensive care unit and we assessed the role of support by the family members.

Methods: This retrospective study conducted at the University Hospital of Thessaly and included patients who stayed for at least 48 hours in ICU and were alive at discharge between 2014 and 2019. The quality of life was assessed by the questionnaire SF-36.

Results: A total of 671 were included. The SF score overall was 51.32. There were correlations between SF score and daily duration of support by spouses ($r=0.2046$, $p<0.0001$), friends ($r=-0.2536$, $p<0.0001$) and duration of hospitalization ($r=-0.2324$, $p<0.0001$). Patients who were supported by their spouses for more than 8 hours daily or patients who were supported by their friends for more than 3 times/week or were hospitalized for less than 10 days had increased SF compared to the rest of the cohort [mean(SD) 54.49(28.07) vs 50.14, (28.69), $p=0.05$ and 58.07 (28.54) vs 45.20 (27.93), $p<0.0001$, and 68.45, 27.57) vs 49.07 (27.53) $p<0.0001$, respectively].

Conclusion: The present study shows that the quality of life of patients following ICU discharge may be positively affected by the support from spouses or friends.

Evaluation of demographic and clinical characteristics in intensive care unit with critical end stage renal disease patientsE. N. Karaoglu¹; M. Caliskan¹; M. Yildirim¹; A. Merve¹; S. Temel¹; M. Sungur²; K. Gundogan³

¹Internal medicine, Erciyes University, Kayseri, Turkey; ²Division of critical care medicine, department of internal medicine, Erciyes University School of Medicine, Kayseri, Turkey, Kayseri, Turkey; ³Department of internal medicine, division of intensive care, Erciyes University, School of medicine, Kayseri, Turkey

Correspondence: E.N. Karaoglu*Intensive Care Medicine Experimental* 2020, **8(2)**: 000508

Introduction: Patients diagnosed with end stage renal failure (ESRD) who are likely to be hospitalized due to comorbidities, advanced age, immunocompression caused by uremia and phagocyte dysfunction.

Objectives: The aim of this study is to prospectively monitor and evaluate the clinical and laboratory features of the patients with ESRD in the intensive care unit(ICU).

Methods: This study was performed prospectively in the Medical ICU. Patients in need of ICU admission, over 18 years old and diagnosed with ESRD were included in the study.

Results: A total of 100 patients were included in the study. The mean age of patients was 68±14 years.The most common reason for ICU admission were sepsis/septic shock (26%) and respiratory failure (21%).The most common causes of ESRD were diabetes mellitus (DM) (49%) and hypertension (HT) (21%). Mean APACHE II score was 22± 6. Median SOFA score was 8 (min:2-max:19). A total of 52% of patients

received dialysis treatment (96% of hemodialysis, 4% peritoneal dialysis) before admission to ICU. The length of ICU stay was 7 (min:2 max:36) days. Cox regression analysis was performed to determine the factors affecting mortality. APACHE II score was identified as an independent risk factor that determined mortality. (OR:1.059, 95 CI, 1.01-1.09, $p=0.015$). ICU mortality rate was 45%.

Conclusion: As a result of this study, DM was the most common cause for ESRD. High APACHE II score was identified as an independent risk factor for mortality in ICU with end stage critically ill renal failure patients.

A modified SOFA score: testing a new prognostic score for critically ill patientsALN. Gobatto¹; GL. Silva¹; MS. Manciola¹; MSM. Reis¹; CC. Starteri¹; LS. Sancho¹; VOS. Junior¹; MCC. Bispo¹; JC. Ribeiro¹; SF. Da Guarda¹; JGR. Ramos¹; RDH. Passos¹¹Critical care medicine, Hospital São Rafael, Salvador, Brazil**Correspondence:** M.S. Manciola*Intensive Care Medicine Experimental* 2020, **8(2)**: 000573

Introduction: The Sequential Organ Failure Assessment (SOFA) score was created in 1994, in an effort to describe organ dysfunction/failure over time in the critically ill, and has been widely used in medical practice ever since. However, the need for future alterations was highlighted by the original paper, as better parameters could be suggested by future re-evaluation and updated data. Thus, additional studies are appropriate for re-evaluating current parameters of the SOFA score, as well as possibly providing a modified version with higher accuracy for outcome prediction.

Objectives: This study aimed to test the accuracy of a modified SOFA score as a mortality predictor by using different parameters for neurological and gastrointestinal evaluation.

Methods: A prospective cohort was performed in a Brazilian private tertiary hospital between June and November 2018. Inclusion criteria were adult patients in the intensive care unit (ICU) under nutrology follow-up. Demographic and clinical characteristics, nutritional status, laboratory results, physiological parameters, use of medical devices and outcomes were collected from electronic and physical medical records.

Glasgow Coma Scale (GCS) and Richmond Agitation-Sedation Score (RASS) were used to determine the neurological component in SOFA and RSOFA, respectively. Total bilirubin and the Acute Gastrointestinal Injury (AGI) score were used to determine the gastrointestinal component in SOFA and ASOFA, respectively. AGI score and RASS were used to determine the gastrointestinal and neurological components of ARSOFA, respectively. To test our hypothesis, accuracy of the SOFA, ASOFA, RSOFA and ARSOFA scores to predict mortality was determined by the area under the curve (AUC) using the Receiver Operating Characteristic (ROC) curve.

Results: During the study period, 52 patients met the inclusion criteria and were included. Patients' demographic characteristics were: median age 73.9 [60.47-84.01]; male, 25 (48.1%); on admission: 26 patients were on mechanical ventilation (50%), mean SAPS III was 52.3 (±15.5), mean APACHE II was 23.2 (±11.4), mean SOFA score was 3.7 (±2.5) and 33 (63,5%) individuals had sepsis. The AUC of the SOFA, RSOFA, ASOFA and ARSOFA scores were 0.813, 0.831, 0.793 and 0.807, respectively. See the attached figures.

Table 1. Patients' characteristics

Variables	All patients (n=52)
Age, years	73.9 [60.47-84.01]
Male, n	25 (48.1%)
On mechanical ventilation at admission	26 (50%)
SAPS II	52.3 (±15.5)
APACHE II ^a	23.2 (±11.4)
SOFA score ^b	3.7 (±2.5)
Septic at admission	33 (63.5%)
Pre-existing conditions	
Hypertension	31 (59.6%)
Diabetes Mellitus	21 (40.4%)
Chronic Heart Failure	4 (7.7%)
Chronic Renal Disease	5 (9.6%)
Other	34 (65.4%)

Table 1: Values are expressed as the mean (standard deviation), median [25th-75th percentiles], or a number (percentage). SAPS II: Simplified Acute Physiology Score II. APACHE II: Acute Physiology and Chronic Health Evaluation II. SOFA: Sequential Organ Failure Assessment. ^a: data from 7 patients missing. ^b: datum from 1 patient missing.

Table 2. Reported outcomes

Variables	Frequency
Hospital length of stay, days ^c	24.9 days (±22.3)
ICU length of stay, days ^d	11.6 days (±13.4)
Hospital mortality, n	19 (36.5%)
ICU mortality, n	15 (28.8%)

Table 2: Values are expressed as the mean (standard deviation) or a number (percentage). ^c: data from 2 patients missing. ^d: data from 16 patients missing.

Conclusion: The RASS scale and bilirubin level as neurological and gastrointestinal components, respectively, had higher accuracy for mortality prediction than the GCS and the AGI score. Therefore, the use of the RSOFA score should be encouraged over traditional SOFA score. The ASOFA and ARSOFA scores, which used the AGI scale, must not be used as it had lower accuracy than currently used bilirubin levels.

Predictors of lethality in ICU patients with COVID-2019 pneumonia

O. Dymova¹; M. Petrushin²; M. Babaev³; A. Eremenko³

¹Clinical diagnostic laboratory, Petrovsky National Research Centre of Surgery, Moskva, Russia; ²Intensive care unit, Tver Regional Hospital, Tver, Russia; ³Intensive care unit, Petrovsky National Research Centre of Surgery, Moskva, Russia

Correspondence: M. Babaev

Intensive Care Medicine Experimental 2020, **8(2)**: 000779

Introduction: Understanding the risk factors and early predictors of the severe course of the disease allows us to choose the right treatment tactics.

Objectives: To identify risk factors and predictors of poor outcome in patients with COVID-19 pneumonia.

Methods: We performed a retrospective analysis of the treatment results of 118 patients admitted to ICU of Tver Regional Hospital in April-May 2020. The mortality rate was 61% (72 from 118 patients). Patients were assessed according to 21 clinical and laboratory indicators using a multivariate analysis of the obtained data.

Results: Using the comparative and ROC analysis, we selected 4 most informative predictors of the development of the lethal outcome from 17 initial indicators. These 4 predictors were used to build a multidimensional regression equation. In the obtained regression equation, each of the 4 qualitative predictors had a certain weight: age over 65.5 years (31 points), SOFA score > 3.5 (29 points), serum creatinine > 149.5 μmol / l (25 points), the ratio of CRP (mg/l) to the relative number of lymphocytes (%) > 8.18 (16 points). The obtained regression equation allows us to assess the risk of death (AUC 0.859, 95% CI 0.792-0.927, see Figure 1). The risk of death increased to 93% (CI 89-97%), OR = 12.85, (95% CI 4.8-34.2, p = 0.0000) when a sum of values approached to 50.5 points. It is also possible to use a simplified regression equation, where each of 4 predictors means 1 point (AUC 0.840, 95% CI 0.767-0.913). In patients without the risk factors the probability of death was 7.7%. If any 1 predictor was noted, the probability of death was 30%, two - 61.9%, three - 96%. None of the patients with 4 risk factors at the admission survived.

Figure 1. ROC-curves for the functions of predicting the development of lethality in patients with COVID-19

Conclusion: The group of the highest risk for adverse outcomes in patients with COVID-19 is represented by patients over 65 years of age who have signs of impaired renal function and/or a pronounced inflammatory reaction upon admission.

Intensive Care Medicine Experimental 2020, **8(2)**: 000845

Introduction: The vast majority of patients with severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection are primarily admitted to the Intensive Care Unit (ICU) for mechanical ventilation. The role of multi-organ failure during ICU admission as driver for outcome remains to be investigated yet.

Objectives: The aim of the study was to determine whether patients who survive the ICU develop a lower (i.e. decreasing) Sequential Organ Failure Assessment (SOFA) score over time compared to patients that die in the ICU.

Methods: Prospective cohort of mechanically ventilated critically ill with SARS-CoV-2 infection. The study includes 81 participants (23% women) of the *Maastricht* cohort of whom 54 reached primary outcome at follow-up. The median length of stay was nine days, with a maximum of 30. The study includes a total of 1101 serial SOFA scores, an established score to evaluate multi-organ function in the ICU on a daily basis. The cohort was divided into survivors (n=28, discharged from the ICU) and non-survivors (n= 26, died during their ICU stay). Serial data were analysed using linear mixed-effects models.

Trial registration: Netherlands Trial Register number NL8613.

Results: On admission the mean SOFA score was 7.8±2.8. Survivors improved on average one SOFA score point more per four days (95% CI: 2.5-9) than non-survivors. Adjustment for age, sex, the presence of chronic lung, renal and liver disease, body-mass index, diabetes mellitus and cardiovascular risk factors, and Acute Physiology and Chronic Health Evaluation II score did not change this result. This association, however, was stronger for women than men (P-interaction 0.006).

Conclusion: The decrease in SOFA score associated with survival strongly suggests involvement of multi-organ failure during the clinical course of mechanically ventilated patients with SARS-CoV-2 infection. Surviving women appeared to improve faster than surviving men. Serial SOFA scores may unravel an unfavourable trajectory and guide decisions in mechanically ventilated patients with SARS-CoV-2.

Intensive Care Medicine Experimental 2020, **8(2)**: 000920

Introduction: It has been observed that some physiological parameters are altered in the hours prior to a critical hospital event. With the application of early warning systems by evaluating the physiological parameters of patients, they can be classified as low, intermediate or high clinical risk of suffering a critical event, reducing or anticipating the risk of critical events.

Objectives: Analyze the capacity of clinical alert and describe the characteristics of patients who suffer a critical event in a conventional ward.

Methods: Prospective, observational and multicenter study. The patients admitted to the conventional plant who suffered a critical event from February to May 2019 were analyzed. The NEWS-2 (NHS Early Warning Score-2) was calculated to stratify the patient's clinical risk prior to the event: low (<5), medium (5-6) and high (> 6) or some parameter of the NEWS-2 = 3.

Qualitative variables are expressed as percentages and quantitative variables are expressed as means and standard deviations (SD).

Results: 231 patients from 5 hospitals in Catalonia were included. Table 1: describe the main characteristics of the population.

Table 1	VARIABLE	N = 231
	Age mean (SD)	70.9 (15.6)
	Male (%)	56
	Medical patient (%)	83
	Hospital (%)	48
	Event occurs at night or on a holiday (%)	53
	Cause of the event related to the admission (%)	72
	Active infection at the time of the event (%)	46
	Patient monitored prior to the event (%)	44.6
	NEWS-2 at the time of the event . mean (SD)	8,.2 (3.8)
	Some parameter of the NEWS-2 = 3, 48 h before the event. mean (SD)	7.1 (3.7)
	Some parameter of the NEWS-2 = 3, at the moment of the event (%)	69.7
	Some parameter of the NEWS-2 = 3, 48h before the event (%)	53.7
	Hospital long of stay, mean (SD)	17.6 (20.5)
	Hospital mortality (%)	60

Critical event: unexpected admission to the ICU 27%, ICU consultation without admission 22%, non-resuscitable death on the ward 37% PCRHIH 9%. Medical Service: Internal Medicine (44.6%), Onco-Hematology: 22.6%. Frequency in taking constants: <6 h (35.1%), 6 h (21%), 8 h (34%), > 8 h (9.2%). Nursing: patient ratio: 1: 8 (40%), 1:14 (23%), 1:10 (18%). Most frequent pre-event infection: respiratory 56%. Cause of the event: Hypoxemia (39%). 72% of patients received supplemental pre-event O₂. In 42% of the cases some of the NEWS-2 parameters were missing, 60% the Respiratory F. and 10% the Sat. O₂. Figure 1 describes the clinical risk calculated using the NEWS-2 at the time of the event and 48 h before.

Conclusion: A medium and high clinical risk up to 48 h prior to a critical event in a conventional plant is frequent. Respiratory function is the most affected and its clinical record is the most incomplete.

Intensive Care Medicine Experimental 2020, **8(2)**: 000921

Introduction: It has been observed that some physiological parameters are altered in the hours prior to a critical hospital event. With the application of early warning systems by evaluating the physiological parameters of patients, they can be classified as low, intermediate or high clinical risk of suffering a critical event, reducing or anticipating the risk of critical events.

Objectives: To analyze the clinical alert capacity and the factors related to the mortality of patients who suffer a critical event in a conventional ward.

Methods: Prospective, observational and multicenter study. The patients admitted to the conventional plant who suffered a critical event from February to May 2019 were analyzed. Demographic and clinical data were collected. The NEWS-2 (NHS Early Warning Score) was calculated to stratify the patient's clinical risk prior to the event: low (<5), medium (5-6) and high (> 6) or some parameter of the NEWS-2 = 3. Qualitative variables are expressed as percentages and were compared using the X²-test, quantitative variables are expressed as means and standard deviations (SD) and were compared using Student's t-test. Multivariate logistic regression was performed for hospital mortality.

Results: 231 patients from 5 ICU hospitals in Catalonia were included. Prior to the nursing event, between 1 and 4 medical alerts per patient were performed in 75% of the events, and between 1 and 2 medical consultations per patient were performed in 58% of the events. Hospital mortality was 60%. Table 1 shows the factors related to mortality.

Table 1	Variables	ALIVE	DEAD	p < 0,05
	Age mean (SD)	62,56 (17,1)	76,8 (12,2)	0,001
	Hospital discharge < 30 days (%)	24,6	75,4	0,001
	Event occurs at night or on holiday (%)	37,6	62,4	0,001
	Patient comes from chronic center (%)	13,2	86,8	0,001
	Medical patient (%)	62,7	37,3	0,001
	Cause of admission related to critical event (%)	34,3	65,7	0,001
	Some parameter of the NEWS-2 = 3,			
	Pre- Event (%)	26,7	73,3	0,001
	Some parameter of the NEWS-2 = 3,			
	48 h before the event (%)	26,9	73,1	0,001

Figure 1 shows the relationship between hospital mortality and Pre-Event risk and 48 before the event.

Figure 2 shows the multivariate analysis of the factors related to mortality.

	Ods Ratio	P
Age	0,91-0,97	0,014
Hospital discharge < 30 days	0,25-2,01	0,001
NEWS-2 Prior to the event	0,78-0,99	0,04

Conclusion: The mortality of patients admitted to the conventional ward who present a critical event is very high and is related to the level of clinical risk of the patient prior to the event.

Intensive Care Medicine Experimental 2020, **8(2)**: 000923

Introduction: It has been observed that some physiological parameters are altered in the hours prior to a critical hospital event. With the application of early warning systems by evaluating the physiological parameters of patients, they can be classified as low, intermediate or high clinical risk of suffering a critical event, reducing or anticipating the risk of critical events.

Objectives: Objectives: to analyze the clinical alert capacity and describe the characteristics of the patients who suffer a critical event in the conventional ward.

Methods: Prospective, observational and multicenter study. The patients admitted to the conventional plant who suffered a critical event from February to May 2019 were analyzed. The NEWS-2 and qSOFA of the patients who had active infection at the time of the event were calculated, and the risk of progressing to sepsis / septic shock was assessed: NEWS-2 low (<5) and high (≥ 5) and qSOFA: low (0-1) and high (2-3). Qualitative variables are expressed as percentages and were compared using the X²-test, quantitative variables are expressed as means and standard deviations (SD) and were compared using Student's t-test. Multivariate logistic regression was performed for hospital mortality.

Results: 231 patients from 5 ICU hospitals in Catalonia were included. 46% of patients had an active infection at the time of the event, the most frequent type of infection was respiratory (56%). 44% evolved towards sepsis / septic shock, Figure 1 shows the prognostic capacity of the NEWS-2 and qSOFA score.

Hospital mortality was 62%. Table 1 shows the relationship between hospital mortality and factors related to infection.

Table 1	Variables	ALIVE	DEAD	p < 0,05
	Age mean (SD)	62,9(16,4)	74,5(12,7)	0,001
	Patient comes from chronic center (%)	11,8	76,5	0,014
	qSOFA= 2- 3 (%)	22,2	77,8	0,004
	NEWS-2 Pre- Event ≥5 (%)	30,7	69,3	0,001
	NEWS-2 48 h before the event ≥5 (%)	26,7	73,3	0,001
	Some parameter of the NEWS-2 = 3,	25	74	0,001
	Pre- Event (%)			
	Some parameter of the NEWS-2 = 3,	26,9	73,1	0,001
	48 h before the event (%)			

Figure 2 shows the multivariate analysis of the factors related to mortality.

	Ods Ratio	p
Age	0,87-0,97	0,02
qSOFA	0,045-0,89	0,03
NEWS-2, 48 h prior to the event ≥5 (%)	0,02-0,89	0,04

Conclusion: The infection is present in a very high percentage of patients at the time they present a critical event in the conventional plant, presenting a high mortality that can be predicted by qSOFA and NEWS-2 up to 48 hours prior to the event. In our population, qSOFA better predicts evolution to sepsis / septic shock than NEWS-2 in these patients.

Assessment prognostic value of gravity scores in cirrhotic patients admitted in intensive care units

H. Pérez Chomón¹; M. Pinilla-De-Torre¹; M. Blázquez Romero¹;

J. Garnacho-Montero¹

¹Servicio medicina intensiva, hospital universitario virgen macarena, Sevilla, Spain

Correspondence: H. Pérez Chomón

Intensive Care Medicine Experimental 2020, **8(2)**: 001104

Introduction: Cirrhotic patients often develop severe complications requiring ICU admission. The evolution in treatments and liver transplant programs have improved the prognosis of critical cirrhotic patients, a fact that has facilitated their admission to the intensive care units (ICU). However, knowledge on the pathogenesis, diagnosis and treatment of these complications and the prognostic assessment of critical cirrhotic patients is still limited.

Objectives: To know survival prognosis of cirrhotic patients admitted to the ICU and the prognostic value of general scores for critically ill patients and those specific for cirrhosis.

Methods: Prospective, descriptive and analytical study. All patients admitted to our ICU from April 2017 to May 2020 with a history of liver cirrhosis were evaluated and were followed after 90 days of admission. Different variables such as age, sex, cirrhosis etiology, reason for admission, laboratory data, APACHE II and SOFA scales at baseline and specific scales score (Child-Pugh, CLIF-SOFA, Life Score and MELD) were registered upon admission, 7 days and discharge or death. The need for invasive mechanical ventilation, continuous renal replacement therapy or vasoactive support, as well as the development of infectious complications, were also noted.

Statistical analysis: qualitative variables are expressed as percentages. For quantitative variables, measures of central tendency and dispersion were used. The comparison of quantitative variables was performed using the Student T test. Chi-square test was used to compare qualitative variables. ROC curves were built to evaluate the ability of prognostic scores to predict mortality at 90 days of admission.

Results: One hundred and one patients (77 men) were included; age 56.61 ± 11.41 years. APACHE II mean at admission was 22.38 ± 10.08. SOFA average 9.06 ± 4.89. Average MELD 20.73 ± 9.91. 43.6% (n = 44) presented Child-Pugh C. 43.6% (n = 44) had CLIF-SOFA grade 3 and 35.6% (n = 36) had an intermediate risk Life- Score. Mortality in the

ICU and at 90 days was 41.6% and 53% respectively. Statistical analysis showed worse APACHE II, SOFA and MELD values at admission ($p < 0.000$) in patients who died in the ICU and at 90 days. There were no significant differences regarding age. Analysis of ROC curves showed that the SOFA (0.738) and APACHE II (0.762) calculated in the first 24 h of admission predicted mortality at 90 days whereas the AUC of specific scores were 0.783 for Child-Pugh and 0.780 for MELD.

Conclusion: Cirrhotic patients who died during their stay in the ICU or at 90 days of follow-up showed significantly higher values in all prognostic scores at admission compared to those who survived. Child-Pugh and MELD seem to be the better predictors of 90-day mortality.

Intensive Care Medicine Experimental 2020, **8(2)**: 001119

Introduction: Covid-19 pandemic has conditioned a high demand for critical care beds. The develop of a prognostic score could help to better management of health resources.

Objectives: Our aim was to obtain a prognostic prediction model for critically ill patients with severe SARS-COV-2 coronavirus infection (Covid-19).

Methods: Prospective observational study of patients with diagnosis of Covid-19 admitted to critical care units of the H.G.U Gregorio Marañón. Epidemiological data, previous comorbidities, clinical and analytical data, specific treatments administered, organic support used, complications during stay and final outcome, were collected. Descriptive data were described as medians with interquartile range (IQR) and as percentages for categorical data. The continuous variables were categorised according to maximum discrimination point by the area under the receiver operating characteristic curve (AUROC). Univariate analysis was performed using a simple logistic regression (OR). The predictive model was obtained by means of multiple logistic regression analysis. For model validation, its discrimination capacity (AUROC), its calibration capacity (Hosmer-Lemeshow test) and its quality diagnostic indices (sensitivity, specificity, positive and negative predictive value), were analysed.

Results: One hundred and fifty patients were included, 71% male. Age was 61 years (49-71) and Charlson Comorbidity Index 1 pts (0-3). Severity scores were: APACHE II 16 pts (12-20), SOFA 6 pts (4-8). 88% of patients required mechanical ventilation, 77% prone-position and 63% vasopressor therapy. Acute renal failure was present in 33% (10% needing renal replacement therapy). 77% presented any complication. Some specific treatment was administered in 98%. Hospital mortality was 40.5%.

In the **univariate analysis** the variables related to mortality were: **Age** (decades) OR 1.59; 95% CI 1.21-2.09, **Charlson I.** OR 1.40; 95% CI 1.14-1.72, **SOFA > 3 pts** OR 3.03; 95% CI 1.06-8.63, **Mechanical ventilation** OR 13.1; 95% CI 1.69-101.78, **Prone-positioning** OR 2.93; 95% CI 1.27-6.75, **Vasopressors** OR 4.45; 95% CI 2.05-9.68, **Atrial fibrillation** OR 3.58; 95% CI 1.63-7.87, **C-reactive protein** OR 1.03; 95% CI 1.01-1.06, **Procalcitonin** OR 1.05; 95% CI 1.01-1.10, **IL-6 400 pg/ml** OR 6.31; 95% CI 2.55-15.61, **D-dimer 4000 ng/ml** OR 7.00; 95% CI 3.36-14.57, **Lactate 2 mmol/l** OR 7.26; 95% CI 3.47-15.21

The **prognostic predictive model** included the following variables: **age** (decades) (OR 1.72; 95% CI 0.98-2.99), **Charlson I.** (OR 1.44; 95% CI 0.92-2.26), **SOFA > 3 pts** (OR 5.59; 95% CI 0.89-34.79), **IL-6 > 400 pg/ml** (OR 4.05; 95% CI 1.15-14.18), **D-Dimer > 4000 ng/ml** (OR 11.85; 95% CI 2.95-57.66), **Lactate > 2 mmol/l** (OR 5.41; 95% CI 1.56-18.68).

The **model obtained** (figure 1) had a good **discriminatory capacity**: AUROC 0.90; CI 0.84-0.96, a **proper calibration** (Hosmer-Lemeshow test): Chi-square 3.38, $p = 0.9$, and good **diagnostic quality indices**: S 81%, E 81%, PPV 0.73, NPV 0.87, VPR 4.26, VNR 0.23.

Conclusion: In our experience, the predictive model created using clinical and analytical data obtained early on ICU admission, was able to discriminate the prognosis of Covid-19 patients.

Emergency department visits, Emergency Severity Index and Intensive Care Unit admissions in the era of COVID19; A single center experience

G. Karlis¹; S. Orfanos¹; P. Zafeiriadou¹; S. Kolokytha¹; S. Christakopoulos¹; K. Georgiopoulos¹; A. Sofianou¹; K. Tsekouras¹; P. Batiani¹; E. Ntikoudi¹; V. Kaldis¹

¹Emergency department, Sismanogleio General Hospital, Marousi, Greece

Correspondence: G. Karlis

Intensive Care Medicine Experimental 2020, **8(2)**: 001142

Introduction: The purpose of triage in the Emergency Department (ED) is to prioritize incoming patients and to identify those who cannot wait to be seen (1). One of the most widely used triage tools is the Emergency Severity Index (ESI), which includes a five-level scale with ESI 1 describing a patient that requires immediate life-saving intervention/resuscitation and ESI 5 a non-urgent patient (2). COVID19 has set new challenges in the organization and practice of emergency and critical care medicine, prompting for re-evaluation of existing tools.

Objectives: To assess the effects of the "lockdown" on ED visits and the relationship between ESI 1 patients and short-term outcomes in the era of COVID19, in a tertiary Greek hospital.

Methods: ED data from Sismanogleio General Hospital, a tertiary Greek hospital in Athens metropolitan area, was retrospectively studied from 1/1/2020 to 30/6/2020. In Greece, a full "lockdown" was imposed between 13/3/2020 and 4/5/2020.

Results: The number of ED visits per month was significantly affected by "lockdown". We noted 42.2% reduction in total ED visits during March-April compared to January-February and 41.7% compared to March-April 2019. After the "lockdown" period a 24.1% increase in the number of ED visits was seen (Fig.1). Interestingly, the peak of epidemic in Greece did not influence ED attendances for immediate life-threatening conditions (Fig.2). In our analysis patients assessed as ESI 1 constituted 0.46% of all ED patients for the 6-month period. Furthermore, in the group of patients triaged to ESI 1, 20.8% died, 65.3% were admitted to the ICU and 13.9% were admitted to the ward. None was discharged home from the ED (Fig. 3).

Conclusion: Our data is consistent with other reports of dramatic falls in ED attendances amid the outbreak of SARS-CoV-2, due to fear of contracting the disease (3,4). However, we noticed that individuals with critical illness (ESI 1) found their way to the ED at any given time during the coronavirus crisis. From previous research we know that most ESI 1 patients are admitted to ICU, while some die in the ED (5,6). Our results show that during COVID19 crisis, ESI 1 was associated with high likelihood of ICU admission and death in the ED, suggesting that it remains a useful tool for predicting short-term outcomes of critically ill ED patients.

Introduction: Clinical information systems (CIS) have been developed in intensive care units (ICU) to aggregate information, promote operational efficiency, and obtain accurate records. However, in settings wherein hospital electric medical record (hEMR) systems have operated, the differences in the operability and performance between CIS in ICUs and hEMR systems and the constraints of cooperation of both the systems can lead to new errors when using both the systems in ICUs. However, the incidence rate and the type of errors recorded at an early-stage after implementation of CIS in ICUs are unknown.

Objectives: To investigate the incidence rate and the type of errors in ICUs for 9 months after implementation of CIS.

Methods: CIS (PrimeGaia, Nihon Kohden, Tokyo, Japan) was introduced into our medical and surgical ICU (18 beds, nursing-to-patient ratio 1:2) and intermediate medical care unit (IMU, 15 beds, nursing-to-patient ratio 1:4) at a university hospital (1,335 beds). After implementation and a 3-month training period, CIS was used in all the patients starting in April 2019. The data of incidents and accidents in the ICU and IMU in the 9-month period after the launch of the CIS (from January to September 2019) were extracted from the hospital's incident reporting system, and the incidence rate was determined. In our incident reporting system, errors have been divided into two categories: "incident" (indicating no error or error that caused no harm such as near-misses) and "accident" (indicating error resulting in harm and error resulting in patient death). Poisson distribution was used

to calculate the 95% confidence interval (CI) of the incidence rate of events.

Results: From January to September 2019, CIS was used in 942 (90%) of the 1,046 patients admitted to ICU and in 1,278 (89%) of the 1,439 patients in IMU. The total length of stay in ICU and IMU was 3,854 and 2,728 patient-days, respectively, and the duration of using CIS was 3,200 and 2,311 patient-days, respectively. The number of incidents and accidents was 123 in ICU and 140 in IMU. The incidence rates of events were 31.9 (95%CI 25.5–38.0) and 51.3(43.2–60.6) events per 1000 patient-days, respectively. The number of incidents and accidents related to CIS were 18 (15%) in ICU and 15 (11%) in IMU. The incidence rates of events were 5.6 (3.3–8.9) and 6.5(3.6–10.7) events per 1000 CIS operation patient-days, respectively.

The major background factors for the incidents and accidents related to CIS were unfamiliarity with its operations (11/33), inadequate coordination between the CIS and hEMR (11/33), specifications of the CIS (7/33), and others (4/33).

Conclusion: Our study has revealed that 12% of the incidents and accidents in ICU and IMU were related to CIS and that the incidence did not vary with the management intensity of care units. The errors during the early stages after implementation of the CIS occurred because of unfamiliarity with its operation, inadequate coordination between CIS and hEMR, or the specifications of CIS.

Can anyone talk to me? Communication with families during the days of corona in intensive care unit

Introduction: With the outbreak of the Corona virus SARS-CoV-2, communication with family members became even more challenging and critical than it had been in the first place. Group meetings for families which we usually convened every week were no longer possible due to the prohibition on gathering, and therefore we were in need of a solution that would meet the needs of patients and their families. On April 10, all family visits were stopped in order to prevent infection. This situation created a new reality, where family members could not visit the unit at all and could not see their loved ones. This reality required us to make a quick assessments and response to the situation, understanding that the emotional burden would weigh heavily on the families.

Objectives: Our objective was to find a way to preserve the critical connection and communication lines between the families in the ICU to their loved ones and the staff in a way that met their emotional needs, while operating within the existing limitations that were necessary to prevent the spread of the virus.

Methods: The program was implemented on four levels: (1) Initiated conversations of physicians with the primary caregiver: From April 10th until May 5th the doctors made phone calls to family members of 42 patient. (2) Video calls of the single UI with the families via tablet: During video calls that were connected and accompanied by the social worker, the families could see the patient and speak to them. (3) Providing telephone information by the nursing staff: Since the family members did not enter the unit at all, it was decided that the information they provided would be slightly more detailed than usually acceptable and tailored to their needs. (4) A video that provides general information to families, in order to familiarize them with the unit, the management team, and the nature of the outpatient care: The video was created as a replacement for family gatherings where information is usually transmitted. The video will be used in the future as it was found to be helpful as a day to day tool as well.

Results: As a result of the program, we were able to positively influence intensive care patients' families, include them in the treatment process without being physically present in the unit, and maintain quality communication that influences their motivation and commitment to the care plan and hospitalization provided by their loved ones. We received immediate positive feedback from the families that took part, verbally, via text messages and thank you letters. In addition, there was a decrease in the amount of pressure and phone calls to the nursing station from families who were trying to get information, once they started getting the information in an organized way initiated by the multi-professional staff.

Conclusion: The coronavirus, which has spread rapidly around the world, has tested the readiness of the health system to cope with pandemic conditions and the entire system has had to reformulate coping methods in many areas including communication between patients and their families in isolation and risk of infection. The program was implemented on four levels that combined the knowledge and practice we accumulated and is the basis upon which we added more knowledge during each shift. We hope to continue developing as we proceed.

Intensive Care Medicine Experimental 2020, **8(2)**: 000398

Introduction: Medication errors have been a frequent and safety-relevant problem in medical care for years[1]. In this context, the lack of standardized, automatic, reliable, consistent documentation and information systems represents a major obstacle. The high dependency on manual input in many steps of the process is a particular challenge[2].

Objectives: This work aimed to analyze the medical records of intensive care unit (ICU) patients admitted to a large university hospital in Germany, as well as to explore and propose an information technology (IT) standard to build an interoperable medication interface.

Methods: We accessed a series of databases to collect the information about 81 medications that were frequently used in our ICUs from the hospital's IT department, pharmacy, as well as the ICU's Patient Data Management System (PDMS). We further obtained data drawn from the most comprehensive German medication register, the ABDA/ABDAMED database[3]. To gather data according to European standards, we used information available on the European Directorate for the Quality of Medicines and HealthCare (EDQM)[4].
